The consumption of sucrose with relatively little complex carbohydrate and other nutrients might indeed lead to reactive hypoglycemia, arising from overstimulation of insulin secretion. However, the behavioral aftereffect of consuming a large amount of sugar is if anything drowsiness, not agitation. Sucrose challenges specifically to children diagnosed as suffering from attention-deficit hyperactivity disorder have mostly shown no effect on physical activity. However, the sedative effects could acutely impair attention and, in theory, a child's awareness of this might exacerbate problem behavior in attention-demanding situations. It must be noted, on the other hand, that a parent's or institution staff's concern about the sugar intake of a problem child may be no more than a desperate hope for some remedy for the unmanageable behavior. These relations between diet and behavior also need careful sociopsychological analysis before biomedical investment.

Somewhat paradoxically in the light of the above, it has been recently suggested that administration of glucose might improve memory in the elderly, perhaps via norepinephrine (noradrenaline) systems in the brain. However, animal experiments have involved administering concentrated glucose solutions; these are stressful and may improve memory simply by alerting the rat.

Dietary Effects on Monoamine Neurotransmitters

A meal that is high in carbohydrate and low in protein content stimulates insulin secretion in the rat. The insulin facilitates uptake by muscle of circulating branched-chain amino acids (BCAAs: leucine, isoleucine, and valine). These amino acids compete with other large neutral amino acids (LNAAs) for transport from the blood into the brain. The LNAAs include tryptophan, the precursor of the neurotransmitter 5-hydroxytryptamine (5-HT, or serotonin), and phenylalanine and tyrosine, precursors of the catecholamine transmitters dopamine and norepinephrine (noradrenaline). The supply of precursor can limit the rate of synthesis of the transmitter, especially in the case of 5-HT. Thus reduced competition by BCAAs for brain tryptophan uptake is liable to increase the activity of serotonergic (5-HT-transmitted) synapses. (*See* **Amino Acids**: Properties and Occurrence.)

Serotonergic neurons are important in the control of sleep. Oral administration of a substantial dose of tryptophan is sedative. This tryptophan supply effect on brain 5-HT probably explains why a high-carbohydrate meal promotes postprandial sleep in the rat. (*See* **Carbohydrates**: Requirements and Dietary Importance.)

The LNAAs are abundant in protein mixtures of high biological quality. Thus, although a high-protein, low-carbohydrate meal also provokes insulin secretion in the rat, plasma levels of BCAAs are kept high by absorption and are not reduced enough to have a substantial effect on competition with tryptophan for transport into the brain. Hence the high-protein meal does not increase 5-HT activity and induce sedation by that mechanism. (*See* **Protein**: Requirements.)

Relatively modest dietary levels of protein, e.g., 10–15% in the rat, keep the ratio of tryptophan to other LNAAs in blood plasma low enough to have no effect on brain 5-HT levels. However, as little as 4% protein keeps the plasma ratio low in human subjects. Few eating occasions provide that little protein. Even chocolate and sugar confectionery may contain a milk protein and/or grain protein. Hence it is unlikely that carbohydrate-rich foods induce sedation or other mood changes in people via the 5-HT mechanism.

This is a difficulty for the suggestion that drugs and psychiatric disorders affecting serotonergic activity

induce a craving for carbohydrate via the action of carbohydrate-rich foods on tryptophan uptake, 5-HT, and mood. Another difficulty is that many of these foods are sweet, an oral sensation that by itself apparently dampens distress via opioid mechanisms. In addition, the high-carbohydrate foods reportedly craved are high-fat foods, and the creaminess or crispiness, with or without sweetness, makes them highly palatable. They can therefore be pleasurable and cheering to eat, independently of postingestional factors.

Finally, in a further illustration of the need for psychosocial analyses of diet and behavior, these craved foods are generally convenience products that are recognized as nutritionally less desirable (so-called junk foods). Hence they may be avoided and as a result become tempting and craved for. Their consumption could then have the powerful impact on mood of any guiltridden sensual indulgence ('naughty but nice'), by purely cognitive processes with no particular neurotransmitter mediation.

Meals

A modest amount of food is widely regarded as mentally and physically energizing or refreshing. However, a heavy meal is expected to make one drowsy (while not necessarily promoting a good night's sleep). Recent behavioral research has provided some support for these conventional beliefs but the physiological mechanisms involved remain obscure.

There is a semicircadian rhythm of arousal, including a period of reduced performance in midafternoon as well as a more profound reduction in the small hours after midnight. A series of experiments has shown that a substantial lunch tends to depress objective and subjective alertness further for a few hours. Going without lunch can therefore improve cognitive performance in midafternoon, although other consequences may not be desirable. Caffeine helps to counter the 'postlunch dip' and alcohol makes it worse. Different aspects of attention are affected by different protein:carbohydrate ratios in the meal. There is as yet no clear basis for this theory, in terms of either the cognitive processes or the physiological actions of food involved in these effects.

Breakfast is reputed to improve performance at work, although the evidence has been largely correlational with accident rates or school reports. Such effects are likely to depend on the size and composition of the breakfast, the physiology, personality, and attributions of the consumer and the activities and tasks that follow the meal. (*See* **Breakfast and Performance**.)

BERIBERI

K J Carpenter, University of California, Berkeley, CA, USA

Occurrence in Asia

The first Western physicians allowed to work in Japan in the 1870s were surprised to discover the existence of a serious disease previously unknown to them and 'second only to smallpox in its ravages.' In Japan, it was known as 'kakké,' but was soon recognized as being identical to the disease known in South-east Asia as 'beriberi,' a native name now universally adopted, which may originally have meant 'great weakness.' Characteristically, it began with a feeling of weakness in the legs and a loss of feeling in the feet. Then, in many but not all cases, the legs and then the trunk would swell with retained water. Finally, the heart would be affected so that the subject gasped for breath, and would die from heart failure.

Older records from both Japan and China showed that it had been known for some centuries, although it had been the opinion of two eighteenth century Japanese physicians that the disease had become worse after about 1750. The early records also indicated that it was largely a disease of the wet summer months and could attack even the well off.

Infection or Malnutrition?

Those most at risk were men in the newly modernized Japanese army and navy, and also prisoners. As these were all people living together in large groups, and with the excitement in this period at other diseases being traced to the transmission of pathogenic bacteria, this seemed a likely cause for beriberi also. Yet, it was difficult, on this basis, to explain the frequent observation that a naval ship would leave its base with all its crew in good health, yet, after a month or more in isolation at sea, the disease would sweep through the crew.

Kanehiro Takaki, a surgeon on the naval staff, was directed in 1878 to work on the problem. He knew that the ships had been built in Britain and that they followed the general practices of the British navy where there was no beriberi. The only difference that caught his attention was in the rations issued to the men: the Japanese issues contained less protein and did not meet the high standard in force at that time in Europe. He therefore persuaded his superiors to permit a trial of modified rations with a proportion of the rice being replaced by meat, condensed milk, vegetables, and barley. The change was a complete success, and it was found that even just the use of barley in place of one half of the rice staple was enough to prevent the disease, which Takaki now believed to have resulted from a deficiency of protein in the earlier rations.

The Japanese army, perhaps as the result of inter-service rivalry, did not follow the navy and in the short Russo-Japanese war of 1904–1905, some 100 000 of their soldiers had to be invalided home from Manchuria suffering from beriberi.

A Disease in Chickens

Meanwhile, the disease had become an equally serious problem in the Dutch East Indies (now Indonesia) (Figure 1). After a punitive military expedition had to be withdrawn because of a beriberi epidemic, the Dutch government dispatched a small commission to try to identify the bacteria responsible for the disease. After a few months, it was thought that the microorganism had been found, and Christiaan Eijkman, a young Army physician, remained behind to confirm its activity in animal models.

Some of the chickens that Eijkman had injected with blood from beriberi patients developed signs of leg weakness, but so did some of his uninjected controls, suggesting that the condition was so infectious that it could 'jump' from cage to cage. Autopsies of the affected birds showed degenerated peripheral nerves. But in the following months, none of the next batch of birds developed the condition. Eijkman discovered that when the leg weakness had appeared, the man in charge of the birds had been feeding them on cooked white rice left over from feeding the beriberi victims in the adjoining hospital, instead of buying rough, feed-grade rice.

A long series of feeding trials confirmed that birds fed on white rice would become sick with leg weakness, whereas those given supplements of rice polishings (still present in feed-grade rice) remained healthy. This was only an animal disease, but a survey by the medical inspector of prisons in Java showed that prisoners who had been receiving white rice as their staple issue were susceptible to beriberi, whereas those receiving brown rice were not.

The Concept of a Vitamin

Eijkman, who believed that the disease was a kind of starch poisoning, now had to be invalided home with malaria. His successor, Gerrit Grijns, found that birds

Figure 1 Two prisoners in Java with beriberi and needing assistance to walk. From Vorderman (1897) *Onderzoek naar het gevangenissen op Java en Madoera en het voorkomer van beri-beri order de geintemeerden* Batavia: Jav. Boekh & Drukkerij.

became sick even when fed on meat that had been autoclaved. After further work, his statement in 1901 was perhaps the progenitor of the 'vitamin era' in nutritional research: 'there occur in various natural foods substances which cannot be absent without serious injury... they are easily disintegrated... and cannot be replaced by simple chemical compounds.'

The work of Eijkman and Grijns was confirmed by British investigators in Malaysia and by Americans in the Philippines, and attempts began to extract the active material from rice polishings and to concentrate it. There are moving accounts of scientists in Manila being implored by local doctors to bring a few spoonfuls of extracted syrup to save the lives of infants with beriberi, and of the babies' spectacular recoveries. Women themselves seemed less susceptible to beriberi than men, but when mothers were receiving a diet of low thiamin content, their breast-fed babies were at a high risk of dying with acute infantile beriberi.

Isolation of Thiamin

Isolation of the active factor proved very difficult. Each stage of extraction, and then further partitioning by reprecipitation involved biological assays with birds. Eventually, the next generation of Dutch workers in Indonesia was successful, obtaining a few milligrams of active crystalline material after starting with one-third of a ton of rice polishings and going through at least 16 separation stages in which much of the vitamin was lost. It was found that adding just 2 p.p.m. of the crystals to white rice was enough to keep birds healthy. In 1931, the crystals were found to contain sulfur as well as carbon, hydrogen, nitrogen, and oxygen, and the chloride salt was shown to have the empirical formula $C_{12}H_{18}N_4SO_2Cl_2$.

There were, of course, almost innumerable ways in which these atoms could be combined. By good fortune, Robert R. Williams in the USA found that adding sodium sulfite to a solution of the vitamin led to its division into two roughly equal halves. Further work at a number of centers showed that one of these compounds contained a pyrimidine and the other a sulfathiazole ring. By 1937, a synthesis of the active molecule was achieved. It was named 'thiamin or thiamine' (i.e., the sulfur-containing vitamin) and soon began to be produced and marketed as a pharmaceutical.

The Analysis of Foods

Thiamin can be oxidized to a highly fluorescent derivative, 'thiochrome.' This property is used to measure the thiamin contents of different foods, even at levels of less than 1 p.p.m. The procedure is specific, and no other naturally occurring compounds have been found that give the thiochrome reaction. However, thiamin can react with polyphenols and a compound present in garlic to give derivatives that are still biologically active (as will be referred to again) but do not give the thiochrome reaction. The analytical procedure may therefore underestimate the efficacy of a product. It is essential, therefore, to have a confirmatory bioassay before knowing for certain that any kind of processing has caused significant loss of thiamin.

Rice and Other Staples

Figure 2 illustrates the thiamin levels in the world's major staple foods, both when fully milled and when minimally processed. In the case of grains, the latter means removal of the husk (or hull) but no more. It is clear that, for each grain, the full milling that removes both the bran and germ results in the loss of a major portion of the thiamin originally present.

White rice is not that much lower than white wheat flour in its content of the vitamin, but after the grains have been prepared for consumption, the difference is increased. White rice is normally washed several times, and this alone can remove half the thiamin present, and boiling in excess water can again halve the level of remaining vitamin. In contrast, white wheat flour is most commonly baked into bread with yeast as the raising agent, and this causes little loss of thiamin.

There is no evidence that cooked white rice has any positively harmful qualities, but if it is the major item in a diet that contains only small amounts of foods that are richer in thiamin, so that the diet as a whole provides no more than about 0.25 mg per 1000 kcal, it is not surprising that beriberi should gradually develop.

The data in Figure 2 also explain the Japanese experience that serious problems with beriberi in their navy in the late 1800s disappeared when one-half of their rice ration was replaced by barley.

The same figure also shows the low thiamin content of tapioca prepared from cassava roots. This explains the existence of beriberi in Brazil at the same period among even well-off people whose favorite foods were tapioca and molasses. Their preferred protein supplement was dried, salted cod, which had to be soaked for several days to leach out most of the salt, which also removed most of the vitamin.

The very first reports of beriberi to reach Europe came from Portuguese priests working in the Molucca

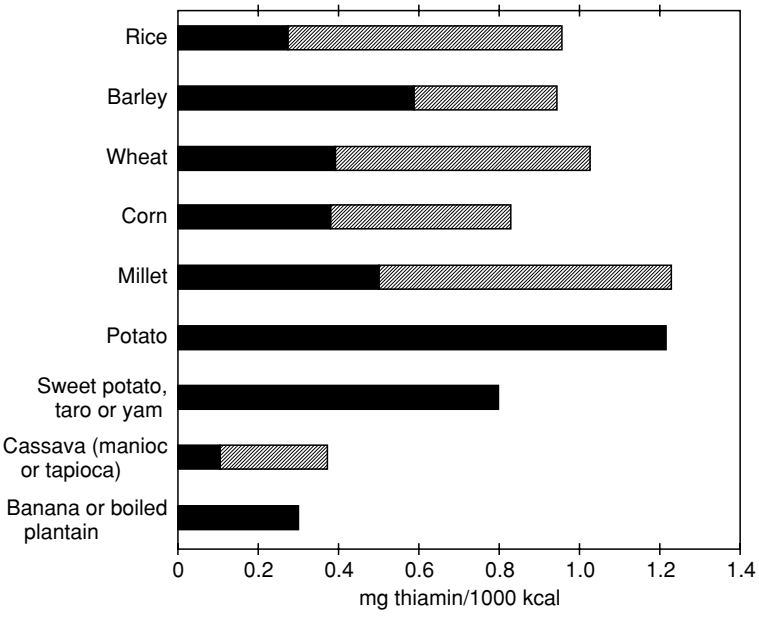

Figure 2 Representative analytical values for the thiamin content of different staple foods: (a) after husking only (■ ▨) and (b) after full processing (■), as explained in the text, and also for some staple root crops, etc. Sago meal is not shown, as it contains only an insignificant level of thiamin. Islands (at the Eastern end of Indonesia) in the 1500s. Their staple was the locally produced sago meal, now realized to be almost pure starch, and the priests correctly attributed their weakness to a lack of 'something' in this food and asked to be provided by their superiors with wheat flour.

Beriberi was also a serious problem in early spring in isolated communities in Newfoundland in the early years of the twentieth century. Their families, who would be cut off for the winter, had to buy 6 months of supplies, with white flour as their staple. They were also apparently not familiar with using yeast to leaven bread, but cooked their flour with baking soda, and it is known that much of the thiamin present would be destroyed under the alkaline conditions during this procedure.

The Improvement of Rice

Once the association of beriberi with white rice in Asia had been established, attempts were made to replace it in some way with other foods. As already mentioned, barley was an economic and well-accepted alternative in the diet of the Japanese armed forces.

In the Philippines, a proposal was made to enforce the use of brown rice by the local military. This, of course, is rice from which the husk has been removed but not the entire bran layer and germ (embryo and scutellum) (Figure 3). This was the traditional staple of villagers in South-east Asia who had no access to mechanical rice mills. They would pound their paddy (i.e., rice still in the husk) in some kind of bowl and then winnow the product so that the lighter husks blew away, and the grains fell in a pile.

This procedure was time-consuming but created no problems when only enough was pounded for immediate use in the next 24 h. However, it was repeatedly found that in the tropics, brown rice on storage would become infested with insects of different kinds, and the oil in the bruised germ would become rancid. Since large organizations, or an army on the move, needed large-scale supplies ready for cooking, brown rice did not provide a practicable staple.

The early workers who discovered the association of beriberi with white rice had assumed that the important micronutrient was concentrated in the bran of the grain. However, it was later realized that more was present in the germ area (Table 1). Japanese millers then attempted to modify their machinery so as to remove the bran without removing the germ from the grain. The so-called 'germ rice' that they were able to produce proved to be both palatable and an improved source of thiamin. However, millers were only able to produce it with certain varieties of rice, and not with the bulk of the rice favored in Japan.

A traditional method of processing rice common in Bengal is called parboiling. It had been found that if rice in the husk were to be steeped for a period in hot water and then allowed to dry in the sun, the husks

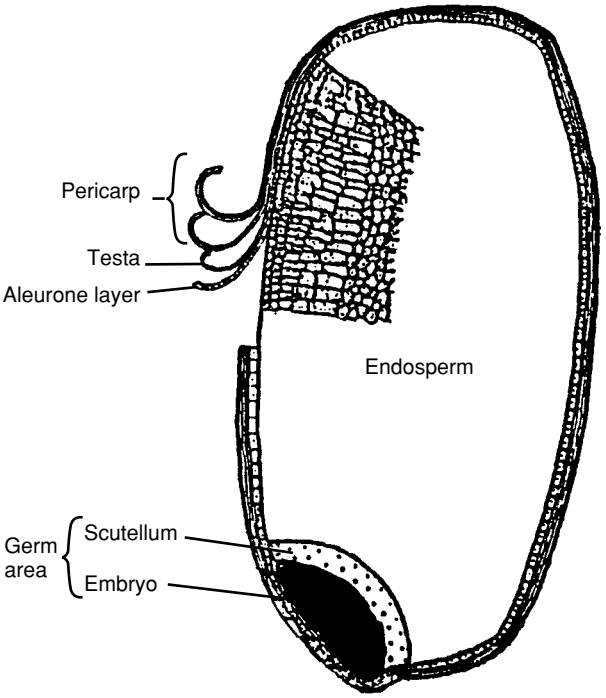

Figure 3 Dissection of a dehusked rice grain. From Carpenter KJ (2000) *Beriberi, White Rice and Vitamin B*. Berkeley, CA: University of California Press, with permission.

Table 1 Thiamin contributed by the different parts of a sample of dehusked rice grains

Dissected parts of rice grain		*Proportion by weight (%)*	*Thiamin*		
			Concentration in fraction (mg per 100 g)	*Contribution to 100 g grain (mg)*	
Pericarp + testa + aleurone layers		6	3.1	0.186	
Germ area	Embryo	1	5.9	0.059	0.248
	Scutellum	1	18.9	0.189	
Endosperm		92	0.05	0.046	
Total		100		0.480	

From Carpenter KJ (2000) *Beriberi, White Rice and Vitamin B*. Berkeley, CA: University of California Press, with permission.

cracked off more easily on pounding, and there was less breakage of the grains. Broken grains had a lower commercial value.

In Malaysia, where many immigrant groups were employed as laborers but living on their habitual diets, it was realized in about 1910 that Bengalis were remarkably free from beriberi, and studies in a mental hospital showed that replacing ordinary white rice with polished rice prepared from parboiled grains relieved the inmates from the disease. After thiamin had been identified, analyses showed that the initial soaking of the grain caused thiamin to diffuse into the endosperm and to remain there as the grains dried out.

Again, this does not appear to be something that could be applied more widely. The traditional soaking and sun-drying leaves the rice with a characteristic musty flavor and slight discoloration, which is acceptable only to people who have grown up with it. The process can be modernized, with controlled autoclaving and vacuum-drying for so-called 'conversion' of the rice, but this makes it too expensive for mass consumption in developing countries.

The final procedure for the production of 'enriched' rice is to fortify it with the synthetic vitamin. For a flour, such as white wheat flour, this is relatively simple, requiring only very careful mixing of the traces of vitamin with a small quantity of flour, then the blending of the premix to larger batches. This is familiar, and indeed compulsory practice, in the USA and UK, together with other vitamins and trace minerals. As a powder, thiamin cannot be blended with grains of white rice. However, methods have been developed of preparing vitamin-rich granules with the size and appearance of rice grains, and blending these in at the ratio of one granule to 200 grains, so that the mix has at least the thiamin content of brown rice. To reduce loss of the vitamin during washing and cooking, the granules are coated with a nontoxic resin at the final stage of their production. This method of enrichment has been tested in an area of the Philippines where beriberi was endemic and has proved successful in greatly reducing its incidence. Unfortunately, where widely separated villages each had a small electric mill, there were practical problems in persuading millers to pay for the premix when the product appeared unchanged, but the price had to be a little higher.

Supplementing Foods

Unfortunately, there is no convenient food that is extremely rich in thiamin. Dried brewers yeast contains 15 mg per 100 g, but many people cannot tolerate it in more than extremely small regular doses. Of the meats, pork is richest with lean pork containing 1 mg per 100 g. Beef has only about one-tenth as much. Dry peas and beans contain about 0.5 mg per 100 g. Potatoes are another useful supplement – on a dry matter basis, they have slightly more than brown rice.

In practice, reaching a desirable intake of thiamin comes usually from eating a wide variety of foods. Beriberi, being restricted almost entirely to the summer months among nineteenth century Japanese, may be explained by their, at that time, regarding most foods other than rice as being 'heating' and therefore to be restricted in that season.

Is there an Antithiamin Problem?

There are many references in the literature to at least a suspicion that certain foods and beverages may be responsible for beriberi appearing in people whose intake of thiamin would otherwise be adequate.

Thiaminases

Many species of fish contain enzymes in their viscera that split thiamin molecules at the junction between its two ring structures. This was discovered when foxes, being reared for their fur and fed on a mix containing a large proportion of whole raw fish, developed a form of paralysis that responded to injections with thiamin. A similar condition was seen later in cats that had been fed on a canned food containing a large proportion of whole fish. It was believed that the thiamin in the mix had been largely destroyed after the mix had been prepared and was waiting to be autoclaved.

These experiences led to investigations as to whether humans could be similarly at risk, but it appears not. The enzymes are not present in fish muscles (i.e., fillets), and even where small fish are eaten whole, they are not ground up with other items of diet before being cooked. Lastly, it was found in animal studies that a subsequent meal with different constituents was not affected by thiaminases being present in an earlier meal.

Another source of thiaminases was found to be bracken, and their presence explained the condition known as 'staggers' that occurs in horses that have been feeding on bracken. Cooked bracken, in which the thiaminase was inactivated, proved harmless to horses. The only known case of thiaminase poisoning in humans occurred in a group exploring the interior of Australia in the 1860s. Running out of provisions on their return journey, they lived on the sporocarps in the fronds of a particular fern that is now known to contain a high level of a particularly heat-resistant thiaminase. All four men developed leg weakness

and lassitude; three died, and the survivor remained lame even after his safe return.

Heat-stable Antithiamins?

It has been found that when the thiamin in a food comes into contact with polyphenols such as caffeic acid, it no longer gives a fluorescent product in the usual thiochrome procedure for the estimation of thiamin. This led some workers to suppose that drinking large quantities of tea or coffee, or chewing betel nut – all sources of polyphenols – might induce a condition of thiamin deficiency. However, biological assays have indicated that the vitamin is still fully available.

When thiamin is incubated with garlic extracts, it undergoes a reaction with the allicin present in which the thiazole ring opens, and the sulfur atom in the ring links to the alkyl sulfide to form a disulfide compound. This is not measured in the thiochrome reaction, but in the body, it is reduced to re-form the active vitamin. In fact, compounds of this type can be absorbed more efficiently by alcohol-damaged intestinal walls than ordinary thiamin. Thiamin tetrahydrofurfuryl disulfide in particular is approved for this purpose in some countries.

Although there is no confirmed evidence of naturally occurring heat-stable compounds that inactivate thiamin, chemists have synthesized such materials. One, named 'oxythiamin,' has the amino group attached to the pyrimidine group in thiamin replaced by a hydroxy group. Giving it to animals results in the more rapid production of some of the signs of thiamin deficiency, although it differs from thiamin in being unable to pass the blood–brain barrier.

Acute Deficiency in the West

With the discovery that autoclaving yeast powder would destroy the thiamin, whereas the other B-vitamins were retained, it was possible to place volunteers on an artificial diet essentially free of thiamin. To the surprise of investigators, some subjects had lost appetite within 2 weeks and became nauseated and dizzy, with other mental symptoms, by 6 weeks, but with no sign of peripheral nerve damage or cardiac abnormality, which are characteristic of classic beriberi.

Trials using pigeons and rats with very deficient diets also produced appetite loss and death before any sign of leg weakness had developed. It appeared that in both humans and animals, acute deficiency of thiamin resulted in damage to the central nervous system. With slightly higher intakes, the CNS had priority, whereas peripheral nerves gradually degenerated.

Deficiencies in Total Parenteral Nutrition

There are many reports of people recovering from surgery of the gastrointestinal tract who have developed acute thiamin deficiency. They had been fed intravenously with a solution providing energy, amino acids, and minerals but no vitamins. This is adequate for a short period, but thiamin is the first vitamin to become depleted.

In a number of cases where this type of parenteral feeding has continued for some weeks, a condition called 'Wernicke's encephalopathy' has developed. Patients are confused and have characteristic involuntary eye movements. Where patients have died, autopsies have shown brain lesions analogous to those found in acutely deficient animals. The same outcome has been seen in subjects voluntarily fasting for long periods or being unable to take food because of persistent vomiting in pregnancy.

Alcoholism

One material that can be responsible for the production of thiamin deficiency is ethanol (i.e., 'alcohol' in everyday speech). In developed countries where nearly everyone can afford a well-balanced diet, most of those diagnosed as being thiamin-deficient are 'alcoholics.' The continued ingestion of high levels of alcoholic beverages has many undesirable effects. In the present context, two are relevant. First, the alcoholic typically no longer bothers to eat a normal range of foods, partly because the beverages provide a large portion of their calorie needs and partly from nothing but their next drink being of immediate interest. Second, the high level of alcohol ingestion damages the intestinal wall so that thiamin is absorbed less efficiently, and the requirement for the vitamin increases.

Unfortunately, a small proportion of such victims develop Wernicke's encephalopathy, which may lead in turn to Korsakoff's psychosis. Such people, sometimes referred to as suffering from the Wernicke–Korsakoff syndrome, are at present incurable and have to be maintained in a mental hospital for the rest of their life. The cost of this to the state is such that some specialists have argued that it would actually be cheaper to have all beer and wine fortified with thiamin as a preventive.

There may be a genetic factor making some Western people susceptible to the cerebral form of beriberi and the Wernicke–Korsakoff syndrome, since it was seen even in Western prisoners of the Japanese in World War II who had white rice but no alcohol, but apparently has not been seen in Asian subjects.

BIFIDOBACTERIA IN FOODS

A L McCartney, University of Reading, Reading, UK

Historical Beginnings

Historically, bifidobacteria have been incorporated into foods for preservation purposes or to combat spoilage organisms. With modern technologies, including sterilization/pasteurization techniques, cold-storage facilities, preservatives, and transportation, more traditional microbiological methods are less necessary. In spite of this, the last decade has seen a minor resurgence in biopreservative applications of bifidobacteria, with extended shelf-life demonstrated for meat and fish products treated with organic acid salts and bifidobacteria. In general, however, modern foods containing bifidobacteria are produced and marketed for prophylactic and/or therapeutic applications, so-called 'well-being' foods or functional foods. The aim of this review is to discuss the relevant issues and current status of foods containing bifidobacteria. As such, we will cover the history of functional foods, the bifidobacterial microflora of humans, potential health benefits of bifidobacteria in humans, considerations for incorporating bifidobacteria in food products, and the regulations/legislation surrounding such products.

The concept that diet impacts the health and well-being of the host animal has long been established. Historically, the ingestion of foods containing lactic acid bacteria (including bifidobacteria) has been commonplace. However, the traditional consumption of fermented milk products largely resulted from the need to reduce putrefaction of foods and preserve them for leaner times. The first scientific contribution to the phenomenon that is now known as 'Functional Foods' was in the early 1900s by Elle Metchnikoff. In his book, 'The Prolongation of Life,' Metchnikoff promoted the ingestion of fermented milks for health and longevity of life. At the same time, work by Tissier demonstrated that there were distinctive bacterial populations harbored by breast- and formula-fed infants. Bifidobacteria were the predominant organisms in fecal samples from breast-fed infants, whereas their formula-fed counterparts harbored a more diverse fecal microbiota in which bifidobacteria were less dominant. Taken together with the general acceptance that breast-fed infants are healthier and better able to resist enteric infections than those fed formulae, the interest in bifidobacteria and methods of enhancing their dominance in the human gastrointestinal (GI) tract was born.

Functional foods are defined as foods that provide benefits to the consumer beyond that of simple nutrition. Much interest has been seen in the potential of

functional foods to modify the gut microflora, both of humans and animals, and in the health benefits of such modulation. Initial work in this area concentrated on *probiotics* (live microbial feed supplements that beneficially affect the host animal by improving its intestinal microbial balance). Lactic acid bacteria (LAB), especially lactobacillus and bifidobacteria, have accordingly received enormous attention from both the scientific community and the food industry. More recent developments in the area of functional foods have targeted *prebiotics* (nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon). Such food components are considered to be preferable to probiotics, since they lack stability problems, both within the food product and during transit through the upper GI tract, and they are aimed at enhancing the indigenous LAB. However, this is beyond the scope of this review, and we will concentrate on bifidobacteria in foods rather than bifidogenic foods (foods containing bifidobacteria and/or compounds that enhance bifidobacteria). Additionally, there are some instances where probiotics are advantageous, owing to species- and/or strain-specific properties and/or limited indigenous LAB.

Bifidobacteria in the Human Colon

The normal colonic microflora of humans is extremely large and complex. The composition of this bacterial population is affected by host-mediated factors, microbial factors, microbial interactions, and environmental factors. Examples of each of these factors are listed in Table 1. Bifidobacterial levels fluctuate in humans throughout their lifespan (although they are relatively stable during adult life), with the largest numbers usually seen in exclusively milk-fed infants and reduced levels seen in the elderly. Compromised individuals can also harbor low bifidobacterial populations. Indeed, extensive antibiotic treatment and chemotherapy have been demonstrated to markedly reduce the bifidobacteria levels of humans. Low bifidobacterial levels often correspond to greater susceptibility to enteric infections and outbreaks of diarrhea.

Feeding bifidobacteria to humans (either in food products or as freeze-dried preparations) has most often led to recovery of the administered strain in intestinal or fecal samples. The ingested probiotic is usually lost from the intestinal flora relatively soon after administration ceases (often within 4–7 days). When bifidobacteria are administered to healthy humans, whose microflora is undisturbed, the effect on the bacterial population levels is usually low. However, metabolic changes have been observed in some investigations of bifidobacterial feeding in healthy humans.

Table 1 Examples of factors affecting the composition of the normal microflora of humans

Type	*Examples*
Host-mediated	Gastric secretions
	Gastrointestinal motility
	Host physiology
Microbial characteristics	Ability to adhere
	Nutritional flexibility
	Generation time
Microbial interations	Synergistic
	Antagonistic
Environmental	Diet
	Stress

Potential Health Claims of Bifidobacteria

A number of health benefits have been attributed to LAB, including: colonization resistance, stimulation of host immune function, anticarcinogenic activity, lowering cholesterol levels, alleviation of lactose intolerance, vitamin synthesis, and re-establishing a balanced intestinal flora. These are discussed in more detail below. However, the scientific evidence for some of these claims is weak and/or contradictory at best. Often, inappropriate animal models or poorly designed *in vitro* and *in vivo* studies have been employed. In the following pages, we will endeavour to summarize the current knowledge on the benefits of bifidobacteria to human health. Table 2 lists a number of human studies investigating various effects of oral administration of bifidobacteria.

Colonization Resistance

One of the most common claims associated with dairy foods containing bifidobacteria, and other LAB, is the 'maintenance or re-establishment of healthy intestinal microflora.' The normal colonic flora provides an important barrier function against pathogenesis, often termed 'colonization resistance.' Multiple mechanisms may be involved in the exclusion of undesirable organisms by bifidobacteria, including competition for receptor sites and/or nutrients and production of inhibitory factors and/or conditions [e.g., organic acids or antimicrobials, as well as physiological factors (lowering of pH and/or stimulating the immune system)]. Perhaps the most compelling evidence of the therapeutic effect of bifidobacterial food products is seen during dietary intervention studies of individuals with a disturbed colonic flora. The best examples of such data have

Table 2 Compilation of experimental results showing the effect of feeding bifidobacteria in humans

Organism	*Control*	*Test*	*Effect*
Bifidobacterium bifidum, Lactobacillus acidophilus	15 humans receiving no fermented milk	15 humans Fermented milk	Increased total IgA levels
B. bifidum, L. acidophilus	Baseline[a]	14 humans	Increased phagocytic activity
B. bifidum, Streptococcus thermophilus	Placebo	55 hospitalized infants	Reduced incidence of diarrhea (70% of observed diarrhea cases caused by rotatvirus)
Bifidobacterium spp.	Baseline	Humans Fermented milk	Lowered β-glucuronidase levels
B. bifidum, L. acidophilus, S. lactis, S. cremoris	Baseline	Humans Fermented milk	Lowered nitroreductase levels
B. longum	Baseline	10 humans Fermented milk	Lower fecal pH
B. longum, L. acidophilus	Placebo	30 humans Fermented milk	Lowered fecal volatile fatty acids levels and reduced GI discomfort
B. longum	Baseline	6 humans Fermented milk	Increased bifidobacterial dominance
B. longum	Placebo	12 humans Fermented milk	Increased fecal bifidobacteria levels
B. bifidum, L. acidophilus	Placebo	Humans Lyophilized bacteria	Delayed reduction of bifidobacteria due to antibiotic treatment and induced earlier re-establishment of bifidobacteria, postantibiotic therapy
B. bifidum	Baseline	12 elderly dyspepsia patients Lyophilized bacteria	Increased fecal bifidobacteria levels and reduced symptoms
B. bifidum, L. acidophilus	Placebo	20 humans Lyophilized bacteria	No significant differences during amplicillin administration
B. bifidum	Placebo	15 humans Lyophilized bacteria	Decreased chronic inflammation of sigmoid colon and increased humoral immunity
B. longum BB536	*B. longum* ATCC15707	48 Humans Fermented milk	Reduced clostridia, bacteroides, coliforms population levels
Bifidobacterium spp.	Pasteurized bifidus-fermented milk	60 Humans Fermented milk	Reduced colonic transit time
Bifidobacterium spp.	Baseline	Patients with hepatitis or liver cirrhosis	Lowered blood ammonia and phenol levels, reduced urinary indican levels, increased fecal bifidobacteria levels and improved appetite and weight gain
B. lactis	13 control subjects given placebo milk	12 healthy elderly humans Supplemented milk	Increased interferon-α levels and polymorphonuclear cell phagocytic capacity
B. longum	Baseline	5 humans Lyophilized bacteria	Reduced lecithinase negative clostridia numbers, lowered NH_3 and β-glucuronidase levels in feces and reduced fecal pH
Bifidobacterium spp.	Baseline	Bedridden elderly humans Fermented milk	Increased stool frequency
B. bifidum, L. acidophilus	10 elderly humans	15 elderly humans	Reduced inflammation of sigmoid and descending colon
Bifidobacterium spp.	Baseline	15 humans	Reduced stool frequency in intractable diarrhea
B. longum	Yogurt without bifidobacteria	10 Humans Fermented milk	Reduced erythromycin induced gastrointestinal effects
Bifidobacterium spp.	Baseline	Humans Fermented milk	Lowered nitroreductase and glucuronidase levels

[a]Same subjects prior to feeding.

come from investigations of the antidiarrheal effect of bifidobacteria. Indeed, the biotherapeutic potential of foods containing bifidobacteria (and other LAB) has been well established for antibiotic-associated diarrhea outbreaks and rotavirus infections. In a double-blind, placebo-controlled trial in 55 hospitalized infants, oral administration of *Bifidobacterium bifidum* and *Streptococcus thermophilus* reduced the incidence and severity of rotavirus diarrhea. There is also some evidence that fermented milk products containing bifidobacteria may protect against traveler's diarrhea. However, work to date suggests that the

probiotic strain/mixture as well as the destination are paramount.

Physiological Effects

The production of organic acids (acetic and lactic acid) by bifidobacteria inhibits the growth of pathogenic organisms (directly and indirectly) and stimulates intestinal peristalsis. Acetic acid is a stronger antagonist against Gram-negative bacteria than lactic acid. As such, the potential applications of bifidobacteria against microbial perturbation may surpass those of lactobacilli. Additionally, the organic acids produced by bifidobacteria have been shown to inhibit the growth of many nitrate-reducing bacteria. Human studies using bifidobacteria as a dietary adjunct have shown the relief of symptoms in constipated elderly persons (Table 2). Several investigations have also reported a reduction of fecal pH in individuals consuming fermented milk products containing bifidobacteria. Lowering the pH of the intestinal tract produces an environment less favorable to some pathogenic bacteria and thus helps prevent their overgrowth.

Anticarcinogenic Activity

Increasing evidence, from *in vitro* experiments and animal studies, indicates the potential protective influence of probiotic bacteria (including bifidobacteria) against cancer. To date, three plausible mechanisms have been identified: (1) inhibition of putrefactive organisms that produce carcinogens (such as *N*-nitroso compounds, phenolic products of tyrosine and tryptophan, and metabolites of biliary steroids); (2) binding and/or inactivation of carcinogens; and (3) inhibition of tumor cell formation. Bacterial enzymes (including β-glucuronidase, β-glucosidase, nitroreductase, and azoreductase) are responsible for converting some procarcinogens into carcinogens. As such, the levels/activities of these enzymes are considered a useful biomarker for cancer risk in humans, enabling noninvasive estimation of carcinogen levels. Several human studies have employed this method to determine the effects of different diets on the risk of colon cancer. A number of investigations have shown a reduction in fecal enzyme activity during ingestion of bifidobacteria-containing milk products, compared with initial levels before bifidobacterial consumption (i.e., baseline levels). Although these results are encouraging, they are inconclusive regarding the effects on cancer risk. Much more research is required to establish clear links between enzyme activity and cancer risk. Animal studies have enabled more definitive investigations of the anticancer effects of bifidobacterial feeding. Several such reports from murine models have identified an antitumor effect of bifidobacterial feeding (with or without prebiotics). Cases affording protection against both aberrant crypts (precancerous lesions) and tumors have been published. However, animal studies are speculative at best, regarding the protective nature of these strains against the development of cancer in humans.

Stimulation of Immune Functions

Several probiotics, including some bifidobacterial strains, are claimed to enhance the immune system in a nonspecific manner, thereby stimulating immunity to a number of antigens. A number of studies have also shown the ability of certain LAB strains to alter cytokine production and/or increase secretory IgA levels. However, most work in this area has either involved inappropriate animal models or concentrated on intermediary endpoints (such as cytokine production) rather than disease symptoms. Poor study designs have also led to difficulty in confirming the immunomodulatory agent. Preliminary data demonstrate the potential of probiotics in modulating certain immune responses and indicate their potential role in allergy, autoimmunity, and gastrointestinal disease.

Cholesterol-lowering Ability

Mann and Spoerry identified correlations between daily consumption of fermented milk and low serum cholesterol levels in East African Masai warriors. Subsequent *in vitro* work has demonstrated the ability of bifidobacteria to both assimilate cholesterol and coprecipitate it with deconjugated bile acids. Such observations have led to great interest in the cholesterol-lowering capacity of a diet containing fermented milks. However, much contradictory data exist regarding the effects of consuming foods containing bifidobacteria on serum cholesterol levels. Confounding the issue has been the use of different strains, dosages, and/or food vehicles in the various studies carried out so far. Additional criticisms of the current data have included lack of stabilization of baseline cholesterol levels, inadequate size and/or duration of studies, and difficulty in controlling the diet and physical activity of subjects.

Lactose Intolerance

Lactose malabsorption affects large portions of the population (estimated by some to affect over half the world's population), with a higher prevalence in those of Oriental or African ancestry. Symptoms normally include abdominal discomfort, flatulence, and/or diarrhea. However, lactose-intolerant individuals

can consume cultured milk products (containing bifidobacteria and/or lactobacilli) without any deleterious effects. Two mechanisms have been proposed for the improved digestibility of lactose in such products: (1) the β-galactosidase activity of the probiotic strains; and (2) stimulation of host mucosal β-galactosidase activity by the ingested strains.

Nutritional Value

Bifidobacteria are known to produce thiamine, riboflavin, vitamin B_6, and vitamin K. There have also been reports of their ability to synthesize folic acid, niacin, and pyridoxine. These vitamin B complexes are slowly absorbed in the human body. However, the impact on human nutrition of such vitamin synthesis by bifidobacteria in the colon is unknown. Available information on the nutritional properties of fermented milks containing bifidobacteria indicates that they have lower residual lactose and higher levels of free amino acids and vitamins than nonfermented milks. Additionally, they preferentially contain L(+)-lactic acid [produced by bifidobacteria in addition to acetic acid, whereas lactobacilli produce D/L(−)-lactic acid], which is more easily metabolized by humans. This is particularly important for infants less than 1 year old, in whom metabolic acidosis can be a problem. Consuming bifidobacterial food products may also improve the bioavailability of certain minerals, including calcium, zinc, and iron, by lowering the gastric pH (facilitating ionization of minerals, which is necessary for their uptake).

Product Development

Technically, bifidobacteria may be incorporated into foods either to produce certain product characteristics, such as organoleptic and/or nutritional properties, or as a probiotic. In the latter case, the viability of the strain is essential during both manufacture and storage of the food product. Indeed, the generally accepted recommendation is that probiotic strains must be present at levels of $> 10^6$ viable cells per milliliter at the time of consumption. This is based on the minimum therapeutic daily dose of 10^8–10^9 cells.

Bifidobacterial cultures incorporated into foods for therapeutic purposes may be added either during fermentation (along with or as part of the starter culture) or to the finished fermented or fresh product prior to shipment. Storage of food products under the appropriate refrigeration conditions after manufacturing restricts subsequent fermentation. As such, products to which bifidobacteria are added immediately prior to distribution are organoleptically indistinguishable from the unfortified version. Products fermented with bifidobacteria, however, often have a mild acidic flavor. The selection of culture strains and ratios is as critical in determining the final product characteristics as the fermentation parameters (temperature, duration, chemical composition and level of inoculum).

Selection Criterion

The selection of bacterial strains is vital since different strains (even within the same species) have distinctive metabolic and probiotic characteristics, as well as different growth rates. The main factors to consider include rate of acid production, type of polysaccharide fermentation, ability to synthesize vitamins, proteolytic characteristics (which may result in bitter compounds) and capacity to produce flavor compounds. An additional consideration is the growth characteristics of the bacterial strains. This is particularly important regarding mixed inocula and determining both the optimal mixture and the ratio of strains, as well as the appropriate time in processing to add the organisms. Recent studies have shown that bifidobacteria inoculated into sour cream and buttermilk either at the time of setting or at the time of breaking allowed appropriate numbers of bacteria to survive during normal storage of the products. Additional work suggests that the best procedure for incorporating bifidobacteria in cottage cheese is in the creaming mixture, whereas addition immediately after cooking (prior to hooping) is suitable for Edam cheeses. In the production of yogurts containing bifdiobacteria, it is common practice to use premixed cultures of *Streptococcus thermophilus, Lactobacillus delbrueckii* ssp. *bulgaricus, L. acidophilus*, and *Bifidobacterium* species. However, bacterial 'loading' is also practiced, where the lactobacilli and bifidobacteria are grown separately prior to addition to the product. A number of studies have also demonstrated successful manufature of probiotic cheeses, especially hard cheeses (e.g. cheddar, Canestrato Pug liese and Gouda-type), by either incorporating bifidobacterial strains in the starter culture or using bifidobacterial fermented cream.

As bifidobacteria are anaerobes, it is useful to select species or strains that are less oxygen-sensitive (such as *B. infantis* and *B. longum*), perform gas flushing with nitrogen (a process often used for preserving yogurts), or include an oxygen scavenger in the fermentation inocula (such as *S. thermophilus*). The growth and survival characteristics depend on the pH (and its buffering capacity), the fermentation and storage conditions (especially temperature and duration), and the presence of competing microorganisms or microbial inhibitors (such as H_2O_2 and NaCl).

Regarding biotherapeutic considerations, the strain(s) must be selected, based on their ability to elicit the desired beneficial effect at the target. This necessitates their survivability within the product and during transit through the upper GI tract. As such, it is pertinent to use bifidobacteria of human intestinal origin as they are better suited to the physiological needs of the host than strains from other sources. Finally, it is essential to demonstrate the safety of probiotic strains. They must be confirmed as non-pathogenic, have a well-established safety record, or have 'generally regarded as safe' (GRAS) status. Many publications have listed recommendations of selection criteria for probiotic strains. These fall into the four general categories of (1) appropriateness, (2) technological suitability, (3) competitiveness, and (4) performance and functionality.

Technical Considerations

Besides strain selection, careful monitoring throughout the manufacturing process is required to insure efficient control of the final product (pH, metabolic products, cell density, and flavor). Incorporation of LAB above the necessary starter organism to produce specific product characteristics demands examination of the final product to confirm the desired property. For example, *in vitro* demonstration of a strain's ability to synthesize vitamins is inadequate on its own, as the fermentation characteristics and final product composition (including the levels of the desired vitamins) need to be determined.

A number of methods have been reported to increase the survival of LAB whilst maintaining the desirable attributes of yogurt. These include enrichment with whey protein concentrate; lowering incubation temperature (to 37 °C); terminating fermentation at a higher pH (e.g., > 5); hydrostatic pressure treatment or heat-shock of yogurt (to prevent postmanufacture acidification); and storing below 3–4 °C.

Market for Foods Containing Bifidobacteria

To date, food products containing bifidobacteria have largely been of dairy origin and include yogurts, fermented milks, fresh milks, cheeses, buttermilk, sour cream, cream cheeses, cottage cheeses, frozen dairy desserts (including icecream and frozen yogurts), and dips. Research has further demonstrated the feasibility to incorporate bifidobacteria in vegetable spreads, fermented vegetable products (such as kimchi, a traditional Korean food), mayonnaise, cookies, and some beverages. A list of some of the commercially available fermented milk products containing bifidobacteria and some of their claims is provided in Table 3.

The increased awareness of consumers towards general health and well-being, together with the accepted impact of diet on health, has led to a greater demand for healthy and/or functional food products. As such, the upward trend currently seen in bifidobacterial foods is projected to continue. As much as 70% of milk products on the market in some European countries, such as Sweden, contain bifidobacteria. The Japanese and European food industry and markets are well ahead of the USA and Canada, regarding functional foods. However, the influx of foods containing bifidobacteria on these markets has begun. A recent article estimated double-digit annual growth rates of the world-wide market for such products.

Regulations and Legislation

The generally accepted minimum level of probiotics in foods at the time of consumption is $> 10^6$ cells per milliliter. However, the standard developed by the Fermented Milks and Lactic Acid Bacteria Beverages Association of Japan is $> 10^7$ cells per gram at the time of manufacture. In the USA, 10^8 bacteria per gram at the time of manufacture is the criterion of the National Yogurt Association (NYA). As well as the concern of viability of probiotics within the consumed product, there is increasing interest (from the scientific community, food industry, and national authorities) in establishing codes of practice regarding the legislation and regulations of health claims for food products. To this end, definitive evidence demonstrating the efficacy of products is essential. As such, statically significant, well-designed (double-blind, placebo-controlled) clinical trials are demanded for health-promoting food products. The need to prove safety is equally important to substantiating efficacy. Key areas for demonstrating nutritional safety include intake, extent of use, implications/impact on gut microflora and metabolic pathways, compositional analysis (including the presence of antinutritional or toxic factors), and potential effects in compromised individuals or specific target populations.

Currently, there is no world-wide regulatory or legislative control on the labeling and health claims of food products. However, most legislative bodies prohibit the use of 'medicinal' claims for food products (including functional foods). That is, claims suggesting the prevention of, treatment, and/or cure for human disease are not permissible for food products. However, health claims are deemed acceptable and usually involve the promotion of health benefits,

Table 3 Commercially available fermented milk products containing bifidobacteria

Product	*Bacterial strains*	*Claims*	*Country*
A-38	*L. acidophilus, B. bifidum, Leuconostoc mesenteroides* ssp. *cremoris*, mesophilic lactococci		Denmark

Yukijirushi Nachure	*L. acidophilus, B. longum*	Promote the maintenance of a good intestinal environment	Japan

reduction of disease risk, or general well-being of the host. Health claims may not include specific claims such as 'improves resistance against pathogenic infection' but could state 'improves normal intestinal function.' As one can see, the line between medical and health claims is very gray, and the presentation or wording of the claims is usually important in defining under which heading they fall. Indeed, one published explanation of medical foods (medicine) and functional foods gave the following definitions. Medicines include 'a food product which has a direct preventative effect on a disease,' whereas health claims may

include maintenance of 'good health as part of a life style' and/or potential reduction of 'the risk of disease occurring.'

In Japan, a voluntary system is in place where industry may apply for 'Foods for Specified Health Use' (FOSHU) approval. Information on the safety and efficacy in humans (including definitive scientific evidence) and nutritional analyses are required for such approval. FOSHU labeling, therefore, effectively demonstrates that the product is approved as a functional food, according to the advertised claim.

In the USA, Federal Drug Agency (FDA) approval is necessary regarding any labeling of health claims on food products. Furthermore, the claims must be founded on an 'authoritative statement' from an appropriate Government scientific agency responsible for 'public health protection or research.' However, 'structure/function' statements are permitted on dietary supplements relating the food ingredient to 'normal, healthy functioning of the human body.' Such claims are not normally used on conventional foods, but rather for foods intended to supplement the diet. That said, foods containing bifidobacteria are generally marketed as dietary supplements in the USA, and therefore fall within a loophole. Currently, however, most manufacturers of such products simply name the added bacteria (at least to genus level) for labeling purposes and do not state any functions or claims.

In Europe, there is no collective regulation or legislation regarding functional foods. In general, the primary focus is on the safety of the products. Food products or food ingredients that were not available on the European market for human consumption prior to April 1997, and can be classified as novel (owing to raw materials, composition, or manufacturing process), must undergo regulatory approval. The second regulatory focus in Europe is the labeling and health claims of the food product. The general rule of thumb is that health claims may not attribute the property of preventing, treating, or curing a human disease, or any such implications. Currently, seven European Union member states are developing their own Codes of Practice regarding legislation and regulation of health claims and labeling of functional foods. The level of scientific substantiation needed for such health claims differs between some codes. However, the Codes of Practice for the UK, Belgium, and The Netherlands all include principles for human (clinical) trials.

Summary

Results to date clearly indicate the potential benefits of consuming a diet incorporating foods containing bifidobacteria. Several food vehicles have been identified within the dairy industry, and appropriate manufacturing techniques are available to insure that the desired product characteristics and viability of probiotic strains are attained. Essential to the future of functional foods are adequate studies confirming the safety, efficacy, and viability of such products (especially well-designed human clinical trials). Current developments within the scientific community, food industry, and regulatory bodies are all pursuing this end.

BILE

A Lanzini, University of Brescia, Brescia, Italy

Background

Bile is a complex aqueous solution of organic and inorganic compounds secreted by the liver. It contains bile acids, a class of detergent-like molecules that exert their biological functions as lipid solubilizers within the biliary tree and the gut lumen. The bile acids are restricted to the enterohepatic circulation, so as to reutilize many times these biologically valuable molecules. This chapter reviews the composition and physicochemical properties of bile, the mechanism involved in bile formation, and the function of bile acids as solubilizers of biliary and dietary lipids.

Composition of Bile

Inorganic compounds in human hepatic bile comprise electrolytes in concentrations similar to those in plasma, with the noticeable exception of HCO_3^- concentration which is higher in bile. The osmolarity of human hepatic bile is also similar to plasma osmolarity, at about 300 mOsm l^{-1}.

Organic compounds in bile comprise protein and bile pigments in addition to the three biliary lipids, bile acid, cholesterol, and phospholipid. Proteins account for 4.5% of organic compounds in bile, and their concentration ranges between 0.3 and 3.0 g ml^{-1} in typical human bile. The most abundant biliary protein is albumin derived from the plasma pool. In general, the biliary concentration of other plasma proteins is inversely related to their molecular weight. Bile also contains immunoglobulin A, lysosomal enzymes, and plasma membrane enzymes. The secretion of these latter proteins is influenced by the bile acid secretion rate.

Bile pigments constitute less than 0.3% of organic compounds in bile, and their concentrations range between 0.8 and 3.2 mmol l^{-1} in human hepatic and gallbladder bile, respectively. Conjugation with glucuronic acid is essential for biliary bilirubin excretion, and bilirubin diglucuronide is the major pigment in human bile. The maximal bilirubin excretion capacity depends on bile flow and is increased during enhanced bile acid secretion rates. About 30% of bilirubin excretion is thought to be bile acid-independent, suggesting that incorporation of bilirubin into mixed micelles is not essential for its biliary excretion.

Many other endogenous substances are present in human bile in addition to those listed above. These include vitamins (mainly D_2, B_{12}, folic acid), steroid (estrogens), and thyroid hormones. Exogenous compounds such as contrast media, some antibiotics (ampicillin, metronidazole), cardiac glycosides, and opiates may also be excreted in bile and undergo some degree of enterohepatic circulation.

Biliary Lipid Chemistry and Physicochemical Properties

Bile Acids

Bile acids comprise a class of molecules derived from the hepatic catabolism of cholesterol. More than 200 bile acids have been isolated in human bile, and 92–99% of total bile acids are constituted by mono-, di-, and tri-hydroxy derivatives of a 24-carbon atom steroid, cholanoic acid (Figure 1). The brief and systematic names and the relative proportions of individual bile acids in human bile are shown in Table 1.

Virtually all biliary bile acid are amidated in man almost exclusively with glycine or taurine at a ratio of about 2:1. Sulfation on the steroid nucleus of bile acids occurs to a significant extent in man only for lithocholic acid, and glucuronidation is a trace metabolic pathway in man.

From a physicochemical point of view, bile acids are planar amphiphiles in that they exhibit both hydrophilicity with one part of the molecule and hydrophobicity with the remainder. In commonly occurring bile acid molecules, the hydrophobic face is constituted by the β side of the steroid nucleus, and the hydrophilic face by the α side of the nucleus and by the side chain. The relative potency of the hydrophilic and hydrophobic functional groups in affecting the physicochemical properties of bile acids is referred to as the hydrophilic–hydrophobic balance. The order of increasing hydrophilicity, as assessed by high-pressure liquid chromatography, follows the order taurine conjugates > glycine conjugates > unconjugated bile acid; and trihydroxylated > dihydroxylated>monohydroxylated bile acids.

Bile acid solubility is strongly dependent on amidation. Unconjugated bile acids (pK_a 5.0) are insoluble at a pH below 6–7, and glycine-(pK_a 3.8) and taurine-conjugates (pK_a < 1.0) are soluble at pH 4–5 and below 2, respectively. Fully ionized common bile acids are present in physiological solutions as their sodium salts. They are extremely water-soluble, with a monomeric solubility of 1–3 mmol l^{-1} (Figure 2).

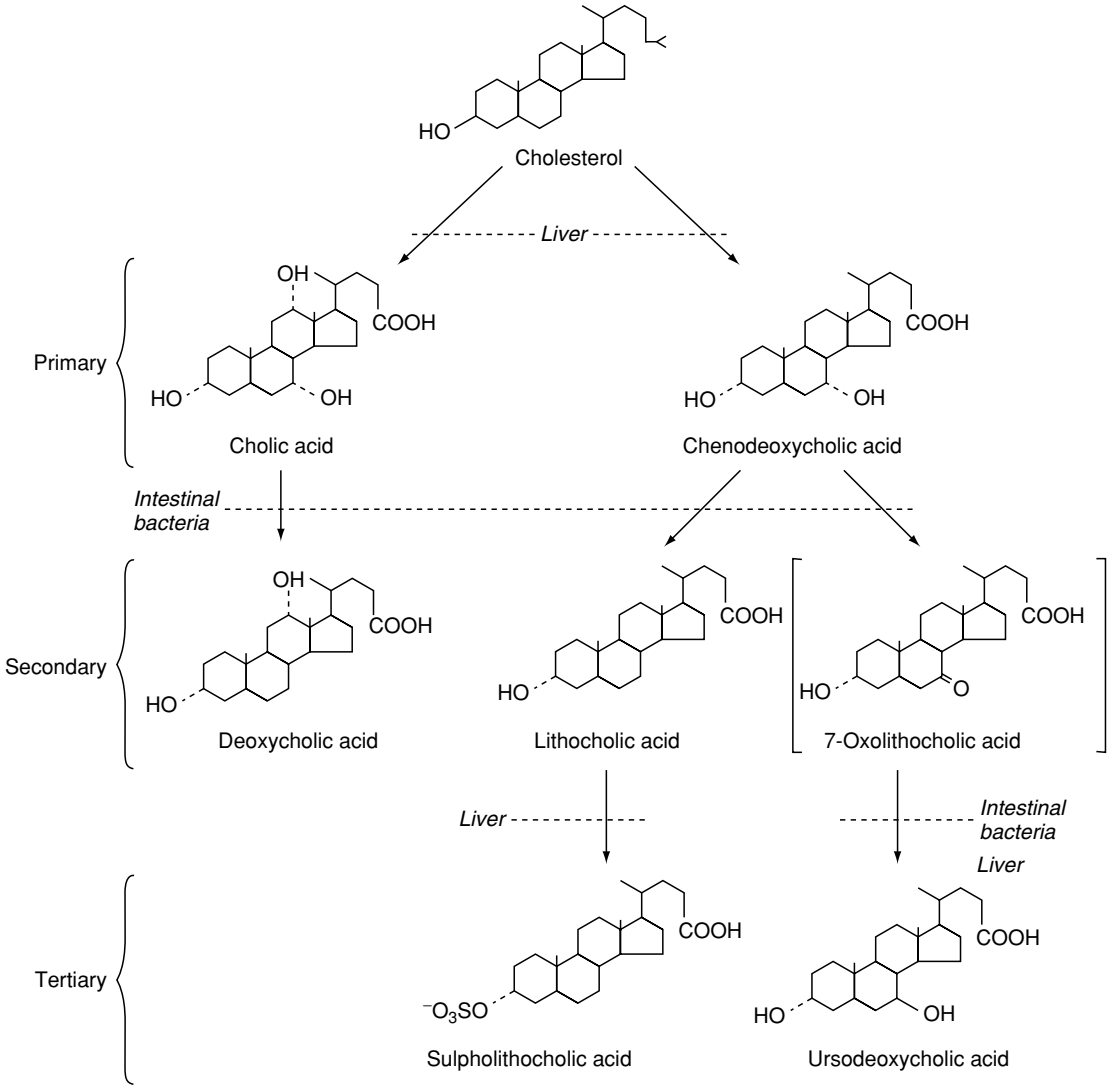

Figure 1 Structural formulae and sites of synthesis and metabolism of common bile acids in man. From Carey MC and Duane WC (1994) Enterohepatic circulation. In: Arias IM, Boyer JL, Fausto N *et al*. (eds.) *The Liver: Biology and Pathobiology*, 3rd edn, pp. 719–767. New York: Raven Press, with permission.

They are present in diluted water solutions as monomers in the bulk water phase, and as an unstable film on the water surface. Upon concentration, a critical monomeric concentration is reached, called the critical micellar concentration (CMC), at which bile acid monomers self associate to form multimolecular aggregates called micelles. Micelle formation involves back-to-back agglomeration of the hydrophobic side of the bile acid molecules, with the hydrophilic side facing water. At concentrations above the CMC, bile-salt micelles have the capacity of incorporating and solubilizing otherwise insoluble compounds, thus acting as detergents. In general terms, hydrophobic bile acids form micelles at lower concentration than hydrophilic bile acids, and the CMC ranges between 0.5 and 11 mmol l^{-1} for common bile acid (Table 1).

Phospholipids

The most abundant biliary phospholipid species are phosphatidylcholines (lecithins), which account for 80–95% of phospholipids in human bile. Phosphatidylcholines are insoluble swelling amphiphiles, with a monomeric solubility in water of about 1 pmol l^{-1} (Figure 2). Upon hydration (> 45% water), phospholipids swell to form liquid crystalline phases consisting of choline bilayers with interposed water layers. These liquid crystalline phases may fold and aggregate to form vesicular structures.

Cholesterol

From a physicochemical point of view, cholesterol is an insoluble nonswelling amphiphile, with a monomeric solubility in water of about 1 nmol l^{-1} at 37 °C (Figure 2). Upon hydration, crystals of cholesterol monohydrate are in equilibrium with water-containing monomers of cholesterol monohydrate.

Table 1 Name and composition of biliary bile acids of typical human bile

Brief name of bile acid	*Systematic name*	*CMC (mmol l^{-1})*	*Percentage in bile*[a]
Cholic	3α,7α,12α-Trihydroxy-5-cholanoic acid	11	35
Chenodeoxycholic	3α,7α-Dihydroxy-5-cholanoic acid	4	35
Deoxycolic	3α,12α-Dihydroxy-5-cholanoic acid	3	24
Ursodeoxycholic	3α,7β-Dihydroxy-5-cholanoic acid	7	tr.–4
Lithocolic	3α-Monohydroxy-5-cholanoic acid	0.5	tr.–3

[a]Individual bile acids as a percentage of total bile acids. CMC, critical micellar concentration; tr, trace.

Bile Formation

Bile formation involves a number of secretory processes in the hepatocyte and in the ductular cells generating an osmotic gradient between the cells and the biliary canaliculus and ductulus, with passive water movement along this gradient until osmotic equilibration is achieved. Canalicular and ductular bile flow contribute 470 and 150 ml, respectively to the typical total daily bile flow of 620 ml in man. Bile flow varies from 1.5 to 15.4 μl min^{-1} kg^{-1}, and is linearly related to bile acid secretion rate (Figure 3). The contribution of canalicular to total bile flow is defined by the linear relationship between bile acid secretion and biliary clearance of sugars (erythritol or mannitol) acting as bile-flow markers. This relationship identifies the so-called bile acid-dependent canalicular bile flow (about 60% of total canalicular bile flow) generated by active bile acid transport into the canaliculus. Extrapolation of the linear regression function relating bile acid secretion rate and erythritol clearance to a value of zero bile acid secretion rate yields a positive zero intercept. This linear extrapolation identifies the so called bile acid-independent bile flow (about 40% of total canalicular bile flow).

Bile acid-independent bile flow is generated by active transport of glutathione and organic anions

(bilirubin glucuronide, thyroid and steroid hormones, drugs) into the canaliculus. Glutathione is synthesized in the hepatocyte, secreted into bile, where it is hydrolyzed into the constituent amino acids. These amino acids exert the osmotic gradient responsible for bile acid-independent paracellular entry of water into the biliary canaliculus. Na^+ and HCO_3^- also contribute to generating the osmotic gradient responsible for the bile acid-independent bile flow.

Bile acid-dependent bile flow is a complex phenomenon involving captation, intracellular transport and biliary secretion of bile acids (Figure 4). Bile acid captation occurs on the basolateral membrane of the hepatocyte and involves two transport systems. The first is a Na^+-taurocholate cotransporter polypeptide dependent on a sodium gradient energized by the Na^+–K^+–ATPase system. The second transport mechanism is independent of sodium gradient and consists of an organic anion transporting polypeptide. This system is not specific for bile acids, and transports other organic anions such as bilirubin, bromosulfophthalein, and estrogens.

The process of intracellular bile acid transport is poorly understood, and it is thought to occur by diffusion of bile acid bound to cytosolic protein from the sinusoidal to the canalicular pole of the hepatocyte. Vesicular transport may also play a role in regulating intracellular bile acid traffic, as suggested by the finding that vesicle poisoning results in cholestasis.

Bile acid secretion into the biliary canaliculus involves two ATP-dependent transport systems and an electrogenic system driven by membrane potential. Monovalent bile acids are transported by an ATP-dependent canalicular bile salt export pump, and sulfated or glucuronated divalent bile acids are transported by a canalicular multispecific organic anion transporter. This latter transport system is also involved in biliary excretion of bilirubin diglucuronide, glutathione, bromosulfophthalein, and other anionic dyes.

Phospholipid secretion into bile is also an active ATP-dependent process mediated by *p*-glycoprotein encoded by two genes in humans (multidrug-resistant; MDR1 and MDR3) that make cells resistant to a variety of amphipatic drugs (colchicine, vincristine, doxorubicin, and others) by stimulating their extrusion from the cell. MDR3 protein is expressed exclusively on the bile canalicular membrane and is specialized in biliary export of phospholipid, as indicated by the finding that homozygous disruption of the murine mdr2 gene (the equivalent of human MDR3) leads to complete absence of phospholipid in bile.

Cholesterol secretion into bile is tightly coupled with that of phospholipid, but it is not clear whether cholesterol secretion is carrier-mediated, as demonstrated for phospholipids. It is likely that cholesterol translocation to the outer leaflet of the bile canalicular membrane is mediated by a spontaneous flip-flop mechanism.

The current hypothesis to explain the phenomenon of lipid secretion into bile is summarized in Figure 5. Bile acids are continuously pumped out of the bile canalicular membrane into bile. When the outer leaflet of the bile canalicular membrane is sufficiently enriched with phosphatidylcholine, it 'buds out,' forming a phospholipid–cholesterol bilayer that adsorbs to bile acids and dissolves into mixed bile acid–cholesterol–phospholipid micelles (see below).

Bile flow and composition changes along the biliary tree, due to water and inorganic electrolyte movements across the duct system. The net result of these movements is an increase in bile flow due to secretion of bicarbonate and water. This process is under control of the enteric hormone secretin that stimulates secretion of Cl^- by a 'cystic fibrosis

transmembrane conductance regulator' acting as a chloride channel on the apical membrane of the biliary epithelial cells. Cl^- secretion stimulates a Cl^- bicarbonate exchanger, resulting in bicarbonate secretion and bicarbonate driven choleresis (Figure 6).

Bile Acid Synthesis and Enterohepatic Circulation

Bile Acid Synthesis

Biliary bile acids are derived from two sources, *de-novo* hepatic synthesis and hepatic recycling via the enterohepatic circulation. The former mechanism compensates for a daily fecal loss of about 200–600 mg. The liver is the unique site for bile acid synthesis, and cholesterol is the obligatory precursor. Bile acid synthesis involves both nuclear and side-chain transformation of cholesterol molecules, and about 25 intermediate compounds have been isolated along this pathway. A 'neutral' and an 'acidic' bile acid biosynthesis pathway have been identified, and the end products of the 'neutral' synthetic pathway in man are two bile acids, cholic and chenodeoxycholic acid, conventionally called 'primary' bile acids (Figure 1). 7-α-hydroxylation of cholesterol, a process catalyzed by microsomal 7-α-hydroxylase, is the rate-limiting step in 'neutral' bile acid synthesis. The first step in the 'acidic' pathway is catalyzed by sterol 27-hydroxylase, a mitochondrial P_{450} enzyme, and chenodeoxycholic acid is the predominant end product of this pathway. The contribution of the 'acidic' pathway to the total synthesis is unclear, but it can be as large as 50% of total synthesis. Bile acids resulting from subsequent bacterial modification of the two primary bile acids in the enterohepatic circulation are termed 'secondary' bile acids (see below). Bile acids resulting from hepatic sulfation of lithocholic acid and hydrogenation of 7-oxo-lithocholic acid are termed 'tertiary' bile acids (Figure 1).

It is generally agreed that bile acids returning to the liver via the enterohepatic circulation regulate their own synthesis by a negative-feedback mechanism. Bile acid synthesis may increase as much as 20-fold during interruption of the enterohepatic circulation in the bile fistula rat, and an opposite effect is achieved by increasing bile acid return to the liver. Inhibition of both cholic and chenodeoxycholic acid synthesis accompanies intraduodenal or intravenous infusion of either bile acid in the bile fistula rat. Individual bile acids appear to exhibit a specific inhibitory capacity for synthesis, which is less marked for the more hydrophilic bile acid. This inhibitory effect of hydrophobic bile acids involves transcriptional downregulation of cholesterol 7-α-hydroxylase. By contrast, increased supply of cholesterol to the cell turns on the 7-α-hydroxylase gene, thus enhancing cholesterol elimination via bile acid synthesis.

Enterohepatic Circulation and Gallbladder Storage of Bile

The movement of bile acid molecules is mainly restricted to the biliary tree, intestinal lumen, portal blood and liver, topographically referred to as the enterohepatic circulation. The driving force for the enterohepatic circulation is provided by two chemical pumps and two mechanical pumps. The chemical pumps are provided by the active transport processes underlying ileal absorption and hepatic uptake, and the mechanical pumps are gallbladder-emptying and small intestinal transit. (*See* **Liver**: Enterohepatic Circulation.) Gallbladder motor function is the major factor affecting delivery of bile into the intestine, thus influencing bile acid recycling frequency in the enterohepatic circulation. As a result of gallbladder storage and emptying functions, duodenal bile acid output typically varies from 5 μmol kg^{-1} h^{-1} in the interdigestive period to 25 μmol kg^{-1} h^{-1} postprandially. Low duodenal bile acid output during the interdigestive period is accompanied by diversion of about 90% of hepatic bile into the gallbladder. Gallbladder filling alternates with gallbladder emptying occurring synchronously with the periodic aboral progression of the intestinal interdigestive migrating motor complexes. This alternation of filling and emptying also occurs postprandially, and this 'bellows' effect may play a role in mixing of gallbladder content during the whole 24 h. The net effect of these alternating episodes of filling and emptying is that the gallbladder stores only about 50% of the hepatic bile that enters it during overnight fasting. Given a capacity of 20–40 ml, the gallbladder would be filled very soon during fasting beyond its storage capacity if it were not for its marked capacity for active NaCl and $NaHCO_3$, and passive water reabsorption.

Functions of Bile Acids

Bile

Despite the very low solubility of both phospholipid and cholesterol in water, bile is an optically clear solution that does not contain a macroscopically detectable solid phase in health. At physiological bile salt–lecithin–cholesterol molar ratios (approximately 75%–15%–5%), cholesterol monomers are solubilized in large mixed micelles having a mixed disk structure (Figure 2). This structure envisages bile acid covering the external surface of the micelles, but also dispersed inside the micellar core together with phospholipid.

The amount of cholesterol in a given bile sample may exceed the solubilization capacity of the micellar mechanism, as determined from *in-vitro* studies on model bile solutions (supersaturated bile). Hepatic bile is normally supersaturated with cholesterol at low bile acid secretion rates (< 10–15 μmol kg^{-1} h^{-1}), and gallbladder bile is often supersaturated in healthy subjects. Cholesterol monohydrate crystals are not found in these supersaturated biles when analyzed immediately following collection. However, if these supersaturated biles are stored under appropriate laboratory conditions, phase separation and cholesterol crystal formation occur within days or weeks (nucleation time). These observations indicate that bile behaves as a metastable system, and a nonmicellar mechanism of cholesterol transport must be involved to account for this prolonged metastability. This mechanism involves the formation of spherical unilamellar vesicles composed mainly of cholesterol and lecithin (ratio ranging between 1:1 and 5:2, Figure 2). The proportion of cholesterol carried in vesicles relative to that carried in mixed micelles is about 50% in hepatic bile and 40% in gallbladder bile. This proportion is not constant, and the vesicular system prevails at low bile acid secretion rates. The degree of metastability of supersaturated human bile, as assessed by *ex-vivo* nucleation time, is greater than that predictable from the nucleation time of model bile systems. A protein component of bile, probably a lipid-containing bile protein, may act as a 'stabilizer' of supersaturated normal biles.

Phase transition occurs during passage of bile down the biliary tree and during storage in the gallbladder (Figure 7). Cholesterol/phospholipid vesicles are probably excreted by the biliary canaliculus as such by a mechanism independent of that involved in bile acid monomer secretion (Figure 5). As soon as the bile acid concentration reaches the CMC within the biliary canaliculus, vesicular lipids are dissolved in mixed micelles. Supersaturated mixed micelles in hepatic bile rapidly form stable cholesterol/lecithin vesicles, probably unsaturated with cholesterol. On entry into the gallbladder, this lipid fraction may be slowly redissolved into mixed micelles unsaturated with cholesterol. This latter effect occurs as a result of the increased total lipid concentration in concentrated gallbladder bile, and this is known to enhance the micellar capacity for cholesterol. In supersaturated gallbladder bile, cholesterol-rich vesicles may remain stable as a result of protein–vesicle interaction.

Small Intestine

According to the classical theory of Hofmann and Borgstrom, normal fat digestion can be divided into two closely related events: a chemical event – lipolysis;

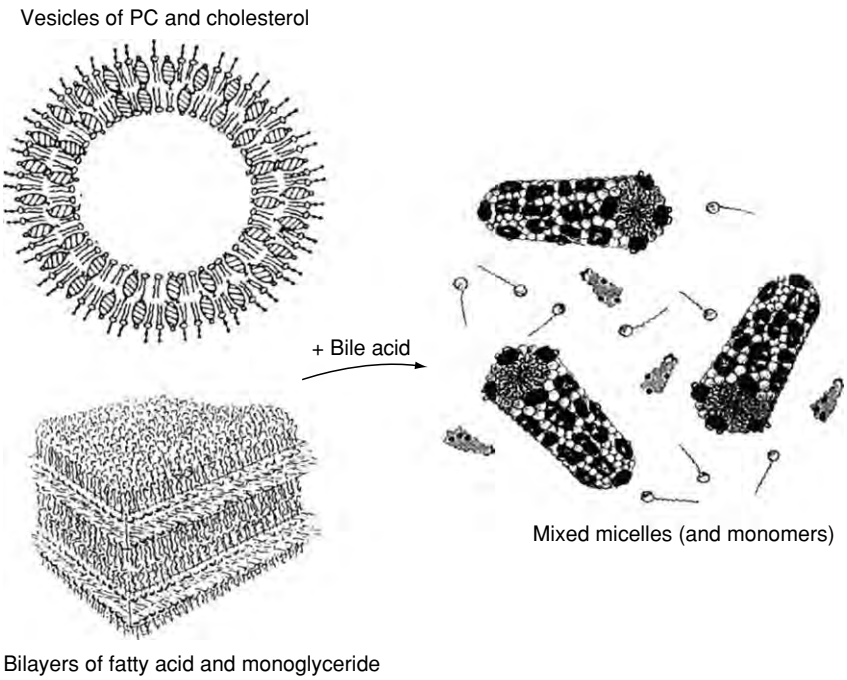

Figure 7 Conversion of phosphatidylcholine (PC)–cholesterol bilayer to mixed micelles in bile, and of fatty acid–monoacyglycerol lamellae to mixed micelles during fat digestion in the intestinal lumen. From Hofmann (1999) The continuing importance of bile acids in liver and intestinal disease. *Archives of Internal Medicine* 159: 2647–2658, with permission.

and a physical event – acqueous solubilization. Pancreatic lipolysis of dietary fat is a prerequisite for its micellar solubilization, and micellar solubilization is a prerequisite for its absorption. Bile acids play a key role in both these events.

From a physicochemical point of view, fat droplets consist of long-chain triacylglycerol stabilized mainly by phospholipids in natural food, and by other emulsifiers (arabic gum, mono- or diacylglycerols) in processed food. Dietary triacylglycerol is hydrolyzed by pancreatic lipase (lipolysis) to monoacylglycerol and fatty acid. In the absence of bile acids, access of lipase to lipid droplets is prevented by the emulsifiers surrounding the oil droplets. Bile acids have the ability to wash these off the oil droplets, thus giving access to lipase. Bile acids would also wash off the lipase, a phenomenon prevented by colipase. This coenzyme binds to lipase and bile acid, thus fixing the lipase molecule in contact with the underlying triacylglycerol.

Following digestion, the products of lipolysis are kept in solution by the natural detergents, bile acids, mainly in form of mixed bile acid–phospholipid–fatty acid–monoacylglycerol micelles. Unilamellar vesicles consisting of the products of lipolysis have been observed under the microscope to 'bud off' the lipid emulsion surface following lipase digestion. These vesicles are rapidly dissolved by biliary micelles freshly delivered by bile, so that during intestinal fat digestion, saturated mixed-disk micelles coexist with vesicles having the same lipid composition (Figure 7). Both micelles and vesicles contribute to transport of solubilized lipids across the intestinal unstirred water layer lining the gut lumen. It is not known whether lipid absorption involves monomeric absorption or vesicle fusion with the plasma membrane of the enterocyte.

Colon

Two hundred to 500 mg of bile acids escape the enterohepatic circulation and enter the colon daily. In the human colon, bile acids are exposed to obligate anaerobes bacteria capable of producing hundreds of metabolic products of bile acid. The two main biotransformations of bile acids in the colon are bacterial deconjugation and 7-α-dehydroxylation. As a consequence of the former biotransformation, conjugated bile acids are totally absent from the colon. As a result of 7-α-dehydroxylation of the primary bile acids, cholic and chenodeoxycholic acid, the majority of fecal bile acids consist of deoxycholic acid (about 50%) and lithocholic acid (33%) (Figure 1). Since these two bile acids are reabsorbed and resecreted in bile along with the two primary bile acids, they are termed 'secondary' bile acids.

Most of the bile acids precipitate in feces, since the slightly acidic pH of feces is lower than the pK_a value for unconjugated bile acids. The bile acid concentration in fecal water is about 0.5 mmol l^{-1}, and a small proportion of these bile acids are reabsorbed from the colonic mucosa by passive nonionic diffusion and reenter the enterohepatic circulation. If the value of 1.5 mmol l^{-1} for bile acid concentration in fecal water is exceeded, bile acids exert a cathartic effect by inhibiting water absorption and, at higher concentrations, by promoting colonic electrolytes and water secretion. The cathartic effect of bile acids depends on the bile acid structure, and it is at a maximum for α-dihydroxylated bile acids.

BIOAVAILABILITY OF NUTRIENTS

S J Fairweather-Tait and S Southon, Institute of Food Research, Norwich, UK

Concept and Definition of Bioavailability

Bioavailability (biological availability) is a term used to describe the proportion of a nutrient in food that is utilized for normal body functions. Although the overall concept is simple, it is very difficult to describe the bioavailability of most nutrients in quantitative terms. Therefore, to facilitate its measurement and interpretation of the data, the bioavailability of nutrients can be subdivided into its three constituent phases: (1) availability in the intestinal lumen for absorption; (2) absorption and/or retention in the body; and (3) utilization. The reasons for studying bioavailability are to evaluate the nutritional quality of foods and diets and to provide data for establishing dietary requirements for nutrients.

The amount of any nutrient that is available for absorption depends upon its release from the food macro- and microstructure during digestion, chemical and physical interactions with other food components during digestion, the form in which the nutrient is presented to the absorptive cells of the intestine, and regulatory mechanisms in the intestinal mucosa that reflect the individual's physiological need for the nutrient. These factors contribute to the (often) highly variable proportion of absorbable nutrient which is taken up and used by the body and may explain the generally poor association between total amounts of micronutrients consumed and indices of micronutrient status.

Low absorbability of some minerals and vitamins may be the underlying cause of certain nutritional inadequacies. If intakes are well in excess of

physiological requirements but bioavailability is a limiting factor, nutritional deficiency disorders may occur, as for example with iron.

Determinants of Bioavailability

There are many factors, both dietary and physiological, that influence nutrient bioavailability. Examples include: (1) the physical form of the nutrient within the food structure and the ease with which the nutrient can be released from that structure; (2) the chemical form of the nutrient in a foodstuff and its solubility in the lumen; (3) the presence of proteolytic enzyme inhibitors (commonly associated with legumes such as soybeans) which reduce the body's ability to digest protein; and (4) the presence of enzymes such as thiaminase which partially hydrolyzes thiamin and makes it less biologically active.

Diet-related factors include:

- Food structure
- Physicochemical form of the nutrient
- Enhancers of absorption, e.g., ascorbate (for iron), some organic acids, sugars, amino acids, bulk lipid (for fat-soluble vitamins), and specific fatty acids
- Inhibitors (primarily of inorganic micronutrient absorption), e.g., phosphates (especially phytate), polyphenols (including tannins), and oxalate
- Competition for transport proteins or absorption sites, e.g., between metals.

Physiological factors include:

- Gastric acidity
- Intestinal secretions
- Gut motility
- Luminal redox state
- Body status (e.g., tissue levels, nutrient stores)
- Short-term homeostatic mechanisms mediated through the mucosal absorptive cells
- Anabolic demands (e.g., growth in infancy and childhood, pregnancy, and lactation)
- Endocrine effects
- Infection and stress
- Genetic polymorphisms and inborn errors of metabolism
- Gut microflora.

Certain food constituents have the ability to bind nutrients, thereby rendering them more or less absorbable. For nutrients that are transported into the mucosal cell by means of a carrier-mediated pathway, the degree of binding is an important determinant of bioavailability. If the chelating compound has a higher affinity for the nutrient than the specific carrier molecule, then the net effect is a reduction in bioavailability. Conversely, a weak chelator may act as an absorption promoter by holding the nutrient in a suitably soluble form ready to be taken up into the intestinal mucosal cells. Binding compounds that impair vitamin bioavailability include the protein avidin in egg white, which binds biotin, making it biologically unavailable.

Competitive inhibitors of nutrient metabolism make up another category of dietary factors affecting bioavailability. It has been suggested that minerals with similar chemical properties may compete for common binding sites or carriers. Transition metals such as iron, zinc, and copper are typical examples of competitive inhibitors. This will only take place at high levels of intake when the sum of ionic species present at the site of absorption exceed the critical threshold relating to the absorption kinetics of the minerals in question. (*See* **Copper**: Physiology; **Iron**: Physiology; **Zinc**: Physiology.)

The bioavailability of lipid-soluble nutrients (including carotenoids, tocopherols, and other fat-soluble vitamins) is markedly influenced by their physicochemical availability for incorporation into mixed micelles during digestion. The release of lipid-soluble components is thought to occur primarily upon ingestion and initial digestion within the stomach. The factors which may influence their release are: localization within the food matrix; physical break-up of the food; chemical/enzymatic breakdown of the food during ingestion and initial digestion; and the presence of a suitable lipid phase in the form of emulsion droplets or free lipid.

The absorbability of a nutrient also depends upon certain physiological factors, such as the composition and volume of gastric and intestinal secretions. The absorption and utilization clearly depend upon a number of host-related variables. Most of these are key participants in the body's homeostatic regulatory mechanisms such as nutritional status, developmental state, gastric and intestinal secretions, mucosal cell regulation, and gut microflora.

Methods of Determining Bioavailability

Various techniques have been employed to assess the bioavailability of nutrients. The best estimate is probably obtained by combining the results from several different methods. By and large, the methods chosen depend on the resources available since detailed human studies on nutrient bioavailability use specialized techniques, which can be very expensive.

In Vitro Techniques

These range from simple measures of chemical solubility and fractional dialysability following simulated

digestion to measures of uptake and transport by mucosal tissue from experimental animals. The substance of unknown bioavailability is incubated with a variety of intestinal preparations, including intestinal rings, everted loops (sacs), isolated mucosal cells from cell culture, and vesicles. Uptake of the nutrient into the tissue is determined and equated with absorbability. Perfused loops, with an intact blood supply, can be used to measure the transport of the nutrient into the body. More recently, Caco-2 cell systems have been used for iron transport studies and these have generated good predictive data for iron bioavailability. This cell system may be useful for predicting the bioavailability of other micronutrients. Measurements *in vitro* of the kinetics and extent of partitioning of the lipid-soluble nutrients into oil and micellar phases also provide a means of determining the amount of these nutrients available for absorption.

Generally speaking, *in vitro* techniques are reproducible and can be used for studying dietary factors that affect nutrient bioavailability. They are relatively simple and inexpensive, but their relevance to utilization in humans requires validation. Results obtained from *in vitro* studies are only an indication of the proportion of a nutrient that is available for absorption, and cannot be used to predict utilization *in vivo* as this is dependent on many host-related factors.

Balance Studies

Fecal Metabolic Balance Approach

This relies on measurement of the difference between input and excretion of the nutrient and is used to attempt to quantify amount absorbed. Analysis of intake and fecal content of the nutrient over the balance period, or after an acute dose, must be extremely accurate because relatively small differences need to be detected. The diet must be carefully controlled during and sometimes for periods before and after the dose. Fecal markers need to be employed to determine the start and end of the balance period and to insure complete collection, and it must be assumed that feces are the only significant excretory mechanism, and that none of the unabsorbed nutrient has undergone biotransformation (due to digestive processes or microbial action), or otherwise been lost. It is also essential to consider enterohepatic circulation because the nutrient may have been absorbed, re-excreted in the bile, and then lost to feces. Similarly, enteric recycling can occur within the gut, involving absorption, excretion, and reabsorption of nutrient over several cycles. In both cases, the nutrient enters the body pool where it will have an impact on the metabolic kinetics and would therefore be considered to be bioavailable.

It is likely that for many nutrients these assumptions cannot be made because of their susceptibility to microbial and oxidative degradation in the gut, so that the unabsorbed portion will not be quantitatively recovered from the feces. Nevertheless, much of our information on the extent of absorption of certain nutrients is based on either acute or chronic fecal mass balance methods which, not surprisingly, show great variability in results.

The Gastrointestinal Lavage Technique

This approach has been used in an attempt to overcome some of the problems inherent in the 'simple' fecal mass balance approach. In the gastrointestinal lavage technique the entire gastrointestinal tract is washed out by consuming a large volume of Colyte containing polyethylene glycol and electrolyte salts. Washout is complete with the production of clear rectal effluent and the volunteers then consume the test meal and are permitted only water or 'diet' soft drinks for the next 24 h. All the effluent is collected and pooled with the effluent collected on the following day when another dose of Colyte is given to wash out the remainder of the test meal. The compound recovered in the stool is subtracted from that fed to obtain an absorption figure. The advantage of this approach is that the residence time of the compound in the gastrointestinal tract (particularly the large bowel, where fermentation occurs) is reduced and is standardized. The disadvantages are that the method is time-consuming, may give an underestimation of absorption if Colyte causes excessive transit rates and, again, the method depends upon there being no degradation or loss of unabsorbed compound.

The Ileostomy Mass Balance

In individuals who have undergone ileostomy the colon has been surgically removed and the terminal ileum brought to a stoma on the abdominal wall. Ingested food passes through the stomach and ileum in around 6 h as it would in the intact individual. The digesta (ileal effluent) can be collected at regular intervals (over about 12 h) from a test meal given in the morning after an overnight fast. During this time the volunteers may consume meals and beverages which are free of the nutrient being studied. Using this approach, the unabsorbed compound can be recovered from the ileal effluent in real time without the delay of the colon and rectum, or the confounding influence of the colonic microflora.

Bioassays

The response of experimental animals or humans to graded levels of the nutrient in the diet can be used to assess bioavailability. The response criteria employed should specifically reflect the utilization of the nutrient of interest, either by direct measurement of the nutrient or its metabolites in tissues, blood, or urine, or by employing functional measurements, such as enzyme levels.

Plasma Response: Acute Doses

Measurement of changes in plasma, serum, or whole blood concentration following acute or chronic dosing is currently the most well-used approach for estimating absorption and clearance. However, changes in blood concentration, particularly following a single acute dose of dietary amounts of a nutrient, can be difficult to detect and the results from such studies are those most frequently misunderstood and misinterpreted. The plasma response approach depends upon frequent blood sampling after an acute dose of an isolated compound, or after a single meal. Changes in concentration of the compound of interest are measured and plotted against time to produce a response curve. The area under the curve (AUC) is then calculated and used to determine the extent of absorption.

At its simplest, the AUC is dependent upon the rate at which the newly absorbed nutrient enters the blood and the rate of disposal to other body compartments, both of which are occurring at the same time. Changes in the characteristics of the AUC within a study may therefore be due to differences in absorption, or differences in kinetics of disposal, or both. There may also be a problem of reexportation of the compound between the plasma and other compartments, so that the AUC now consists of three components: newly absorbed compound entering the plasma; disposal of the compound to other tissues and possibly urinary excretion; and reexportation of the compound from a tissue (or tissues) into the plasma. In isolation, and without a mechanistic understanding of the processes of absorption and disposal, the AUC cannot usually provide quantitative data on the extent of absorption. However, if sufficient time points are obtained, and if metabolic modeling techniques are employed, it is possible to calculate both the rate and extent of absorption. This approach is particularly useful for hydrophilic nutrients present in the aqueous plasma phase. For lipophilic nutrients quantifying amounts absorbed is more complex because the whole plasma response is a multicomponent response involving the transfer of the nutrient (and/or its metabolites) to, and between, carriers in the blood which each have their own absorption and clearance kinetics. A better approach for lipophilic nutrients is to examine that blood fraction which contains the newly absorbed nutrient, e.g. the triglyceride-rich lipoprotein (primarily chylomicron) fraction.

Plasma Response: Chronic Doses

Chronic dosing with foods or isolated nutrients needs to be carried out until the plasma concentration reaches a plateau, being careful not to 'flood' the system, e.g., not to exceed the renal threshold. Absolute absorption cannot be determined by chronic dosing (only relative absorption) and differences between individuals in disposal rate to the tissues can be a confounder when interpreting changes in plasma concentration. As with acute plasma response AUC, chronic response cannot be used to compare different nutrients whose absorption and clearance kinetics are not known.

Isotopes

Many of the problems of lack of measurement specificity can be overcome by using radio- or stable isotopes. Foods can be labeled with isotopes, and the fate of the labeled nutrient following ingestion monitored in the body. The method used to label the food is an important consideration. Extrinsic labeling, as used for heme and nonheme iron, is the simpler technique. The isotope is mixed into the food just before consumption and is assumed to exchange fully with the nutrient in the food. However, intrinsic labeling, in which the isotope is incorporated into the foodstuff whilst it is growing, is necessary for some minerals (e.g., selenium) and most vitamins.

Isotopes can be used to measure the absorption, and sometimes the utilization, of nutrients in the body from different foods and under different dietary and physiological conditions. A number of isotope techniques can be used and alternative approaches or refinements of existing methods are currently under development, particularly for stable isotopes. These include whole-body counting (for gamma-emitting isotopes), fecal and urinary monitoring, double isotope techniques (urinary and plasma measurements), and plasma appearance/disappearance kinetics (similar to methods used for measuring the bioavailability of drugs). Selection of technique depends on the nutrient under study, the questions to be answered, and the experimental conditions.

The use of radioisotopes for human studies is restricted by ethical considerations. The hazards associated with exposure to ionizing radiation preclude the use of radioisotopes in infants, children, and

pregnant women. Since these groups are most vulnerable to nutritional deficiency, they are the subject groups for whom nutrient bioavailability is of particular interest. Thus alternative methods to study bioavailability have been sought using stable isotopes, which are safe and ethically acceptable. The main disadvantages of stable as compared to radioisotopes stem from the larger quantities that have to be employed, usually far exceeding the tracer amounts required for radioisotope studies, and the difficulties associated with their measurement. (*See* **Immunoassays**: Radioimmunoassay and Enzyme Immunoassay.)

Minerals

For many nutrients the bioavailable fraction is high (i.e., 90% or more), but for a number of inorganic elements it is low and variable. Examples of ionic species that have a low (< 25%), medium (25–75%), and high (> 75%) absorption are:

- Low: Fe, Mn, Cr, Ni, V
- Medium: Ca, Mg, Zn, Cu, Se, MO, CO, PO_4
- High: Na, K, Cl, I, F.

Iron

Iron deficiency is a worldwide problem, yet iron is one of the most abundant elements in the earth's crust. This paradox can be explained in terms of bioavailability. The main factors that influence the bioavailability of iron from the diet are the amounts of heme and nonheme iron, the presence and amounts of dietary factors influencing iron absorbability, and the iron status of the individual. (*See* **Iron**: Physiology.)

Heme and nonheme iron are absorbed by two separate pathways: the heme complex is absorbed intact into the mucosal cell, whereas nonheme iron is bound to a transport protein. The absorption of nonheme iron is very variable and generally much less than heme iron. Absorption of heme iron is relatively constant (approximately 20–30%), and only marginally affected by dietary factors that enhance or inhibit nonheme iron absorption. These include meat, ascorbic, and certain other organic acids, all of which increase iron bioavailability; tannins, phytate, and calcium decrease bioavailability. (*See* **Ascorbic Acid**: Physiology; **Phytic Acid**: Nutritional Impact; **Tannins and Polyphenols**.)

Physiological variables have a profound influence on iron bioavailability, notably body iron status. Previous dietary iron intake will also affect the bioavailability of subsequent iron, probably mediated via mucosal cell regulation. Iron is one nutrient for which it is possible to estimate true bioavailability because absorbed iron is utilized for hemoglobin production. Therefore the incorporation of isotopically labeled food iron into red blood cell hemoglobin can be measured to assess dietary iron bioavailability. Another method involves measuring the rate of hemoglobin regeneration in deficient subjects in response to different dietary sources of iron compared with a reference substance (e.g., ferrous sulfate).

Zinc

A number of dietary factors affect zinc bioavailability. Phytate is probably the most important zinc antagonist, especially in the presence of calcium, as it forms a chelate with zinc which is unavailable for absorption. Other cations with similar physicochemical properties (copper and cadmium) or mutual affinity for carrier protein (iron) also reduce zinc bioavailability. Some proteins have been shown to improve zinc bioavailability, but the mechanisms for the effect are not yet clear. (*See* **Cadmium**: Toxicology; **Copper**: Physiology; **Zinc**: Physiology.)

Zinc homeostasis in the body is controlled by alterations in efficiency of absorption coupled with changes in the quantities of endogenous zinc secreted into the intestine. Thus, body zinc status plays an important role in determining dietary zinc bioavailability.

Calcium

Calcium absorption is vitamin D-dependent; therefore bioavailability depends upon vitamin D intake and status. The efficiency of absorption is related to physiological requirements for calcium and is dose-dependent. Dietary inhibitors of calcium absorption include substances that form complexes in the intestine, such as phytate. Protein and sodium may also modify calcium bioavailability in that high levels increase urinary calcium excretion. Although this is accompanied by an increase in intestinal absorption, the net result may be a reduction in the proportion of dietary calcium utilized by the body, i.e., lower bioavailability. Lactose, on the other hand, promotes calcium absorption. Other potential enhancers of calcium absorption are currently under investigation with regard to the development of functional foods for the prevention of osteoporosis, such as caseinophosphopeptides and nondigestible oligosaccharides. (*See* **Calcium**: Physiology; **Cholecalciferol**: Physiology; **Protein**: Interactions and Reactions Involved in Food Processing.)

Vitamins

A number of vitamins are not fully bioavailable to the human body. The more important ones are folate, vitamin B_6, niacin, vitamin A, carotenoids, and vitamin E. (*See* **Vitamins**: Overview.)

Folate

Folate exists in nature as a range of vitamers based upon the parent compound folic acid (pteroyl monoglutamic acid). Vitamers differ in the extent of the reduction of the pteroyl group, the presence of one-carbon substituents, and the number of glutamyl residues. The polyglutamyl form of folate makes up approximately 80% of dietary folate and must be cleaved by folate conjugase to the monoglutamate form for absorption.

There appears to be little or no difference in the extent of absorption of the various monoglutamyl forms, although stability in the gastrointestinal tract and *in vivo* retention may differ.

Numerous dietary and physiological factors influence the deconjugation and absorption of folate, and its subsequent utilization in the body. Dietary factors that may reduce folate bioavailability include conjugase inhibitors in foods, as found for example in pulses and yeast extracts, and dietary fiber such as wheat bran. Physiological factors that may reduce folate bioavailability include intraluminal pH (maximal absorption occurs at pH 6.3), and certain nutrient deficiencies, including zinc, vitamin B_6, and vitamin B_{12} deficiency. Although food processing and storage can cause losses of folates, it is conceivable that the action of endogenous conjugases during food preparation may increase the bioavailability of naturally occurring polyglutamyl forms. (*See* **Cobalamins**: Physiology; **Folic Acid**: Physiology.)

Vitamin B_6

Vitamin B_6 (3-hydroxyl-5-hydroxymethyl-2-methylpyridine) exists in foods as either the free or phosphorylated form of pyridoxine, pyridoxamine, and pyridoxal. Plant foods also contain pyridoxine glycosides (forming 5–50% of the total vitamin B_6 content), and it has been suggested that the observed lower bioavailability in plant than animal foods is associated with this form of vitamin B_6. (*See* **Vitamin B_6**: Properties and Determination.)

Niacin

Niacin deficiency is associated with diets containing high levels of maize because the niacin is chemically bound to carbohydrate by ester linkages and unavailable for absorption. However, alkali treatment, as used by certain cultural groups when processing foods in the traditional way, renders the niacin more bioavailable. Other grains, such as sorghum, wheat, barley, and rice, contain niacin in chemically bound forms. (*See* **Niacin**: Physiology.)

Vitamin A, Carotenoids, Vitamin E

These vitamins and provitamins need to be dissolved and carried in lipid and lipid plus bile salt systems (micelles) in order to be absorbed at the enterocyte brush border. This mass transfer from bulk aqueous food to lipid and micellar phases is a complex process that is hindered by the presence of food structure. Digestion products of dietary proteins (peptides) may play a role in stabilizing micelles because of their ability to act as surface active agents. Efficient absorption of retinol is dependent on the presence of normal mature enterocytes and is compromised in inflammatory bowel disease, protein-calorie malnutrition, zinc deficiency, and alcohol abuse. (*See* **Retinol**: Physiology.)

In addition to the level and type of fat, a number of other factors influence the bioavailability of carotenoids from foods. The major controlling factors are food structure and the physical form of the carotenoids within the food matrix (e.g., crystalline or lipoprotein complexed). The absorption of carotenoids from uncooked foods can be very low but cooking can enhance absorption by increasing the ease with which carotenoids are released from the food structure. Chopping and other types of food preparation leading to particle size reduction also improve absorbability. *In vitro* results indicate that gastric pH is an important physiological determinant of carotenoid availability. (*See* **Carotenoids**: Physiology.)

There are at least eight compounds of plant origin that have vitamin E activity, but α-tocopherol accounts for almost all of the vitamin E activity in foods of animal origin. This isomer has by far the highest biological activity of all the natural isomers. Under normal dietary conditions about 20–80% of ingested vitamin E is absorbed, depending on dose and lipid content of the meal. Efficiency of absorption decreases when large amounts of tocopherols are consumed, or when individuals suffer from disorders associated with fat malabsorption. It is reported that high intakes of pectin, wheat bran, alcohol, and polyunsaturated fatty acids also reduce vitamin E absorption. Dietary constituents such as vitamin A, iron, selenium, and zinc may affect vitamin E utilization. (*See* **Tocopherols**: Physiology.)

Nutritional Implications of Bioavailability

The ultimate goal in nutritional science is to understand the interactions between diet and health. This requires a detailed knowledge of nutrient bioavailability, without which it is impossible to relate dietary intakes to indices of physiological function used to assess health. Estimates of dietary requirements cannot be made without the appropriate bioavailability factors. Where diets are marginal or inadequate in one or more micronutrient it is often possible to improve the quality of the diet by increasing the bioavailability of the nutrients in question, with consequent improvements in the nutritional status of people consuming it. Future research should utilize recently developed techniques to quantify the different phases of bioavailability, differentiating where possible between dietary and physiological factors. The ultimate goal is to combine all the information to form a coherent picture of bioavailability of nutrients for different foods and diets.

BIOFILMS

G Wirtanen, E Storgårds and T Mattila-Sandholm, VTT Biotechnology, Espoo, Finland

Formation of Biofilm in the Food Industry

When hygiene is poor, foodstuffs can be contaminated by microbes, e.g., bacteria or fungi from various sources, including raw materials, process equipment, packaging materials, or air. Common contamination sources in the process include transfer gears, packaging machines, flow plates, unhygienic valves, pumps, and pipe fittings. The number of microbes in packages is dependent on the materials from which they are manufactured. In packages made from recycled paper materials, fungal counts may rise to >100 colony-forming units (CFU) 100 cm^2, while foils containing plastics usually show significantly lower levels. The distribution of microorganisms in the air is highly dependent on local air flow, humidity, temperature, air pressure, settling properties of the

microbes, and their resistance to dehydration and ultraviolet (UV) radiation from the sun. High relative humidity leads to a higher number of airborne microbes. Airborne mold and yeast particles in general have a medium equivalent diameter of approximately 2–20 μm. Therefore, gravitational and inertial forces play a major role in their distribution, resulting in higher fungal counts close to surfaces than at higher levels in the air.

The formation of biofilm in air-conditioning systems does not occur without a water reservoir. Normally, there is no water in air-conditioning systems, but it can accumulate through condensation. A study carried out in various industrial ventilation ducts has shown that bacterial and fungal biofilms can accumulate rapidly within the ducts, especially where oil has been left on the duct surfaces. The microbial population in the air channels is dependent on the environment, filtration membranes, and positioning of air. The membranes in the air-conditioning system and the walls in the air-conditioning channels are places where biofilms start to grow.

Biofilm formation causes problems in many areas, such as industrial water systems, medicine, and in the food-processing industry. According to the literature, biofilm problems in food processes have been found in air-handling systems, cooling systems, milk transfer lines, on conveyors, in packaging machines, on vegetable-processing surfaces, heat exchanger surfaces, ultrafiltration and reverse osmosis membranes, in blancher extractors, on mixers, slicers, gaskets, floors, and in drains. In addition to causing problems in cleaning and hygiene, biofilm can cause energy losses and blockages in condenser tubes, cooling fill materials, water circuits, and heat exchangers. Biofilms may enter a food-processing system by causing reduced effectiveness in ion-exchange and membrane processes. In food-processing water supply systems, biofilms cause problems in granular activated-carbon columns, reverse osmosis membranes, ion exchange systems, degasifiers, water storage tanks, and microporous membrane filters. It can be seen from this list that problems generating from biofilm can occur anywhere in the food process if design and maintenance are not carried out properly. Biofilm formation in these systems is a symptom of disturbance in the process. Therefore, equipment design plays the most important role in combating biofilm formations. Dead ends, corners, cracks, crevices, gaskets, valves, and joints are vulnerable points for biofilm accumulation. Poorly designed sampling valves can destroy an entire process or give rise to incorrect information due to biofilm effects at measuring points.

Biofilm can generally be produced by any microbes under suitable conditions, although some microbes naturally have a higher tendency to produce biofilm than others. Common contaminants on food contact surfaces include bacilli, enterobacteria, lactic acid bacteria, micrococci, staphylococci, thermophilic streptococci, and pseudomonads. The bacterial slime of one *Bacillus* strain enhanced the heat resistance of the bacterium, extending the autoclaving time required for successful sterilization to several hours. It is somewhat alarming that pathogens such as *Listeria monocytogenes, Salmonella typhimurium*, and *Yersinia enterocolitica* can readily produce biofilms, causing severe disinfection and cleaning problems on surfaces in the food industry. The most common microbes in cooling waters are the slime-forming *Gallionella* and *Pseudomonas*, as well as common algae. From a hygienic and health point of view, infection and disease problems with *Legionella pneumophila* biofilms can occur in hot-water systems. The slime-forming microbial flora involved in biofilm formation in manufacturing of packaging material can be divided into primary slime-formers, e.g., bacteria of the *Bacillus*, *Pseudomonas*, and *Enterobacter* strains and fungi of the *Aspergillus*, *Mucor*, and *Penicillium* strains, and secondary slime-formers, e.g., bacteria of the *Alcaligenes*, *Flavobacterium*, *Klebsiella*, *Micrococcus*, and *Staphylococcus* strains and fungi of the *Paecilomyces*, *Tricoderma*, and *Trichosporum* strains.

The lubricants used in conveyors are a problem, especially in dairies and breweries. *Acinetobacter* spp., *Algaligenes* spp., *Pseudomonas* spp. and sulfate-reducing bacteria have been isolated from lubricants. The biofilm microbes in the lubricant can indirectly promote corrosion. *Listeria monocytogenes*, an opportunistic pathogen, has been isolated from lubricants in dairies. Yeasts belonging to *Saccharomyces*, *Candida*, and *Rhodotorula* have been isolated from biofilms on conveyor tracks.

There are very few published studies concerning yeast biofilms in food processing. As mentioned above, there are many publications dealing with food-processing biofilms; the biofilms dealt with are mainly bacterial in nature. Yeasts belonging to *Candida*, *Rhodotorula*, and *Saccharomyces* have also been isolated from biofilms on can and bottle warmers in packaging departments of the beverage industry. Additionally, these biofilms contained bacteria and molds. Yeasts have also been observed in biofilms in draught beer dispensing lines at pubs, where they often grow mixed with bacteria. Contaminants introduced into the dispensing system are attracted to the pipe surface by electrostatic interactions but cannot actually adhere due to close-range repulsion. Yeasts overcome this charge barrier by extending surface fimbriae, which anchor them to the conditioning film (**Figure 1**).

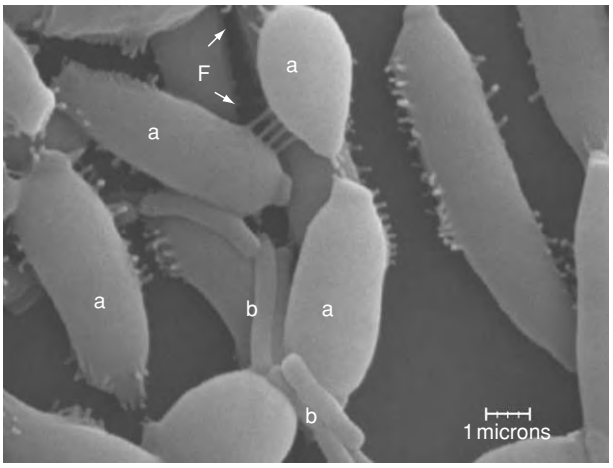

Figure 1 Scanning electron micrograph of a mixed biofilm on a polyvinyl chloride (PVC) surface. a, yeast cells; b, bacteria, F, protruding fimbriae. Reproduced from Storgårds E (2000) *Process Hygiene Controls in Beer Production and Dispensing*. VTT publications 410. Espoo: Otamedia Oy, with permission.

The biofilm formation tendency of *Dekkera anomala*, *Issatchenkia orientalis* (anam. *Candida krusei* var. *krusei*), *Pichia anomala*, *P. membranaefaciens*, *Rhodotorula mucilaginosa*, and *Saccharomyces cerevisiae* isolated from brewery samples has been studied. The biofilm production was found to be strain-dependent rather than species-dependent and additionally dependent on medium and incubation time. The area covered by biofilm varied from 2 to 4% in 10 days for slower-growing strains to approximately 100% in 2 days for fast biofilm producers. Reliable identified strains of the same yeast species differed markedly in their tendency to form biofilm under constant conditions. Sugars included in the media increased biofilm formation. Later, mixed biofilms containing lactic acid bacteria, enterobacteria, and yeasts have been used in cleanability.

The choice of materials and their surface treatments, e.g., grinding and polishing, are important factors in inhibiting the formation of biofilm and in promoting the cleanability of surfaces. The surface structure of stainless steel is very important in avoiding biofilm formation; it has been reported that, although the grain boundaries of AISI 316L stainless steel constitute 3–20% of the total surface area, over 90% of the adherent bacteria were found attached to the grain boundaries. Hoses, tubes, and filters containing polyvinylchloride increase the risk of contamination. The number of free planktonic cells in the water does not necessarily correlate with the amount of biofilm on the pipe surfaces. Costerton *et al*. found that the numbers of microbial cells adhered to surfaces were 500–50 000 times the numbers of planktonic cells in water. Inadequate cleaning and sanitation of surfaces coated with biofilm cause contamination, because the biofilm protects the microbes against sanitizers and disinfectants.

Elimination of Biofilms

Physical, chemical, and microbiological cleanliness are essential in food plants. Cleaning agents are applied to remove soil, microbes, and biofilms from surfaces. Factors governing the selection of detergents and disinfectants in the food industry are that the agent should be efficient, safe, not damage or corrode equipment, be easily rinsable, and not affect the sensory values of the product produced. Physical cleanliness means that there is no visible waste, foreign matter, or slime on the equipment surfaces. Chemically clean surfaces are surfaces from which undesirable chemical residues have been removed, whereas microbiologically clean surfaces imply freedom from spoilage microbes and pathogens. Removal of biofilm is important for the maintenance of the equipment, since the debris left on surfaces can act as nutrients for the build-up of new biofilm. Attached bacteria or bacteria in biofilms can be a problem in food processing, because they adhere to the surfaces, and if cleaning is insufficient the remaining bacteria begin to grow and multiply after cleaning and contaminate the product. To minimize biofouling, it is best to clean the equipment at frequent and regular intervals using suitable, efficient cleaning procedures for the process before the biofilm has the opportunity to develop.

Metal chelators have been used in the break-up of biofilm layers. Disinfection is required in food plant operations where wet surfaces provide favorable conditions for the growth of microbes. Disinfectants approved for use in the food industry contain chlorine-based compounds, iodine compounds, alcohols, quaternary ammonium compounds, oxidants, or surfactants. The use of disinfectants in food plants is dependent on the material used and the adhering microbes. Disinfective agents are not very effective at penetrating the polysaccharide and glycoprotein matrix left on the surfaces after an ineffective cleaning procedure, and thus do not destroy all the microbes within biofilms.

Microbes have also been found in disinfectant solutions. This means that microbial contaminants can be spread on the surface to be cleaned instead of being cleaned. It was reported that chlorhexidine mixtures were contaminated with *Pseudomonas* spp. *Pseudomonas* spp. have also been found in concentrated iodine solutions. Viable *Serratia marcescens* cells were found in a disinfectant containing 2% chlorhexidine after 27 months. Microbial contamination has

also been found in solutions of aldehydes, quaternary compounds, and amfotensides. Other microbes that have been isolated from disinfectants include *Alcaligenes faecalis*, *Enterobacter cloacae*, *Escherichia coli*, *Flavobacterium meningosepticum*, and *Pantoea agglomerans*. *Pseudomonas* spp. are relatively resistant to chlorine treatments and can even multiply when chlorine has been used. Even increased amounts of chlorine ($2.0\,mg\,l^{-1}$) did not kill *Escherichia coli* grown in biofilm. Capsular *Klebsiella pneumoniae* grown on glass surfaces has been shown to have a 150-fold resistance to chlorine compared with that grown in suspensions. On metal and carbon surfaces the corresponding resistance ratios were about 2400 and 3000 times the value in suspension, respectively.

Detection of Biofilm

Many reviews have been published on the formation and detection of biofilms in the laboratory. Methods of studying biofilm formation include microbiological, physical, chemical, and microscopic methods. The biofilm consists of about 85–96% water, which means that only 2–5% of the total biofilm volume is detectable on dry surfaces. If the actual monitoring practice involves only sampling of the liquid phase, it does not reflect the location or extent of microbes growing on surfaces. Advances in molecular biology are producing methods by which detection and enumeration of specific organisms on surfaces can be performed.

Hygiene testing in the food industry is currently based on conventional cultivation using swabbing or contact plates. These classical evaluation methods suffer from several serious deficiencies. Conventional cultivation measures only the number of living cells able to grow on the chosen agar. The quantification of cells in the biofilm is difficult to perform because they adhere strongly to the surfaces (Figure 2). In the cultivation of biofilm microbes it is important that the sample is detached and mixed properly. It has been reported that ultrasonics provide a suitable tool for sampling of biofouled surfaces. Cultivation showed that the use of ultrasonics detached about 10 times the number of cells from the surface compared with swabbing.

Despite extensive efforts to develop reliable control methods for practical hygiene assessment in the food industry, there are still no such methods available. The conventional swabbing procedure of equipment surfaces should be modified, e.g., by chemical loosening of the remaining biofilm cells from the surface at the moment of assessment. A study performed on industrial premises showed that a a mild detergent solution improved microbial sampling. The surface-wetting protocol was developed in laboratory studies using stainless-steel surfaces covered with biofilm. The evaluated test kit comprises a composition designed for the pretreatment of process and equipment surfaces before sampling.

The chemical methods used in the assessment of biofilm formation are indirect methods based on the utilization or production of specific compounds, e.g., organic carbon, oxygen, polysaccharides, and proteins, or on microbial activity (adenosine 5′-triphosphate or ATP) content. ATP measurement is a luminescence method based on the luciferine-luciferase reaction. The ATP content of the biofilm

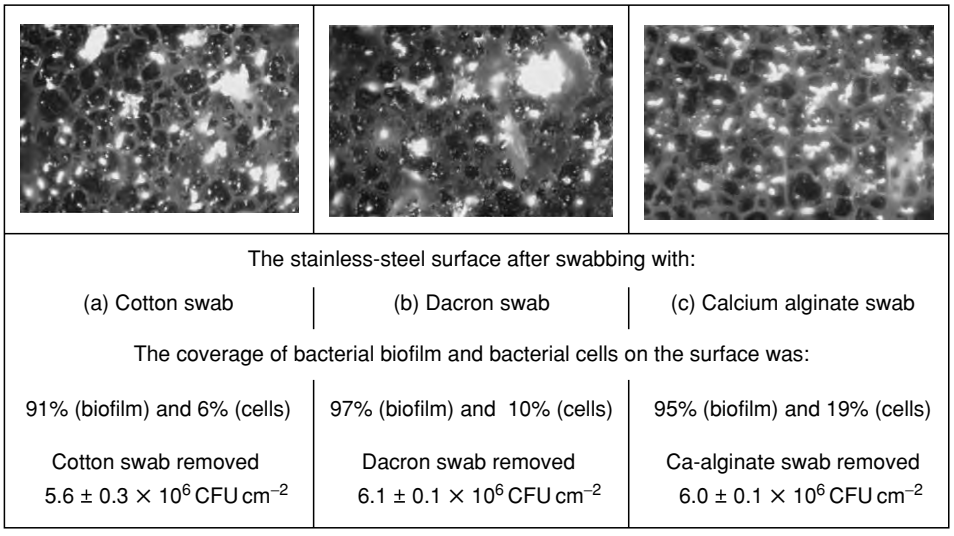

Figure 2 (see color plate 10) Epifluorescence images of 5-day-old *Pseudomonas fragi* biofilm on stainless-steel surfaces (AISI 304, 2B) after sampling with cotton, Dacron, and calcium alginate swabs.

is proportional to the number of living cells in the biofilm and provides information on their metabolic activity. Kinetic data obtained for freely suspended cells should not be used to assess immobilized biomass growth, e.g., biofilm. The ATP method is insensitive and therefore not suitable for hygiene measurements in equipment where absolute sterility is needed. Impedance measurement is used in the food industry to control product quality and to assess the effect of cleaning agents and disinfectants.

Microscopic techniques such as epifluorescence microscopy and, especially, scanning (SEM) and transmission electron microscopy (TEM) are very informative tools in biofilm research and hygiene studies. Electron microscopy has been used to identify biofilm structures. SEM provides accurate information on surface materials and the position of biofilm cells, but it does not provide quantitative data for statistical analysis.

One advantage of epifluorescence image analysis is that it measures the adherent cells on the surface, rather than cells that have been detached by some method from the surface. Epifluorescence microscopy of multilayered biofilms can only be counted two-dimensionally. This technique has been used to determine the effects of antimicrobial agents and biofilm formation by monitoring attachment rates, detachment rates, growth, motility, viability, morphology, and cell area. More accurate information is obtained on the chemical and biological relationships between microbes and their microenvironment *in situ* in real time using confocal microscopy. Laser microscopy permits optical sectioning of biological materials without optical interference from other focal planes. Confocal microscopy has been used to study both growth and metabolism of living cells in biofilms.

Conclusions

Equipment surfaces in the food industry provide the microbes growing in biofilms with the interface needed for growth and with easily obtainable liquids and nutrients needed for growth. Biofilm formation on food-processing surfaces should be combated, using efficient cleaning procedures to improve process hygiene. Cleaning in the food industry should be based on systematic planning. The knowledge that microbes grow differently on surfaces and in suspensions is the first step towards developing advanced regimes in process hygiene. It is very important to bear in mind that the biofilm contains 85–96% water. Biofilms are less likely to accumulate in well-designed systems that can be cleaned effectively. Detection of deposits built up on equipment surfaces at an early stage enables effective countermeasures and thus results in improvement of process hygiene. Methods used for monitoring process hygiene are often based on conventional cultivation, using various types of agar plates or ATP. Conventional cultivation requires several days before the result can be obtained, and it measures those cells that are able to form colonies on the given agar. ATP is used for measuring total hygiene. Many valuable methodological tools used in biofilm research can be applied in industrial monitoring. Online monitoring techniques transferred from various industrial fields, e.g., glass-fiberoptics, infrared techniques, ion mobility techniques, bioluminescence, microelectrodes, and heat transfer could be used for control of microbial and chemical contaminants on process surfaces.

BIOSENSORS

I E Tothill and A P F Turner, Cranfield University, Silsoe, UK

Introduction

Consumers and legislators are placing farmers, food manufacturers, and retailers under increasing pressure to provide food that is high in quality, free from polluting compounds and chemical residues, and consistent in nutritional value. The demand for fresh natural foods, ready-prepared, and cook-chill foods containing less preservatives and additives, more nutritional value and free from pathogenic microorganisms and genetically modified (GM) material has fueled demands for rapid sensing methods. Food analysis is usually carried out by 'off-site' methods, in which the samples are sent to a laboratory for testing. These methods suffer from the disadvantage of being expensive and time-consuming, and require the use of highly trained personnel. However, central analytical facilities do generally provide the highest accuracy in quantification and the lowest detection limits. Many assays are available on the market today that promise results within 24 h or less, such as immunoassays, polymerase chain reaction assays (PCR), and adenosine triphosphate (ATP) detection methods. These assays are used to measure the concentration of a variety of hormones, allergens, viruses, bacteria, and chemical pollutants. However, for today's environment and lifestyle, there is an increasing need for more easy-to-use, robust, rapid, and relatively inexpensive technologies. The availability of these assays would facilitate 'on-site' sample analysis, and the number of samples requiring further analysis using laboratory-based instruments could then be reduced. Hence, there is a clear need for simpler, alternative analysis systems and preferably methods that allow real-time monitoring in the field such as biosensors.

Clark and Lyons pioneered the underlying concept of the biosensor in a paper published in 1962. They reported an 'enzyme electrode,' comprising an immobilized enzyme at an electrochemical detector, and

hence produced a sensor that was responsive to the substrate of the enzyme. Since then, the field of biosensors has greatly expanded due to advances in signal transduction technologies and also to huge advances in the receptor technology used as the sensing element. There is now a wide array of biological and synthetic sensing receptors and signal transducers available to construct a particular biosensor. The approach generally employed is to identify the analytical target and then to choose the sensing molecule that gives the required affinity, selectivity, and dynamic range for the analyte or analytes of interest. The assay format signal transduction strategy can then be selected based on the analytical requirements of the final device (Table 1).

The study of biosensors has been strongly driven by the needs of medical diagnostics. Instant analysis of medical samples can provide better patient care and disease management. There has also, however, been a wide appreciation of biosensor technology in other areas such as veterinary care, animal husbandry, food and process control, and environmental analysis. While work initially concentrated on biosensors for the aqueous phase, more challenging environments such as the gas phase and organic solvents have been explored recently. The diagnostics industry is very diverse, with numerous markets requiring different products. The main controlling influences are price of both the instrumentation and the test, the accuracy, sensitivity and number of parameters required, speed, and portability. The types of instruments required for the diagnostics market can be divided into large multianalyte analyzers, bench-top portable instruments and one-shot disposable sensors. Many of the instrumentations developed to date have been designed for the medical diagnostics market. However, a number of these have been adapted for the agrofood market. In addition, the market for diagnostics continues to grow. To date, an astounding diversity of research on biosensors has been reported in the literature, and these papers offer an almost infinite number of suggestions for biosensor construction.

Definition

Biosensors are analytical devices incorporating a biological material, a biologically derived material or a biomimic as the recognition molecules, which is either intimately associated with or integrated within a physicochemical transducer or transducing microsystems. The usual aim is to produce a digital electronic signal that is proportional to the concentration of a specific analyte or group of analytes (Figure 1). This signal can result from a change of proton concentration, uptake or release of gases such as oxygen and ammonia, light emission, reflectance or absorption, heat emission, or other mechanisms, brought about by the action of the sensing molecules. This signal can then be converted by the transducer into a measurable response. Both the biological and the electrical signal can be manipulated further by amplification or processing. While the signal may in principle be continuous, devices can be configured to yield single measurements to meet specific market requirements.

The analytical capabilities of biosensors have been further increased by miniaturization and the improved processing power of modern microelectronics. Different biosensor formats have been developed for single target analytes and for broad-spectrum monitoring. From this definition, it can be seen that a number of different biosensor devices either already exist or are theoretically possible.

Sensing Elements Used in Biosensors (Receptors)

Natural Receptors

There is a wide range of naturally produced molecules from plants, animals, and microorganisms that can be used as the receptor in biosensors. These molecules may be broadly classified into two groups: the biocatalytic group (e.g., enzymes, whole cells, mitochondria, and tissue slices); and the affinity reaction group (e.g., nucleic acids, antibodies, and cell receptors). In each case, the biosensor exploits the selective binding capabilities inherent in biomolecules. Table 2 list the most frequently used sensing molecules and their respective analytes. In catalytic sensors, the change in the concentration of a component resulting from the catalyzed reaction is detected to give the sensor signal. In the case of an affinity sensor, the binding event itself (between the receptor and the target analyte) is monitored.

Because of their specificity and catalytic properties, enzymes have found widespread use as sensing elements in biosensors (enzyme biosensors). Since

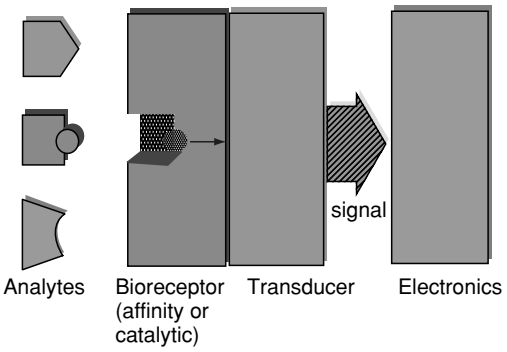

Figure 1 The biosensor.

Table 2 Biological systems most frequently used in biosensor construction for sensing their respective binding substance

Sensing molecule	*Analyte to be detected*
Enzyme	Substrate analog, inhibitor, cofactor, metal chelaters, dyes
Antibody	Antigen, virus, cell
Nucleic acid	Complementary base sequence, histone, nucleic acid polymerase, binding protein
Cell	Cell-surface-specific protein, lectin
Receptor, carrier protein	Hormone, vitamin

the development of the first glucose sensor based on the immobilization of glucose oxidase on an oxygen-sensing electrode, there has been a proliferation of applications involving a wide variety of substrates. A variety of enzymes belonging to classes of oxidoreductases, hydrolases, and lyases have been integrated with different transducers to construct biosensors for applications in health care, veterinary medicines, the food industry, environmental monitoring, and defence. However, the most important group has been the oxidoreductases, catalyzing oxidation or reduction events using either oxygen or cofactors. Enzymes are either used alone, as in catalytic biosensors, or used in conjunction with other components, such as antibodies as the signal marker.

Whole cells of living organisms, such as bacteria, yeast, fungi, plant and animal cells, or even tissue slices, have been used as the recognition component in biosensors (whole-cell sensors). The sensing principle is usually based on interrogating the general metabolic status of the cells by detecting oxygen or substrate consumption, the production of carbon dioxide or metabolites, bacterial luminescence, or direct electrochemical sampling of the electron transport chain. A range of whole-cell or microbial sensors have been constructed to detect toxic and pollutant compounds. Interest in these types of devices for environmental and toxicity monitoring is increasing because of their ability to monitor directly biological effects, as opposed to simply providing a total chemical analysis, which may not be related to the bioavailability of the contaminant.

Antibody–antigen binding reactions are used mainly in affinity sensors. However, other biological components such as cell receptors, single-stranded DNA (to bind and detect its complementary sequence), and lectins (plant proteins used to bind carbohydrates) are also being used. Combinations of the above biological components have been utilized to provide new or improved analytical capabilities. The developments of polyclonal antibodies (Pabs) and the huge advances in monoclonal antibodies (Mabs) and recombinant antibody production have created a major force in the diagnostics market. Antibodies are widely applied in a range of devices from rapid wet chemistry assays such as immunoassay kits, to dipsticks and biosensors. The use of antibody fragments and molecularly engineered antibodies is a future area of growth for immunosensors. A new research approach is to recover the genes of useful antibodies, express them in bacteria or plants, develop three-dimensional structural models, and then derive improved variants by directed and combinatorial mutagenesis. The affinity and selectivity of the recombinant antibody can thus be adapted to make it more suitable as an analytical tool.

The main disadvantage of using biological molecules in sensor devices is their poor stability, which is often the stumbling block preventing wider commercialization. Research in improving the stability of these compounds is expanding, and methods include the use of soluble, positively charged polymers, such as diethyl amino ethyl, dextran, lacitol, and sugar derivatives. A new approach to overcome the stability problem of biological molecules is to replace them with artificial receptors or biomimics.

Artificial Receptors (Biomimics)

New advances in receptor discovery such as the development of artificial receptors using the combined approach of computer (molecular) modeling and molecularly imprinted polymers or combinatorial synthesis has increased the range of receptors that can be used for the construction of suitable sensing layers for biosensors.

Molecular modeling is a powerful tool to study molecular recognition, the specific interaction between substrate and receptor. The affinity interactions between synthetic receptors and target analytes comprise hydrogen bond interactions, π-stacking interactions, Van der Waals interactions and electrostatic interactions, which constitute molecular forces

involved in molecular recognition processes. To design the artificial receptors, computer modeling is used to provide structure information for the target analyte, which will then be used to guide the design of combinatorial libraries and rational design of the artificial receptors. Molecular modeling allows the prediction of ligands that are expected to bind strongly to key regions of biologically important molecules (e.g., enzymes, macromolecular receptors) of known three-dimensional structure, so as to inhibit or alter their activity.

Molecular-imprinting polymerization is currently the focus of intense research interest and is being used in a wide range of application areas, e.g., in the preparation of selective separation materials, artificial antibodies, and synthetic enzymes and in molecular recognition. Molecular imprinting relies upon the presence of complementary interactions (noncovalent or reversible covalent) between sites in the template molecules (the analyte) and the functional monomer(s) used in the polymerization process (Figure 2). The functional monomer(s) is a key component in the imprinting process, though generally constituting a relatively small percentage of the resultant MIP. The complexation of a template by these building blocks prior to, and during, polymerization to yield the complementary positioning of functionalities, is the central dogma of molecular imprinting.

The combinatorial library technique (combinatorial chemistry) is a fast developing area of receptor discovery and has been widely used by the drug industry to both discover and optimize lead compounds. An example is the optimization of the antidepressant drug, benzodiazepine. Combinatorial libraries consist of a large array of diverse molecular entities, generated by the systematic and repetitive covalent connection of a set of different 'building blocks' of varying structures. The number of possible compounds (n) generated in a single library can be found using the relationship:

$$n = b^x,$$

where b represents the number of building blocks for each step and x, the number of synthetic steps.

Enormous effort has been devoted to the development of new strategies for peptide and nonpeptide libraries. The principle is illustrated in Figure 3. A large number of compounds can be generated in a very short time using combinatorial library techniques, which would be near impossible using classical organic synthesis methodologies. Molecular modeling is also used as a combined approach with combinatorial chemistry to facilitate a more efficient receptor discovery process. Combinatorial chemistry has been used to generate affinity ligands, which can be used as synthetic receptors in biosensor devices.

Research activity in the area of artificial receptor discovery has increased in the last few years, in particular the production of synthetic receptors for medical and environmental diagnostics. The development of artificial receptors for various purposes remains an important challenge. Combinatorial synthesis and molecularly imprinted polymers are two of the most exciting and rapidly growing areas in ligand discovery, which can overcome the stability problems inherent in natural ligands. However, the challenge is to produce receptors that compete with the natural molecules with respect to sensitivity and stability.

Transducers

The transduction element of a biosensor must be capable of converting a specific biological response

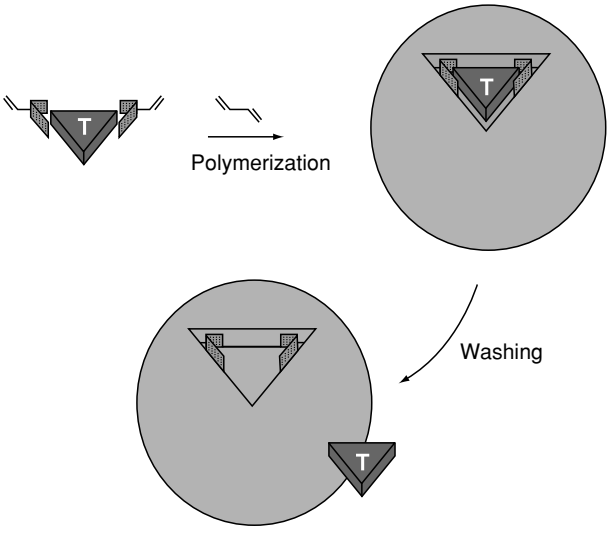

Figure 2 Molecularly imprinted polymers (MIPs).

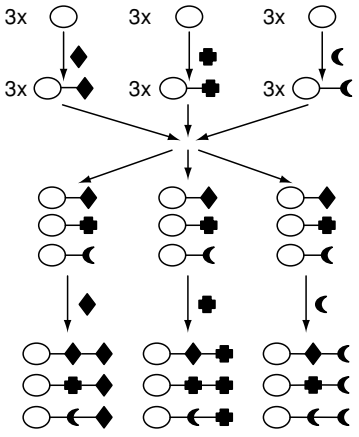

Figure 3 Combinatorial chemistry.

into a quantifying signal. The transducers must also be suitable for receptor immobilization at, or close to, its surface. A list of transducers that have been used in the construction of biosensors is given in Table 3. Considerable work is being carried out to improve transducer designs, with the blending of a variety of different technologies. The operation principle of commonly used transducers is described briefly below.

Electrochemical Transducers

Electrochemical devices usually monitor the current at a fixed voltage (amperometry) or the voltage at zero current (potentiometry), or measure conductivity or impedance changes. Amperometric biosensors were the first type to be developed and have been in use as glucose biosensors for over 35 years. These devices have continued to be the most popular, largely due to their simplicity, ease of production, and the low cost of the devices and instruments. The signal in amprometric devices is dependent on the rate of mass transfer to the electrode surface. The most commonly used devices monitor the analyte concentration by measuring the fall in O_2 tension, the production of H_2O_2 or determination of the redox reaction of a mediator molecule (electron shuttle). A large number of mediators are available, but the most widely used include potassium ferricyanide, tetrathiafulvalene (TTF), tetracyanoquinodimethane (TCNQ), and the ferrocenes.

A potentiometric sensor operates under conditions of near-zero current flow and measures the difference in potential between the working electrode and a reference electrode. Ion-selective electrodes (ISEs), of which the pH electrode is a well-known example, are the most important of this class of transducer.

Table 3 Transducers used in biosensors

Transducer	*Output*

Mass	
Piezoelectric (surface acoustic wave devices)	Acoustic wave
Magnetic	

Specificity is conferred by selective membranes, which may be formed from metal salts or polymer membranes containing ion-exchangers or neutral carriers. To date, there is a range of commercially available ISEs that can detect specific ions (i.e., calcium, nitrate, potassium, copper, barium, chloride, etc.). Devices can also include the gas-sensing electrodes (GSEs), which are ISEs modified by the use of a gas-permeable membrane, and the chemically sensitive field-effect transistors (FETs), which are semiconductor devices that respond to the surface electric gradient or charge at the gate electrode. More recently, light-addressable potentiometric sensors (LAPSs) have been developed, based on silicon technology. A chemical reaction at the surface of the silicon chip will shift the surface potential and hence affects the current, which allows the rate of the reaction to be monitored.

Conductimetric biosensors are based on measuring the time dependence of the change in conductivity as a result of the receptor recognition of its complementary analyte. Impedance is the total electrical resistance to the flow of an alternating current being passed through a given medium. Typically, during measurement, impedance decreases, while conductivity and capacitance increase.

Optical Transducers

Optical transducers use a number of principles, such as the effect of the biological event on light absorption, fluorescence, refractive index, or other optical parameters. These types of transducers have become increasingly popular over the last few years with many devices now commercially available. The early-developed optoelectronic devices utilize a color change induced in pH-sensitive dyes by the action of an enzyme that generates or consume protons. More recent approaches to measure pH changes related to the analyte use optical sensor devices based on dynamic quenching by molecular oxygen of a fluorescence of an indicator.

Most of the recent work on optical biosensors has concentrated on the use of evanescent wave technology. When light is totally internally reflected during, for example, transmission through an optical waveguide, a small amount of energy propagates beyond the optical interface. In an unclad waveguide, this can be coupled to fluorescent labels constrained close to the optical interface as a result, for example, of antibody–antigen interactions. Alternatively, a direct immunosensor can be constructed, which does not require the use of labels, by measuring the change of refractive index due to the sensing receptor interaction with the target analyte. Surface plasmon resonance (SPR) is currently receiving the most interest

in this area and forms the basis of a successful commercial instrument. The technology is based on the excitation of the electron plasma (surface plasmon) of a thin metal layer covering the surface of the waveguide. The change in angle of the incident light or the reflectance minima due to the change in the refractive index in the vicinity of the metalized surface can be monitored.

Calorimetric Transducers

Thermometric devices operate by measuring enthalpy changes during the biological reaction using one of a range of thermometers, thermopiles (array of thermocouples), or thermistors.

The detection of heat during the enzyme catalysis can be used in the construction of calorimetric enzyme biosensors. Since heat is either produced or consumed in most reactions, these can be converted to analytical signal to monitor analyte concentrations.

Piezoelectric Transducers

Sensors based on piezoelectric principles use the change in the resonant frequency of wave propagation through a piezoelectric material. These principles can be used to measure mass, viscosity, or density changes at the sensor surface. These devices are able to generate and transmit acoustic waves in a frequency-dependent manner. Bulk wave devices operate by transmitting a wave from one side of the crystal to the other, while surface acoustic wave (SAW) transmit waves along a single crystal face.

Magnetic transducers

Very recently, a few papers have been published describing biosensors based on magnetic transduction. Hall-effect transducers, for example, have been used to detect magnetic labels in immunosensors. Practical application of this type of devices has been limited, but they are included here for completeness.

Fabrication of Biosensors

The commercial production of devices such as the ExacTech home blood-glucose biosensor (MediSense, Inc., Cambridge, MA) has verified the importance of automated manufacturing technologies where large numbers of inexpensive, reproducible electrochemical devices are required. The capability of printing materials at high precision and speed is very desirable for the mass production of analytical devices such as biosensors. Techniques such as screen-printing, ink-jet printing, air-brushing, and Cavro deposition have been developed under microprocessor control and adapted for biosensor fabrication, especially

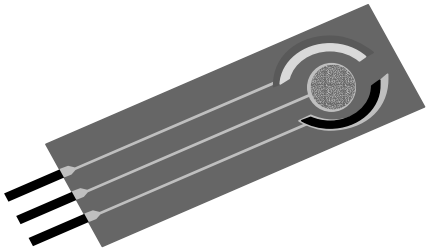

Figure 4 Screen-printed biosensor.

thick-film biosensors (Figure 4). These deposition techniques are rapid and flexible with regard to the ink characteristics employed. Thin-film deposition has also been used, which involves the application of material through a mask, under vacuum, via evaporation due to heating, or by placing the substrate to be coated between two electrodes (sputtering). This process is able to create patterns less than 1 μm thick, making it suitable for the construction of microsensors. Thin-film sensors are generally produced by a variety of vapor-deposition techniques, electrochemical methods, and, more recently, by the use of Langmuir–Blodgett technology. Thin metallic films, usually deposited by vapor deposition, have been used extensively for the production of sensors utilizing surface plasmon resonance. These sensors have been primarily directed towards affinity sensors.

Silicon fabrication technology has been increasingly used as a means of mass production of biosensors. The use of silicon microfabrication for both electrochemical and optical sensors is expanding and the capability of on-chip electronic signal amplification and data processing is very attractive. This is an area of intense research activity mainly by diagnostics companies. Several companies are using microelectronics technology based on silicon to produce optical chips for biosensor application.

Biosensors Based on Biocatalitic Interactions (Biocatalytic Sensors)

The biosensor market has been dominated for many years by electrochemical biocatalytic sensors. The majority of biocatalytic sensors are based on enzyme or whole-cell sensors. Amperometric enzyme biosensors form the majority of commercial biosensors available today. In the enzyme electrode, for example, an enzyme specific for the substrate of interest is immobilized on the sensor surface. The chemical conversion of the analyte is catalyzed as it enters the enzyme layer, and either the cosubstrate or the product of the reaction is transduced to an electrochemical signal, which is proportional to the concentration of

the substrate. The simplest biosensor approach is to measure amperometrically the oxygen depletion or hydrogen peroxide production associated with the reactions involving oxidase enzymes. The combination of simplicity, ease of manufacture, high sensitivity, availability, and low cost of instrumentation is highly attractive in this type of devices. A variety of enzymes belonging to classes of oxidoreductases, hydrolases, and lyases have been applied in enzyme-based sensors. These enzymes can act on fatty acids, sugars, amino acids, organic acids, and phenols. Biosensors based on the use of redox mediators to shuttle the electrons, resulting from the catalytic oxidation or reduction of the substrate of interest, to the electrode has been an area of great interest to many researchers. Much of the work is centered on the use of redox mediator compounds such as ferrocene, TTF, TCNQ, hexacyanoferrate (III), methylene blue, quinones, and their derivatives. Careful selection of the mediator can also eliminate interference problems from other substances in the sample.

To date, there are several successful biosensor devices on the market based on the different amperometric transduction principles outlined above. These include the MediSense mediated blood glucose analyzer for medical application and the Yellow Springs hydrogen peroxide-based systems (YSI, Yellow Springs, OH) developed for both medical and food analysis and for bioprocess control. The YSI 2700 SELECT™ Biochemistry Analyser (**Figure 5**) can be used for on-line fermentation monitoring or off-line sample analysis for food and drink fermentation. Nutrient and bioproducts analysis can be carried out using the biosensor system including glucose, L-lactate, L-glutamine, L-glutamate, ethanol, lactose, sucrose, galactose, and methanol. Other commercially available biosensors for food analysis include; Sensomat B10, for alcohol analysis (Gonotec, Germany); Microzym-L for lactate analysis (Kalger GmbH, Germany) and Glu-11 for glucose analysis (TOA Electronics, Japan). A range of single and multianalyte biosensors based on the same principle are being developed for a diverse range of applications in the food industry.

Figure 5 YSI 2700 SELECT™ Biochemical Analyzer. Photo courtesy of YSI incorporated, Yellow Springs, USA.

The majority of biosensors developed for food analysis are water-based systems. Organic-phase enzyme electrodes, however, have been developed to work in organic solvents and have been used for the analysis of compounds such as cholesterol, alcohols, organic peroxides, and phenols. This technique has the advantages of ease of sample preparation from materials, such as fats and oils, and increased enzyme stability. In principle, analytes soluble in fatty substances can also be measured using biosensors. Enzyme biosensors have also been widely applied to the detection of phenolic compounds. Contamination by these aromatic compounds results from the production of drugs, dyes, and antioxidants and also from the paper and pulp industry. Enzymes used in biosensor development for this type of compounds are phenol oxidases (tyrosinases), laccases, and peroxidases.

Biocatalytic sensors based on enzyme inhibition are the most commonly reported biosensors for the detection of toxic compounds and heavy metal ions. These sensors are based on the selective inhibition of specific enzymes by classes of compounds, or by more general inhibition of enzyme activity. The measurement of the enzyme activity can be used as a screening test to evaluate the contamination by compounds such as organophosphorous and carbamate insecticides and the triazine herbicides and other compounds that display similar toxicological behavior. Enzymes used include: choline esterase, horse-radish peroxidase, polyphenol oxidase, urease, and aldehyde dehydrogenase.

Biosensors based on the use of whole cells as the sensing layer generally respond to more than one analyte, but can offer increased stability when compared with enzyme-based sensors. Whole-cell biosensors have been utilized commercially for environmental monitoring and capitalize on the broad sensitivity of microorganisms to a wide range of toxins. Whole-cell biosensors may contain living bacteria, yeast, fungi, plants, or animal cells. Biosensors able to monitor indicators of pollution, such as biochemical oxygen demand (BOD), have been developed. Sensors such as the ARAS BOD Biosensor System (Dr Bruno Lange GMbH, Düsseldorf,

Germany), the BOD module biosensor produced by (Prufgerate-Werk Medigen, Germany), and Nissin's (Japan) BOD Sensor are commercially available. A range of biosensors based on this principle have been developed for polluting compounds such as pesticides, in particular for water monitoring.

Electrochemical sensor approaches to hygiene monitoring based on the metabolism of living cells have also been commercialized. The Bactometer (Bactomatic Inc., Princeton, NJ) and the Malthus 2000 (Malthus, Stoke-on-Trent, UK) use impedance and conductance, respectively, to plot bacterial growth. A more rapid approach is the use of amperometry. The method comprises the use of mediators to detect the metabolic activity of the cells, and the resulting current can be related to the numbers of organism present in the sample.

Catalytic optical biosensors are usually based on optical fibers or planar wave-guide films. Various fiber-optic biosensors based on pH opt(r)odes have been constructed for glucose, urea, penicillin, and creatinine analysis. Commercial examples of fiber optic sensors for monitoring blood pH, dissolved oxygen and carbon dioxide concentrations. The transfer of these technologies to the agrofood and environmental sector can be anticipated in the near future.

Affinity Sensors

Antibodies have been used as recognition elements in tests and assays since the 1950s and in biosensor devices since 1970s. In the past decade, there has been phenomenal growth in affinity-based sensor research and development. Affinity-based sensors can be define as analytical devices that use an antibody, receptor protein, or other molecules with affinity-recognition powers interfaced to a signal transducer to measure a binding event. Various research groups have pioneered different types of affinity-based sensor configurations. By utilizing the immunorecognition properties of antibodies in immunosensors and affinity sensors, the range of analytes that can be measured has been broadened considerably.

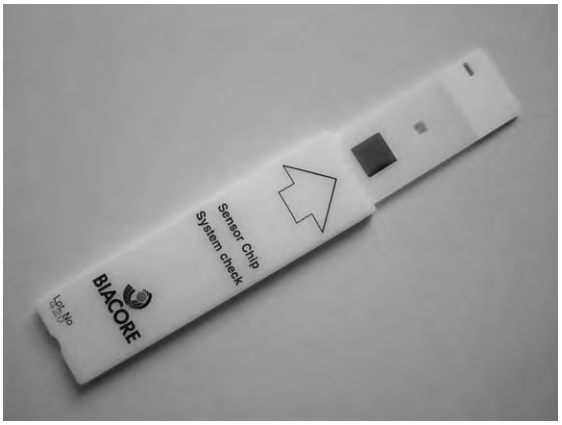
Immunosensors offer a wide range of potential applications to the food industry, water companies, and regulatory authorities. In immunosensors or immunoprobes, the antibody (Ab) or the antigen (Ag) constitutes the biospecific component in the sensor structure. A range of immunosensors are being developed, and with minor adaptations, these can replace immunoassays. At present, immunodiagnostic tests are used in pollution detection in food and water samples and also on-farm monitoring of livestock reproduction (milk progesterone), and quality control of foodstuffs originating from livestock production (authenticity and adulteration testing). These tests can be developed to a new generation of rapid immunosensors for real-time and on-site applications. A range of research projects have been undertaken to develop immunosensors for residues in food (antibiotics, toxins, and pesticides), the presence of additives, and hormones. The availability of the required antibody can limit the potential for diverse analyte detection by immunosensors. Increased research in the development of specifically tailored antibodies such as plantibodies produced in plants, recombinant antibodies, catalytic antibodies or abzymes, artificial receptors, and molecularly imprinted polymers should overcome some of these problems.

Immunosensors can be divided into classes depending on the transducer technology employed. Electrochemical immunosensors generally rely on the use of electroactive labels, usually based on enzyme labeling and amplification techniques. The sensors can be inexpensive and may achieve low detection limits (< 1 p.p.b.). Different types of electrochemical immunosensors and affinity sensors have been developed for environmental analysis using various transducers. The scientific literature increasingly contains reports of the development of one-shot disposable or on-line immunosensors for a diverse range of analytes. However, the technology required to manufacture these types of sensors has not yet reached the level of sophistication achieved for enzyme electrodes, and hence, these devices are at an earlier stage of commercialization.

Optical devices have a clear advantage over electrochemical methods due to their ability to monitor binding reactions directly. The major drawback to the application of optics remains the high cost of many optical components, but these costs are constantly falling. Optical phenomena such as SPR and evanescent wave (EW) technology have shown promise in providing direct measurement of Ag–Ab interactions occurring at the surface–solution interface, the surface usually consisting of a glass prism on a gold or silver metal layer. SPR is a phenomenon that occurs when a beam of light is directed on to a glass–metal interface, which results in changes in the resonance angle. The BIAcore™ biosensor system based on SPR technology was developed by a Pharmacia (Uppsala, Sweden) spin-off company and is now commercially available from Biacore AB (Uppsala, Sweden). This instrument represents a significant breakthrough in optical immunosensor technology. BIA technology enables detection of biomolecules in real time without the use of labels, but the instruments are expensive and mainly laboratory-based, and require trained

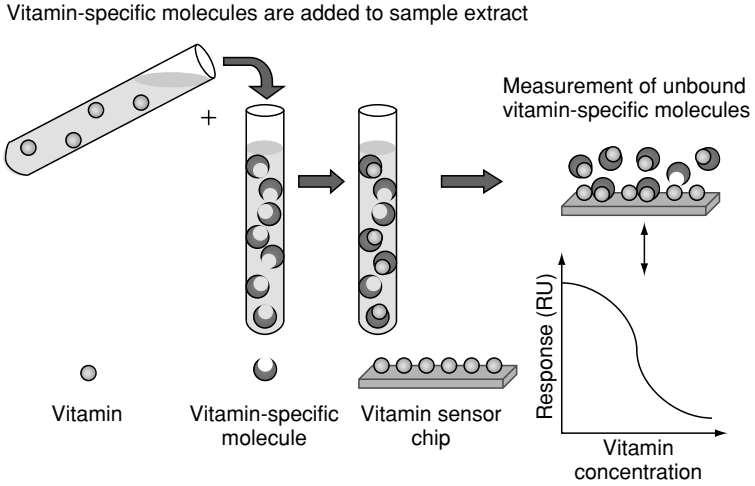
personnel to interpret the results. The Biacore system has been reported to be able to detect atrazine at $0.05\,\mu g\,l^{-1}$ and *E. coli* O157 in food samples. Recently, Biacore AB have launched the BIAcoreQuant™, for the automated analysis of vitamins in foods (Figure 6). The assay is designed as an inhibition assay, and similar principles are applied for the determination of drug residues in meat and milk products using BIACORE 2000. Amersham International plc has been active in research into SPR-based immunosensors for infectious diseases and has developed immunotechnology that employs antibodies labeled with latex particles (beads). The beads amplify the change in refractive index at the sensor surface–solution interface, which occurs when the antibodies bind to the immobilized antigen layer and thus cause a large change in the resonance angle. An alternative direct optical immunosensor to compete with SPR technology has been developed by Affinity Sensors (Cambridge, UK). The resonant mirror technology is marketed as the IAsys (IAsys and IAsys *Auto*+) and also enables analysis of biomolecular interactions in real-time. Reusable cuvettes offer a choice of derivatized sensor surfaces and chemistries. The ligand is simply and efficiently immobilized on to the sensor surface, and binding of the analyte can be detected immediately.

The alternative approach of using fluorecent labels detected via evanescent wave interactions with an optical fiber has also been applied successfully. One example is the Raptor developed by the US Navy Research Laboratory for the detection of biological



Sensor chip

(a)



(b)

Figure 6 The BiacoreQuant™ surface plasmon resonance system for the automated analysis of foods, (a) the sensor chip, (b) the procedure. Photo courtesy of Biacore AB.

warfare agents. Unilever (Bedfordshire, UK) has developed a fluorescence-based EW immunosensor that incorporates a novel capillary-fill design. The system consists of two glass plates separated by a narrow capillary gap of $\sim 100\,\mu m$. The lower plate acts as an optical waveguide and contains an immobilized layer of antibodies on its surface. These sensors benefit from the capillary fill system, which draws a fixed volume of sample into the space between the plates, regardless of bulk sample volume.

Piezoelectric transduction approaches and, in particular, SAW devices have also been widely used to detect antibody binding to an immobilized antigen. The most widely used acoustic transducer is the quartz crystal microbalance, which measures small changes in surface properties, such as bound surface mass and viscosity, resulting from the binding of molecules to the sensor surface. Again, the attraction of piezoelectric sensors is their ability to monitor directly the binding of Ab–Ag reaction encountered in affinity sensing, but they suffer from the disadvantage of having a low sensitivity for small molecules.

Potential areas of application for affinity-based sensors are similar to those for biocatalytic sensors. However, affinity sensors can offer enhanced sensitivity and specificity when compared to biocatalytic sensors. Commercial immunosensors may not have been developed specifically for use in the agrofood and environmental sectors yet, but their long-term potential is evident. As the commercial success of immunoassays becomes more evident in health care, food, and environmental monitoring, the demand for faster techniques will be sufficient for continued affinity sensors development. The development of disposable electrochemical affinity sensors for the rapid detection of residues of anabolically active illegal androgens, antibiotics, and other residual compounds in food samples would allow regulatory bodies to improve their screening program. A potential market for immunosensors is genetically modified (GM) foods testing for protein analysis. Immunoassay tests as a plate test or dipstick devices for the detection of GM foods in plant tissues, raw agricultural commodities, and also food ingredients are marketed today by SDI Europe Ltd. (Hampshire, UK). These types of tests may well be developed into immunosensors devices in the near future.

DNA Biosensors

DNA is a double-stranded helical molecule that can be split into its two complementary strands by treatment with alkali. By using the correct environmental conditions, the two strands can come together again (reassociate) in a process that forms the basis of all DNA hybridization techniques. This technique involves a small quantity of a pure DNA probe that is labelled and made single-stranded so that it can seek out and hybridize to its complementary sequence in a large amount of DNA. The probes can be labelled with an enzyme marker. Nucleic acids, the building blocks of DNA and RNA, are universally present in all living cells and are utilized as a general method of microbial detection and identification. PCR is a widely used method for amplifying trace amounts of DNA for analysis. To date, it has been used mainly for qualitative analysis, but the need for quantitative information has resulted in further development of PCR protocols. Quantitative PCR methods are shown to be extremely sensitive, and fully automated detection systems that should be rapid, simple to use, and inexpensive are being developed. DNA biosensors are currently used in the detection of infectious diseases and genetic abnormalities, where the main approach has been by the use of immunobased sensors. This technology is well established, and the performance of these tests is good. PCR is widely used to amplify the signal in DNA probes, but it is time-consuming. There is intense current interest in microsystems for DNA analysis. An electrochemical DNA sensor based on a gold electrode modified with DNA probes and an electroactive hybridization indicator has been reported in the literature. A range of detection systems have also been applied in DNA probes such as the use of enzyme label, an SPR-based biosensor, an EW biosensor and an acoustic-based sensor. Affymetrix (Santa Clara, CA) has developed a platform for acquiring, analyzing, and managing complex genetic information. The system is based on disposable DNA probe arrays (GeneChip) containing selected gene sequences on a chip, and an instrument to process each chip, and analyze the information. This 'lab-on-a-chip,' offers traditional, laboratory-based biological assays in convenient on-site or on-line instruments. DNA chips are used for microorganism identification or detection of GM foods. The company is developing new chips for microbial contamination diagnosis in environmental samples. GeneScan Europe (Hanse Analytik GmbH, Freiburg, Germany) markets test kits for the detection of genetically modified components in human and animal foods by DNA analysis using PCR techniques. These tests can also be developed into DNA biosensor devices.

Electronic Noses

The application of the electronic nose concept or artificial olfaction has been of tremendous emerging importance in recent years. Electronic noses are based

on the use of artificial receptors in the sensor array, and their application in food analysis justifies their inclusion in this article. In recent years, a great deal of research in the development of the electronic nose has taken place with a diverse range of applications. This type of sensor instrument mimics the olfactory system in the nose. The instrument consists of an array of gas sensors with different selectivity patterns, a signal collecting unit, and data analysis software, which analyses the signal by pattern-recognition methods, such as principal component analysis, discriminant function analysis, cluster analysis, and artificial neural networks. The results are comparative, rather than quantitative, and are presented as a 'fingerprint.' A variety of sensors are used, ranging from metal oxides to conducting polymers, which can be highly sensitive but not specific and can respond to volatile compounds with molecular weight ranging from 30 to 300. Molecules such as alcohols, ketones, fatty acids, and esters give a strong response, whereas fully oxidized species, such as CO_2, NO_2, and H_2O have a lower response. The sensor array can also recognize molecules containing sulfur and amine groups. Furthermore, they are not in direct contact with the measuring media, since they are used for gas-phase measurements.

There has always been considerable waste during the storage and handling of food. Moreover, food often constitutes an ideal growth medium for microorganisms. The composition of volatile compounds evolved from the food can reflect the activity and type of microorganisms present and also can be related to food quality. Thus, electronic noses appear to be a useful means of detecting these kinds of changes. Electronic noses have been used in medical, environmental, and food diagnoses. The majority of the current research concentrates on quality control in the foods and drinks industry, such as the detection of microbial contamination (bacteria, fungi, and yeast), freshness of meat and fish, and authenticity (beverages, coffee, and meat).

Conclusions

The food and drink industry deals with a wide range of materials and products with different characteristics and diverse processing procedures. The shared theme, however, is that the raw materials are organic, subject to environmental pollution, degradations and microbial contamination. The food diagnostics market is expanding rapidly and covers a wide range of disciplines. The establishment of appropriate technologies to apply biosensors to practical agriculture and horticulture is expected to produce a significant effect on quality improvement and cost reduction. Biosensor applications in the medical diagnostics market have been highly successful, but their potential success in the food, agriculture, veterinary diagnosis, and environmental market still remains to be established. Biosensor systems, which are relatively small portable instruments, have an on-site application, and their relatively low cost is clearly desirable in agrofood analysis. Research is being undertaken in diagnostic companies and research institutions to develop biosensor technologies for the food and environmental sector. Nevertheless, moving the technology to the market place involves many challenges. Biosensors will have to offer perceived advantages over existing and competing technologies.

BIOTECHNOLOGY IN FOOD PRODUCTION

S Pérez-Magariño and M L González-Sanjosé,
University of Burgos, Burgos, Spain

Introduction

Biotechnology's origins lie in the ancient crafts of brewing, baking, and the production of fermented foods such as yogurt and cheese, although it was not until 1859 that microorganisms were identified as the cause of both desirable and undesirable changes in food. During the 1940s, microorganisms, as submerged cultures in large vessels, were developed. Nowadays, similar fermentation technology is applied to obtain a wide range of bioproducts.

In the 1950s, the primary structure of proteins and DNA was first determined. These discoveries led to the development of molecular biology in the 1960s and genetic engineering techniques in the 1970s. Techniques developed using microorganisms have been applied to plants and animals, and these transgenic plants and animals have been produced to make many useful products.

For centuries, humans have been selecting, sowing, and harvesting seeds to produce better food more efficiently. In recent decades, global food demand has increased enormously, and biotechnology has offered the technology required to produce more nutritious and better-tasting foods, higher crop yields, and plants protected against disease and insects.

Definition of Biotechnology

The term 'biotechnology' has come to mean different things to different people. In general, biotechnology is the integration of natural sciences and engineering in order to provide new products and services by the application of organisms, cells, parts thereof, and molecular analogs.

In a broad sense, biotechnology covers many of the tools and techniques that are commonplace in agriculture and food production. However, in a narrow sense, biotechnology considers only the new DNA techniques, molecular biology, and reproductive technological applications. Thus, 'biotechnology' for many people refers specifically to the genetic engineering techniques that have been developed in the last 30 years.

Food Biotechnology

Biotechnology provides powerful tools for the sustainable development of agriculture as well as the food industry, improving the production of foods and making them more available and nutritious. Food biotechnology is a rapidly expanding field of science with many different applications, which is clear from the large number of scientific papers published in the last 10 years. The Food Science and Technology Abstracts (FSTA) database reveals at least 4150 articles on Food Biotechnology published between 1990 and 2000, which represents almost 4% of the number of total published papers on food.

According to FSTA information and the current situation of the food industry, some of the main areas of application of food biotechnology are: the production of new kinds of foods and drinks, both by modern developments of conventional techniques and by genetically modifying the products themselves, or producing them using genetically modified (GM) organisms or their products.

The majority of articles deal with fermentation processes, the use of enzymes and microorganisms (Figure 1). These fields have been the most important and traditional applications of biotechnology in food production. However, in the last few years, investigations into genetic engineering, molecular biology, and cell cultures have been increasing significantly.

Traditional Food Biotechnology

Traditional biotechnology refers to the conventional techniques that have been used for many centuries to produce beer, wine, cheese, bread, and other foods, all of them foods obtained by fermentation processes.

The fermentation of food is the oldest biotechnological process, and is the oldest form of food preservation. In brief, fermentation is anaerobic conversion of certain carbohydrates (such as reducing sugars, mainly glucose) to other products such as:

- alcohol, glycerol and carbon dioxide, the principal products of the fermentation of yeast sugars (alcoholic fermentation);
- butyl alcohol, acetone, lactic acid, and acetic acid, the principal products of bacterial action (such as acetic, lactic, and malolactic fermentation).

Of the many possible types of fermentation processes, lactic acid fermentation and alcohol fermentation are the two most common. These processes are carried out by specific microorganisms (several yeasts and

Figure 1 Percentage of published papers on different fields of biotechnology in food production.

bacteria), and they are regulated by the action of specific enzymes.

Traditional biotechnology is most closely related to food production both in the selective breeding of food plants and animals and in food processing using microbial enzymes. Traditional selection techniques have been employed to develop a great variety of plants, animals, and microorganisms for the production of a wide range of food products and ingredients for processed foods.

In addition, enzymes have been applied to practical uses for thousands of years, in the form of crude animal or plant preparations or as a consequence of permitted microbial development. Improvements in modern techniques, which allow purification and purification of specific fungal and microbial enzymes and their production at an industrial level, has made it possible to use enzymes in order to facilitate and improve some food manufacturing processes.

Current technology for dealing with complex organisms advances modern biology and permits us to understand many traditional processes in which biological agents are involved, allowing the application of new fermentation and enzyme technological processes to food production. This new situation has opened the doors to an exciting dimension of food biotechnology, which has been called 'modern food biotechnology.'

Modern Food Biotechnology

Modern biotechnology embraces all methods of genetic modification by recombinant DNA and cell-fusion techniques together with the modern developments of 'traditional' food biotechnological processes. Genetic modification techniques (GMT) are now being used in the production of new foods and drinks. Genetic modification involves the insertion of one or a small number of scientifically well-characterized genes into the food plant, animal, or microorganism. These techniques will play an increasingly useful and economic role, and they are strongly related to fields such as genetic engineering, molecular biology, protein engineering, biochemical engineering, and processes involving monoclonal antibodies, which are beginning to have a considerable impact on food processing.

Modern biotechnology will pursue not only the production of new foods but also the preservation of raw materials, increased shelf-life of final products, and the planned alteration of their nutritional and functional properties. It also affects the development of processing aids and direct additives that can improve the overall utilization of materials. GMT are being used to achieve many of the same aims as traditional breeding and selection methods but have at least two main advantages. First, they provide the means of controlling the introduction of genes with much greater prediction and precision than can be achieved by traditional methods. Second, they make it possible to introduce copies of genetic material into unrelated species hitherto impossible to achieve by traditional techniques.

Some applications of genetic engineering techniques are:

- increasing the resistance of plants to diseases and pests, herbicides or pesticides;
- developing plants to withstand more extreme environmental conditions (drought, frost, and soil salinity, amongst others);
- developing foods with specific properties and improved quality (sensorial and nutritional characteristics);
- adapting microorganisms for more efficient food production and to produce natural food ingredients (amino acids, organic acids, volatile fatty acids, vitamins, etc.);
- obtaining enzymes, antibodies and microorganisms to monitor food production and processing

systems for quality control. Microbial probes and biosensors are being used experimentally as indicators of bacterial and other types of contamination; and
- improving animal farming by genetic modification of crop plants for animal feed, of microorganisms or enzymes to improve the nutritional value of animal food stuffs and in the animal health sector for pharmaceuticals.

Benefits and Risks of Food Biotechnology

For centuries, farmers have relied on the newest technology to produce and enhance foods that possess specific beneficial traits. The use of biotechnology benefits not only the grower or producer but also the consumer.

The current benefits of biotechnology include disease resistance, reduced pesticide use, herbicide tolerance, more rapid growth of crops, producing higher yields. Hence, biotechnology benefits the environment, including water and soil conservation, and is safer for workers and the ecosystem. Also, it can enhance the nutritional characteristics of foods and improve food taste and quality.

Biotechnology has been used in a number of crops for several years. The volume of biotechnological crops in developmental stages continues to grow. In the early 1990s, many people were skeptical that transgenic crops could provide improved products. During the last five years, the planting of transgenic crops has increased, thus demonstrating that the early promises of transgenic crops are meeting the expectations of farmers of both large and small farms planting these crops in both industrial and developing countries. However, two-thirds of total transgenic crops are in the developing countries, where yields are lower, and the need for improved production of food is the greatest.

More genetically enhanced products are expected to be on the market in the years to come, many of which are similar in nature to products already on the market. Benefits that can be expected in the near future include:

- reduced levels of natural toxins in plants;
- simpler and faster methods to locate pathogens, toxins, and contaminants; and
- extending the time before spoilage.

The world population is expected to double by the year 2050. Few other new technologies will be able to approach biotechnology's potential to help avoid starvation in the next century. Another economic and environmental benefit is in the area of fertilizer use. Much of the fertilizer used is wasted and can end up in water sources, damaging the environment. Some plants, such as corn, might also be modified to draw nitrogen from the soil, thereby reducing the need for fertilizer. Benefits that can be expected further down the road include:

- producing safer foods through reduction of allergenic proteins;
- drought and flood tolerance;
- salt and metal tolerance; and
- heat and cold tolerance.

In general, according to most scientific papers published, the use of biotechnology poses no specific risk, and products should not be discriminated against on the grounds of their method of production. The scientific consensus is that the risks associated with food biotechnology are fundamentally the same as for other foods. Current science shows that foods made using biotechnology are safe to consume and safe for the environment. Although there is no such thing as 'zero risk' for any food, consumers can be confident that foods produced using biotechnology meet the government's most stringent food-safety standards. Years of research and no evidence of promoting health harm indicate that the benefits of agricultural biotechnology far outweigh any risks.

However, there are people, amongst them ecologists and activist groups, who do not agree with this. Some of their arguments against biotechnology are that the use of GM products could reduce genetic diversity indirectly if, for example, farmers adopt genetically uniform varieties of plants and other organisms. The inclusion of novel genes for herbicide resistance in plants may increase the occurrence of weeds with resistance to certain agrochemicals. Others are concerned about the possible appearance of allergens or toxins and possible causes of different human diseases.

Thus, despite the benefits to be gained from modern biotechnology, the products obtained need to have appropriate legislation and safeguards to protect human health and the environment.

Current Concerns, Regulations, and Labeling

According to the concerns expressed about the possible existence of health hazards associated with the consumption of food containing modified genetic material, it is clear that rational policies are needed, regarding the regulatory status of bioengineering products.

Studies about public perceptions, consumer attitudes, and ethical implications of biotechnology in food and drink production have shown that certain

applications are more acceptable than others. For example, according to the European Federation of Biotechnology, the use of biotechnology to change plants was considered more acceptable than using it to change animals. In addition, around 85% of interviewees said that food obtained with genetic techniques should be clearly labeled. It will be necessary, therefore, to develop programs to educate the public about the benefits and problems of biotechnology in the production and processing of food. Governments and scientific institutions must be encouraged to share knowledge on transgenic foods with society, such that people are well informed about the impact of biotechnology on the environment, food safety, sustainability, and global food safety. In addition, as with any technology, there are limits that will and must be subjected to law. Countries must be helped to develop appropriate legislation and to set up proper regulatory bodies for all aspects of biosafety. Appropriate regulation is a prerequisite from the point of view of both the general public and the food industry.

In the USA, there are three organizations responsible for controlling GM organisms and products. The Environmental Protection Agency (EPA) and the United States Department of Agriculture (USDA) oversee the effects of GM organisms on the environment and on plant production. The Food and Drug Administration (FDA) is responsible for overseeing the safety of food, which is determined by the characteristics of the consumed or processed product rather than the method by which it was produced. The FDA policy statement also addresses the labeling of foods obtained from new plant varieties. It states that labeling is only required when a food obtained from a GM variety differs from that obtained from a conventional counterpart.

Nowadays, in Europe, there is no equivalent overall agency for food regulation, although a European Institute will be in operation in the near future. Until this time, the European Commission has therefore proposed harmonizing regulation between member states. The Council of the European Community (EC) adopted the Directive 90/220/EC on the deliberate release into the environment of GM organisms. This directive had two main objectives: to protect human health and the environment and to provide a harmonized regulatory framework of GM organisms with the EC.

In the EC, the safety of GM foods is controlled by Regulation (EC) No. 258/97 concerning novel foods and novel food ingredients, and the labeling of GM foods is regulated by two regulations, with important differences with American Regulations. First, Commission Regulation (EC) No. 49/2000 establishes that the foodstuffs shall not be subject to the additional specific labeling requirements when the material derived from the GM organisms is present in a proportion no higher than 1% of the food ingredients individually considered or food comprising a single ingredient, or this presence is adventitious. Second, Commission Regulation (EC) No. 50/2000 establishes the labeling of foodstuffs and food ingredients containing additives and flavorings that have been genetically modified or have been produced from GM organisms. In addition, novel foods and GM foods also have to fulfill the general labeling requirements set out in the Directive 2000/13/EC, which deals with an approximation of the laws of the Member States relating to the labeling, presentation, and advertising of foodstuffs.

With so many foods traded internationally, there is a clear need to reach a harmonized approach to labeling GM foods if potential trade barriers are to be eliminated. Therefore, it will be necessary to develop international safety guidelines.

In 1990, Food and Agriculture Organization (FAO) and the World Health Organization (WHO) took the first steps towards international harmonization of the food safety assessment of GM foods. It was recommended that the safety assessment of foods produced by biotechnology should take into account the molecular, biological, and chemical characteristics of these foods. The 1996 FAO/WHO report defined substantial equivalence as 'established by a demonstration that if the characteristics assessed for the GM organisms, or the specific food product derived therefrom, are equivalent to the same characteristics of the conventional food, then it can be assumed that the new food is as safe as the conventional equivalent.' In 1999, the FAO/WHO of Codex Alimentarius established the Codex *Ad Hoc* Intergovernmental Task Force on Foods derived from Biotechnology to elaborate norms and guidelines for the foods derived from biotechnology. The Task Force held its first session in March 2000, and approved the elaboration of major texts with a set of broad general principles for risk analysis and specific guidance on the risk assessment of foods derived from biotechnology. It will also have to prepare a list of available analytical methods including those for the detection or identification of these kinds of foods.

The Task Force agreed that the labeling was covered by the Codex Committee on Food Labeling, and the environmental risk was addressed by other bodies such as the Cartagena Biosafety Protocol under the Convention on Biological Diversity, the International Plant Protection Convention, and the Commission on Genetic Resources for Food and Agriculture.

Biotechnology in the Food Industry

As we said earlier, biotechnology applied to food production has a long history, beginning in cottage industries such as bread-making, cheese-making, and brewing. Many biotechnology advances have been made in the food industry over the last century. A major advance has been in food preservation, which is basically the prevention of undesirable microbial and enzyme activity in foodstuffs. This allows the storage of food over much longer periods and permits transport over great distances. The development of genetic techniques also represents a great advance, providing opportunities for much innovation.

According to the data obtained from the FSTA data base (Figure 2), food biotechnology processes are applied more to manufacturing foods of vegetable origin (38%) than to foods of animal origin (26%). In addition, the fields of study covered by the two largest groups of papers were vegetables and fruits first (19%) with dairy products in second place (15%). Papers on beverages, cereal products, meat products and fish products have been published more or less in the same quantity. During the last few years, the most frequent applications of biotechnology in food industries have been as follows.

Biotechnology in the Vegetable and Fruit Industries

Enzyme applications are very common in this industry. The presence of acid phenols and tannins in fruits has been studied, owing to their effect on bacterial growth during lactic fermentation.

Pectinolytic enzymes and cellulolytic enzymes are the most commonly used. These enzymes have applications in plant tissue maceration and in fruit juice processing, improving the clarification of juices and manufacturing processes of fruit such as peeling. Owing to the importance of these enzymes, many works have studied their activities during the ripening of fruits. These enzymes have even been extracted from fruits and purified later to be characterized and applied in different food industries.

Vegetables and fruits are used as substrates in some reactions, owing to their enzymatic systems, to produce other chemical compounds, such as volatile flavor compounds, lipids, vitamins, enzymes, pigments, etc.

The genetic variation of some vegetable and fruit crops, and the effect of genotype and environment on yield and quality, have been investigated, using random amplified polymorphic DNA. This DNA-based technology and others have resulted in a substantial increase in the number of genes identified and characterized, which will make it possible to produce transgenic crops of several vegetables and fruits.

Biotechnology in the Beverage Industries

In general, fermented beverages are obtained by the presence of determinate microorganisms, so the majority of published papers deal with this topic.

Many applications focus on the selection of yeasts capable of performing alcoholic fermentation under extreme conditions (high sugar concentration, high amounts of SO_2 or ethanol). GM amylolytic yeasts, which can hydrolyze starch, have been used to improve fermentation processes.

Some studies on the evaluation of the use of non-*Saccharomyces* yeasts, separating those that could positively affect the taste and flavor of alcoholic beverages from others that produce large amounts of negative byproducts, have also been developed. Yeasts selected have been applied to obtain fruit drinks with a slightly acid and less sugary taste. The use of immobilized cells in fermented beverages for continuous production has also been studied.

Another field is the use of different methods such as the combination of pressure, heat, and bacteriocins, and a flow-through photoreactor, to render inactive foodborne pathogens in some juices and some microorganisms in water, respectively.

Other studies have investigated the molecular and catalytic properties of different types of enzymes (proteinases, glucosidases), which have particular

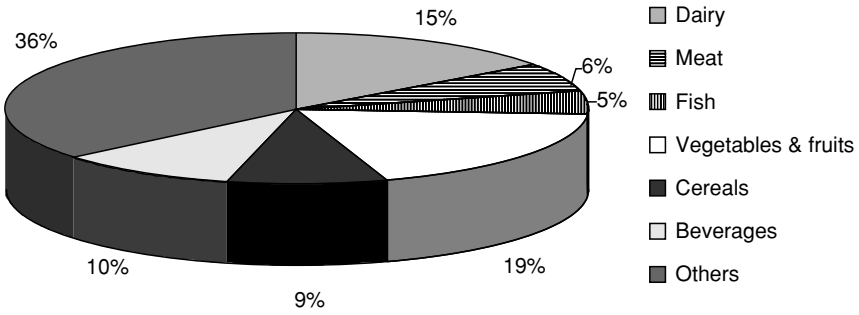

Figure 2 Percentage of food biotechnology published papers in different sorts of food industries.

importance in the production of fermented beverages. Commercial purified pectinolytic enzymes have been applied to improve clarification processes and aroma and color compound extraction, in beverage industries. The beverage industry has used genetic engineering techniques mainly for the selection of yeasts.

Biotechnology in Cereal Industries

The most important field has been fermentation. Isolation and characterization of both desirable and undesirable microorganisms (pathogens) have been carried out. The role of cereal as a substrate to obtain antimutagenic or anticarcinogenic fungic compounds has been evaluated.

The cereal breeding industry is also investigating the application of genetic techniques to improve major grain parameters (e.g., resistance to herbicides, viruses, fungal disease, temperature variations).

Biotechnology in Dairy Industries

A great deal of research has been carried out on selection, industrial production conditions, immobilizing processes, and applications of different dairy starters. The most studied microorganisms group has been the lactic acid bacteria (LAB), which have been applied to improve and increase industrial productions of traditional food, without any loss of popular acceptance; to increase the nutritional and health value of dairy foods; to increase selected flavor generation; and to improve the texture of dairy products.

Potential health benefits of bifidobacteria have been studied, and their application in yogurt and cheese production has been described. Some LAB have been genetically modified to utilize the lactose, and have been applied to obtain new yogurts with a sweet alanine flavor, longer shelf-life, or improved clinical probiotic value.

Other important studies have been concerned with the isolation of microbial enzymes, developments in GM enzymes, and their application in dairy industries. Clotting enzymes (chymosin), proteases, and lipases are the most studied and applied. Immobilized or free lipases have been used in many different aspects, such as for the production of food additives (e.g., antioxidants by esterification of phenols) and desirable flavors (e.g., in cheese, buttermilk), for synthesis of flavor thioesters, or as emulsifiers or food spoilage agents. Immobilized esterases have been employed in butter oil to obtain dairy flavor products. Thermally stable microbial β-glycosidase has been used to avoid problems of human lactose intolerance.

Some microorganisms are selected to improve the safety of dairy products, which are able to biosynthesize biopreservative compounds (e.g., reutenin). Different biotechnological practices (selected microorganisms or their metabolites) can be applied to control and predict bacteriophage contamination in dairy products, and bacteriocins isolated from different cultures have been applied to render inactive milk pathogens.

Many papers on probiotic dairy food have been published in relation to mechanisms, underlying their effects on human health, and some microorganisms have been applied to reduce the level of cholesterol and increase the availability of provitamin D_3.

Recent works have studied the use of genetic engineering to modify the composition of milk indirectly by using transgenic animals. These studies have been carried out to obtain low-lactose milk or to improve the quality of milk (increasing the fat level) to make special cheeses such as mozzarella.

Different papers have shown biotechnological applications on dairy effluents such as cheese whey. Microbial fermentation of whey for the production of biosurfactant sophorolipids or some enzymes with important industrial and environmental applications has been described.

Biotechnology in the Meat-product Industries

Fermentation processes in order to increase microbial activities and the production of bacteriocins have been extensively studied with satisfactory results, and new starter cultures (LAB) have been developed.

In addition, different kinds of proteinases alone or accompanied by lipases and esterases have been studied and applied usefully for the tenderization and ripening of meats and their products. Proteinases have been also used to hydrolyze peptides isolated from different animal meats to obtain new flavors.

In meat production, amylases, cellulases, and pectinases have been mixed and applied to obtain new animal feed, which increases the body weight and the percentage of protein and ash of the meat.

The main genetic technique used is the polymerase chain reaction, which uses a DNA-based identification system for testing the species origin of meat samples and is suitable for authenticating processed meat products.

Biotechnology in the Fish-product Industries

The development of new fermented products (fish and sauces) with special attention on desirable sensory properties has been one of the most important fields of study in these industries.

The second field has been the production of ω-3 polyunsaturated fatty acids, using immobilized lipase, or looking for marine organisms (bacteria, microalga,

fungi, and zooplankton) that can biosynthesize these acids.

Other applications have been the use of different enzymes for the tenderization and ripening of fish and to obtain new flavors. Fish enzymes and proteins have been isolated and applied in the food industry. LAB and their bacteriocins isolated from fish intestines have been genetically characterized, and their potential use in food preservation evaluated.

BIOTIN

Contents

Properties and Determination

R Bitsch, Friedrich-Schiller-University, Jena, Germany

Biotin

The molecular structure of biotin is characterized by three chiralic C atoms leading theoretically to eight stereoisomers. Only the D(+)-isomer is biologically active. The most commonly used microbiological assays (bioassays) for quantitation are more recently replaced by protein binding assays, with avidin showing higher precision and enhanced detection limits. Besides these methods, biotin can also be analyzed mainly in pharmaceuticals using photometric and fluorometric procedures or chromatographic techniques (TLC and HPLC).

Properties

The molecular structure of biotin (CAS No. 58–85–5) is a bicyclic ring system comprising an imidazolidone ring fused with a tetrahydrothiophene ring that is substituted with a valeric acid side chain. The stereochemistry reveals that both ring systems are fused in a

boat-like configuration at an angle of 62° (Figure 1). The chemical nomenclature of this compound is like a *cis*-hexahydro-2-oxo-1H-thieno[3,4-D] imidazole-4-pentanoic acid as was elucidated by Kögl 1937 and Du Vigneaud in 1941. The molecule contains three chiralic centers (*), and so eight stereoisomers are possible. Only the D-(+) isomer with a *cis*-configuration at the chiralic centers possesses vitamin activity and is found in natural products. The empiric formula is $C_{10}H_{16}N_2O_3S$ (molecular weight 244.3 Da). The molecular structure was confirmed in 1943 by Harris *et al.*, who were the first to achieve total biotin synthesis. In the meantime, a stereospecific synthesis for commercial production was developed by Goldberg and Sternbach in 1949.

Physicochemical Characteristics

D-Biotin as a free acid with a pK_a value of 4.51 crystallizes in colorless needles with a melting point of 230–232 °C (decomposition). The substance is slightly soluble in water (0.82 mM = 0.2 g l^{-1} at 25 °C) and ethanol 95% (3.27 mM = 0.8 g l^{-1}), readily soluble in dilute alkali, and almost insoluble in most organic solvents. The specific optical rotation $[\alpha]_D^{22}$ in 0.1 N NaOH is + 92 °C ($c = 0.3$) (Table 1).

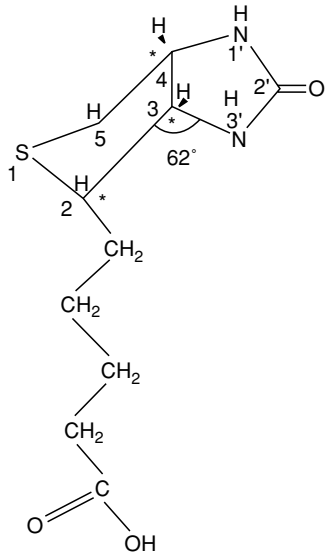

Figure 1 D(+)-Biotin. *, chiralic centers.

Crystalline D-biotin is fairly stable on exposure to air, daylight, and heat. Gradual destruction is observed on exposure to ultraviolet radiation. In weakly acid or alkaline solutions between pH 4.0 and 9.0, it is relatively stable, too. The molecule is also resistant to autoclaving in 2 N or 6 N sulfuric acid for 2 h (the commonly used extraction procedure).

Biotin is, however, susceptible to oxidation at the sulfur atom of the thiophene ring with the sequential formation of biotin sulfoxide and biotin sulfone. This oxidation, which is negligible in concentrated solutions, provides a primary step for vitamin activity losses in processed foods producing a mixture of D- and L-sulfoxides. While D-biotin sulfoxide exhibits a similar growth promoting activity for some microorganisms to that of biotin (e.g. *Lactobacillus* and *Saccharomyces* sp.), subsequent oxidation to biotin sulfone leads to complete loss of the biological activity. Biotin sulfoxide also seems to be a product of the biotin metabolism and can be detected as a minor excretion component in urine. In addition, microbial growth can drastically lower the concentration of nonsterile dilute solutions of this vitamin.

Besides the sulfoxide and sulfone, further metabolites and analogs have been identified as intermediate products of the biosynthesis (e.g., dethiobiotin) or of the metabolism (e.g., bis- and tetranorbiotin) in bacteria, yeasts, and fungi or as byproducts of the chemical synthesis (e.g., oxybiotin) (Figure 2). The growth response of microorganisms to these analogs is variable and thus may lead to conflicting results in terms of vitamin activity in biological samples when measured by means of microbial assays (see Table 2). Bisnorbiotin, tetranorbiotin, and biotin sulfone, as well as other derivatives, are potent antagonists of biotin and do not support microbial growth. Apart from the sulfoxide and sulfone, these analogs are of little practical importance in foods. Nevertheless, more recent results indicate that in human urine samples, besides unchanged biotin, about 11% D-biotin-sulfoxide, 29% bisnorbiotin, and 4% biotin sulfone plus bisnorbiotinmethyl-ketone and tetranorbiotin-L-sulfoxide could be identified, but no

degradation products of the cyclic urea ring were found to be excreted.

In natural products, biotin exists either in free form or protein-bound. Generally, the free form predominates in plant food, whereas a greater part in animal food is protein-bound. Therefore, less drastic hydrolysis with 2 N sulfuric acid is required to liberate biotin from plant material than from products of animal origin, which need 6N sulfuric acid. The biotin content in selected foods is shown in Table 3.

If protein-bound, the vitamin is linked through an amide bond between the carboxyl group of the valeric acid side chain and an ε-amino group of terminating lysine. This ε-*N*-biotinyl-L-lysine (biocytin) is naturally occurring, too, and is partly formed by proteolysis of biotin enzymes. Occasionally, biocytin is indicated as the real prosthetic group of biotin-dependent enzymes.

The most prominent antagonist of biotin is avidin. This is a glycoprotein from egg white with a MW of 68 000, which is formed within the oviduct of avian

Table 2 Growth response of biotin derivatives to some microorganisms

species and reptiles. It has a tetrameric structure with four identical subunits (MW 17 000), each containing a binding site for biotin, so 4 moles of biotin are bound by 1 mole of avidin.

The interaction of avidin with biotin is the strongest noncovalent binding ever found in living organisms with a dissociation constant of the binding sites, $K_d = 10^{-15}$ M. Because avidin is a basic protein with an isoelectric point of pH 10.5, by oral intake, not only the dietary but also the enterally synthesized and enzymatically bound biotin can be irreversibly bound. The avidin–biotin complex is not cleaved within the gastrointestinal tract.

Raw egg white contains 2 mg of avidin per 100 g, so about 15 μg of biotin are fixed by one egg (c.50 g) and made unavailable for man and animal. Not only free or enzymatically bound biotin but the structural isomers with an intact ureido ring in the *cis* configuration compete for complexing, too, as is shown in Table 4. The very stable avidin–biotin complex is only split by autoclaving with strong acid. Avidin, however, is only in raw egg white active as an inhibitor of the biotin availability and is denaturated by heat, thereafter losing its binding capacity.

The exact physiological role of avidin is not well understood, but it is generally thought to be effective as a bacteriostat. With respect to the stoichiometric binding, avidin has served as a useful diagnostic tool in the identification and study of biotin-dependent enzymes.

Besides avidin, streptavidin (MW 60 000) has been isolated from *Streptomyces avidinii*, which is also composed of four subunits with a biotin-binding affinity similar to that of avidin. On the basis of the stoichiometric binding of biotin by avidin and streptavidin in a stable complex, current analytical methods to quantitate biotin and its metabolites in biological materials have been developed.

Determination

Microbiological Assays

As with other B vitamins, biotin has been exclusively assayed for longer times by microbiological methods. Biotin is a growth factor for a variety of bacteria, fungi, yeasts, and flagellatae. For assay purposes, in foods and other biological materials such as blood, plasma/serum, urine, and various tissues (liver, brain), *Lactobacillus plantarum*, *L. casei*, *Saccharomyces cerevisiae*, *Neurospora crassa*, and *Ochromonas danica* have been used. Besides the variable response to biotin analogs, as shown in Table 2, the lack of specifity is also due to certain amino acids, fatty acids and their metabolites, which are able to stimulate the growth and replace biotin, thus affecting the validity of the assay. Results achieved with different microbial assays are often therefore hardly comparable, particularly if the relationship of biotin to these interfering factors is poor.

Table 4 Quantitation (%) of biotin analogs and derivatives by various binding proteins and microbial assay (comparing equimolar amounts), according to Baur, Helbich-Endermann, and Salz (unpublished results)

Derivative	*Avidin*	*Streptavidin*	*Neutravidin*	*Lactobacillus plantarum*
Biotin	99	88	100	98
Biocytin	103	98	83	0.1
Biotin-D-sulfoxide	97	87	35	83
Biotin-L-sulfoxide	96	36	24.5	14
Biotinsulfone	96	54	28	0.2
Bisnorbiotin	49	0.4	5.5	0.2
Dethiobiotin	10	–	–	0

Minor growth activity for *L. plantarum* exhibits oleic acid, elaidinic acid, linoleic and linolenic acid, as well as a few other lipids, which have to be removed either by filtration or by ether extraction. Aspartate and several other amino acid metabolites, pimelic acid, and oleic acid interfere with the *Saccharomyces* assay. Less frequently used microorganisms are *N. crassa* and *O. danica*, although *O. danica* is rather specific and responds, besides biotin, only to biocytin and protein-bound vitamin. The *O. danica* assay was applied for biotin assessments in blood, serum, urine, liver, brain, and muscle. The validity of the method established by recovery experiments was demonstrated to 96–103% biotin recovery.

In order to extract the vitamin, in most assays, the biological material is subjected to acid (sulfuric acid) or enzymatic hydrolysis. Protein-bound biotin is also cleaved by papain, a proteolytic enzyme hydrolyzing specifically lysine-bound substances.

Principle of the *Lactobacillus plantarum* (ATCC 8014, formerly *L. arabinosus*) assay To liberate protein-bound biotin, foods, feeds and other biological samples are extracted with sulfuric acid for 2 h at 121 °C. Plant products as well as whole blood, plasma, and urine samples are autoclaved with 2 N sulfuric acid, and animal samples otherwise with 6 N sulfuric acid. The ratio of sample to acid should be 1:20, whole blood, plasma or urine at a ratio of 3 ml of sample to 8 ml of acid. For pharmaceuticals and premixes, dilution with 0.1 N sodium hydroxide at a concentration of about 0.2 ng ml^{-1} and, if needed, centrifugation or filtration to clarify is the preferred extraction mode. Stronger acid concentrations for sample extraction should be avoided, because a high sodium sulfate concentration in the assay is inhibitory to the test organism. Furthermore, using strong sulfuric acid, followed by autoclaving, biotin may be partly oxidized to inactive biotin sulfone.

Hydrochloric acid should not be used in place of sulfuric acid, as the hydrochloric acid may inactivate biotin probably because of the presence of chlorine. High-fat samples must be extracted, prior to acid cleavage, with hexane or ethyl ether to avoid fatty acid stimulation.

After cooling, the samples are adjusted to pH 6.75 with concentrated NaOH, and biotin in the extract is determined by means of its growth response to an inoculum suspension prepared from a stock culture of *L. plantarum* and diluted with culture medium. After incubation at 37 °C, the absorbance (nephelometric) is measured at 660 nm, and the biotin content is calculated by comparing with a standard curve using D(+)-biotin concentrations of up to 0.80 ng per 5 ml. The detection limit of this microbiological assay is 122 pg biotin ml^{-1} (0.5 pmol ml^{-1}). The coefficient of variation (CV) for whole blood analysis amounts to about 19%.

A modification of the standard biotin assay with *L. plantarum* has been developed by a radiometric-microbiological assay (RMA) based on the measurement of $^{14}CO_2$ from the metabolism of L-1-[^{14}C]-methionine by *Kloeckeria brevis* (ATCC 9774). The amount of $^{14}CO_2$ is measured with the aid of a gas-flow ionization chamber system and is proportional to the present biotin amount. The assay sensitivity has been found to be 10 pg of biotin (41 fmol)/vial (= 5.2 ml). This test has been employed for plasma, as well as food, analysis. Biocytin and biotin-D-sulfoxide have the same biological activity as biotin in equimolar concentrations, but dethiobiotin and other analogs as well as fatty acids and aspartate did not interfere with the biotin measurement (see Table 2). The RMA allows some simplification of the sample preparation and assay procedure (no filtration of the sample extract and no turbidimetric measurement). Its application for biotin analyses, however, is limited by the need for special laboratory devices.

The application and detection limits of the most commonly used microbial assays are summarized in Table 5.

Isotope Dilution Assays (Radioligand Binding Assays)

The strong and specific affinity of the glycoprotein avidin to biotin was taken very early on as the basis

Table 5 Microbiological assays

Microorganism	*Principle of assay*	*Biotin release*	*Application*	*Detection limit*
Lactobacillus plantarum ATCC 8014	Growth-promoting acticity	2–6 N H_2SO_4 (121 °C, 2 h)	Biological samples, food analysis	122 pg ml^{-1} (0.5 pmol ml^{-1})

Kloeckeria brevis ATCC 9774	$^{14}CO_2$ detection from [^{14}C]-methionine	2 N H_2SO_4 (foods) papain proteolysis (plasma)	Plasma, food analysis	10 pg per vial (5.2 ml) (41 fmol)

for methods to quantitate biotin and certain metabolites in biological materials. The competition between radioactive and nonradioactive (cold) biotin for avidin binding is the principle of isotope dilution assays. The radioactivity of the avidin–biotin complex depends on the dilution of the added radioactively labeled biotin by the unknown (nonradioactive) vitamin content in the sample. ^{14}C-Biotin, ^{125}I-biotin, or ^{3}H-biotin can be used as a competing tracer. Techniques to separate protein bound from unbound biotin differ in adsorption and separation of either the avidin–biotin complex (bentonite or nitrocellulose) or the exceeding free biotin (charcoal) in the sample.

Radiochemical assays previously using ^{14}C-labeled material (biotin) have often lacked the sensitivity necessary to measure the physiological concentrations of biotin because of the low specific activity of the available [^{14}C]-carboxybiotin (45 mCi per mmol of biotin). The detection limit of 1 ng of biotin per assay (4.0 pmol) or 5 μg of biotin kg^{-1} (20.5 mmol) was only capable of detecting the biotin content in tissue samples and animal feed.

By using a ^{125}I-labeled conjugated of biotin, a biotin detection limit in the femtomolar range has been made possible, thus being sensitive enough to determine the biotin content in the small volumes of blood available in pediatric studies. The drawback of this assay, however, is the extensive and cumbersome synthesis of the ^{125}I-biotin beforehand.

The lack of sensitivity has been overcome when using ^{3}H-labeled biotin as a tracer, which is commercially available with a considerably enhanced specific radioactivity (30–46 Ci per mmol of biotin). Assays based on ^{3}H-biotin are sensitive enough to quantify biotin in the picomolar, or even femtomolar, range, as required for biological material (tissue, blood, and urine).

Non-bound biotin, as well as free ^{3}H-biotin, is separated by means of adsorption of the avidin–biotin complex on bentonite or filtration through nitrocellulose filters. Alternatively, nonbound biotin can be adsorbed on dextran-coated charcoal. In principle, biotin analogs or metabolites with an intact ureido ring as well as protein-bound biotin are also complexed by avidin and, if present in the sample, should be assayed by the radioisotope dilution methods (see Table 4).

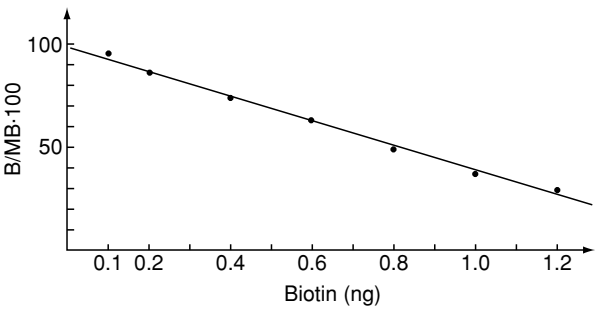

Figure 3 Calibration curve. B, bound ^{3}H-biotin; MB, maximal binding capacity. B = bound ^{3}H-biotin, MB = maximal binding capacity. From *Deutsche Lebensmittel-Rundschau* 82 (1986) 80–83, with permission.

A problem may arise in terms of the extraction procedure of bound biotin from the sample material. With acid hydrolysis, there is the problem of achieving maximal liberation of bound forms without any detectable vitamin losses or oxidative damage. Furthermore, large amounts of salt are produced on neutralization of the acid extracts, which may interfere with the following adsorption of biotin on bentonite or charcoal. Dilution is necessary, therefore, to lower the high salt concentration, but this may create problems in bringing the biotin content to within an appropriate sensitivity range. Such difficulties can be avoided by means of enzymatic cleavage by papain digestion, instead of acid hydrolysis. A typical calibration curve using ^{3}H-biotin as a tracer and avidin as a binder is shown in Figure 3.

This modification of the radioligand test has been applied to biotin determinations in plasma, urine, and animal and plant food samples. Food samples are pretreated with liquid nitrogen followed by homogenization and papain digestion. Comparing analyses by use of the microbiological assay with *L. plantarum* correlated well with this radioligand test. The detection limit is 0.4 pmol of biotin per tube (= 0.1 ng of biotin).

Another modification makes use of a sequential solid-phase assay based on ^{125}I-labeled avidin. A fixed amount of ^{125}I-labeled avidin is incubated with either standards of biotin or sample biotin in serum or urine. An aliquot of this incubate is then transferred to microtiter plates previously coated with biotin linked to bovine serum albumin. Depending on the amount of biotin bound to ^{125}I-biotin in the first incubation step, the counts bound in the second incubation step vary and can be compared with the counts for the standards. The assay sensitivity is 10 fmol per assay well (100 fmol ml^{-1}).

Table 6 summarizes details of the aforementioned isotope dilution assays.

Assessment by Competitive Enzyme Protein Binding Assay (EPBA) or Sequential Solid-Phase Assay

Very recently, highly improved and sensitive protein binding assays have been developed by means of either enzyme-linked avidin or streptavidin, or biotinylated chromophores or fluorophores, respectively.

The principle of the EPBA is similar to isotope dilution assays, to prevent enzyme-coupled avidin from binding to a biotinylated protein adsorbed to plastic by the unknown sample's vitamin content. These tests have been improved by the introduction of microtiter plates in solid-phase sequential assays. In most cases, the detector molecule is avidin linked to horse-radish peroxidase (HRP), and the microtiter plates are coated with bovine serum albumin (BSA) covalently linked to biotin.

The typical sequence of a sequential solid phase assay is as follows:

- A constant amount of avidin linked to horse-radish peroxidase (HRP-avidin) is incubated in a microtiter plate with known amounts of biotin and with dilutions of the sample to produce the standard curve and the unknown response (incubation 1).
- An aliquot of the first incubation is then transferred to corresponding microtiter plates previously coated with biotin covalently linked to bovine serum albumin (biotinyl-BSA) and incubated, too (incubation 2). During this incubation step, HRP-avidin molecules in surplus with unoccupied biotin-binding sites will bind to the biotinyl-BSA. Unbound HRP-avidin molecules with no available biotin-binding sites are washed away thereafter.
- The amount of HRP-avidin bound to the biotinyl-BSA is quantitated by measuring the rate of

^{125}I-Avidin	Biotin–bovine serum albumin	Serum, urine	Sequential solid-phase assay (molecular sieve chromatography on Sephadex)	0.1 pmol ml^{-1}	D M Mock: *Methods in Enzymology* 184 (1990) 224

peroxidation of *o*-phenylenediamine (OPD) used as an indicator dye. Peroxidation is stopped by the addition of acid (e.g., H_2SO_4), which also intensifies the absorbance of the peroxidized dye (OPD). The absorbance maximum at 490 nm is finally quantitated in a plate-reader spectrophotometer.

Analogous to RIA, a biotin increase in the standard additions or unknown samples decreases the number of free biotin-binding sites on HRP-avidin during the initial incubation. Thus, fewer molecules of free HRP-avidin are bound to the plates coated with biotinyl-BSA, and the final color development is progressively less.

This sequential solid-phase test was applied for biotin measurement in serum, urine, and milk. The detection limit is reported to about 5 fmol of biotin and about 10 parts per trillion (p.p.t.). Separate quantitation of biotin and analogs such as biotinsulfoxide and bisnorbiotin is necessary, because the biotin-binding affinity of HRP-avidin varies among biotin and its metabolites. These derivatives thus have to be separated beforehand by HPLC on RP18 columns, and the binding affinity of each metabolite has to be determined separately. The measured total avidin-binding substances therefore do not equal the stoichiometric sum of the vitamin and its metabolites.

Variations of this sequential solid phase test are described using streptavidin as the binder and biotinylated enzyme, e.g., alkaline phosphatase, and free sample vitamin as the competitors for binding. The activity of alkaline phosphatase as an indicator is determined by measuring the absorbance of *p*-nitrophenylphosphate as a chromogenic enzyme substrate at 405 nm. The biotin-binding affinity of streptavidin is slightly lower than that of avidin, but biotin metabolites are bound much more weakly by streptavidin (see Table 4).

Assays utilizing enzyme-linked biotin as an indicator are applicable to quantify either biotin or avidin/streptavidin. The lower limits of those assays are 0.2–20 pg of biotin per well (0.8 fmol to 0.08 pmol).

A superior replacement for avidin or streptavidin appears to be the introduction of neutravidin, a modified avidin with no carbohydrate components. The deglycosylation procedure is carried out under mild conditions, so as not to affect the stability or the biotin-binding affinity. The suitability for biotin assessments seems to be more advantageous in so far as the cross-reactivity for structure analogs is weaker compared with the other binding proteins (Table 4). An ELISA test has been developed, based on neutravidin-coated microtiter plates and biotinylated HRP competing with sample biotin. The absorbance of the chromogen tetramethylbenzidine after oxidation by the enzyme conjugate and urea peroxide is detected at 450 nm in a plate-reader photometer. The detection limit of this commercial test is 1.1 pg of biotin (4.5 fmol) or 11 ng of biotin per liter of sample (45 pmol). Using this assay, the biotin content of biological materials (plasma, urine) as well as in several plant and animal food samples was analyzed after release of the protein bound vitamin by papain digestion. The biotin content correlated well with microbiologically determined vitamin using *L. plantarum* ($r = 0.973$). A typical biotin calibration curve obtained when using the RIDASCREEN® assay with neutravidin as a solid-phase binder is shown in Figure 4. The principles and detection limits of typical competitive EPBAs are summarized in Table 7.

Enzymatic Determination

An older enzymatic assay is based on the formation of holopyruvate carboxylase from apopyruvate carboxylase and biotin, followed by determination of the pyruvate carboxylase activity in the presence of holoenzyme synthetase, measuring the incorporation of $H\text{-}^{14}CO_3^-$ into oxaloacetate, which is reduced to acid-stable malate. The apoenzyme and the holoenzyme synthetase have been obtained from the biotin-free cultivated yeast, *S. cerevisiae*.

The reaction of the test is as follows:

$$\text{Apopyruvate carboxylase} + \text{biotin} \xrightarrow[\text{Synthetase}]{\text{Holoenzyme}} \text{Pyruvate carboxylase}$$

$$\text{Pyruvate} + H\text{-}^{14}CO_3^- \xrightarrow[\text{Pyruvate carboxylase}]{\text{ATP, } Mg^{2+}, K^+} {}^{14}\text{C-oxaloacetate.}$$

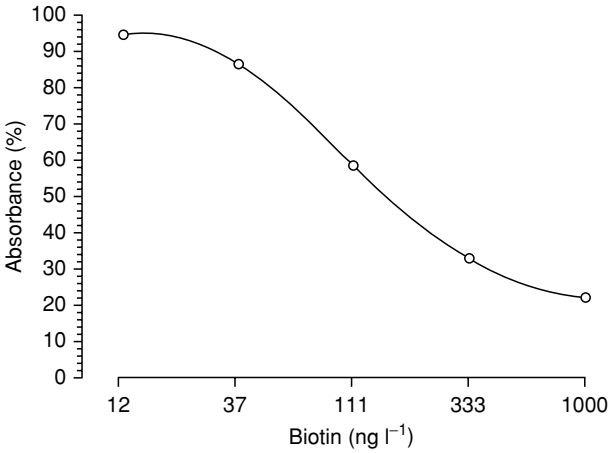

Figure 4 Calibration curve of RIDASCREEN® with biotin.

Table 7 Enzyme immuno(sorbent) assays

Enzyme conjugate	*Indicator dye*	*Solid phase (microtiter plates)*	*Application*	*Detection limit*	*Author*
HRP-Avidin	OPD	Biotinyl-BSA	Serum, milk, urine	5 fmol per well (10 p.p.t.)	D Mock: *Methods in Enzymology* 279 (1997), 265
HRP-Streptavidin	OPD	Biotinyl-BSA	Aqueous solution	0.1 pmol per well	E Z Huang: *Methods in Enzymology* 279 (1997) 304
HRP-Streptavidin	[2,2-azinodi(3-ethyl-benzthiazoline) sulfonic acid	Biotinyl-goat antirabbit IgG	Aqueous solution, clinical samples	1 pg ml^{-1} (4 fmol)	D Shiuan: *Methods in Enzymology* 279 (1997) 321
Biotinyl-HRP	Tetramethylbenzidine + urea peroxide	Neutravidin	Plasma, urine, food samples	4.5 fmol per well	M Helbich-Endermann: Doctoral thesis (1999) Jena/ Germany

The enzyme activity is proportional to the amount of available biotin. The method is somewhat difficult, and the absolute minimum amount of biotin detectable is 5 pg. Of the biotin analogs and precursors, only biocytin has been found to interfere in this test.

Photometric and Fluorimetric Determinations

Based on the high affinity of biotin, earlier methods took advantage of the spectral shift, the fluorescence change, or the chemiluminescence induction after displacement of an avidin-bound dye by biotin. After addition of the azodye 2-(4′-hydroxyazobenzene) benzoic acid (HABA) to avidin, a complex is formed with an absorbance maximum at 500 nm. Titration with biotin quantitatively displaces the dyefrom avidin, leading to a spectral shift, which can be monitored spectrophotometrically. This test can be employed for the quantitation of biotin as well as avidin. The sensitivity is no higher than 2 μg of biotin per ml (8 nmol ml^{-1}). Biotin analogs with an intact ureido ring react in a similar way. Depending on their binding constants, these analogs may reduce the sharpness of the endpoint but do not affect the titer.

Another spectrophotometric assay for biotin and avidin has been proposed, which is based on the inactivation of biotinylated glucose-6-phosphate dehydrogenase when complexed with avidin. The degree of inactivation of the biotinylated enzyme in relation to the avidin concentration is detected in a coupled reaction with NADH at 340 nm. The detection limits have been reported to be 100 ng of biotin per ml (0.4 nmol ml^{-1}) and 2.5 ng of avidin per ml.

Fluorescence and chemiluminescence determinations The competition between biotin and a biotin luminol derivative for avidin was utilized for a chemolumimetric detection. Biotin is covalently linked to the amine function of isoluminol to yield the conjugate. This conjugate emits light when oxidized by either a hydrogenperoxidase–lactoperoxidase or a superoxide. The peak light intensity increases about 10-fold when the conjugate is incubated with avidin prior to oxidation. When the isoluminol-biotin conjugate and free biotin compete for the avidin binding sites, the peak light intensity produced in subsequent chemiluminescent reactions decreases with increasing biotin levels. In this way, biotin is measured quantitatively at levels as low as 50 nM.

A greater sensitivity is achieved by measuring the quenching of the chemiluminescence of aminobutylethylisoluminol (ABEI)-labeled biotin when bound to fluorescein-labeled avidin. The chemiluminescence decrease in the range of 460–525 nm compared with unbound ABEI-biotin is capable of detecting biotin in human sera in the range of 1.2–4.3 nM. However, the disadvantage with this is the laborious preparation of the ABEI-biotin and its purification by TLC and HPLC.

Another modification of fluorescence detection in a competitive binding assay includes HPLC separation of biotin and biocytin coupled with a postcolumn reaction detection system. In one analytical approach, biotin or biocytin displacement of 2-anilinonaphthalene-6-sulfonic acid from its binding site to avidin yields a decrease in the fluorescence intensity at 438 nm. The other analytical approach utilizes the increase in fluorescence of (strept) avidin labeled with fluorescein isothiocyanate (FITC) at 518 nm after binding with the analyte (biotin, biocytin) in the postcolumn eluate. However, the detection limits of both methods are relatively low in the range of 5×10^{-7} M up to 1.8×10^{-8} M biotin or biocytin,

so these methods are only applicable for analyses of the biotin content of vitamin preparations, liquid infant formula, etc.

A maximal intensification of the chemolumimetric biotin detection can be achieved by using the bioluminescent protein aequorin as a label in a competitive binding assay. Aequorin is a photoprotein from the jellyfish *Aequorea victoria*. Aequorin associates noncovalently with its chromophore coelenterazine, which is oxidized into a metastable excited state, resulting in the emission of photons at 469 nm.

In a homogenous assay, the aequorin–biotin conjugate competes in a one-step procedure with free biotin for binding to avidin in solution. Binding of the conjugate to avidin results in partial quenching of the bioluminescence signal, and so the decrease in luminescence can be related to the concentration of biotin in a sample. The detection limit is reported to be around 10^{-14} M biotin (= 10 fM).

The competition assay can also be performed in a heterogenous system by using immobilized avidin (agarose, polyacrylamide). Both methods need special equipment (luminometer operating in a photon-counting mode). The amounts of avidin and biotinylated aequorin must be optimized beforehand, as the relative amounts of avidin and biotinylated aequorin influence the response characteristics of the assay (e.g., detection limits and sensitivity).

Chromatographic Analysis

Earlier methods attempted to separate and quantify biotin from vitamin mixtures or feed supplements. After dissolution of the lyophilized preparation and addition of the internal standard (2-imidazolidone), the sample was applied on a TLC plate and eluted with chloroform/methanol/formic acid. Biotin was visualized by spraying with *p*-dimethylaminocinnamaldehyde and determined *in situ* by reflectance measurements. Spraying with paraffin after the coloring procedure increased the sensitivity to a detection limit of 10 ng of biotin per spot.

Quantitation by HPLC requires derivatization of the molecule, because biotin does not absorb in the visible or UV region. For the derivatization 9-anthryldiazomethane was used to produce fluorescent biotin-9-anthrylmethylester followed by separation on C 18 bonded columns with acetonitrile/water as the mobile phase and fluorimetric detection (excitation = 365 nm, emission = 425 nm). Alternatively, *p*-bromophenacyl bromide esters and 4-bromomethylmethoxycoumarin derivatives of biotin were produced for UV and fluorescence detection, respectively, after separation on RP 18 columns with methanol/water or tetrahydrofuran/water as eluents.

Standards of biotin and 13 metabolites and analogs can be separated by HPLC on a C 18 RP phase using gradient elution with trifluoroacetic acid/acetonitril and UV detection at 220 nm. An HPLC separation of six vitamins including biotin from almonds has been performed on an LC-8-DB column with hexanesulfonic acid sodium salt/methanol as the eluent and detection at 200 nm. The limit of biotin detection has been found to be as low as 0.9 mg per 100 g.

When biotin is derivatized with panacyl bromide in the presence of crown ether, a fluorescence compound results with fluorescence maxima at 380 nm (excitation) and 470 nm (emission). After extraction from biological tissue with trichloroacetic acid and purification by solid-phase extraction combined with ion-exchange chromatography on DOWEX and TLC, biotin is derivatized with panacyl bromide in the presence of crown ether. The resulting panacylester can be separated on normal-phase HPLC using isocratic elution with methanol/dichloromethane as well as on RP phase HPLC using gradient elution (water/methanol). Dethiobiotin is taken as an internal standard.

With this method, the biotin content in rat small intestine has been assessed. The detection limits are reported to be 10 pmol of biotin (normal phase HPLC) or 100 pmol of biotin (RP-HPLC), which is less sensitive than with protein-binding assays. Criticism results from the facts, that the clean-up required for biological sample extracts prior to derivatization is very extensive, the derivatization should not only include biotin, and the cross-reactivity to biotin analogs has to be examined.

Introduction

Biotin is a water-soluble vitamin that serves as essential coenzyme for four mammalian carboxylases. Biotin may also play a role in the replication and transcription of DNA, possibly by an effect on biotinylation of histones. Frank biotin deficiency causes clinical findings such as hair loss and skin rash. Marginal biotin deficiency is frequently seen in pregnant women and theoretically could have teratogenic effects. Biotin status may be assessed using urinary excretion of biotin and its metabolites, and certain organic acids that are byproducts of deficiency of biotin-dependent carboxylases. Direct measurement of biotin-dependent carboxylases and biotin in lymphocytes and fibroblasts also show promise as indicators of biotin status. Inborn errors of biotin metabolism (e.g., biotinidase deficiency and holocarboxylase synthetase deficiency to a variable degree) can produce symptoms similar to biotin deficiency. For adults, the safe and adequate daily dietary intake of biotin is 30 μg. Available data suggest that pure biotin administered orally is absorbed completely. Uptake of biotin into cells of the intestine and peripheral tissues is mediated by a sodium-dependent transporter that requires metabolic energy. Mammals catabolize biotin by β-oxidation of the valeric acid side chain and by sulfur oxidation in the thiophane ring. Biotin, bisnorbiotin, and biotin, *d,l*-sulfoxide are the most abundant biotinyl compounds in urine and plasma.

Biochemical Function

In mammals, holocarboxylase synthetase (EC 6.3.4.10) catalyzes the covalent binding of biotin to the ϵ-amino group of lysine in four different apocarboxylases to form the active holocarboxylases (**Figure 1**). For acetyl-CoA carboxylase (EC 6.4.1.2), a cytosolic (acetyl-CoA carboxylase α) and a mitochondrial form (acetyl-CoA carboxylase β) have been identified. Both the α and β forms catalyze the binding of bicarbonate to acetyl-CoA to form malonyl-CoA; the latter is a substrate for fatty acid synthesis. Although the α and β forms of acetyl-CoA carboxylase catalyze the same reaction, they appear to have different roles in intermediary metabolism. Acetyl-CoA carboxylase α controls fatty acid synthesis in the cytosol by providing the substrate malonyl-CoA; acetyl-CoA carboxylase β controls fatty acid oxidation inside the mitochondria via malonyl-CoA inhibition of fatty acid transport into mitochondria. (*See* **Fatty Acids**: Metabolism.)

The three other mammalian biotin-dependent carboxylases are located exclusively in mitochondria: pyruvate carboxylase (EC 6.4.1.1), propionyl-CoA carboxylase (EC 6.4.1.3), and β-methylcrotonyl-CoA carboxylase (EC 6.4.1.4). By synthesizing oxaloacetate, pyruvate carboxylase provides a tricarboxylic acid cycle intermediate and catalyzes a step in gluconeogenesis. Propionyl-CoA carboxylase catalyzes an essential step in the metabolism of isoleucine, valine, the cholesterol side chain, and products of dietary carbohydrate breakdown by intestinal microorganisms. β-Methylcrotonyl-CoA carboxylase catalyzes an essential step in leucine metabolism.

Biotin deficiency causes reduced carboxylase activities; substrates are shunted to alternative pathways (**Figure 1**). For example, reduced activity of propionyl-CoA carboxylase results in increased formation of 3-hydroxypropionic acid and 2-methylcitric acid; reduced activity of β-methylcrotonyl-CoA carboxylase results in increased formation of 3-hydroxyisovaleric acid and 3-methylcrotonyl glycine. Increased urinary excretion of these organic acids has been used to diagnose biotin deficiency, as discussed below.

Biotin may also play a role in the regulation of DNA transcription and replication on the basis of the following observations:

1. Biotinidase (EC 3.5.1.12) specifically biotinylates histones. Histones are DNA-binding proteins that

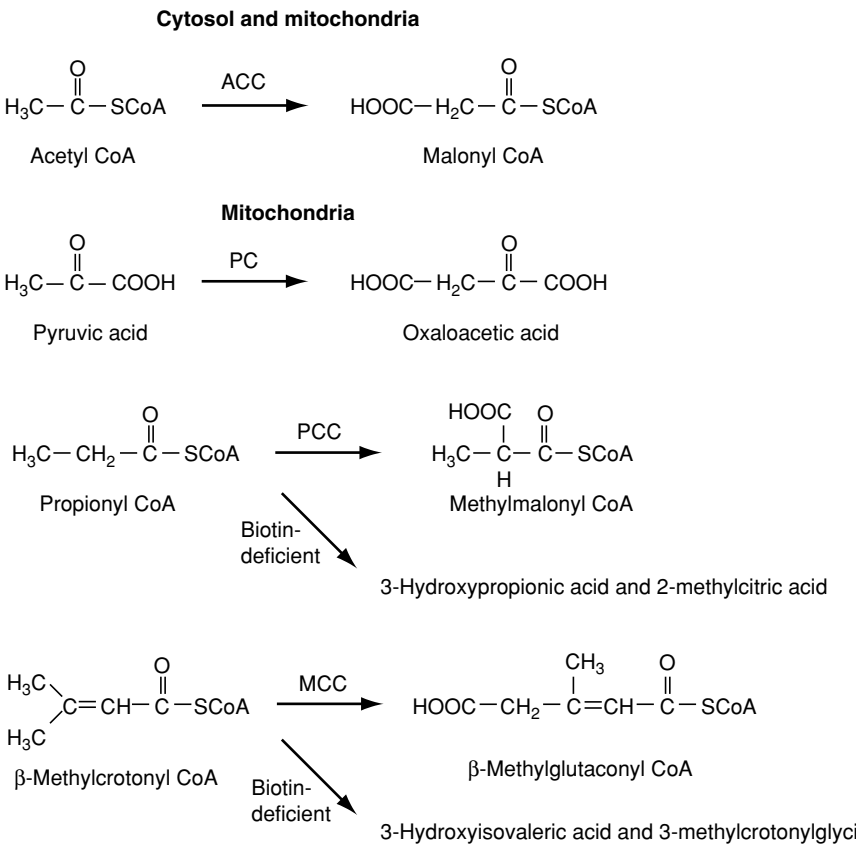

Figure 1 Biotin-dependent carboxylases. ACC, acetyl-CoA carboxylase; PC, pyruvate carboxylase; PCC, propionyl-CoA carboxylase; MCC, β-methylcrotonyl-CoA carboxylase.

regulate transcription and replication of DNA. Biotinylation of histones might play some role in DNA packaging in analogy to other covalent modifications such as acetylation, methylation, phosphorylation, or adenosine diphosphate (ADP)-ribosylation of histones. Biotinidase is ubiquitous in mammalian cells, and 25% of the cellular biotinidase activity is located in the nucleus. Indeed, the following observations are also consistent with a role for biotin in modifying histones and in turn affecting the packaging of DNA: first, histones dissociate from the DNA in biotin-deficient rats, and second, biotin deficiency in rats results in decreased phosphorylation and methylation of histones as well as increased acetylation of histones.

2. Rates of biotin uptake are greater in proliferating than in nonproliferating lymphocytes. This increase is mediated by an increased number of biotin transporters on the cell surface. Cell proliferation requires a substantial increase of both replication and transcription. Theoretically, the observed increased uptake of biotin by proliferating cells may be in response to increased demand for biotin to biotinylate histones. This is a potential mechanism by which biotin exerts an effect on cell replication.
3. Biotin status affects gene expression. Biotin deficiency causes a 40–45% reduction of rat liver glucokinase activity; the activity is restored by biotin administration. Injection of biotin into rats causes a 4–19-fold increase of mRNA encoding glucokinase.

In addition to this effect on mRNA synthesis, biotin may affect the synthesis of some proteins at the posttranscriptional level. When human-derived liver (HepG2) cells were cultured in biotin-deficient medium, expression of the asialoglycoprotein receptor was reduced despite normal protein synthesis, total cellular protein content, and mRNA coding for asialoglycoprotein receptor; addition of biotin or biocytin restored receptor expression. These observations suggest that a biotin-dependent posttranscriptional event can affect the ultimate expression of asialoglycoprotein receptor.

Storage, Metabolism, and Excretion

Depletion and repletion experiments of biotin-dependent carboxylases in rat liver provided evidence that mitochondrial acetyl-CoA carboxylase may serve as a reservoir for biotin. Neither cytosolic acetyl-CoA carboxylase nor the mitochondrial pyruvate carboxylase, propionyl-CoA carboxylase, or β-methylcrotonyl-CoA carboxylase seem to serve as biotin reservoirs.

The liver accumulates a significant percentage of ingested biotin. For example, rat liver accumulates approximately 4% of [^{14}C]biotin within 1 h of intravenous administration. Once steady-state conditions are attained, biotin is located mainly in liver mitochondria (30% of total [^{14}C]biotin) and cytosol (59%); smaller amounts can be found in microsomes and nuclei. Greater than 80% of the [^{14}C]biotin present in the cytosolic fraction is acid-precipitable, suggesting that biotin has become covalently bound.

During the normal intracellular turnover of proteins, holocarboxylases are degraded to biotin linked to lysine (biocytin) or biotin linked to an oligopeptide containing at most a few amino acid residues. Biotinidase catalyzes the hydrolysis of the amide bond between biotin and lysine. Biotinidase likely serves in both absorption of biotin (cleavage of protein-bound dietary biotin) and recycling of biotin (cleavage of biocytin). Biotinidase also catalyzes a specific biotinylation of histones, as noted above. (*See* **Protein**: Synthesis and Turnover.)

A significant proportion of biotin undergoes catabolism before excretion (Figure 2). Two principal pathways of biotin catabolism have been identified in mammals. In the first pathway, the valeric acid side chain of biotin is degraded by β-oxidation. β-Oxidation of biotin leads to the formation of bisnorbiotin, tetranorbiotin, and related intermediates that are known to result from β-oxidation of fatty acids. The cellular site of this β-oxidation of biotin is uncertain. Spontaneous (nonenzymatic) decarboxylation of the unstable β-keto acids (β-keto-biotin and β-keto-bisnorbiotin) leads to formation of bisnorbiotin methyl ketone and tetranorbiotin methyl ketone; these catabolites appear in urine.

In the second pathway, the sulfur in the thiophane ring of biotin is oxidized, leading to the formation of biotin *l*-sulfoxide, biotin *d*-sulfoxide, and biotin sulfone. Sulfur oxidation may be catalyzed by a NADPH-dependent process in the smooth endoplasmic reticulum. Combined oxidation of the ring sulfur and β-oxidation of the side chain lead to metabolites such as bisnorbiotin sulfone. In mammals, degradation of the biotin ring to release carbon dioxide and urea is quantitatively minor.

On a molar basis, biotin accounts for approximately half of the total avidin-binding substances in human serum and urine (Table 1). Bisnorbiotin, bisnorbiotin methyl ketone, biotin *d,l*-sulfoxide, and biotin sulfone account for most of the balance. Using thin-layer chromatography and staining with *p*-dimethylaminocinnamaldehyde, tetranorbiotin *l*-sulfoxide was also identified in human urine. However, avidin binding of this metabolite was too weak to allow quantitation.

The biliary route of biotin excretion is quantitatively minor. For example, in rats, approximately 2% of intravenously administered [^{14}C]biotin was excreted in bile but approximately 61% was excreted in urine.

The relationship of metabolite profile to biotin nutritional status has not been fully elucidated. In human and rat urine, the percent excretion of biotin increases when the biotin intake is increased from physiologic to pharmacologic amounts. This may reflect saturation of renal reabsorption, metabolic pathways, or both.

Deficiency

Clinical Symptoms of Frank Biotin Deficiency

The fact that humans have a requirement for biotin has been clearly documented in two situations: first, parenteral nutrition without biotin supplementation in patients with short-gut syndrome and other causes of malabsorption; and second, prolonged consumption of raw egg white. The critical event in the egg white-induced biotin deficiency is a highly specific and very tight binding ($k_b = 10^{15}\,\mathrm{mol\,l^{-1}}$) of biotin by avidin, a glycoprotein found in egg white. Avidin is resistant to intestinal proteolysis in both the free and the biotin-bound form. Thus dietary avidin binds and prevents the absorption of biotin. Cooking denatures avidin, rendering it susceptible to digestion and hence unable to interfere with absorption of biotin. (*See* **Eggs**: Dietary Importance.)

Biotin deficiency has also been reported or inferred in several other circumstances, including pregnancy, individuals undergoing dialysis, individuals suffering from chronic gastrointestinal disease, Leiner's disease, and sudden infant death syndrome.

The clinical findings of frank biotin deficiency in adults and older children are similar regardless of whether deficiency is caused by egg-white feeding or omission of biotin from parenteral nutrition. Typically, the findings begin to appear gradually after an interval of 6 months to 3 years of parenteral nutrition or after 6 weeks to several years of egg-white feeding. Thinning of hair, often with loss of hair color, was

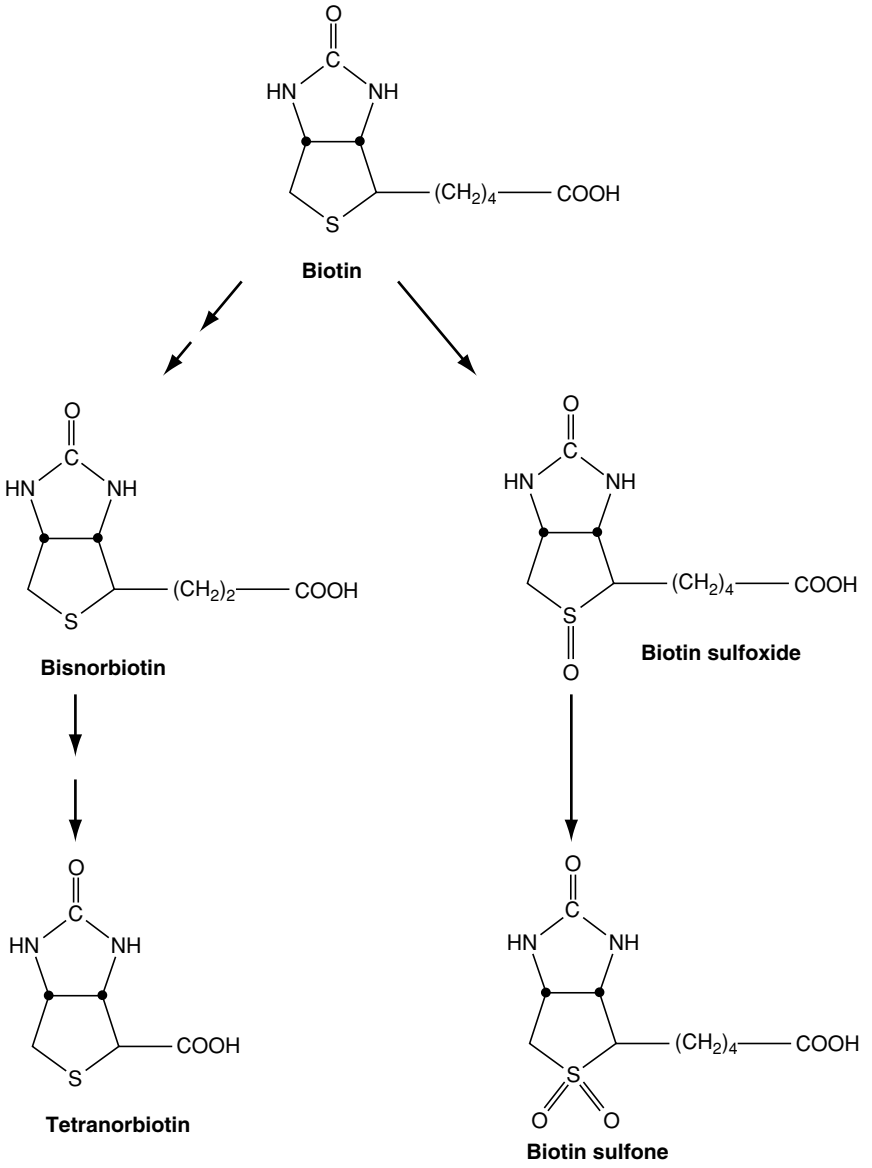

Figure 2 Pathways of biotin catabolism.

reported in most patients. A skin rash described as scaly (seborrhoeic) and red (eczematous) was present in the majority; in several, the rash was distributed around the eyes, nose, and mouth. Depression, lethargy, hallucinations, and paresthesias of the extremities were prominent neurological symptoms in the majority of adults.

In infants who developed biotin deficiency, the signs of deficiency began to appear within 3–6 months of initiation of total parenteral nutrition. The rash initially appeared around the eyes, nose, and mouth; ultimately, the ears and perineal orifices were involved. The appearance of the rash was similar to that of cutaneous candidiasis (i.e., an erythematous base and crusting exudates); typically, *Candida* could be cultured from the lesions. The character and distribution of the biotin deficiency rash are quite similar to the rash of zinc deficiency. In some infants, hair loss can progress to total baldness, including loss of eyebrows and lashes. The most striking neurological findings in biotin-deficient infants was hypotonia, lethargy, and developmental delay. In these infants, a peculiar withdrawn behavior was often noted and may have reflected the same central nervous system dysfunction diagnosed as depression in adult patients.

Biochemical Markers of Biotin Deficiency

Our studies provide evidence that marginal biotin deficiency is much more common than frank biotin

Table 1 Biotin and metabolites in human serum and urine

Compound	*Serum (pmol l^{-1})*	*Urine (nmol 24 h^{-1})*
Biotin	244 ± 61	35 ± 14
Bisnorbiotin	189 ± 135	68 ± 48
Biotin *d,l*-sulfoxide	15 ± 33	5 ± 6
Bisnorbiotin methyl ketone	ND[a]	9 ± 9
Biotin sulfone	ND[a]	5 ± 5
Total biotinyl compounds	464 ± 178[b]	122 ± 66

Means ± SD are reported ($n = 15$ for serum; $n = 6$ for urine).
[a]ND, not determined. Bisnorbiotin methyl ketone and biotin sulfone had not been identified at the time when this study of serum was conducted and hence these unknowns were not quantitated against authentic standards.
[b]Including three unidentified biotin metabolities.
From Zempleni J and Mock DM (1999) Biotin biochemistry and human requirements. *Journal of Nutrition and Biochemistry* 10: 128–138, with permission.

deficiency. Diagnosis of marginal biotin deficiency requires sensitive metabolic indicators. The best validated indicators of marginal biotin deficiency are urinary excretion of biotin and metabolites and urinary excretion of organic acids such as 3-hydroxyisovaleric acid (see above: Figure 1). These organic acids are synthesized and excreted in increased quantities in biotin-deficient individuals because the normal catabolism of their precursors by biotin-dependent carboxylases is reduced. Activities of biotin-dependent carboxylases in lymphocytes and fibroblasts and plasma concentrations of biotin and metabolites have been reported to be abnormally low in individuals who developed frank biotin deficiency after 1 month of biotin-free intravenous feeding.

Teratogenic Effects of Biotin Deficiency

Biotin deficiency is teratogenic in several animal species at degrees of deficiency that produce no obvious findings in the pregnant animal. Hens with marginal biotin deficiency produce eggs with higher embryonic mortality, reduced hatchability, chrondystrophy ('parrot beak' deformity), perosis (an abnormality of bone tendon formation that results in a deformity analogous to 'club foot'), micromelia, and syndactyly. Effects on hatchability and viability have been reported in turkey poults. In some strains of mice, asymptomatic biotin deficiency during pregnancy causes substantial increases in fetal malformations and mortality. Ninety-four percent of pups from biotin-deficient dams had cleft palate, 85% had micrognathia, and 41% had micromelia; multiple malformations were common.

Biotin status may be reduced during human pregnancy. In the majority of pregnant women, excretion of 3-hydroxyisovaleric acid is significantly greater than the upper limit of normal. The serum concentration of biotin commonly decreases significantly from early to late pregnancy and reaches values that are below the lower limit of normal in some individuals. Likewise, the urinary excretion rates of biotin and bisnorbiotin are often significantly less in late pregnancy than in early pregnancy.

Inborn Errors of Metabolism

Two important classes of inborn errors of biotin metabolism have been identified:

1. Biotinidase deficiency is an inborn error of metabolism that is characterized by partial (70–90%) or profound (>90%) reduction of biotinidase activity. The combined incidence of partial plus profound biotinidase deficiency is 1: 60 000 newborns. Clinical findings of biotinidase deficiency largely mimic biotin deficiency and include developmental delay, seizures, skin infection, hepatomegaly, and splenomegaly. These symptoms are thought to be a consequence of one or more impairments leading to reduced biotin status: (i) deficient salvage of covalently bound biotin during holocarboxylase turnover may result from incomplete release of biotin from biocytin; (ii) substantial amounts of biocytin are lost in urine; (iii) release of covalently bound dietary biotin may be impaired, leading to malabsorption. Biotinidase-deficient patients respond well to physiologic or pharmacologic doses of biotin.
2. Multiple carboxylase deficiency is an inborn error of metabolism in humans that is caused by deficiency of holocarboxylase synthetase, leading to less efficient biotinylation of apocarboxylases. Isolated carboxylase deficiencies are caused by mutations of genes encoding the mammalian apocarboxylases.

(*See* **Inborn Errors of Metabolism**: Overview.)

Intestinal Absorption

Studies in rats provided evidence that intestinal uptake of biotin occurs by two distinct mechanisms. The first is a saturable, structurally specific transporter located in the brush border membrane. This transporter is dependent on sodium and energy, and is electroneutral. As judged by the maximal transport rate (V_{max}) of the transport process, the transporter is appropriately up- and downregulated by biotin deficiency and biotin excess, respectively. In the rat, biotin transport is most active in the upper small bowel; activity of biotin transport declines proceeding from the jejunum to the ileum to the colon. However, activity in the colon is still 3% of jejunal values, leaving open the possibility that biotin synthesized by

enteric flora might contribute to absorbed biotin. In the rat, activity of the biotin transporter increases with age from suckling to weanling to young adult (aged 3 months). As with the other changes observed in the biotin transporter, the mechanism leading to increased transport appears to be an increase in the number or activity of the carriers, rather than changes in the affinity of the carrier.

The second mechanism of intestinal biotin absorption is passive diffusion. This process predominates at large luminal biotin concentrations; at that point, the biotin transporter is likely saturated.

The biotin transporter in human intestine is similar to that identified in rats. The human transporter is saturable, electroneutral, sodium-dependent, and capable of accumulating biotin against a concentration gradient. The anatomical distribution along the human gastrointestinal tract is similar to that observed in the rat. Changes in transport activity appear to be mediated primarily by an increase in the number or activity of transporters, rather than by changes in the affinity of the transporter. The exit of biotin from the enterocyte (i.e., transport across the basolateral membrane) is also carrier-mediated; however, biotin export is independent of sodium, is electrogenic, and cannot accumulate biotin against a concentration gradient.

Recently, a biotin transporter in human tissues has been cloned, sequenced, and expressed in mammalian cells. This multivitamin transporter binds and transports not only biotin but also pantothenic acid and lipoic acid. Binding affinities are similar for these nutrients.

Clinical studies have also provided evidence that biotin is absorbed from the human colon. When biotin is instilled directly into the lumen of the colon, the plasma concentration of biotin increases; however, when the same dose of biotin is given orally, the increase in plasma concentration is greater.

Bioavailability

Recent reports provide evidence that biotin is absorbed almost completely even if large doses of biotin are ingested. However in these studies, biotin was administered in aqueous solution rather than being endogenous to the diet. A large percentage of biotin in food may be bound to protein and therefore is likely to require cleavage from the protein in order to be transported into enterocytes by the biotin transporter. Biotinidase is thought to be responsible for release of biotin from protein. The release of biotin might occur in or near the intestine mucosa via the action of mucosal biotinidase; biotinidase in pancreatic juice might release biotin during the luminal phase of proteolysis. Theoretically, biotinyl oligopeptides might also be absorbed directly, either by a specific biotin transporter or by a peptide transporter. However, the mechanism remains to be elucidated. Biotinidase is present in pancreatic juice and in intestinal mucosa, but biotinidase activity is not enriched in intestinal brush border membranes. Currently, only limited data are available regarding the bioavailability of protein-bound biotin in food. (*See* **Bioavailability of Nutrients**.)

Transport of Biotin from the Intestine to Peripheral Tissues

Biotinidase has been proposed to serve as a biotin-binding protein in plasma and as a carrier protein for the transport of biotin into the cell. Two biotin-binding sites on biotinidase have been identified. One had an equilibrium dissociation constant (k_d) of $3\,\text{nmol}\,\text{l}^{-1}$ and a maximum binding capacity ($B_{\max}$) of 0.065 mol of biotin per mol of biotinidase; the other had a k_d of $59\,\text{nmol}\,\text{l}^{-1}$ and a $B_{\max}$ of 0.79 mol of biotin per mol of biotinidase. However, empirical studies with [^{3}H]biotin provide evidence that biotin binds primarily to albumin. Of the total biotin in human plasma, 81% is free, 12% is covalently bound, and 7% is reversibly bound.

Transport of Biotin in Liver and Peripheral Tissues

Biotin Uptake into Liver

Rat liver cells accumulate biotin by a transporter-mediated process that depends on metabolic energy; uptake is sodium-dependent and Na-K-ATPase-dependent. The ureido portion of the biotin molecule plays a role in binding to the transporter. Organic anions such as bilirubin and cholic acid compete with biotin uptake by hepatocytes.

Biotin uptake into HepG2 cells is also transporter-mediated, energy-dependent, sodium-dependent, and Na-K-ATPase-dependent; a free carboxyl group on the valeric acid side chain of biotin is essential for recognition by this transporter. Apparent Michaelis constant (K_m) and $V_{\max}$ in HepG2 cells are $19.2\,\mu\text{mol}\,\text{l}^{-1}$ and $6.8\,\text{nmol mg protein}^{-1}\,\text{min}^{-1}$, respectively.

Biotin Uptake into Lymphocytes

In analogy to liver cells, human lymphocytes accumulate biotin by a transporter that requires metabolic energy and is dependent on Na-K-ATPase. Apparent K_m and $V_{\max}$ values of this biotin transporter are

2.6 nmol l^{-1} and 2.9 fmol 10^6 cells^{-1} 30 min^{-1}, respectively. In lymphocytes, the thiophane portion of the biotin molecule is more important than the ureido portion for binding to the transporter. The biotin transporter in lymphocytes is very specific for biotin; inhibition of biotin transport by hexanoic acid, lipoic acid, bilirubin, and pantothenic acid is minor. The same transporter that mediates biotin uptake into lymphocytes also accounts for biotin efflux from these cells as judged by countertransport experiments.

Biotin Uptake into the Central Nervous System

Biotin enters the central nervous system by a saturable transport system. A free carboxylic acid group is important for transport across cerebral capillaries; pantothenic acid and nonanoic acid compete for uptake, suggesting that uptake is mediated by an organic anion carrier. In the brain, biotin is covalently bound to proteins, presumably biotin-dependent carboxylases.

Placental Transport of Biotin

A biotin transporter is present in the placental brush border membrane. In mammals, a single protein termed the multivitamin transporter can transport biotin, pantothenic acid, and lipoic acid across the placenta; this protein has been cloned and functionally expressed. A recent study of fetal and maternal plasma concentrations of biotin at 18–24 weeks' gestation of normal human pregnancies reported a fetal-to-maternal biotin ratio ranging from 3 to 17:1, consistent with active transport across the placenta.

Requirements and Adequate Intakes

Adequate Intakes

For biotin, scientific knowledge is currently insufficient to estimate average requirements and formulate recommended dietary allowances. Notwithstanding, the Food and Nutrition Board of the National Research Council has published recommendations for adequate intake of biotin (Table 2). These data are based on empirical biotin intakes in a group of healthy people.

Table 2 Adequate intake of biotin

Life-stage group	*Adequate intake (μg day^{-1})*
Infants	
0–6 months	5
7–12 months	6
Children	
1–3 years	8
4–8 years	12
Males and females	
9–13 years	20
14–18 years	25
≥19 years	30
Pregnancy	30
Lactation	35

From Yates AA, Schlicker SA and Suitor CW (1998) Dietary reference intakes: the new basis for recommendations for calcium and related nutrients, B vitamins, and choline. *Journal of the American Dietary Association* 98: 699–706, with permission.

Factors that Affect Biotin Requirements

Pregnancy (see above) and lactation appear to produce an increased demand for biotin. Biotin secretion into breast milk accounts for the higher recommendations for adequate intake of biotin in lactating compared to normal women (Table 2). At 8 days postpartum, biotin in human milk is approximately 8 nmol l^{-1} and accounts for 44% of biotin plus measured catabolites; bisnorbiotin and biotin *d,l*-sulfoxide account for 48% and 8%, respectively. By 6 weeks postpartum, the biotin concentration increases to approximately 30 nmol l^{-1} and accounts for about 70% of biotin plus catabolites; bisnorbiotin and biotin *d,l*-sulfoxides account for about 20% and less than 10%, respectively.

Accumulating data provide evidence that long-term anticonvulsant therapy in adults and children can lead to biotin depletion severe enough to interfere with amino acid metabolism. This conclusion was originally based on decreased plasma concentrations of biotin as determined by the *Lactobacillus plantarum* bioassay; the incidence of biotin concentrations below the normal range was approximately 75% in a cumulative study group of 274 adults undergoing long-term therapy with a variety of anticonvulsant drugs. The diagnosis of biotin deficiency was strengthened by the demonstration of increased urinary excretion of the characteristic organic acids (e.g., 3-hydroxyisovaleric acid) in adults and children receiving long-term anticonvulsant therapy. (*See* **Drug–Nutrient Interactions**.)

The mechanism of biotin depletion during anticonvulsant therapy is not known. The anticonvulsant drugs implicated include phenobarbital, phenytoin, carbamazepine, and primidone. These drugs each have a carbamide (-NH-CO-) moiety in their structure, as does biotin; in some cases they incorporate a full ureido group (-NH-CO-NH-). Physiological concentrations of primidone and carbamazepine specifically and directly inhibit biotin uptake by brush border membrane vesicles from human intestine. This finding suggests that impaired intestinal absorption of biotin may contribute to biotin deficiency. In addition, phenobarbital, phenytoin, and carbamazepine displace biotin from biotinidase and thus

conceivably could have an effect on plasma transport of biotin, renal handling of biotin, or cellular uptake of biotin. Recently, increased urinary excretion rates of biotin *d,l*-sulfoxides and bisnorbiotin have been demonstrated in adults and children receiving long-term anticonvulsant therapy, raising the possibility that accelerated catabolism of biotin contributes to the biotin deficiency associated with long-term anticonvulsant therapy.

Intake

Biotin is widely distributed in foodstuffs, but the content of even the richest sources is low when compared to the content of most other water-soluble vitamins. Foods relatively rich in biotin include egg yolk, liver, and some vegetables. The average dietary biotin intake has been estimated to be 70 μg per day for the Swiss population. These data are in reasonable agreement with the estimated dietary intake of biotin in a composite Canadian diet (62 μg per day). Calculated intake of biotin for the British population was 35 μg per day.

Infants who ingest 800 ml of mature breast milk per day ingest approximately 6 μg (24 nmol) of biotin. It remains unclear whether biotin synthesis by gut microorganisms contributes importantly to the total biotin absorbed. However, an infant developed biotin deficiency while consuming a biotin-free elemental formula.

BISCUITS, COOKIES, AND CRACKERS

Contents

Nature of the Products

S Zydenbos and V Humphrey-Taylor,
New Zealand Institute for Crop & Food Research Limited, Christchurch, New Zealand

Background

Biscuits, cookies, and crackers are enjoyed the world over by consumers who select their favorites based on flavor and appearance, but to bakers, distinguishing between these baked products can be a complex task. The basic characteristic that separates a biscuit, cookie, or cracker from other baked products, such as bread or cake, is a moisture content below 5%. Biscuits, cookies, and crackers have a cereal base of at least 60%. This is usually wheat but is sometimes oat, barley, rye, or rice. Other major ingredients are fat or shortening, and sugar. While water is also added to a biscuit, cookie, or cracker dough, this is not a major component of the final product since it evaporates during baking.

In this article, the history and usage of biscuits, cookies, and crackers are examined. This is followed by a discussion of the classification of biscuits, cookies, and crackers, the definitions of which overlap and are geographically dependent. Finally, some features of the different types of biscuits, cookies, and crackers are considered.

History and Usage

The origin of the name biscuit comes from Latin, where *bis coctus* means twice-baked. There is also an Old French word, *bescoit*, that has a similar meaning. It is thought that these products have been baked for thousands of years. The original process consisted of baking the biscuits in a hot oven and subsequently drying them in a cool oven. It is very rare to find this double baking technique in modern biscuit production. However, a special type of microwave oven is often connected after a gas-fired oven in factories. Cookie is derived from a Dutch word, *koekje*, which means little cake, while the sound of a cracker being eaten probably led to use of that name.

Biscuit, as defined above, is a term used in the UK (and in New Zealand, Australia, and South Africa). The word biscuit is also used for a baked product in the USA. This is a leavened bread-like product that is similar to the UK scone and is not discussed in this article. In the USA, the word cookie describes the same type of products that are called biscuits in the UK. Cracker is a generic term used throughout the world and refers to products with very low sugar and fat contents.

The low moisture content of biscuits, cookies, and crackers means that these products have a long shelf-life and a relatively low risk of spoilage by micro-organisms. This has led to a history of usage in epic journeys, such as the flight of the Israelites from Egyptian slavery and the sea voyages of the fifteenth-century explorers. British and European traditions usually served biscuits in a semiformal situation with tea or coffee between main meals, especially in the afternoon. Small biscuits were usually made so that a range of appearances and flavors could be eaten without a large intake of food. Modern biscuits, cookies, and crackers are often used as a casual snack food, especially in the USA. Many of these are much larger than traditional biscuits, as they are sometimes eaten to replace meals by consumers who have busy lifestyles.

Classification

Biscuit classification varies according to geographic location. Different and quite specific systems are used in the UK and USA, while in other parts of the world, the distinction between biscuits or cookies and cakes is not as clear; these products are often classified as small confectionery products. For example, biscuits in France are often classified under the title *petits fours sec*. These words literally translate as small oven dry, giving the implication that these are small, dry baked goods. However, petits fours secs may also encompass other products that are outside the biscuit

definition given above, such as cake-, meringue-, and pastry-based products. Biscuits that are too large to be put in the mouth at one time, would be called *les petits gâteaux secs*, meaning small dry cakes. A similar distinction exists in Germany where biscuits are called *kekse* or *konfekt*, but only if they are small.

In the UK, biscuits are classified on their formulation, the two major categories being hard and short doughs. Hard doughs are similar to bread doughs but have a much stiffer consistency. With hard doughs, the three-dimensional gluten network is well developed during the mixing process, so the dough is both elastic and extensible. The formula for hard doughs is very lean, as the content of fat and sugar relative to flour is very low. Crackers are made from hard doughs, as are semisweet, unsweetened, and savory biscuits. Short doughs are more closely related to cake doughs than bread doughs, although they have less water than a standard cake formula. Short doughs are named for the higher content of shortening or fat than hard doughs. They also have a higher sugar content. The increased levels of fat reduce dough extensibility, causing this type of biscuit or cookie to break easily. The flour in short doughs is given very little mixing, so the development of a gluten network is minimized. The consistency of short doughs has been compared with wet sand; they hold together under pressure but crumble easily. Short doughs have a subgroup called soft doughs that have higher levels of fat and sugar, resulting in a dough with an even softer consistency.

Biscuit classification in the USA is based on the method of processing and, in particular, the way the biscuits are shaped. The four main categories are sheeting or cutting (sometimes called cutting machine doughs), rotary molding, wire cutting, and depositing. Sheeting is used for doughs that would be classified as hard doughs in the UK and is always used for making crackers. The dough is passed through a series of rollers until it reaches the required thickness. The biscuit or cracker shapes are then cut out of the dough sheets using a plastic or metal die. It is important that the dough is strong and elastic so that the biscuits and cracker shapes do not deform when excess scrap dough is removed from around the shapes. Rotary molding is used for short doughs, and requires a dough with a relatively stiff consistency that is not too sticky. The dough is compressed into dies mounted on the surface of a roller, and any excess dough is scraped off. The molded dough piece retains its shape as it is pushed out of the die on to the baking sheet or band. Short doughs may also be shaped by wire cutting, which involves extruding the dough through a die and slicing it with a tight wire at appropriate intervals. The tension placed on the dough during extrusion and the thickness of the wire will vary for different types of doughs. Because soft doughs are similar to a batter, having a semifluid consistency and lacking cohesiveness, they are shaped by depositing. The dough is extruded through a nozzle and dropped on to the baking sheet or band. To achieve uniformity in size and shape of the biscuits or cookies, the flow of dough is cut off at regular intervals.

Features of Biscuits

To further explore the nature of biscuits, cookies, and crackers, this section examines the main types of these products in more detail. Products are categorized by the hard and short dough classification with a discussion of the distinct features necessary for the different forming processes. The wide range of shapes, sizes, textures, flavors, and colors of biscuits is illustrated in Figure 1.

Crackers made from Hard Doughs

Crackers are characterized by very low fat and sugar levels. They are often used as a base for a savory topping, such as cheese or tomato, but the modern snack cracker, with its tasty coatings and flavors, may be eaten without additions. Crackers may be further subdivided into those that are fermented, including soda crackers, saltines, and cream crackers, and those that are chemically leavened like the popular snack cracker.

Soda crackers have been popular in the USA for over 150 years. They are typically 4 mm thick and 50×50 mm square. The shortening content is 8–10%. Saltines are a smaller, more dainty type of soda cracker with an increased amount of shortening. Traditional soda cracker manufacture involves a long fermentation using a sponge starter. Soda crackers have a significant amount of sodium bicarbonate added to the dough (1%), which increases the alkalinity and is the reason for the name of the cracker. Once the dough is mature, it is sheeted to about 4 mm and then laminated six to eight times. The cracker is cut by making lines of perforations and baked as a whole sheet, a process that minimizes the amount of waste dough. A feature of soda crackers is the nine hole docking pattern on each cracker, set out in a 3×3 grid pattern. After baking, the sheet of crackers is split along the perforation lines, usually to make a block of four crackers for packaging. The final product is quite flaky but crisp. The spring between the docking holes on the top of the cracker should be even, and the bottom surface should be almost flat with numerous small blisters. Because soda crackers are quite dry and bland, they are not usually eaten

Figure 1 (see color plate 9) Biscuits come in a wide range of shapes, sizes, textures, flavors, and colors.

alone and are often used as an accompaniment to soup.

In the UK, soda crackers are rare, and cream crackers fill a similar market niche. Despite their name, cream crackers contain no cream! They have a slightly higher fat content (12–18%) than soda crackers. Cream crackers are generally a 65×75 mm rectangular shape and are slightly thicker than soda crackers with around 6.5 mm between biscuits stacked in a column. Unlike soda crackers, they are usually produced as individual units. While, traditionally, the long sponge and dough fermentation process was used for manufacturing cream crackers, modern techniques involve a single-stage mixing and fermentation process, which takes from 4 to 16 h. As with soda crackers, cream crackers are sheeted and laminated. A feature of cream crackers is the laminating 'dust', consisting of flour, shortening, and salt, that is applied between the layers of dough. This causes the laminations to lift apart during baking, giving an extra flaky structure. The movement of the laminations and subsequent surface blistering are quite irregular, giving the cream cracker its characteristic uneven surface. Blisters are present on both the top and bottom surfaces. Cream crackers have a final moisture content of 3–4%, which is quite high for a cracker, and along with the increased fat content, the cracker is relatively soft, will not crumble and should 'melt in the mouth'. Without chemical leavening, cream crackers are bland but have a slightly nutty flavor. They are mostly eaten with a savory topping and are often buttered.

Snack or savory crackers have a more recent history than soda and cream crackers. They have two distinguishing characteristics. The first is that the cracker is sprayed with hot oil as it leaves the oven, and the second is that a topping is applied to the crackers to add flavor. Snack crackers usually contain some sugar (4–10%), which also adds flavor and texture. They are usually chemically leavened, but some snack crackers are made from fermented doughs. Because snack crackers do not have the long fermentation to mature the dough, proteolytic enzymes or sulfites are used to relax the doughs so that the crackers do not deform during sheeting and cutting. Snack crackers come in a wide range of shapes and sizes, but are often round and have docking holes to allow an even lift during baking. Only snack crackers produced by fermentation are laminated. Toppings are generally applied before baking, and include herb, cheese, salt, chicken, and smoke flavors. Sometimes, the crackers are decorated with small seeds, such as poppy, sesame, or celery. Snack crackers have a dense texture and are quite soft. The hot oil spray improves the mouth feel and gives an attractive appearance to the finished product.

Sweet and Semisweet Biscuits made from Hard Doughs

Sweet and semisweet biscuits made from hard dough are generally more popular in the UK than the USA. While the gluten network is relatively well developed by mixing, the higher amounts of sugar (around 20% of flour) and fat (16–20%) than in cracker doughs

make the gluten less elastic and more extensible. Chemicals, such as sodium metabisulfite or other chemical derivatives of sulfur dioxide, can also be used to condition and relax the dough to facilitate processing. Unlike cracker doughs, most hard sweet and semisweet biscuit doughs are chemically leavened. After mixing, the dough is sheeted and formed into shapes. The individual biscuits are cut out of the dough sheet, leaving a web of scrap dough to be removed and incorporated back into the main batch of dough. These biscuits are generally docked and marked with a name or pattern before baking. Sometimes, a milk or egg/milk wash is applied to enhance their appearance after baking, and occasionally, a garnish of sugar or other granular material is applied.

Baked biscuits should have a smooth, even surface with a pale color. The texture of the biscuit is open and even, giving a delicate bite, although this is somewhat dependent on the formula – lower levels of sugar result in a harder bite. The ingredients in sweet and semisweet biscuits are quite plain, so the flavor is usually a mild vanilla, caramel, or buttery flavor. The biscuits are generally served without accompanying food and are eaten with tea or coffee. There are some interesting variations of sweet and semisweet biscuits, such as those that are processed after baking to incorporate a cream sandwich or chocolate coating. The garibaldi fruit sandwich biscuits have a layer of currant or small sultana filling between two layers of hard dough.

Biscuits or Cookies made from Short Doughs

The vast majority of biscuits and cookies consumed world-wide are made from short doughs, and consequently the range of shapes, sizes, flavors, and ingredients is huge. Formulae are correspondingly variable, but there are some consistent requirements. Flour is usually weak, with less than 9.5% protein. While there are no rules for the proportions of fat and sugar, which can range up to 100 and 200% of flour weight, respectively, the quality of these ingredients is important since they make up such a large proportion of the dough. Short doughs are usually mixed in a two-stage process with an initial creaming of the fat and sugar, although modern techniques tend to use the 'all-in' mixing method. The doughs are cohesive and plastic but lack extensibility and elasticity. The consistency of the dough will vary according to the requirements of the machinery used to form and shape the biscuits.

As described above, the two main processes for forming short dough biscuits and cookies are rotary molding and wire-cutting. Rotary molding originated from the simple wooden molds often used in monastery kitchens to produce biscuits and cookies containing inscriptions. With a rotary mold, dough is continually fed from a hopper and forced into a metal die on a rotating roller. The formed dough shape is pressed out of the mold on to the baking band as the roller rotates. Unlike hard doughs, which tend to shrink during baking, short and soft doughs generally spread because of the high sugar and fat content. This is a particular disadvantage of rotary molding as the inscription can become blurred. Tight control of the formula is necessary to reduce spread. Rotary cookies should be thin and smooth with no surface cracks or irregularities. Because of their regular size and shape, rotary cookies may be used to make cream sandwiches in the same way as hard sweet biscuits.

Wire-cutting is a form of extrusion; the dough passes through a die and is sliced at intervals by a tight wire so that the formed dough shape drops on to the baking band. Doughs intended for wire-cutting are usually softer than rotary molding doughs, and more chunky ingredients, such as chocolate chips, nuts, or raisins, may be incorporated. A variation on the wire-cutting process is a rout press that extrudes dough continuously. The dies on a rout press are designed to produce strips, which are cut into short lengths before baking. Both of these techniques can be adapted to coextrude by having two different doughs or a dough and a filling coming from separate hoppers into a single die that forms a dual layer cookie (e.g., chocolate/vanilla) or a dough tube often filled with a fruit paste of similar consistency.

Biscuits or Cookies made from Soft Doughs

Soft doughs have a pourable consistency, are typically rich in fat (65–76% of flour weight), and may be based on whipped egg whites (15–25%). Sugar is around 35–40% of the flour weight. Weak flour is used, and mixing is in a two-stage process. The flour and other dry ingredients are added last, and only minimal mixing takes place to prevent the dough from becoming tough. Often, rich, expensive ingredients, such as ground almonds, coconut flour, or cocoa, are used in soft doughs. However, coarse particles are avoided, because they may block the nozzles during depositing. Dough temperatures are important to achieve the correct consistency for forming the specific type of biscuit or cookie required. Temperatures generally range between 10 and 17 °C. The dough flows from the hopper through a nozzle on to the baking band. The nozzles may be of different shapes and sizes to alter the appearance of the cookie, but because the dough flows a little after depositing, these designs may be rather irregular. Some depositor heads can be rotated to make swirls and circular shapes, while two or more depositors may be

synchronized to combine doughs of different flavors or colors within the same biscuit or cookie. Soft dough biscuits and cookies have a soft, delicate texture and a 'melt-in-the-mouth' feel. However, these properties make them fragile and subject to breakage, and packaging can also be difficult because of the irregular shapes.

Finishing and Decorating Biscuits

While the basic biscuit, cookie, or cracker is distinguished by the processes described so far, the nature of the final product can be significantly altered by secondary processing after baking. A wide range of processes are used to finish and decorate biscuits, cookies, or crackers, some of which have already been referred to. Two of the most popular are cream sandwiches and chocolate coating or enrobing. In a cream sandwich, the cream usually makes up about 30% of the final biscuit weight and consists of sugar, fat, and flavorings, such as fruit acids, cocoa powder, and skimmed milk powder. The cream is either poured into a stencil positioned over the top of the biscuit base or deposited directly on to the base. Working with chocolate is technically difficult because of the necessity to control the temperature accurately. The properties of chocolate are quite variable and depend on the ingredients that were used to make the chocolate. Various methods of fully enrobing or partially dipping the biscuit or cookie into a chocolate bath are used, depending on product specifications. Icings, made from icing sugar, water, and sometimes fat or a gelling agent such as gelatine, are another popular finishing on biscuits. Jellies, jams, marshmallow, caramel, fruit, seeds, and nuts may also be used to enhance the taste and texture of biscuits, cookies or crackers.

Methods of Manufacture

L Doescher Miller, Formerly of The Pillsbury Company, Minneapolis, MN, USA

Background

The manufacturing process used to produce all biscuits, cookies, and crackers consists of a mixing step, a shaping or forming step, and a baking step. The mixing and baking steps are common to the manufacture of all types of these products. What is distinct for the products are the shaping or forming steps. In this article, the processes used to produce these products will be described.

Mixing

Mixing is commonly defined as a process designed to blend separate materials into a uniform, homogeneous mixture. In the context of cookie and cracker doughs, the term takes on a broader meaning in that it also applies to the development of gluten from hydrated flour proteins, the aeration of a mass to give a lower density, and the dispersion of solids in liquids. One or more of the functions is required for the formation of cookie and cracker doughs. These processes are accomplished with three principal types of mixers: vertical spindle mixers, horizontal drum mixers, and continuous mixers. (*See* **Bread**: Dough Mixing and Testing Operations.)

Vertical Spindle Mixers

Vertical mixers were used extensively before the development of the high-speed mixer. Although usage has decreased overall, this type of mixer is still used for crackers and semisweet doughs, for which the vertical spindle design is particularly well suited. The feature that all vertical mixers have in common is the portable dough trough, which serves as the mixing vessel. The trough is usually a wheel-mounted, heavy tub with vertical sides, round ends, and a flat bottom. The trough is designed so that it may be

wheeled into position below the mixer head and locked into place. Mounted on an overhead frame are the drive mechanism and spindles with horizontal paddles or arms. Most mixers of this type are equipped with two or three spindles. The spindles are lowered into the trough and move in either a planetary or a stationary, circular motion when activated. The shape of the arms forces the dough upwards and downwards in the trough, generating a mixing action. The mixer blades are designed to provide a cutting action rather than kneading or stretching the dough.

The advantage of vertical spindle mixers is that they can be used for almost any product. They are very well suited for products such as soda cracker doughs. These doughs require a two-stage mixing sequence separated by a fermentation period. The sponges and doughs do not have to be transferred in and out of the trough at each mixing stage. Instead, they remain in the same trough for the entire mixing/fermentation sequence. Because there is almost no heat generated during the mixing process, this mixer is ideal for doughs that must remain cool. The mixing action is very gentle. Doughs containing ingredients or particulates that are easily damaged may be safely mixed with this mixer type.

The primary disadvantage of vertical mixers is their slow operating speed. The spindles rotate over a limited range at two or three speeds, up to a maximum of approximately 20 rpm. For doughs requiring the development of a gluten network, the mixing time required may be as long as 90 min. Because this is slow relative to the speed of the remainder of the processing line, several mixers may be needed to maintain an uninterrupted dough supply. Other disadvantages include lack of uniformity of the mix, and the labor-intensive nature of the system's design. The latter disadvantage relates to the fact that the dough troughs are very heavy, requiring special equipment to move, lift, and tilt the tubs at each stage of the process.

Horizontal Mixers

The feature that all mixers of this type have in common is a horizontal bowl mounted on a rigid frame that encloses the drive motor. The bowl may be stationary with a vertical front wall that slides down so that the dough may be ejected. More commonly, the mixer bowl is designed to tilt, and the dough is ejected from the tilted position. In both designs, the top cover is fixed so that mixing takes place in an enclosed space.

The blades of horizontal mixers are mounted on a horizontal shaft and may have any of several different shapes, depending on whether a cutting, scraping, or kneading action is needed. Mixing times for cookie and cracker doughs range from 5 min for soft cookie doughs to 30 min for the hard doughs, which require gluten development. Most mixers of this type are fitted with a jacket surrounding the mixing chamber. This allows a coolant to be circulated, so that dough temperatures can be controlled. Without such control, horizontal mixers can increase the dough temperatures to the point where dough handling and finished product properties are adversely affected.

The advantages of horizontal mixers are their high speed, ability to supply dough to a processing line continuously, uniformity of the mixes they produce, and their potential for complete automation. Horizontal mixers may be operated at speeds of 15–80 rpm. Commonly, their power train is equipped for two-speed rotation. Unlike most vertical spindle mixers, ingredients may be added with the blades in motion, and the discharge of the dough from the mixer is simple. Accurate control of dough temperature is possible, because there is a continuously circulating refrigerant.

Horizontal mixers require that all ingredient charging spouts be located overhead or that ingredients be added manually. Charging the mixer with ingredients is typically a significant portion of the total mixing cycle time. During mixing, the blades may throw material to the top of the chamber, so that it is never fully incorporated. With the shaft and mixing blades located in the center of the bowl, dough discharge is not always rapid and may occur in several large fragments. Only one operation (charging, mixing or discharging) may be performed at any one time, so that fast cycling of the dough batches may not be possible.

Horizontal mixers usually have capacities of up to 550 kg. The weight and the vibrations generated by their relatively high operating speeds place special design demands on the production facility. In addition to a reinforced floor, special mounts are necessary to secure the mixer in place.

Continuous Mixers

Continuous mixers are best described as a rotor or screw operating within a barrel jacketed for temperature control. The ingredients are fed continuously, either from one end of the barrel or in successive ports at intervals along its length. The mixing action may be altered from gentle blending and dispersing to vigorous or high-intensity kneading by varying the arrangement of different mixing arms along the length of the barrel. The amount of work put into the dough during its transit may be controlled additionally by restricting the dimension of the outlet orifice, creating a back pressure inside the barrel.

Continuous mixers are favored in some plants because they are capable of providing a constant supply of dough to production line, all of uniform age. Continuous mixers are small in size relative to horizontal mixers and are suitable for complete automation. In spite of this advantage, continuous mixers are not common in cookie or cracker plants, where a single line may be required to produce a variety of products. They are usually used only on high-output lines having a single purpose or similar product types.

The primary disadvantages of this mixer type are its high cost and the additional cost of the associated automated, continuous ingredient feeding systems. Beyond this, continuous mix systems are not particularly flexible; different products usually require completely different types of machines. In addition, the initial process set-up can be difficult, requiring considerable experimentation to determine optimum mixing conditions and sequences. Finally, starting and stopping the process are difficult in the event of any problem along the rest of the production line.

The Forming Process

While the same mixing and baking process may be used for many types of cookies and crackers, the forming step is specific to each product type. There are three processes used to form cookie and cracker doughs: (1) cutting or stamping from a continuous sheet of dough, (2) rotary molding by shaping dough in die cavities cut into the surface of a metal cylinder, and (3) extruding dough through a shaped die.

For each of these methods, the rheology of the dough is different and is designed to be compatible with the process. In general, doughs that are to be sheeted possess a significant gluten network as a result of mixing, and are both elastic and extensible. Those destined for rotary molding lack gluten development and are best described as cohesive. Doughs intended for extrusion are soft, frequently high in shortening, and spread while baking.

Sheeting and Cutting

The most common and versatile method to form cookie and cracker doughs is sheeting and cutting. This method involves the production of a thick sheet of dough, evenly reducing the thickness of the sheet, cutting out the desired shapes, and returning the scrap dough to be reincorporated either in the mixer or early in the sheeting process. This method is used for the production of crackers, semisweet biscuits, and selected soft doughs.

After mixing, the dough is fed into a hopper, below which lie the sheeting rollers. There are typically three rollers below the hopper arranged in a triangular fashion (Figure 1). At least one of the top two rollers, known as forcing rollers (labeled A in the figure), is grooved so that a positive feed is provided to the gauge or gauging roller. The gauging roller (B), which is always smooth, serves to deliver the dough to the conveyor belt (C). The purpose of the sheeting unit is to compact the mass from dough hopper uniformly and provide a sheet of even thickness having the width of the processing line.

The relatively thick dough slab from the sheeter then passes through a series of reduction or gauge rollers (D). These are smooth steel rollers used to reduce the dough sheet to the thickness that is desired before cutting of the finished dough piece. The gauge rollers occur in pairs mounted vertically. For products having sticky or adherent doughs, it may be necessary to mount a scraper blade against one or both of the rollers to release the sheet of dough. On most process lines, there are two or three pairs of rollers. This ensures that the thickness is reduced no more than 50% at any one rolling operation.

Some doughs, such as those of saltines and cream crackers, are laminated before cutting. The lamination occurs by lapping the dough back upon itself in the process direction. At the lapper, the take-away conveyor lies at a 90° angle relative to the line delivering the dough. The number of layers is controlled by

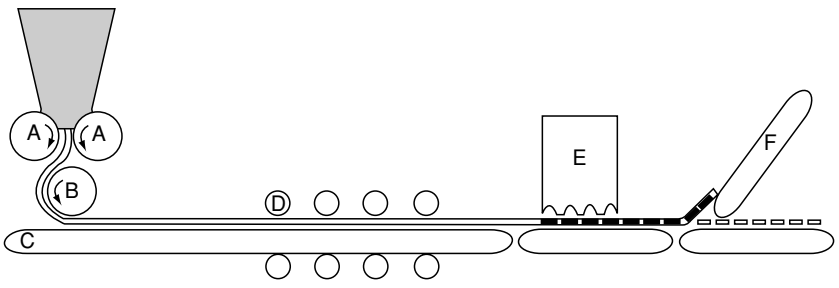

Figure 1 Sheeting and cutting process. See text for explanation. Reproduced from Biscuits, Cookies and Crackers: Methods of Manufacture, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

the relative rate of the lapper and take-away conveyor. The lapped dough then passes through several more sets of gauging rollers to bring the dough sheet to the desired thickness prior to cutting.

The repeated working of the dough in one direction results in the accumulation of stress. If the dough were cut at this point, the resulting pieces would shrink to relieve the stress, and misshapen or distorted products would result. Therefore, it is normal to relax the dough after reduction and before cutting. The relaxation is accomplished by transferring the dough to a conveyor, still moving in the same direction, but at a slower speed.

Once the dough has been relaxed, it passes on to the cutting operation. Two different types of cutting methods exist: reciprocating cutters and rotary cutters. The reciprocating cutters are heavy block cutters that stamp out one or more pieces at a time. The cutter head (E) may have a dual action, whereby the cutter drops first, followed by a docking head or an embossing plate. The equipment operates via a swinging mechanism so that the dough sheet moves at a constant speed, the cutter drops and moves with the dough, and then rises and swings back to the original position. The second type of cutter, the rotary cutter, consists of a rotating metal cylinder. On the face of the roll are formed the desired shapes with a sharp metal edge. As the cutter rotates with the dough conveyor, the metal edges cut into the dough sheet to form the product. The product pieces are then conveyed into the oven.

As a result of either cutting process, 20–60% of the dough sheet remains as scrap. The scrap dough (F) is lifted way from the cut dough pieces and returned either to the mixer or to the sheeter. Return to the mixer permits uniform incorporation of the scrap into the dough mass. However, most systems route the scrap back into the sheeter either along the full length of the hopper or at the back side of the hopper. If dough is incorporated behind the new dough, imperfections will be on the bottom side of the dough sheet and will not be visible on the finished product.

Rotary Molding

The principle of rotary molding is illustrated in Figure 2. Three rollers are placed in a triangular arrangement below a dough hopper. A roller, called the forcing or feed roller (A), has deep grooves designed to pull dough down from the hopper. The dough is forced into the cavities of the engraved roller (B) by the forcing roller. A scraper blade (C) is mounted against the engraved roller to remove any excess dough and return it to the hopper via the forcing roller. Beneath the engraved roller is a rubber-covered extraction roller (D) that serves to drive the take-away belt (E). The extraction roller applies pressure to the engraved roller via the belt, causing the dough to adhere preferentially to the conveyor belt. Dough pieces are dropped from the take-away belt into pans or directly on to the baking belt (F).

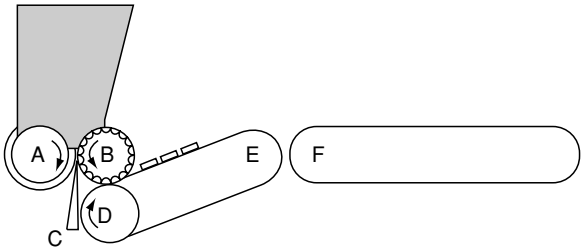

Figure 2 Rotary molding process. See text for explanation. Reproduced from Biscuits, Cookies and Crackers: Methods of Manufacture, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

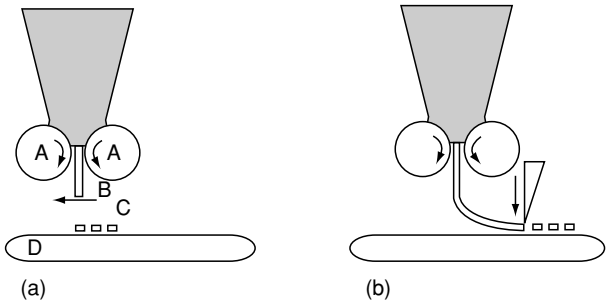

Figure 3 Extrusion process: (a) wire-cut machine; (b) bar/rout-press. See text for explanation. Reproduced from Biscuits, Cookies and Crackers: Methods of Manufacture, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The rotary molding process is suitable only for dry, crumbly doughs. This process offers advantages over sheeting and cutting in that there is no scrap to recycle, and there are very low labor requirements to run the process.

Extrusion

There are two types of devices used in the production of extruded cookies: wire-cut machines and bar/rout-presses. Both systems are very similar in design (Figure 3). A hopper is placed over a system of two or three rollers (A) that force dough into a pressure chamber (B). The rollers may run continuously or intermittently to force dough out of the pressure chamber at the die. For wire-cut cookies, the dough is extruded through a row of dies, and a wire or blade (C) mounted on a frame moves through the dough just below the die nozzle outlet. The cut dough pieces

then drop into a conveyor band (D) for transport to the oven. The wire usually moves only in one direction through the dough, opposite that of the conveyor. The wire-cut machines operate at rates of up to 100 strokes per minute. Difficulties encountered with this type of production are distortion of the extruded dough piece during cutting, and inconsistent placement or drop of the cut piece on to the conveyor. (*See* **Extrusion Cooking**: Principles and Practice.)

The design of the bar- or rout-press is very similar to that of the wire-cut machine. The hopper rollers and pressure chamber are essentially identical to their wire-cut counterparts. Unlike the wire-cut machine, the base of the pressure chamber has a die plate that is inclined in the direction of the extrusion. A continuous ribbon of dough is extruded from a nozzle, which is shaped to impart the desired finished product design. The dough ribbon can be cut into individual pieces by a vertically operating guillotine before the oven or after baking. If the product can be baked as a continuous ribbon the dough is extruded directly on to the oven band; otherwise, it is extruded and cut on to a conveyor belt.

Baking

The cookie and cracker industry relies almost exclusively on band or traveling ovens to bake its products. The band oven is essentially an insulated, heated tunnel equipped with a continuous conveyor. The ovens vary both in length (from 30 to 150 m) and in band width (from 1.0 to 1.5 m). More modern ovens frequently consist of a series of modular units or zones. Each of the zones is equipped with its own set of controls so that the temperature and air flow may be controlled within that zone. The oven band is typically continuous, passing on to a drive drum at the end of the oven and returning underneath the baking chamber to a tension drum at the feed or input end of the oven. The chamber through which the oven belt returns may or may not be enclosed. Frequently, the oven band serves as the baking surface for the product. Depending on the product type, the oven band may be solid or any of a variety of open wire-mesh types. The choice of mesh is a critical factor in the process, as it affects the heat transfer at the bottom of the product. This, in turn, can have a marked effect on the quality of the finished product.

There are three basic types of ovens: direct fired, indirect fired, and fully indirect fired. Ovens are usually heated by the combustion of gas, although there are a few manufacturers who use oil or electricity for economic reasons. The most common type is the direct-fired oven, in which gas is burned inside the baking chamber itself. In these ovens, the burners are placed across the width of the oven at regular intervals, both above and below the oven band. In other oven types, termed 'indirect ovens,' the gas or oil is burned outside the baking chamber, and the heated combustion gases are circulated into and throughout the baking chamber. Indirect-fired ovens typically have a single burner for each section. The hot gases from the burner pass along pipes parallel to the length of the oven, both above and below the oven band. The products of combustion are circulated throughout the baking chamber by large fans. Fully indirect ovens are those in which the heat source is independent from the baking chamber and heat transfer occurs via a heat exchanger. None of the products of combustion circulate inside the baking chamber. This type of oven is not common, except when oil is used as a combustible material. If circulated, the products of this type of combustion would impart an unacceptable flavor to the products.

Cooling

Products hot from the oven must be cooled prior to packaging for several reasons: the products may not be firm enough to withstand the packaging process while warm, the packaging material may shrink around a warm product, or the quality of the products would deteriorate if palletized while warm because the cooling rate across the pallet would be quite slow.

The normal method of cooling products is to place them on an open conveyor and transfer them along a distance 1.5–2 times the length of the oven. The products cool naturally in the ambient factory atmosphere. In a few cases, it is necessary to provide forced air to aid the cooling process.

Chemistry of Biscuit Making

J L Hazelton, J L DesRochers and C E Walker,
Kansas State University, Manhattan, KS, USA

Introduction

What is a biscuit? Depending on the part of the world in which you live, the answer will vary. In the USA it would be described as a chemically leavened bread-type item similar to a scone in the UK. However, in the UK a biscuit is equivalent to a cookie or cracker in the USA. The term 'biscuit' will be used here to include biscuits, cookies, and crackers.

Most biscuits differ from other baked cereal products by having a very low moisture content. Finished breads and cakes typically have moisture contents of 35–40% and 15–30% respectively, whereas biscuits usually contain only 1–5% moisture. Wheat flour, sugar, and fat are the basic ingredients, but thereafter the variety is almost endless. Biscuits can be grouped in many ways, based on their texture and hardness, their change in outline during shaping and baking, the extensibility or other characteristics of the dough, or the ways that the doughs are handled prior to biscuit formation. The groups often overlap, so it is important to see how several types of biscuits are related, based on their proportions of fat, sugar, and water, and then to compare their typical characteristics and processing means.

These differences in formulation, processing, and finished product attributes are all a function of the dough consistency or dough rheology. Certain key ingredients, such as flour, fat, and sugar largely determine the dough rheology and thus what type of forming equipment can be used to produce the biscuit. Based on these fundamental distinctions, five basic categories can be devised: (1) wire-cut; (2) rotary-molded; (3) bar-shaped; (4) deposited; and (5) cut or stamped. Regardless of the category, there are certain rheological requirements for all biscuits, namely the dough must be adequately cohesive for molding/forming, without excessive stickiness, and the dough must have a short, cuttable texture.

Likely the single greatest influence on (biscuit) dough rheology is the degree of gluten development within a dough. Biscuit doughs generally fall into two broad categories – hard and soft doughs. The viscoelastic properties of hard doughs represent the presence of a protein (gluten) matrix which is developed during mixing and sheeting. Hard doughs are stiff, tight doughs that require extensive mixing (work) with a resulting increase in dough temperature. They are similar to bread doughs, except that the sugar and fat contents modify their viscoelastic properties. Hard doughs are usually laminated and sheeted before cutting or stamping. The formed pieces will generally shrink because of the elastic quality of the gluten. During baking, the biscuits may continue to shrink in outline, but become thicker. This type of dough formulation may also be suited for rotary-molded biscuits, due to its firm consistency. (*See* **Bread**: Chemistry of Baking.)

Soft doughs do not have a formed gluten structure, because of their high levels of shortening and sugar, and are generally mealy or sandy in texture. They are usually formed by compressing into dies (rotary-molded) or by extruding and cutting, but some types can be sheeted, then cut. Dough pieces formed from soft doughs tend to retain their shape until baking, but then they spread or flow, becoming thinner.

Deposit biscuits are the machine-made counterpart of the hand-bagged or 'drop' version. Such formulae have been successfully adapted to automated production. Deposit biscuits contain about 25–40% sugar, 65–75% shortening, and 15–25% eggs and possess a spread factor of 79–80 (percentages based on 100 parts flour). Formulations should be such that excessive spread does not occur and the top design of the biscuit is preserved during baking. Adequate adhesive characteristics of the dough are also needed, so that it will adhere to the band and separate from the main tube of dough when deposited (**Figure 1**). This type of formula may also apply to wire-cut biscuits, where the dough is forced through a die and cut into disks by a reciprocating wire.

Although there are many similarities between biscuit and cracker formulations, a few key differences should be pointed out. One is the obvious difference in sugar content. Unlike biscuits, crackers are usually made from laminated dough, where thin sheets of dough are alternately layered with fat. Whereas biscuits are chemically leavened, some crackers, i.e. saltines, are yeast-fermented over long time periods to develop the characteristic flavors. The flour used in crackers is commonly stronger than biscuit flour and often dough relaxers, e.g., proteases, are required to increase the extensibility of the cracker dough. Salt further strengthens dough, increasing its resistance to extension. A series of biscuit and cracker formulae is shown in **Tables 1** and **2**.

Dough Composition

Wheat Flour

Wheat flour is unique among the cereal grain flours in that, when mixed with water, its protein components form an elastic network capable of holding gas and developing a firm spongy structure during baking. The protein substances contributing these properties (gliadin and glutenin), when combined with water and mixed, are known collectively as gluten. The suitability of a flour for biscuit making is generally determined by its gluten. Gluten characteristics are determined by genetics, the wheat's growing conditions, and the milling process. (*See* **Flour**: Dietary Importance.)

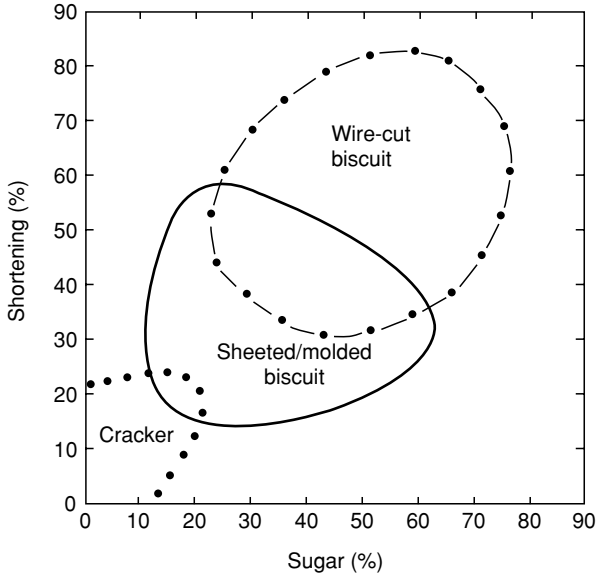

Figure 1 Biscuit composition in relation to sugar and shortening, based on 100 parts flour. (Each dough is processed according to its consistency or water content.)

Wheats are described by millers as hard, medium, or soft, based on the grain's physical characteristics. Hard types tend to have higher protein quantity and quality, possessing a vitreous endosperm, with starch granules tightly packed in a protein matrix. During milling, some starch grains are damaged, resulting in an increased surface area that leads to higher water absorption. The softer wheats have a less compact starch–protein complex which results in less starch damage and lower water absorption. The protein level of soft wheats is usually lower, producing a less resistant, more extensible dough. These 'weaker' flours are traditionally deemed more suitable for biscuit making than the harder flours used for breads. (*See* **Flour**: Roller Milling Operations; Analysis of Wheat Flours.)

Flour protein levels needed for biscuit making typically range from 7 to 10% and are often selected by functionality for end use, price, and availability. Flour should contain no more than about 14% moisture. Biscuit flour is typically left unbleached and unchlorinated.

Sweeteners

All biscuit formulae contain sweeteners, which constitute the bulk of dissolved materials in most doughs. Sugars impart sweetness, act as vehicles for other

flavors, and create an attractive finish. Sweeteners also increase tenderness, crust color, volume, and moisture retention, while maintaining the proper balance between liquids and solids responsible for product contour/shape. Machining properties and baking characteristics are also closely related to sugar. Sweeteners tenderize the finished product by interfering with gluten hydration and starch gelatinization. (*See* **Sweeteners**: Intensive.)

High-fructose corn (maize) syrups are becoming increasingly important, but sucrose from sugar cane or beet is still the major sweetener. Commercial sugars are often categorized as granulated or powdered. Granulated sugars range from coating sugar (extremely fine grain) to coarse. Powdered sugars are made by grinding granulated sugars and screening through fine bolting cloths. Generally, as the size of the sugar crystal increases, the size and symmetry of the biscuit decrease, while the thickness and color increase. Often anticaking agents, e.g., corn starch, are added to insure proper flow of the sugar during raw material handling. Where pumpability may offer a processing benefit, granular sucrose can be combined with water to form 'liquid sugar,' usually at 67% sugar solids or 67°Brix.

Sucrose may be hydrolyzed (inverted) to glucose (dextrose) and fructose (laevulose) by heating it in the presence of a dilute weak acid or mixing it with invertase enzyme. Sucrose is the standard for sweetness, with an arbitrary rating of 100. Fructose and glusose are rated at 170 and 74, respectively. Their combined sweetness in a completely inverted sugar is 127, sweeter than the starting sucrose. Inverted sugars are used primarily for their hygroscopicity and browning reactions, which contribute moisture retention and color development in the biscuits. (*See* **Carbohydrates**: Sensory Properties.)

Shortenings and Emulsifiers

Fats are the third major component used in biscuit making, but are considerably more expensive than flour or sugar. Besides being used in the doughs, fats or oils are used as surface sprays, in cream fillings and coatings (such as chocolate), and as release agents. In dough, they tenderize (impart shortness to) the crumb by being dispersed in films and globules during mixing, which interferes with gluten development. Shortening also aids dough aeration during the creaming step. The overall effect improves palatability, extends shelf-life, improves flavor and, of course, adds caloric energy. (*See* **Fats**: Uses in the Food Industry.)

Animal fats, primarily lard, were originally used by bakers. Compound (part animal and part vegetable source) shortenings and all-vegetable shortenings were then developed. Soya bean, cottonseed, palm, coconut, and peanut oils are the primary vegetable sources used in shortening production. Continued advancements in purification and hydrogenation developed vegetable oils that could replace animal fats with equal or better flavors, melting points, consistency, and availability. Because of current health concerns, most bakeries have switched to fats of plant origin. (*See* **Vegetable Oils**: Types and Properties.)

Surfactants (surface-active agents) are given many names by bakers: crumb softeners, emulsifiers, antistaling agents, or dough conditioners. Examples include lecithin, mono- and diglycerides, diacetyl

tartaric acid esters of fatty acids, polysorbate 60 and sodium stearloyl 2-lactylate. Surfactants at low concentrations act to modify the surface behaviors of liquids. They are believed to complex with the protein–starch structure, thereby strengthening the film, and to delay dough setting during baking. The behavior of surfactants is due to their amphoteric (possessing both hydrophilic and hydrophobic molecular regions) properties. Their behavior varies according to the charges on the molecules, their solubility, the hydrophilic–lipophilic balance, and the type of functional groups involved. (*See* **Emulsifiers**: Uses in Processed Foods.)

Surfactants modify dough consistency and reduce stickiness by reacting with the gluten. The greasiness of biscuits with high fat content is also reduced by surfactants. Crumb softeners also complex with the starch molecules to delay retrogradation and texture staling. The grain pattern and volume of the finished product are often improved, as surfactants increase dough gas-retaining properties.

Antioxidants retard the development of oxidative rancidity during product storage. All fats are subject to oxidative or hydrolytic rancidity which causes objectionable odors and flavors, but antioxidants delay these reactions from occurring within the biscuits' shelf-life. They are usually added to bulk shortenings and are important for preserving low-moisture products, which are expected to remain edible for several months. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

Is Water an Ingredient?

Water is often thought of as a processing aid or catalyst, rather than as an ingredient. It is incorporated at the dough stage but driven off during baking. Water functions in several ways, including hydrating flour proteins and starch, dissolving sugars, salts, and various leavening chemicals, aiding in ingredient distribution and helping control dough temperature.

A dough's consistency is directly related to its water content, or absorption. Many factors affect dough absorption. Approximately 46% of flour's total absorption is associated with the starch, 31% with protein, and 23% with the pentosans. Acceptable consistency can be obtained only after sufficient water is present to hydrate the flour. This is regarded as bound water and controls the dough's consistency. As bound water layers are 'stacked up,' some of the water is held less and less strongly, resulting in water that can escape (evaporation) and/or migrate as free water. Water activity (a_w) is an important way to measure and monitor water's mobility in baked products.

Making Biscuits Lighter

Leavening agents aerate the dough or batter to make it light and porous. The leavening action is responsible for good volume, improved eating quality, and a uniform cell structure. Leavening can be achieved by various methods, including yeast fermentation, the mechanical incorporation of air by mixing and creaming, formation of water vapor during baking, and the creation of carbon dioxide and/or ammonia by chemical leaveners. However, creation of the initial air bubbles during the mixing phase is critical before any of the other leavening agents can take effect. (*See* **Leavening Agents**.)

Small products like biscuits that bake quickly need a fast-acting leavener that will release the gas before the structure sets. The most widely used source of carbon dioxide in chemically leavened systems is the reaction of sodium bicarbonate or baking soda ($NaHCO_3$) with an acid, usually the acidic salt of a weak mineral acid. The leavening acid promotes a controlled and nearly complete evolution of carbon dioxide from sodium bicarbonate in an aqueous solution. Some examples include monocalcium phosphate monohydrate ($CaH_4PO_4)_2.H_2O$), sodium acid pyrophosphate ($Na_2H_2P_2O_7$) and potassium acid tartrate ($KHC_4H_4O_6$). When these agents combine with water, they react to form controlled amounts of carbon dioxide. Sodium bicarbonate also raises dough pH.

Ammonium bicarbonate (NH_4HCO_3) generates carbon dioxide, ammonia, and steam when heated. It increases spread and gives a larger, more desirable surface 'crack' in some types of hard, high-sugar biscuits. However, it can be used only with low-moisture biscuits that are baked sufficiently to drive off all residual ammonia.

Other Ingredients

Milk products, eggs, and salt are added for variety. Milk and eggs are viewed as wholesome ingredients by consumers; however, they are among the most expensive.

Milk and whey are good sources of protein and lactose, which aid in shape retention and browning reactions. They add flavor and nutrients, improve texture, crust color, moisture retention, and control spread. They are usually added in dried form. (*See* **Whey and Whey Powders**: Production and Uses.)

Eggs contribute color, structure, nutritional value, and some flavor. They affect texture as a result of their emulsifying, tenderizing, leavening, and binding actions. The form of eggs used can be fortified or whole components (yolks and whites) in the liquid, frozen or dried state, or combined with sugar.

Salt performs two principal functions in biscuit doughs. The first is flavor. It accentuates or potentiates the flavor of other ingredients (e.g., the sweetness of sugar is emphasized), and it removes the flatness or lack of flavor in other foods. Moreover, salt has a slight effect on the consistency of hard doughs, because it has a strengthening effect on gluten. Salt also controls fermentation and aids in suppressing undesirable bacteria.

Minor ingredients include malt, proteases, mold inhibitors, spices and flavorings. Though used in relatively small amounts, these ingredients have quite important effects on the sensory and physical qualities of biscuits.

Malt is prepared from barley by sprouting it, then drying it at controlled temperatures. Diastatic malt provides enzymes that break starch into simple sugars and add flavor and color. If the malt is heated sufficiently to inactivate the (amylase) enzymes, for use as a flavorant, it is called 'nondiastatic.' (*See* **Malt**: Chemistry of Malting.)

Proteases are important in crackers (low sugar). They are often added to modify the gluten framework. The effect of a protease is to make the dough less elastic, so that shrinkage does not occur during sheeting and cutting. Proteases may occasionally be used in cookie production. A dough containing gluten that is too strong will decrease biscuit spread, so proteases can improve the spread ratio. (*See* **Enzymes**: Uses in Food Processing.)

Mold inhibitors are not generally used in low-moisture cookies and crackers, but some types which are higher in moisture may benefit from their inclusion. Other food products used in biscuits (i.e., fillings, toppings, and creams) may require an inhibitor. Some examples include sodium diacetate ($Na_2C_2H_3O_2.HC_2H_3O_2.\ ½H_2O$), calcium propionate ($Ca(CH_3CH_2COO)_2$) and sodium propionate (CH_3CH_2COONa).

Added Flavors

Our choice of food is largely influenced by taste and flavor. Smell, taste, touch, and sight are all influenced by the chemical and physical properties of the food. Sweet bakery foods are often selected for this reason. Therefore, selecting the correct flavor is extremely critical. Selection of the best flavor is most often achieved through experience and trial and error. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Biscuits may be flavored in one or more of three ways: adding the flavoring to the dough before baking; dusting or spraying the flavor on after baking; or by flavoring a nonbaked portion such as cream filling, icing, or jam that is applied after baking.

Spices are aromatic vegetable products (tree bark, seeds, fruits, and roots), and are usually finely ground. They improve quality through smells and tastes. The most commonly used spices are cinnamon, mace, nutmeg, caraway, anise, allspice, poppy seed, coriander, ginger, cloves, and fennel.

Flavorings are alcohol extracts from fruits or beans. Vanilla is the most common because it blends with and enhances other flavors. Flavorings, such as vanilla or almond, can be either natural or synthetic. Because flavorings are volatile, much of them may be lost during baking.

Added Colors

Color additives are used in biscuits and in fillings, icings, and coatings to create a perception of quality and richness. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; Properties and Determinants of Synthetic Pigments.)

Chemical Changes During Baking

Biscuits are usually baked in a tunnel oven. The dough pieces are placed on either a flexible metal or wire mesh band that travels continuously through the oven's length, which may reach 100 m. Baking is controlled by varying the temperatures in the individual zones within the oven. It is not uncommon for the drier to consist of 5–7 zones. Baking time is regulated by the band speed. Crackers and some biscuits are docked by pressing blunt pins into the dough sheet. Docking dough pieces before baking creates air passages through the crust and seals the top to the bottom, reducing big blisters.

Dough undergoes several changes during baking (Figure 2). Changes in dimension and texture, loss of moisture, and color and flavor development are the most important. Baking is divided into three phases. The first involves dough expansion and the start of moisture loss. Dough expansion and water

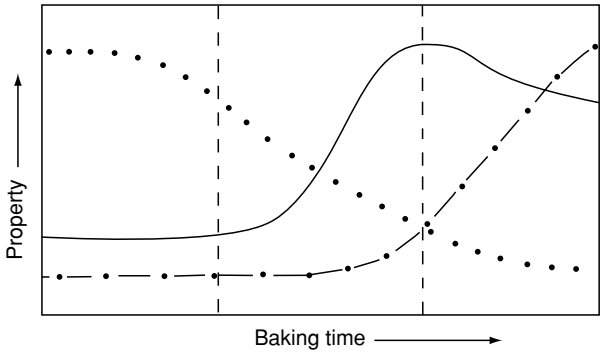

Figure 2 Physical changes in biscuits during baking. Key: —●—, color; —, thickness; ●●●, weight.

loss reach maximum rates and colour development starts during the second phase. The third phase concludes baking with a lower rate of moisture loss, thinning of the biscuit, and increasing surface color.

Dimension and Texture Changes

As dough pieces enter the oven, the biscuit's internal temperature rises, and the sugars and fats melt. The complex matrix contains liquified fat and dissolved sugars. Water evaporation causes the solution to become more concentrated, and the dough temperature continues to increase. Leaveners and steam cause the dough volume to expand. With sufficient heat, limited protein denaturation and starch swelling occur, helping to create some structure. However, the high sugar and fat content inhibit full starch gelatinization.

Doughs rich in fat and sugar, but containing little water, often have unhydrated proteins and ungelatinized starch when baked. With this formulation, a rigid structure cannot be achieved, and is therefore replaced by a soft, sugary matrix. During baking, the dough expands greatly via steam and leavening, but does not set properly, resulting in collapse of the biscuit upon removal from the oven. This expansion–collapse effect is responsible for the characteristic cracked surface of some biscuits.

Moisture Loss

Dough moistures average 11–30% before baking and 1–5% after. Moisture can be lost only from the biscuit surface. It migrates from the center to the surface of the biscuit by capillary action and diffusion. The free water is evaporated very readily, but part of the bound water will also be liberated, in association with color development. Moisture content and water activity are critical parameters, as both directly influence storage life.

Color Changes

One of the most important color reactions is the Maillard reaction. It involves the interaction of reducing sugars with amino groups in the proteins, mainly from lysine, and produces an attractive reddish-brown hue. It is also associated with the dextrinization of starch and the caramelization of sugars. These reactions require very high temperatures, which are reached only at the biscuit surface. (*See* **Browning**: Nonenzymatic.)

Storage and Staling

Most freshly baked biscuits are cooled before packaging or secondary processing, e.g., icing or sandwiching with a cream filling. Snack crackers are sprayed with oil and salted/seasoned prior to cooling. The cooling period is usually 1·5–2 times longer than the baking period. During cooling and storage, the biscuit continues to undergo texture changes. Hard dough biscuits are rigid and crisp immediately after baking. Soft dough products are still flexible at the end of baking, but become firm and crisp after cooling, as a result of sugar recrystallization and glass transition temperature.

Changes in Moisture Distribution

The residual moisture is not uniformly distributed as a biscuit leaves the oven. Most of the moisture lies in a lamella near the center, leaving the surface and the outer periphery almost dry.

'Checking' is a change associated with uneven moisture distribution. Dimensional changes within the biscuit after baking cause it to crack. The center shrinks as it loses moisture, but the rim expands as it absorbs moisture. Checking can happen in almost any type of biscuit or cracker, but is most commonly found in semisweet products.

Wafers

K Tiefenbacher, Vienna, Austria

Background

Wafers – thin, crisp and precisely shaped products from cereals – are a very special part of the biscuits, cookies, and crackers area. The name covers several types of wafers, quite different in recipes, manufacturing equipment, and end use. The fundamental steps of making flat wafers, hollow wafers, molded cones, rolled wafer cones, and wafer sticks are outlined in some detail.

Concepts like water activity and glass transition are of critical importance here. Moreover, the function of wafers as a part of combined food products is discussed. Finally, some important trends in both products and manufacturing equipment should be noted.

Main Wafer Features

Wafers are baked as sheets, cones, and sticks or with different fancy shapes. The characteristic features with respect to other bakery products are:

1. Wafers are very thin biscuits; the overall thickness is usually between less than 1 and 5 mm. They often have a typical 'wafer pattern' on one surface or on both. The surfaces are smooth and precisely formed, with the dimensions and all the details – engravings, logos, etc. – of the baking molds. See **Figure 1** for some examples.
2. Wafers are cereal-based low fat products made of wheat flour, sometimes with addition of other flours or starches. The product density is in the range of 0.10–0.25 g cm^{-3}. In cross-section, the wafer matrix is highly aerated and primarily of gelatinized starch.
3. Wafers, by their typical delicate and crisp texture, combine well with different fillings (cream, ice-cream, foam) and coatings.

There is sometimes confusion in terminology between the crisp 'wafers' as described here and 'waffles,' which are of a soft, cake-like texture but show some kind of wafer pattern, too.

Basic Wafer Types

There are two basic types of wafers:

1. No- or low-sugar wafers. After baking, these contain from zero to a very low percentage of sucrose or other sugars. Typical products are flat and hollow wafer sheets, molded cones, cups, and fancy shapes.
2. Higher-sugar wafers. Well over 10% of sucrose or other sugars are responsible for the plasticity of the hot, freshly baked sheets. These are formed into different shapes before sugar recrystallization occurs. Typical products are rolled sugar cones, rolled wafer sticks or tubes, and deep-formed fancy shapes.

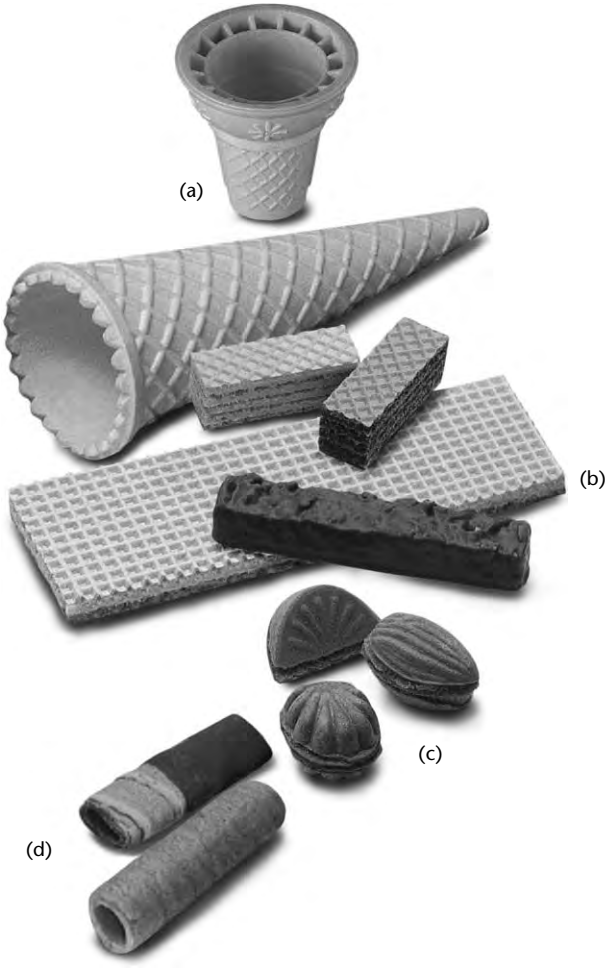

Figure 1 Wafer products. *From top to bottom*: (a), molded cones; (b), flat wafers, creamed/enrobed; (c), hollow wafer pieces; (d), wafer sticks.

As in both wafer types, the main ingredient is flour, wafers fit very well into current dietary recommendations to consume more cereals. They are high-carbohydrate, low fat products. (*See* **Cereals**: Dietary Importance.)

The baking of 'wafers' between hot metal plates has been known since medieval times, but these first wafers were more similar to our waffles or pancakes in their high fat and egg contents and their texture.

Modern wafers are low-fat cereal products, very similar to the altar breads for Christian churches, and are basically made out of flour and water. The first wafer ovens were used after World War I, but more automatic manufacturing lines have been available since the mid-1950s.

Wafer Recipes

Before creating a wafer recipe, two main questions have to be answered:

1. What is the end use of the wafer? If it is part of a cream-filled, chocolate-covered biscuit, where contributing a crisp texture element is far more important than the taste of the wafer itself, recipes with few components are recommended. If the wafers are consumed directly as wafer bread or wafer sticks, more sophisticated recipes are chosen.
2. What kind and quality of raw materials are available? Low- to medium-protein soft wheat flours with a low water absorption work best, especially for no-sugar wafers. Problems with suboptimal flours must be balanced by variations in minor ingredients in the recipe. The use of wholemeal flour is possible, and in some regions, other cereals such as rice or corn are used for wafer production.

Table 1 lists the common ingredient ranges for both types of wafer.

In-line Manufacturing of Wafer Biscuits

Wafer biscuits are the most important products by volume. To explain the different steps of manufacturing, we follow Figure 2.

Batter Preparation (Figure 2, process 1)

Wafers are made from a fluid batter with a typical viscosity in the range of 300–2000 mPs. First, the water-soluble components are dissolved. By adding the farinaceous ingredients, a homogenous suspension, the 'wafer batter,' is obtained within a few minutes of mixing.

Batter Transport and Depositing (Figure 2, process 2)

From an intermediate tank via a ring main, the batter is pumped to the oven and spread on to the baking molds by a depositor head.

Wafer Sheet Baking (Figure 2, process 3)

The baking of wafer sheets is performed in 'tongs,' i.e., pairs of cast-iron metal plates with a hinge and

Table 1 Wafer batter ingredient ranges (weight parts, flour = 100)

	No (low)-sugar wafer	*Higher-sugar wafer*
Wheat flour	100	100
Water	120–160	100–140
Starch	0–12	0–5
Sucrose	0–4	25–75
Oil/fat	0.5–2	1–6
Milk powder	0–2	0–2
Soya lecithin	0.2–1	0.2–1,5
Salt	0–0.6	0–0.6
Sodium bicarbonate	0.1–0.5	0–0.3

Optional minor ingredients: other cereal flours, soya flour, other sugars and syrups, egg-based ingredients; whey powder, yeast, caramel color, cocoa powder, colors, ammonium bicarbonate, enzymes.

latch on opposite sides. Baking plate sizes up to 350 × 730 mm are available. The precisely machined baking plates carry reedings or other engravings. We call the resulting wafers 'flat' wafer sheets, with an overall thickness of no more than 2–5 mm.

But such baking plates can also carry special figures (nuts, sticks, hemispheres, fancy shapes) up to a depth of approximately 20 mm, thus yielding the so-called 'hollow' wafer sheets.

Modern wafer-baking plates often are surface-plated, e.g., with chromium for easier release and reduction of cleaning stops. The plates are edged with metal strips to give a closed baking mold, except for small venting channels for steam release. Wafer-baking ovens frequently have 32–104 pairs of plates, continuously circulating on a chain. They are mostly gas, sometimes electrically heated and operate at mold temperatures between 160 and 190 °C.

The baking process Within a few seconds after batter deposition, the baking molds close and are locked. At first, the batter is distributed mechanically, but then the mold is filled completely by the steam that evolves. A small quantity of batter is extruded as baking waste 'bobbles' through the venting channels. As gelatinization of starch starts immediately, the pressurization of the mold by steam occurs at the right moment, resulting in a well-aerated starch foam.

When most of the water has been driven off, the glass temperature of the wafer matrix rises, and the stable structure is formed. The temperature of the wafer increases to 160–190 °C, the temperature of the baking mold. Then, from Maillard reactions, the typical wafer color and flavor develop. (*See* **Browning**: Nonenzymatic.)

The overall baking times are between 1.5 and 2.5 min, depending on the wafer thickness and baking temperature.

During the wafer manufacturing process, there is no substantial degradation of starch molecules compared with other bakery products such as extruded cereals. Therefore, wafers have two unique textural properties:

1. Extreme crispness on biting and initial chewing.
2. Good mouth feel during prolonged chewing and swallowing owing to the absence of sticky, glutinous stimuli.

Wafer Release and Cooldown (Figure 2, process 4)

At one end of the oven, the plates open to release the baked sheets and to spread fresh batter, and then reclose very quickly. The sheets are cooled to room temperature while passing over an arch-type sheet cooler.

Wafer Conditioning (Figure 2, process 5)

Next, the wafers optionally pass a conditioning unit, where the moisture content of the sheets is carefully increased so as to achieve some stability in both the texture and size of the wafer.

Moisture sorption and wafer texture After baking, the residual moisture is 0.8–1.5%. Looking to the sorption isotherm, this corresponds to a water activity of around 0.1 or even lower. As both the water activity of the air in the production area and the water activity of filling creams or coatings are well above that, wafers pick up moisture very easily. In line with this sorption, the dimensions of the sheet increase by 0.2–0.3% for every 1% of additional moisture. This can result in cracking of the coating in enrobed wafer biscuits.

To compensate for the low water activity, humidity conditioning up to approximately 4.5% wafer moisture is possible. This is recommended, especially if enrobed or chocolate molded wafer products are made, in order to anticipate this first dimension increase and to avoid any cracking of the coating during its shelf-life.

Moreover, with increasing water activity, the wafer texture changes from a soft to a harder crispness, accompanied by a higher mechanical stability, which is good both for handling and for the final product texture. Up to 5–6% moisture content, the wafer sheets keep their typical crisp texture, but higher moisture levels will result in most cases in inadequate, tough, or even soft and soggy textures (see Table 2 for details).

Table 2 Water activity, water content, and texture of wafers

Wafer condition	*Wafer texture*	*Water activity, approx.*	*Moisture (%), approx.*
Freshly baked	Very tender, crisp	< 0.1	< 2
After conditioning	Crisp, harder	0.3	4.5
Limit of crispness	Crisp to tough	0.5/0.55	≥6
Wafers, foam-filled	Soft to flexible	0.7	≥12
Collapse of structure	Very soft, shrinks	> 0.85	> 20

Creaming and Book Building (Figure 2, process 6)

The sheets then pass the creaming station, where a layer of a sugar- and fat-based cream is applied to one side. The type of cream flavor liked most varies regionally, but chocolate, vanilla, hazelnut, milk, strawberry, and lemon are the most common. Creaming is done at temperatures of 30–40 °C either by contact spreading or by depositing a preformed cream film. For flat wafers, several creamed sheets together with a noncreamed top sheet form a so-called 'wafer book.'

For hollow wafers, the cream is added to the hollow parts either by spreading or by controlled single depositing. Again, either two hollow wafer sheets or a hollow and a flat sheet are combined to form a 'book.'

Cooling and Cutting (Figure 2, process 7)

The wafer books pass a cooling tunnel to set the cream, after which they are wire or saw-cut into small biscuits.

Enrobing or Molding in Chocolate, Cooling (Figure 2, processes 8 and 9)

The cut biscuits may be enrobed with chocolate-type coatings, sometimes after the application of chopped nuts or crispies to the top wafer. Molding in chocolate is another possibility. After a final cooling step, the biscuits are ready for packaging.

Packaging (Figure 2, process 10)

The biscuits have to be packed tightly to protect against humidity, but also against oxygen and light to prevent oxidative deterioration and to insure a shelf-life of 6–9 months. Inadequate packaging-film moisture barriers and bad sealing are the most frequent reasons for later complaints by customers. Laminated or specially coated films are used for the typical wafer product packaging in flow packs, boxes, or bags.

Manufacturing of Molded Wafer Cones

Another type of 'hollow' wafers, cones, cups, and fancy shapes with up to 185 mm in length are produced in cast-iron molds. Holes for four to six items are provided in each of these molds, and 12–72 molds are circulated in one oven. The lower part of the mold is made of two symmetric halves that open to release the baked pieces. After their reclosure, they take up a fresh batter deposit, and finally the 'core,' the upper part of the mold, closes the mold for a new baking cycle. The baked cones are cooled down and stacked for packaging.

Recipewise, there are two groups of molded cones:

1. No- or low-sugar cones, generally known as 'cake cones,' whose recipes are similar to those for sheets (see Table 1).
2. The so-called 'molded sugar cones' have an intermediate sugar content, usually below 20 parts of sucrose for 100 parts of flour.

Recent Developments in Molded Wafer Cones (see Figure 2)

Whereas traditionally molded cones have flat tops and regular, symmetric reedings now for a few years molds for more sophisticated products can be manufactured. We now see cones and cups in the market showing curvilinear tops and artfully designed outsides. Figure 3 shows the first of these, which comes from a Japanese cone manufacturer.

Manufacturing of Rolled Wafer Cones (see Figure 4)

'Rolled sugar cones' need a concentration of more than 20% of sucrose or other sugars in the finished product. The first three steps of rolled sugar cone manufacturing are rather similar to no/low-sugar wafer sheet baking with the exception of reduced steam pressure as there are no baking ledges to build up pressure and to extrude 'bobbles.' The deposit is just to form an oval or circular sheet.

1. Batter preparation (Figure 4, process 1)
2. Batter transport and depositing (Figure 4, process 2)

Figure 3 Molded wafer cone: example for new, nonflat top design.

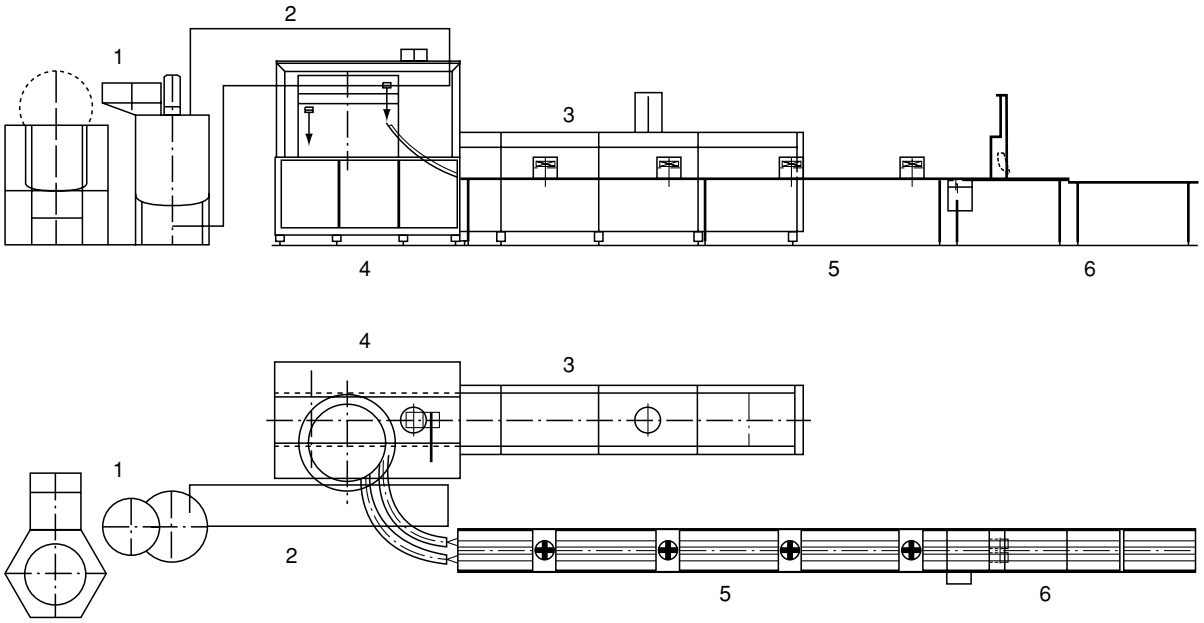

Figure 4 Manufacturing line for rolled sugar cones. 1, batter preparation; 2, batter transport and depositing; 3, wafer sheet baking; 4, take-off, rolling and cone release; 5, cooling of cones; 6, cone sleeving, stacking.

3. Wafer sheet baking (Figure 4, process 3): Nowadays, equipment is available to manufacture up to 13 000 cones per hour.
4. Wafer take-off, rolling, and cone release (Figure 4, process 4): When, after baking, the mold reopens, the sheet is automatically stripped off the plate and rolled immediately on tapered mandrels to form the finished cone. A series of rolling devices mounted on a round table operates continuously: Sheet removal, rolling, release, etc.

Glass Transition and Formability

During the rolling procedure, the wafer temperature is still above the glass transition point. The molten sugar acts as a plasticizer, and so any rolling or deep-forming operation can be performed. Besides the rolled cones, three more types of products are manufactured by the same principle:

1. Wafer 'rolls': Wafer sheets of rectangular shape are baked, stripped off the baking plate, and rolled into a sugar wafer 'rod' without a center hole (different from wafer 'sticks' with a center hole discussed later). The rod is later cut into smaller cylindrical pieces. Typically, these pieces are finally partially enrobed with chocolate-type coatings.
2. 'Deep-formed' wafers (cups, shells), where the hot, flat wafer piece is introduced into a forming tool, sometimes with an additional embossing or stamping device, which defines the final shape.
3. Rolled wafer sticks. These are discussed in a separate chapter below.

Cone Cooling (Figure 4, process 5)

The fresh cones pass through a cooling section, where ambient or cooled air is applied. Here, sugar recrystallization finishes to give the final strong and brittle texture.

Cone Sleeving and Stacking (Figure 4, process 6)

Now, paper sleeves are applied automatically, and these form the packaging material for the typical end product, industrially manufactured icecream cones. Next, is automatic cone stacking and packaging.

Later in the icecream plant, the wafer cones are sprayed inside with chocolate and filled, and finally, the paper cone is closed.

Manufacturing of Rolled Wafer Sticks

Rolled wafer sticks are hollow tubes with walls consisting of very thin multiple layers, similar in texture to crunchy cereals. These layers do not carry a wafer pattern and are approximately 0.5 mm in thickness. But from the recipe, the sticks are typical higher-sugar wafers (see Table 1).

In manufacturing, a stripe of batter is applicated to a heated drum and baked into a continuous wafer band. The band is rolled immediately while hot into a continuous still formable tube with an internal

diameter of about 6–36 mm. From here, there are several options to create a large family of finished products:

1. The tube is automatically cut into wafer stick pieces and cooled. These are consumed as sweet snacks or with icecream, for example. Other end uses include intermediate products for confectioners to finish by additional filling or decorating operations.
2. During the rolling operation, the tube is coated inside with compound chocolate or filled with cream, either partially or fully. Then, cutting and cooldown, followed optionally by a coating and/or decorating process, give the finished product.
3. The filled tube is transformed into small pillow-like bits by a combined squeezing–cutting operation.
4. The wafer tube pieces, nonfilled, coated inside, or partially cream-filled immediately after cutting while still hot, pass a pressing station to form oval or even flat pieces. Such flat pieces may form the center of premium-type confectionery items with a chocolate coating, including chopped nuts or cereal crispies, for example.
5. Larger-diameter tubes are pressed flat, and by an embossing and stamping operation, so-called 'fan wafers' or other elaborate shapes can be generated.

The diameter and length of the sticks as well as the number of very thin, 'glassy' sheets forming the wall of the stick can be adjusted individually. Rolled wafer sticks have a unique brittle wall texture without being too hard in biting and chewing.

Savory Wafer Products

Whereas many end uses of wafers in combination with sweet fillings, coatings, etc. are well known, savory or neutral-tasting wafer products are becoming increasingly popular in some areas. Some examples:

1. Wafers as crispbread, delivering a crunchy but softer texture than traditional hard crisp breads. Besides wheat flour there are several options for other cereal and noncereal flours as raw materials. The products are either neutral in taste to be eaten with sweet or nonsweet toppings or have spices, cheese, and other flavorsome ingredients.
2. Wafers – flat or hollow wafers – with savory fillings, e.g., peanut butter or cheese creams.
3. Wafer sticks, a recent development, made from a nonsweet but still rollable material. These are typically combined with savory cream fillings.

Trends – From the Very Wafer to a More Sophisticated End Product

After discussing the different wafer types and their traditional end uses (for an overview, see Table 3), a sharply increasing number of new confectionery brand products during the last decade are worth mentioning. Here, wafers are only a smaller, but still important, part of the deal. These are small confectionery pieces, mostly in bite-size or sectioned bars, often chocolate-covered, where the wafer has three main functions:

1. To add its typical texture and crispness, e.g., to a soft filling cream with a piece of nut and a chocolate cover, thus imparting a multitextured impression.
2. To make the overall product 'lighter' in calories and nutritionally, as the wafer part is of an extremely low density and cereal-based.
3. To define the precise structure of the piece, e.g., when holding a soft filling, or, for noncoated pieces, to keep the consumer's hands clean if the filling melts due to warmer conditions.

Looking to some of the current trends, we see increasing interest in combining lower fat fillings such as toffee (caramel). Another trend may be newer fat free fruit-type fillings with water activities that are so low that the wafers stay crisp. Even some new examples of fillings with a higher moisture, resulting in a 'soft' wafer part, can be rolled out.

Table 3 Which product from which wafer type?

End product	*No (low)-sugar wafer*	*Higher-sugar wafer*
Wafer crisp bread	Flat wafer sheet	
Sugar wafer biscuits, creamed	Flat wafer sheet	
Wafer biscuits, creamed and enrobed or molded in chocolate	Flat wafer sheet	
Containers, e.g., for icecream	Molded cake cone	Molded sugar cone, rolled sugar cone
Confectionery, filled, enrobed, decorated	Hollow wafer *or* hollow + flat wafer	Wafer stick *or* sugar cone, small
Fan wafers		Wafer stick, pressed, embossed
Wafer rolls, partially enrobed		Rolled sheet
Wafer bowls		Deep-formed sheet

Figure 5 New, inductively heated, low-emission oven for rolled wafer stick manufacturing.

Developments in Wafer-manufacturing Equipment

After a long period of just 'routine' technical optimizations, recent years have seen a few new technical concepts in wafer-manufacturing equipment:

1. The 'stack oven,' with the baking plates vertically stacked. Here, the weight of the stack itself eliminates the need for hinges and for closing mechanisms as in the traditional chain oven. Moreover, the floor area needed is greatly reduced. The coming years will show whether that development will find its way into industrial practice.
2. A new 'low-emission' heating concept together with a 60% reduction in energy consumption for rolled wafer stick ovens. The key is the replacement of the gas-heated drum by a ring, heated by induction. This results in a new, more consistent and more controllable product quality, and results in the elimination of flue gases and a huge reduction in energy consumption for baking, as the first industrial oven prototypes (Figure 5) showed.

BLACKBERRIES AND RELATED FRUITS

D L Jennings, Otham, Maidstone, UK

Introduction

Although in the same genus as raspberries, blackberries are often regarded by the food industry as the Cinderella of the soft fruits. Nevertheless, they have considerable potential, which is likely to be realized to an increasing extent as new and improved cultivars become available. This article first describes the main types of blackberries and their botanical classification. Their anatomy, fruit pigments, and some of the characteristics that determine their fruit quality are then discussed, particularly color and flavor, followed by a discussion on the problems of postharvest storage and the various market outlets.

Types of Blackberries

The botanical classification of blackberries is complex, but from the food viewpoint, it is useful to consider just three types: the traditional blackberries of Europe and eastern North America typified by Evergreen Thornless, Loch Ness, and Triple Crown, the indigenous blackberries of western North America typified by Marion, Kotata, and Helen and blackberry–raspberry hybrids typified by loganberry, tayberry, and boysenberry. World production is concentrated in a few areas, but there are low levels of production in most of the areas where raspberries are grown. Two major production areas are Washington and Oregon on the west coast of America, where cultivars of each type are grown but with a predominance of European forms, another is in New Zealand, where the boysenberry, a blackberry–raspberry hybrid, predominates, and a third is in Arkansas, USA, where locally bred cultivars are grown.

The flavor usually associated with blackberries is that of the European type. The flavor of the western North American type is more intense and pleasantly acidic, and has strong aromatic overtones. The loganberry, tayberry, boysenberry, and youngberry are all hybrids derived from western North American blackberries and red raspberries. They have inherited much of the characteristic flavor of this type of blackberry. Of these hybrids, the loganberry and tayberry contain one-third of raspberry germplasm and have purple fruits; the others contain a lower proportion and have black fruits. The Andean blackberry of South America, *Rubus glaucus*, is the only blackberry–raspberry hybrid to be derived from a black raspberry, which has undoubtedly contributed to its excellent flavor.

Until recently the available cultivars of the western North America type have been low yielding and not widely grown outside their area of origin, but new cultivars such as Kotata, Siskiyou and Helen are much improved in productivity and quality, and are providing new opportunities for blackberry production and usage both in North America and in Europe. Their excellent flavor and early cropping are so different from those of the European type that the two forms complement each other to provide a choice of flavor and a longer season of production.

Fruit Structure

Blackberry fruits are aggregates of drupelets. A drupe fruit is one that develops entirely from a single ovary, and the aggregate of drupelets that makes a blackberry fruit is formed by the ripening together of some 50–100 ovaries from the same flower and adhering to a common receptacle: in a sense, each drupelet is a complete fruit in itself and a miniature homolog of such drupe fruits as the cherry or plum.

The cohesion of these drupelets depends on the entanglement of epidermal hairs, which are unicellular linear trichomes arising from surface cells. The hairs are abundant at the bases and sides of the drupelet, and shorter and less profuse over its dome; they are so tightly enmeshed that the drupelets cannot normally be separated without tearing the skin. A poor set of drupelets or poor cohesion between them causes 'crumbly fruit' and a serious loss of quality.

Internally, the soft part of the drupelet consists of thin-walled parenchymatous cells, radiating from the pyrene in the center to a region of larger, oval-shaped cells that underlie the epidermis, and a slightly collenchymatous hypodermis of one to three cells. Fruits are succulent because the walls of the parenchyma are thin and the cells turgid: variations between cultivars in fruit firmness are influenced by variations in the frequency of cells of small diameter, tissue compactness, and overall cell size, which influences the amount of supporting cell wall. The strength of the epidermis and cuticle influences the 'skin' strength of the berry.

Pyrenes

In the center of each drupelet is a pyrene (often erroneously referred to as the seed) with a hard endocarp

enclosing one or two true seeds. The endocarp consists of two layers of elongated, parallel scleroid cells at right angles to each other and each several cells thick, the outer one forming the characteristic ridged pattern of the pyrene.

The large size of most blackberry pyrenes is one of the main reasons why relatively few blackberries are used for jam-making. Large pyrenes are also undesirable in fresh fruit. Blackberry cultivars show a wide range in this characteristic: surveys showed a range in pyrene weight, which is indicative of size, from 2.10 to 4.83 mg for American cultivars and from 2.10 to 6.10 mg for breeding material at the Scottish Crop Research Institute. The American cultivars Waldo and Kotata have individual pyrene weights of 2.18 and 2.41 mg, respectively, and are examples of cultivars that have small pyrenes and are suitable for jam-making. However, small pyrenes are only advantageous if their small size is associated with good development of the juicy soft tissues that surround them. Another potentially important quality of the pyrenes is their tendency to become 'blind' in jam. Nothing is known about this characteristic in blackberries, because few of them are used in jam-making. Blindness occurs during the storage of raspberry jam when a slow displacement of air from within the pyrenes allows the surrounding syrup to infiltrate and causes them to lose their opacity. They then appear to have merged with the surrounding jam, which acquires a dull appearance and gives the illusion of a low fruit content. The problem could appear if small-seeded blackberry cultivars become popular for jam-making. The rate at which the process proceeds would be expected to vary with cultivar, method of fruit storage, and manufacturing procedure.

Fruit Ripening and Abscission

All the drupelets of a blackberry usually ripen together, but ripening at the top of the fruit is sometimes slightly later to give a red tip to an otherwise black fruit, especially in large, elongated fruits. Ethylene production begins at a late stage of color development in Maryland, USA, where the blackberries studied can therefore be described as 'climacteric' fruits. No ethylene production was detected in a study in Scotland, however. The difference between these two results may be attributable to the temperatures prevailing at the ripening time, because blackberries ripen in mid-summer in Maryland and much later in Scotland, or to the different cultivars studied. It is interesting that in the Scottish study, the behavior of two blackberry–raspberry hybrids, tayberry and tummelberry, was intermediate between that of raspberries and blackberries, and was therefore closer to that described for blackberries in Maryland. For blackberries grown in the USA, the ethylene-releasing chemical 'Ethrel' has been used to hasten ripening for machine harvesting. An abscission layer forms in the tissues as the fruit ripens. In blackberries, it is a single layer at the base of the receptacle, which consequently separates from the plant with the fruit, in contrast to raspberries, in which a large number of abscission layers form, one at the point of attachment of each drupelet to the receptacle, which is therefore retained on the plant after fruit abscission. This is the most fundamental difference between blackberries and raspberries, and it leads to an interesting situation in blackberry–raspberry hybrids, which are genetically heterozygous for both types of abscission. Dominance is not always complete, and the fruits of some hybrids do not abcise exactly like those of either parent, although most of them have the system of their blackberry parent. The tayberry, for example, has a poorly developed abscission layer, but the fruits separate like a blackberry except that the point of separation is frequently proximal to the calyx, which is then retained on the fruit when it is picked.

This difference between blackberries and raspberries in their method of fruit abscission explains why the core of most blackberries is soft and palatable, while that of some blackberry–raspberry hybrids such as tayberry is less so: blackberry fruits have been selected for the edibility of their receptacles, which become the cores of the ripe fruits, whereas the receptacles of raspberries are always left on the plant and are never eaten. Fruits of the hybrids are intermediate and often have a central core that is harder than that of the true blackberries.

Fruit Color

The color of blackberries results from the presence of anthocyanin pigments. The anthocyanin molecule consists of an aglycone with a varying number of sugar residues attached to the hydroxyl group, usually in the 3-position. Only two anthocyanins have been found in blackberries, which have a predominance of the monosaccharide form, cyanidin-3-glucoside, and a trace of the diglycoside cyanidin-3-rutinoside, in which an additional rhamnose sugar is present. This is a very small number of pigments for a *Rubus* fruit, and the presence of other anthocyanins indicates that a fruit has a hybrid origin. Thus, the diglycoside cyanidin-3-sophoroside, which is a characteristic pigment of the red raspberry, occurs in the loganberry, boysenberry, youngberry, and mertonberry, and is consistent with these fruits being related to the red

raspberry. Similarly, the occurrence in the Andean blackberry of the diglycoside cyanidin-3-sambubiose, which is a characteristic pigment of black raspberries, supports the hypothesis that this blackberry is related to the black raspberry.

The identity of the sugar residues attached to the aglycone part of the anthocyanin molecule is thus useful to complement taxonomic observations and establish the hybrid origin of some cultivars. However, there is no evidence to suggest that any particular glycoside should be preferred from the viewpoint of the quality of fruit color.

The concentration of anthocyanins in blackberries is intermediate between those of red raspberries and black raspberries. For example, fruits of the cultivar Ashton Cross, a typical nonhybrid blackberry, were found to contain 65.45 mg of cyanidin per 100 g of fruit (62.56 mg of cyanidin-3-glycoside and 2.89 mg of cyanidin-3-rutinoside), compared with 22.91 mg for a typical red raspberry and 253.77 mg for a typical black raspberry. Hence, black raspberries, and not blackberries, are used as a source of this natural pigment.

Expression of Fruit Color

The color of anthocyanin pigments is influenced by any chemicals that influence the pH of the solutions that contain them. The pigments are chemical indicators that are red in acid solutions, violet, or purple in neutral solutions and blue in alkaline solutions. This may explain why the color of blackberries frequently changes from black to red when the fruit is frozen: freezing causes widespread cellular disruption, which possibly allows mixing of the cells' plasma and vacuolar contents and places the anthocyanins in a solution of lower pH than where they occur in nonfrozen fruits. However, thoroughly ripe blackberries are less prone to turn red when frozen than less ripe fruits, and a more likely explanation of the color change is that many fruits are not fully ripe when picked. Anthocyanins develop first in cells near the surface of the fruit, where they are exposed to sunlight, so that slightly immature fruits cannot be recognized immediately. The immature fruits have a lower concentration of anthocyanins, and the cell disruption following freezing allows the anthocyanins to spread within the tissues and become diluted by cytoplasmic sap: for these fruits, this pigment dilution is probably sufficient in itself to cause the color change. The problem is greater when fast freezing is used, and cultivars with purple–black fruits, such as Bedford Giant and Silvan, are more prone than cultivars with intensely black fruits.

Fruit Chemistry

Blackberries contain about 14% solids, which are approximately equally divided between soluble and insoluble forms. The size of the pyrene and the relative development of the surrounding soft tissues influence the proportion of soluble to insoluble solids. Pectins are an important constituent of the soluble fraction and average 0.8% (w/w, expressed as calcium pectate) with a range of 0.35–1.19%. Loganberries have a lower content. Protopectins form the intercellular cement and contribute towards the firmness of fruit texture, but they decrease with ripening, owing to hydrolysis. Flavor is determined by the content of sugars, acids, and volatiles, all of which vary with cultivar and growing conditions. Flavor is not perceived as a number of separate characteristics but rather as an overall impression. It is therefore not strongly correlated with any of these factors. Fruits of the western North American cultivars have a more aromatic flavor than those of the European types, and fruit grown in areas that have warm, dry summers have more sugars and are more aromatic than fruit grown in wetter and milder regions. The ratio of sugars to acids plays a major part in determining flavor.

The main sugars are the reducing sugars, glucose and fructose, and there is a smaller amount of sucrose; these form the major soluble component of the juice. The main acids are malic acid and isocitric acid with its lactone; there is only a trace of citric acid (Table 1). In boysenberries, the proportion of the different acids was found to change as ripening proceeded: the proportion of malic acid decreased, whereas the proportion of citric and isocitric acids increased. A number of trace acids also occur, especially in blackberry–raspberry hybrids.

Table 1 Typical sugar and acid contents (% w/w) of European blackberries and two blackberry–raspberry hybrids

	Sugars			*Acids*				
	Reducing	*Sucrose*	*Total*	*pH*	*Typical ripe fruit*	*Range*	*Citric*	*Malic*
Blackberry			4.30	3.00	1.50	0.68–1.84	Trace	0.82
Boysenberry	4.20	1.14	5.34	2.91	1.51		1.24	0.21
Loganberry			3.40	2.90	2.63	1.02–3.12	2.10	0.53

Green A (1971) Soft fruits. In: Hume AC (ed.) *The Biochemistry of Fruits and their Products*. London: Academic Press.

The acids have a high buffering capacity, which maintains a stable pH close to 3.0. The best measurement of the amount of acid present is therefore titratable acidity. As fruit development proceeds, this quantity increases at first and then decreases as ripening starts. It is lower at high temperatures. The relationship between titratable acidity and ripeness is so close that it is the best quantitative measure of fruit ripeness and has been used to assess the ripeness of fruits harvested by machine.

Although a large number of volatile compounds that probably contribute to the flavour of *Rubus* fruits have been isolated and identified, blackberry fruits have received relatively little attention, and no conclusions on the identity of the important components are available.

Blackberries are generally poor sources of vitamins, but provide useful amounts of ascorbic acid and vitamin E. They also provide a useful source of fiber. Mineral content is also low, with a predominance of potassium and calcium, and there are low contents of proteins and polypeptides and traces or larger amounts of a number of amino acids (Table 2).

Post-harvest Management

The commercial life of blackberries is short, partly because of the physiological activity of the fruit after harvest, and partly because of the common occurrence of infection by fruit-rotting pathogens, especially the ubiquitous *Botrytis cinerea*. This pathogen infects before fruit harvest, remains quiescent within the fruit until after harvest, and then becomes aggressive and causes gray mold disease.

The fungus can infect blackberries in various ways. It can probably infect at the flowering stage, as in raspberries, it can enter minute wounds in the fruit, and it can infect by the contact of diseased fruit. Its incidence can be reduced by sprays applied from flowering time until a short interval before harvest, and after harvest, the development of the disease can be inhibited by rapid cooling within 3 h of picking. This also prolongs the fruits' shelf life by inhibiting physiological activity. It is done by placing the containers of fruit in a cold but humid airstream in a refrigerated store designed to lower the fruits' temperature from the field level of 20–2 °C in under 4 h.

Respiration is the physiological activity mostly responsible for reducing shelf life. Its rate is closely related to temperature within the range 0–16 °C and is very high at 21 °C. These high rates of respiration are associated with an increasingly high heat of respiration. It is therefore recommended that blackberries for fresh consumption be stored at 0–0.5 °C with a relative humidity of 90–95%, to avoid loss of moisture from dehydration.

Table 2 Typical vitamin, protein, and mineral contents of European blackberries

	Content (mg per 100 g)
Vitamins	
Carotene (total)	0.10–0.59
Thiamin	0.03
Riboflavin	0.034–0.038
Nicotinic acid	0.4
Ascorbic acid	20
Total nitrogen	181
Proteins	0.56
Amino acids	2.25
Minerals	
Ash	0.5
Phosphorus	23.8
Potassium	208.0
Sodium	3.7
Calcium	63.3
Magnesium	29.5
Iron	0.85
Copper	0.18
Sulfur	9.2
Chloride	22.1

Uses

In Europe, most blackberries are marketed as fresh fruit. Although consumers associate them with the autumn, it is interesting that the introduction of varieties of the western North American group that ripen in midsummer has also proved popular: clearly, blackberries can compete with other soft fruits if they are of a high quality. A proportion of the crop is also marketed as individual quick-frozen fruit, mostly for use in the processing and catering industries for pie fillings and flavorings, etc., though this usage is largely limited to North America, where the highly flavored varieties indigenous to the west coast are particularly popular for this purpose. Many of the boysenberries produced in New Zealand are exported in this way. A few blackberries are used for canning, but the large size of their pyrene ('seed') limits the fruit's use for jam manufacture, although significant amounts of seed-free blackberry conserve are produced. The introduction of very highly flavored cultivars with small seeds may change this.

Blackberries and tayberries are used to a small extent in Europe for the production of liquors and wines, for which the tayberry is well suited because of its rich purple color and excellent flavor. The Andean blackberry of Colombia has such a rich flavour that it is used to produce a popular breakfast fruit juice, but little blackberry juice is consumed elsewhere.

BODY COMPOSITION

J R Lustig and B J G Strauss, Monash Medical Centre, Clayton, Melbourne, Australia

Introduction

The assessment of nutritional status involves an understanding of the energy stores of the body. In developing countries, lack of food supply leads to wasting, whilst in developed countries obesity and cardiovascular disease are also important causes of illness. The prevention and management of these disorders require techniques for measuring the extent of these changes in individuals and in populations.

Investigation into body composition began in the nineteenth century. Chemical analyses of fetal and adult cadavers were followed by the development of concepts of different functioning body compartments. In 1906, Adolf Magnus-Levy coined the term fat-free mass. This was further refined in 1937, by Hastings and Eichelberger, who recognized that neutral fat does not bind water, nitrogen, or electrolytes.

Current concepts consider the composition of the human body at a number of different levels. These levels are (1) atomic; (2) molecular; (3) cellular, (4) tissue/organ; and (5) whole body. In the steady state, there are clear relationships within and between each of these levels. These categories also allow human body composition to be related to other areas of biology and clinical medicine. For example, the molecular level relates to endocrinology and biochemistry, the cellular level relates to physiology, the tissue/organ level relates to diagnostic imaging and pathology, and the whole-body level relates to bedside assessment and epidemiology.

Models of Composition of the Human Body

Atomic

The human body is composed of many different elements. The International Commission on Radiation Protection compiled a list of the multitude of elements found in the body of the adult male. These data were based on the chemical analysis of human organs by several investigators, and represent the best estimate of total body content based on a wide review of the literature. Thirty-six elements have been listed as being present in the human body. Approximately 18–20 of these elements have been shown to have a physiological function. The most abundant elements are carbon, hydrogen, oxygen, nitrogen, calcium, and phosphorus. Many factors will determine the amounts of a particular element in the body. Not only the health of the individual at the time of death, but also environmental exposure to an element will contribute to individual differences, for example, exposure to compounds containing lead or mercury, or exposure to radiation fall-out leading to accumulation of caesium and strontium. Gender, age, and size are also important determinants of the amount of differential elements in the body.

Molecular

Water is the most abundant molecule in the human body in health, comprising between 55 and 60% of body weight. It is obtained from food and fluid as well as being a metabolic byproduct of chemical reactions within living cells.

The next most abundant molecule is neutral fat or triglyceride which is stored within adipose cells but is also an essential component of all cell membranes. The fat compartment varies considerably in healthy individuals, but it has a relatively constant density of $0.9\,g\,cm^{-3}$ at 37 °C, and a very small water and potassium content.

Protein, either as a structural molecule or as a component of cellular cytoplasm, is produced under genetic control assuming an adequate food supply. Total-body protein is best assessed by extrapolation from the mass of elemental nitrogen in the body since human protein consists of about 16% nitrogen by weight. This is an example of a fixed relationship between the atomic level and the molecular level of measurement.

Glycogen represents a short-term carbohydrate storage molecule but is difficult to measure by any of the currently available body composition techniques.

There are many other different kinds of molecules in the body, for example DNA and RNA, but their whole-body mass is relatively small.

Cellular

The cellular level of body composition consists of body cells (body cell mass) and their surrounding extracellular water, plus the skeleton and connective tissue. Although there is some lipid in the form of cell membranes, this compartment is largely fat-free and these components are sometimes termed the fat-free mass (FFM) or in older terminology the lean body mass (LBM). The body cell mass is responsible for almost all of the basal energy expenditure of the body, since that is where cellular metabolic and respiration processes take place. Together with the adipose tissue compartment (which consists mostly of fat), this level is often referred to as a two-compartment model, i.e., FFM and fat mass (FM). In the healthy individual, the FFM has a relatively constant composition, with a water content of 72–74%, an average density of $1.1\,g\,cm^{-3}$ at 37 °C, a potassium content of $60–70\,mmol\,kg^{-1}$ in men and $50–60\,mmol\,kg^{-1}$ in women, and a protein content of 20%.

Tissue/Organ Level

More than 80% of the mass of the body is accounted for by skeletal muscle, adipose tissue, the skeleton, and blood volume. Of course, other organs such as the liver, kidneys, heart, and brain are of major importance. Most of these tissues can be imaged and their volume estimated. Magnetic resonance imaging (MRI) or computed tomography (CT) can be used to measure skeletal muscle mass, total fat mass, and its visceral fat subcompartment, and renal and liver volumes. The quality of muscle with respect to its fat content is also able to be estimated using these techniques. Echocardiography can estimate cardiac left ventricular mass, and dual-energy X-ray absorptiometry (DEXA) can measure bone mass and bone density. Dilution techniques can measure blood volume and red cell mass.

Whole-Body-Level

Clinical examination allows the measurement of anthropometric indices, such as height, weight, limb spans and circumferences, and truncal girths, as well as skinfold thicknesses. Using underwater weighing, another whole-body index, total-body density can be assessed.

Gender and Age Differences in Body Composition

Fetal growth rate reaches a maximum during the latter stages of pregnancy. Much of this growth is due to an increase in fat-free weight, consisting of water and protein as components of cell growth. Skeletal muscle contains about the same proportion of total-body nitrogen, potassium, and water in the newborn.

Growth velocity falls during infancy and childhood, reaching a nadir at about 4 years of age. A slow increase follows, culminating in the adolescent growth spurt. During this time there are differential rates of growth of different organs.

There is a small sex difference in FFM throughout infancy and childhood, but in the adolescent period the rate of increase in growth to adult levels of the FFM in males is approximately twice as much as in females. The male adolescent increase in FFM is also of longer duration. This is a function of hormonal action which continues to be an important determinant of body composition throughout life, together with genetic, nutritional, and activity influences.

Adult men have a greater FFM and less body fat then adult women. Women have approximately two-thirds the FFM of their male counterparts, whilst also having a greater relative fat mass. In young adults, the gender difference in FFM is greater then the difference in stature and in body weight.

There is much less variability between FFM values in individuals matched for age and height, compared with the variability in body fat.

The skeletal mass continues to grow until the late third decade. In women, there is an estrogen withdrawal-related decline in bone density over the period of the menopause. (*See* **Osteoporosis**.)

In old age, there is a decline in FFM, with a shift in body water towards the extracellular phase. Bone mass declines further in both sexes. Body fat content shows more variability than FFM, but generally increases with age, and accounts for most of the variance in weight. It also becomes more centrally or truncally distributed.

Fat cell numbers appear to be synthesized and turned over throughout life.

Methods of Measuring Body Composition (Table 1)

Anthropometry

Anthropometric techniques are readily portable and inexpensive. The equipment required includes a tape measure, height stick, scales, and skinfold callipers. Various formulae have been developed which allow the rapid calculation of different aspects of body composition, including percentage fat derived from triceps skinfold (Table 2), and the following anthropometric equations:

1. Body mass index (BMI) or Quetelet's index can be readily calculated from height and weight data: BMI = (weight in kilograms)/(height in meters)^2
2. arm muscle circumference = mid upper-arm circumference − ($n \times$ triceps skinfold)
3. abdominal circumference-to-gluteal circumference ratio
4. abdominal circumference

In populations, an increased BMI has a good correlation with body fatness, as measured by other techniques, and correlates well with morbidity and mortality in the obese individual. In underweight populations, a reduced BMI correlated well with loss of FFM. In individuals, the BMI should be treated as an index of nutrition with more caution, since other factors determining it, such as fitness or the presence of edema, are of nutritional importance.

Trunk circumferences define fat distribution. An abdominal circumference to-gluteal circumference ratio greater than 0.95 (males) and greater than 0.85 (females) is consistent with abdominal obesity, as is an abdominal circumference greater than 103 cm in males and 93 cm in females. The abdominal circumference is measured at the midpoint between the costal margin and the iliac crest in the midaxillary line. The gluteal circumference is measured at the maximal gluteal circumference.

Skinfold thicknesses have been used to measure body fat. This method assumes that subcutaneous fat measurements represent total body fat. Various sites can be assessed and equations applied to derive body density and hence subcutaneous fat mass. Durnin and Womersley developed the regression equation using four skinfolds (biceps, triceps, subscapular, and suprailliac), gender, and age. Equations have been developed using multiple or single skinfold sites.

Precision of skinfold measurement depends on the skill of the operator as well as the character of the subcutaneous fat. In general, the error is 5%, although this can be higher in the very obese individual.

Measurement of the midarm muscle circumference has been used to estimate total body protein stores. The triceps skinfold thickness by itself has been used as a measure of total body subcutaneous fat (Table 3).

Table 1 Summary of body composition measurement techniques

Level	*Method of measurement*	*Component*
Atomic level	Whole-body gamma counting	Total-body potassium
	Neutron activation analysis	Total-body nitrogen
Molecular	Mass spectrometry	Total-body water
	Bioelectrical impedance	
	Derived from total-body nitrogen	Total-body protein
Cellular	Derived from total-body potassium	Body cell mass
	Bromide dilution measured by HPLC	Extracellular water
	Dual-energy X-ray absorptiometry	Bone mass/density
Organ	Magnetic resonance imaging	Skeletal muscle mass
		Visceral fat mass
Whole-body	Anthropometry	Body mass index
	Underwater densitometry	Total body fat

HPLC, high-performance liquid chromatography.

The arm muscle circumference (or arm muscle and bone circumference) can be derived from the arm circumference and the triceps skinfold, and it gives a good indication of protein stores. This correlation holds true particularly in underdeveloped countries, where populations tend to have little subcutaneous fat, and it can be a useful tool in diagnosis and monitoring of progress in the management of protein-energy malnutrition.

In the nonambulant elderly, knee height can be used to predict stature.

Bioelectrical Impedance

Water and electrolyte distribution determine electrical conductance in the living organism. Virtually all the water and electrolytes in the body is found within the FFM which represents a low-resistance pathway. Fat and bone are poor conductors. Reactance is the opposition to the flow of electrical current caused by capacitance. The cell membrane, by maintaining an osmotic gradient between extra- and intracellular compartments, serves as a capacitor. Reactance is a measure of the quantity of cell membrane capacitance and may give an indication of the quantity of the intracellular cell mass. Whereas fat and water offer resistance to an electric current, only cell membranes have reactance.

Application of a constant, low-level alternating current to the body can be used principally to determine total-body water (TBW) and, by regression analysis from other techniques, to determine FM and FFM. Both resistance and reactance are measured.

The measurement of total-body impedance (resistance and reactance) is a vector sum of resistance and reactance in the limbs and torso, with the limbs making the major contribution.

Use of this method has been validated in healthy populations as a determinant of TBW and deduced lean and fat mass. In disease states such as renal failure and dehydration, metabolic function may alter the compartmentation of TBW and bioelectrical

impedance may be less useful and less reproducible, with the literature reporting conflicting results.

The advantage of bioelectrical impedance is that it is cheap, portable, and simple to use.

Heavy-Water (D_2O) Dilution

Water is not present in stored triglyceride and occupies a relatively fixed fraction of the FFM (73%). Estimation of total-body water (TBW) can therefore be used as an index of body composition. Several isotopes have been used, but deuterium oxide (D_2O), the naturally occurring nonradioactive isotope of water, containing hydrogen protons with two neutrons – heavy water – and present as 0.01% of naturally occurring water, is now seen as the gold standard for measurement of TBW.

The technique involves the administration of a known quantity of D_2O, an equilibrium period, and a sampling period. It assumes that the D_2O has the same distribution volume as water and is exchanged by the body in a manner similar to water.

Sampling can be from either serum or saliva and, whilst the analytical equipment is only suited to a laboratory, it enables collection of specimens in the field for later analysis.

A variety of analytical techniques have been used to measure D_2O, including mass spectrometry and Fourrier transform infrared spectroscopy.

Whole-Body Densitometry

Whole-body densitometry is the gold standard for the measurement of body fat. The technique assumes that the body is composed of two distinct compartments (fat and fat-free, each of a known or assumed density) and that the relative amount of each can be determined by measurement of the whole-body density. Underwater weighing is the most widely used technique, based on Archimedes' principle which states that the volume of an object submerged in water is equal to the volume of water that the object displaced. The mass in air of the object and the mass in water of the object is then converted to a total-body density. Body fat mass can then be calculated using one of the empirical equations describing the relationship between fat content and body density.

Valuable body composition data can be obtained using underwater weighing, although there are several inherent disadvantages. Subjects must be accustomed to swimming and submersion in water and must be medically fit enough to endure such procedures. These caveats to its use exclude use of this technique in many hospitalized patients. The apparatus required is substantial in size, and thus only suited for use in large institutions. In addition, variation in bone density owing to ethnicity, gender, or aging is not taken into account in the constant used for nonfat density.

A recent development is whole-body air plethysmography which allows estimation of body volume without underwater immersion and may allow the technique of whole-body densitometry to become available on a wider scale.

In Vivo Neutron Activation Analysis

In vivo neutron activation analysis (IVNAA) provides the only *in vivo* technique currently available to determine simultaneous multielemental composition. Calcium, phosphorus, sodium, and chloride content have been measured, but in current clinical practice only nitrogen is measured (from which total-body protein is calculated).

Neutron activation involves delivery of a beam of neutrons to the subject. These neutrons are captured by the target atoms in the body, creating unstable isotopes; in the case of protein, the isotope formed is ^{15}nitrogen. The isotope reverts to a stable state by the emission of γ-rays of a characteristic energy, which can then be detected by the use of standard γ-spectrographic analysis. This method, targeting nitrogen, allows: (1) the determination of total-body nitrogen and, therefore, total-body protein, which is the principal nitrogen-containing component of the body; and (2) in combination with total-body potassium measurements, the indirect determination of skeletal muscle mass.

Whilst IVNAA is a very useful tool for measurements of body composition, its development in only a few centers has limited the wider application of this methodology. In addition, concern has been expressed over the large expense of this technique.

Total-Body Potassium

The naturally occurring radioactive isotope of potassium, ^{40}K, is present in a known, constant, very low percentage of total potassium. Since body potassium is essentially intracellular, and not present in stored fat, measurement of ^{40}K not only provides an estimate of total-body potassium, but also allows estimation of body cell mass. If total body water is known (from deuterium dilution), extracellular water can be calculated.

The technique requires a highly shielded environment in which to detect the ^{40}K in the body, as ^{40}K also occurs in most environmental structures. In addition, the requirement for appropriate γ-ray detectors and corrections for factors such as body geometry makes the technique expensive.

Dual-Energy X-Ray Absorptiometry

DEXA is a recent addition to the body composition analysis field. It was originally developed to measure regional and total-body bone mineral content, but it is also capable of measuring fat mass. It is more sensitive than dual-photon absorptiometry, which it has now replaced, and exposes the subject to substantially lower radiation doses than total-body calcium measured by neutron activation analysis.

The DEXA technique exposes the subject to low energy irradiation at two different energies. As there is differential absorption by tissues of different densities (bone, lean and fat tissues), values for bone mineral in the hip, spine, whole body, or specialized regions, as well as values for fat or soft tissues, can be derived.

It is a sensitive technique for determining bone mineral content and densities, and has become the gold standard for clinical and research work in osteoporosis.

Because the fat-free nonbone component of the limbs effectively measures limb skeletal muscle mass, of which the proportion to whole-body skeletal muscle is fairly constant, DEXA can be used to measure skeletal muscle mass.

Other Techniques

Other techniques for measuring body composition include CT scanning and MRI. These techniques have been used for accurate measurement of various body compartments. These compartments include visceral adipose tissue mass, increased amounts of which are related to risk for diabetes and vascular disease, and skeletal muscle volume. Whilst their clinical and research use is limited by expense, availability, and, in the case of CT scanning, patient exposure to ionizing radiation, much helpful information has been obtained from the research groups who have utilized such technology.

Error of the Methods

Each of the methods for measuring body composition has intrinsic and biological errors. In general, these are very comparable to the errors of biochemical methods commonly performed in hospital laboratories (Table 3).

Effect of Disease Processes on Human Body Composition

Obesity

The fat compartment – expressed as mass or percentage fat – has importance as an expression of adiposity. The association between increased adiposity and morbidity is well documented. The incidence of diabetes, hypertension, ischemic heart disease, and gallbladder disease is increased at higher levels of adiposity.

Fat distribution is being increasingly recognized as a clinically relevant risk factor. Abdominal obesity, expressed as the abdominal circumference-to-gluteal-circumference ratio, has been shown, independent of other factors, to represent an increased risk for morbidity and mortality. First described in the 1950s, this association has been verified and strengthened by intense research interest in the last decade. More recently, the abdominal circumference alone has also been shown to predict morbidity and mortality. The correlation is not just an epidemiological one: many metabolic abnormalities, such as insulin resistance, are associated with this condition.

With increasing adiposity, it is usual to find an increase in lean mass. This occurs because of the increased skeletal muscle mass required to carry the increased fat mass.

In obese people who have undergone repeated near-starvation dieting, there may be marked wasting of skeletal muscle, even in the presence of adiposity. Similarly, muscle wasting, or even marasmus, can occur in the obese person who has concomitant severe illness. For example, a chronic alcoholic with a poor quality of food intake and liver impairment may be obese (excess fat stores) and also have skeletal muscle wasting.

Undernutrition

In global terms, undernutrition remains one of the greatest determinants of health status. The most common expressions of undernutrition are commonly known as kwashiorkor and marasmus. Intermediate forms are commonly seen. In marasmus, there is a wasting of total-body protein without expansion of the TBW compartment. In kwashiorkor, there is an expansion of the extracellular component of TBW, giving rise to peripheral edema and ascites. Exactly why undernutrition results in these two different forms remains unclear.

Both forms are associated with a reduction in the capacity of the cell-mediated immune system of the body, giving rise to an increased risk of infection. Where food intake is reduced, it is likely that other nutrient deficiencies, such as iron, folate, or vitamin A deficiency, will be present and may mask the extent of the underlying body composition changes.

In developing countries, these forms of undernutrition usually arise from the combination of inadequate food resources and chronic infection. In malnutrition

caused by inadequate food intake, many studies have shown an increase in the ratio of extracellular fluid volume to TBW. Electrolyte abnormalities are common. Reduced levels of sodium, potassium, and magnesium may be found. Protein stores, as measured by IVNAA and expressed as nitrogen index, are reduced.

In developed countries, these conditions are frequently seen in conjunction with malignancy, psychiatric conditions, organ failure, and conditions in which self-feeding is difficult, e.g., stroke or arthritis. (*See* **Malnutrition**: Malnutrition in Developed Countries.)

The wasting seen in many malignancies, even when nutritional intake and absorption is apparently adequate, may be caused by cytokines such as cachectin and tumor necrosis factor.

Visceral mass may be better preserved in cancer patients, suggesting that loss of muscle accounts for the major proportion of weight loss. This may be the result of a difference in metabolic rate between malignancy and anorexia; the rate is often increased in patients with malignancy, but reduced in anorexia nervosa. (*See* **Anorexia Nervosa**.)

In anorexia nervosa, many of the body composition changes seen are similar to those found in starved subjects. Total-body nitrogen, total-body potassium, and blood volume are all reduced. Unlike primary starvation, extracellular water may be reduced by relatively greater amounts than the reduction in TBW owing to induced vomiting or purging. Interestingly, many patients with anorexia nervosa maintain normal levels of hemoglobin and serum albumin and rarely exhibit vitamin deficiencies or develop edema.

Conclusion

An understanding of body composition and its measurement provides the clinician with further scientific data on which to base a nutritional assessment. Advances in this area are now available to provide accurate measurements which previously could only be estimated. Some of these techniques are easily applicable to office general practice or field studies, whilst others require more sophisticated equipment which is only available in specialized centres. Body composition changes in health and disease help to explain the pathogenesis of illnesses which involve alteration in food intake or absorption and metabolism.

BONE

K D Cashman, University College, Cork, Ireland
F Ginty, MRC Human Nutrition Research, Cambridge, UK

Introduction

Bone is a specialized connective tissue that makes up, together with cartilage, the skeletal system. The skeleton serves three important functions: (1) mechanical; support and site of muscle attachment for locomotion; (2) protective; for vital organs and bone marrow; and (3) metabolic, as a reserve for ions, especially calcium and phosphate; for the maintenance of serum homeostasis, which is critical to life.

In bone, as in all connective tissues, the fundamental constituents are the cells and the extracellular matrix (the osteoid). Osteoid is particularly abundant in bone and is composed of collagen fibers and noncollagenous proteins. Bone is distinguished from other forms of connective tissue by the fact that it becomes extremely hard, owing to the deposition within a relatively soft organic matrix of a complex mineral substance, largely composed of calcium, phosphate, and carbonate. Bone is built up during youth to a peak reached probably in the 20s. It then diminishes again, first slowly, then more rapidly, especially in women after the menopause, and in both sexes in the elderly. The regulation of this skeletal growth and development is complex and involves genetic, mechanical, hormonal, and nutritional influences. At a cellular level, bone metabolism or remodeling is coordinated by a multiplicity of interacting local hormones, cytokines, and growth factors. Such bone-associated factors may play a role in the pathophysiology of bone disorders.

Anatomical Features of Bone

Anatomically, two types of bone can be distinguished in the skeleton: flat bones (i.e., the skull bones, scapula, mandible, and ilium) and long bones (tibia, femur, humerus, etc.). External examination of a long bone (**Figure 1**) shows the two wider extremities (the epiphyses), a more or less cylindrical tube in the middle (the diaphysis or midshaft), and a development zone between them (the metaphysis). In a growing bone, the epiphysis and the metaphysis, which originate from two independent ossification centers, are separated by a layer of cartilage, the epiphyseal cartilage or growth plate, which has an important role in the longitudinal growth of bones. The external part of bone is formed by a thick and dense layer of calcified tissue, the cortex or compact bone, which in the diaphysis encloses the medullary cavity where the hematopoietic bone marrow is housed. Cortical bone makes up about 80% of the total skeleton. Toward the metaphysis and the epiphysis, the cortex becomes progressively thinner, and the inner space is filled with a network of thin, calcified trabeculae: this is cancellous bone, also named spongy or trabecular bone. The spaces enclosed by these thin trabeculae also are filled with hematopoietic bone marrow and are in continuity with the medullary cavity of the diaphysis. Cancellous bone is also found in the vertebrae and the majority of flat bones. It makes up about 20% of the total skeleton. The relative proportions of cortical and cancellous bone differ at different sites in

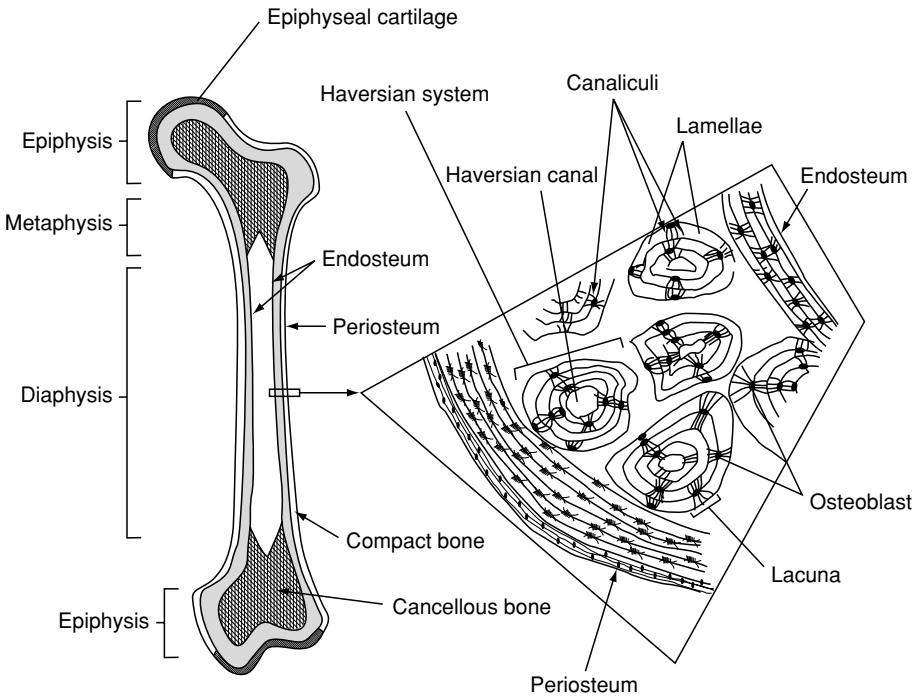

Figure 1 Schematic view of a longitudinal section through a long bone (insert; transverse section through the diaphysis).

the skeleton (e.g., cancellous bone comprises >66% of the total bone in the lumbar spine, but only 25% of the total bone in the neck of the femur). The bone surfaces at the epiphyses that take part in the joint are covered with a layer of articular cartilage that does not calcify.

There are two bone surfaces at which the bone is in contact with the soft tissues (Figure 1): an external surface (the periosteal surface) and an internal surface (the endosteal surface). The surfaces are lined with osteogenic cells organized in layers, the periosteum and the endosteum. Cortical and trabecular bone are constituted of the same cells and the same matrix elements, but there are structural and functional differences. The primary structural difference is quantitative: 80–90% of the volume of compact bone is calcified, whereas only 15–25% of the trabecular bone is calcified (the remainder is occupied by bone marrow, blood vessels, and connective tissue). The result is that 70–85% of the interface with soft tissues is at the endosteal bone surface, which leads to the functional difference: the cortical bone fulfills mainly a mechanical and protective function, while the trabecular bone has a metabolic function. Therefore, at a macroscopic level, bone can be regarded as an outer cortical sheath and an inner three-dimensional trabecular network, which together allow optimal mechanical and biochemical function with minimal weight.

Bone Matrix and Mineral

Chemically, bone is made up of one-third protein matrix and two-thirds mineral. Bone matrix is formed by type I collagen fibers (which make up 90% of the total protein of bone) and numerous noncollagenous proteins (which make up the remaining 10% of total protein of bone; Table 1). Type I collagen is a highly cross-linked fibrillar protein which, through its tridimensional structure similar to rope, gives bone its tensile strength. The functions of the noncollagenous proteins are diverse and some are still poorly understood (Table 1). The urinary excretion and the plasma or serum concentrations of some of these components of the matrix are used chemically to assess bone metabolism (Table 1). Spindle- or plate-shaped crystals of hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$ are found on and within the collagen fibers. They tend to be oriented in the same direction as the collagen fibers.

The preferential orientation of the collagen fibers alternates in adult bone from layer to layer, giving to this bone a typical lamellar structure. The lamellae can be parallel to each other if deposited along a flat surface (trabecular bone and periosteum), or concentric if deposited on a surface surrounding a channel centered on a blood vessel. In cortical bone, the tissue is mainly organized as Haversian systems which represent its basic structural building blocks (Figure 1).

Table 1 Principal noncollagenous proteins in the bone matrix

Protein type/name	*Potential function(s)*
Serum proteins	
Albumin	Transports proteins; inhibits hydroxyapatite crystal growth
α-2HS glycoprotein	Promotes endocytosis; chemoattractant for monocytic cells; mineralization inhibitor
Glycoproteins	
Alkaline phosphatase[a]	A phosphotransferase; potential Ca^{2+} carrier; hydrolyzes inhibitors of mineral deposition
Osteonectin	May mediate deposition of hydroxyapatite; binds to growth factors; may influence cell-cycle antiadhesive protein
Tetranectin	Binds to plasminogen; may regulate matrix mineralization
RGD-containing glycoproteins	
Thrombospondins (I,II,III,IV)	Cell attachment
Fibronectin	Binds to cells
Vitronectin	Cell-attachment protein
Osteopontin	Binds to cells; inhibits mineralization; may regulate proliferation; inhibits nitric oxide synthase; may regulate tissue repair
Bone sialoprotein[a]	Binds to cells; binds Ca^{2+} with high affinity; may initiate mineralization
BAG-75	Binds to Ca^{2+}; may act as a cell-attachment protein; may regulate bone resorption
γ-Carboxy glutamic acid-containing proteins	
Matrix Gla protein	May function in cartilage metabolism, may inhibit mineralization
Osteocalcin[a]	May regulate activity of osteoclasts and their precursors; may mark turning point between bone formation and resorption; regulates mineral maturation
Protein S	Protein S-deficiency may result in osteopenia
Glycosaminoglycan-containing	
Veriscan	May 'capture' space that is destined to become bone,
Decorin	Binds to collagen and may regulate fibril diameter; binds to TGF-β; inhibits cell attachment to fibronectin
Biglycan	May bind to TGF-β
Fibromodulin	Binds to collagen; may regulate fibril formation; binds to TGF-β
Osteoadherin	May mediate cell attachment
Hyaluroan	May work with versican-like molecule to capture space destined to become bone

[a]Their plasma or serum concentrations are used chemically to assess bone metabolism.
RGD, Arg-Gly-Asn; TGF-β, transforming growth factor-β.

In: Murray FJ (ed.) *Primer on the Metabolic Bone Diseases of Mineral Metabolism*, 4th edn, pp. 14–30. Philadelphia, USA: Lippincott/Williams & Wilkins.

Each Haversian system is made up of a central canal, the Haversian canal, which contains an artery, a vein, a lymphatic vessel, a nerve, and some bone cells. This is surrounded by successive rings of lamellae. Lying between the lamellae are a number of small cavities, the lacunae, which contain bone cells, or osteocytes. Fine protoplasmic processes from the osteocytes branch profusely throughout the matrix in very small canal-like structures, the canaliculi (Figure 1). These serve to interconnect the lacunae. Lamellar bone is the form present in adult cortical and cancellous bone. However, when bone is being formed very rapidly (during embryonic development and fracture healing), there is no preferential organization of the collagen fibers. They are not so tightly packed and found in somewhat randomly oriented bundles. This type of bone is called woven bone. This immature bone is usually replaced by lamellar bone, so that it is practically absent from the adult skeleton, except for some that may persist near tendon insertions and ligament attachments.

Bone Cells

Bone is a dynamic connective tissue, comprising an exquisite assembly of functionally distinct cell populations that are required to support its structural, biochemical, and mechanical integrity and its central role in mineral homeostasis. Bone tissue (both cortical and cancellous bone) is constantly turned over by two cell-mediated processes, bone modeling and bone remodeling. In the former, new bone is formed at a location different from the one where it was destroyed (resorbed). This allows bone to elongate and widen, altering the shape of the skeleton. This change takes place principally in the child and adolescent, allowing the development of a normal architecture during growth. It is also the process by which vertebrae increase in size during life. During adulthood, bone remodeling is the primary process of bone turnover, however, modeling does continue to take place at certain skeletal sites such as the periosteum. The physiological repair of fractured bone is also

part-achieved by modeling. Bone remodeling involves resorption and formation of bone and takes place at the same site (known as the bone-remodeling unit), leading to no change in bone shape, but allowing bone rejuvenation, adaptation to stress and strains, the repair of microfractures and therefore the maintenance of mechanical integrity. In addition, bone remodeling has an important role in the maintenance of calcium homeostasis. This bone cell-mediated process replaces 2–10% of the adult skeleton per annum.

The principal cells that mediate the bone-forming processes of the mammalian skeleton are the osteoblasts that synthesize the bone matrix on bone-forming surfaces; osteocytes, organized throughout the mineralized bone matrix, that supports bone structure; and the protective bone-surface lining cells. The principal cells that mediate the bone-resorbing process are the multinucleated giant cells, known as osteoclasts.

Osteoblasts

Osteoblasts are the cells responsible for the synthesis and mineralization of type I collagen. They originate from pluripotent mesenchymal stem cells which, by following a developmental pathway, they initially differentiate into preosteosblasts, and then to mature osteoblasts. A mature osteoblast which is actively synthesizing bone matrix has many distinctive ultrastructural characteristics, including a large nucleus, enlarged Golgi apparatus, and extensive endoplasmic reticulum. It also has unique biochemical characteristics, including high levels of type I collagen, alkaline phosphatase, and osteocalcin (Table 1). These cells form an epithelial-like structure at the surface of bone where they unidirectionally secrete the osteoid. In a second step, this matrix than calcifies extracellularly; the role of the osteoblast in this process is still unclear.

Osteocytes

The osteocytes are the most abundant cells in the bone matrix, with about 25 000 cells per mm^3 bone. However, despite their abundance, their function is still poorly understood. They originate from mature osteoblasts which become embedded in the bone matrix after it becomes mineralized. Osteocytes are physically different from osteoblasts and have long protoplasmic extensions which permeate the bone matrix and allow them to interconnect and communicate with other osteocytes and osteoblasts. Recent research has shown that osteocytes may act as sensors for stresses and strains within the bone matrix and thus may be important in the adaptation of bone to weight-bearing exercise.

Bone-Lining Cells

Bone-lining cells are osteoblasts which are not actively synthesizing bone and thus are known as resting osteoblasts or surface osteocytes. They occupy about 80% of the skeletal surface where they act as a kind of blood–bone barrier. It is thought that they are essential for the maintenance of blood calcium levels, perhaps by actively pumping calcium ions from the bone fluid compartment to the extracellular fluid compartment.

Osteoclasts

Osteoclasts originate from a lineage different from that of other bone cells, namely the hemopoietic system, more specifically from the granulocyte–macrophage colony-forming unit for granulocytes and macrophages (CFU-GM). Before developing into mature resorbing osteoclasts the CFU-GM cells undergo proliferation and further differentiation, after which they migrate to the bone surface where they fuse to become large multinucleated cells. These large, motile, multinucleated osteoclasts, situated either on the surface of cortical or trabecular bone, or within the cortical bone, where they are located at the tip of the remodeling units, are responsible for the resorption of bone at these sites.

Osteoclast differentiation and activation appear to be primarily regulated by the osteoblast and its precursors. Active osteoclasts resorb bone in a closed, sealed-off microenvironment. This is formed by attachment of the osteoclast to the mineralized surface by a marginal rim of contractile proteins, called clear zone or sealing zone. This attachment involves cell membrane receptors, known as integrins, which recognize specific peptide sequences in the matrix. The osteoclast surrounds a chamber lined with membrane folds (the ruffled border) and secretes self-generated protons (via a proton adenosine triphosphatase) which then dissolve bone mineral. Proteolytic enzymes, especially cathepsins (cathepsin K) and collagenases, are also synthesized by the osteoclast and are secreted through the ruffled border into the extracellular bone-resorbing compartment where they digest collagen. Recent evidence suggests that the osteoclast undergoes apoptosis (programmed cell death) after a cycle of resorption.

Integrated Activity of Bone Cells (Bone-Remodeling Unit)

The bone-remodeling process represents the coordinated actions of osteoclasts and osteoblasts on trabecular bone surface and in Haversian systems. Bone remodeling occurs in the bone-remodeling units,

which are focal and discrete packets of bone throughout the skeleton. The remodeling of each packet takes a finite period (taking up to 6 months but differing in cortical and cancellous bone, and probably longer in cancellous bone). The sequence of cellular activity – the bone-remodeling cycle – within every bone-remodeling unit is always identical: (1) activation of osteoclast precursors (possibly by a member of the tumor necrosis factor (TNF) ligand family, known as RANK-L (receptor activator for NF-κB ligand) released by the osteoblast); and then (2) osteoclastic bone resorption (over a period of 20 days), followed by: (3) osteoblastic bone formation to repair the defect (Figure 2). However, the remodeling that occurs in each packet is geographically and chronologically separated from other packets of remodeling. It is believed that this can occur because the activation of the sequence of cellular events responsible for remodeling is locally controlled, possibly by local mechanisms in the bone microenvironment. In a healthy adult, it has been estimated that 12 new bone-remodeling units are started every minute in trabecular bone and 3 per minute for cortical bone.

Coupling of Bone Formation and Bone Resorption

In most circumstances, the coupling of bone formation to previous bone resorption occurs faithfully. Packets of bone removed during resorption are replaced during formation. The cellular and humoral mechanisms responsible for mediating this coupling process (or disrupting it, as in some bone diseases) are still not clear but may involve an osteoblast-stimulating factor (such as insulin-like growth factor (IGF)-I, IGF-II, or transforming growth factor-β).

Remodeling Process: Aging and Disease

With aging there is a bone-remodeling imbalance, with the rate of resorption exceeding that of formation. Bone formation rates have been shown to be dramatically decreased with age and the percentage of bone surface with no activity increases and osteoblasts disappear. In cortical bone, the 'physiologic' imbalance between the two processes leads to an increased porosity which, in turn, is followed by mobilization of bone mineral and a decrease in bone mass. In trabecular bone there are normal or deeper resorption cavities that are incompletely filled with new bone by the osteoblasts, leading to a thinning of the trabeculae, and, in some cases, a perforation of the trabeculae. This will remove the structural basis for the following formative period and the final result will be a hole in the trabecular network, a loss of bone and bone mineral, and a reduced strength of the remaining bone. Therefore, an imbalance of the remodeling process reduces bone mass and causes detrimental architectural changes and increases fracture risk.

Therefore, the balance between bone formation and bone resorption, as effected through cellular

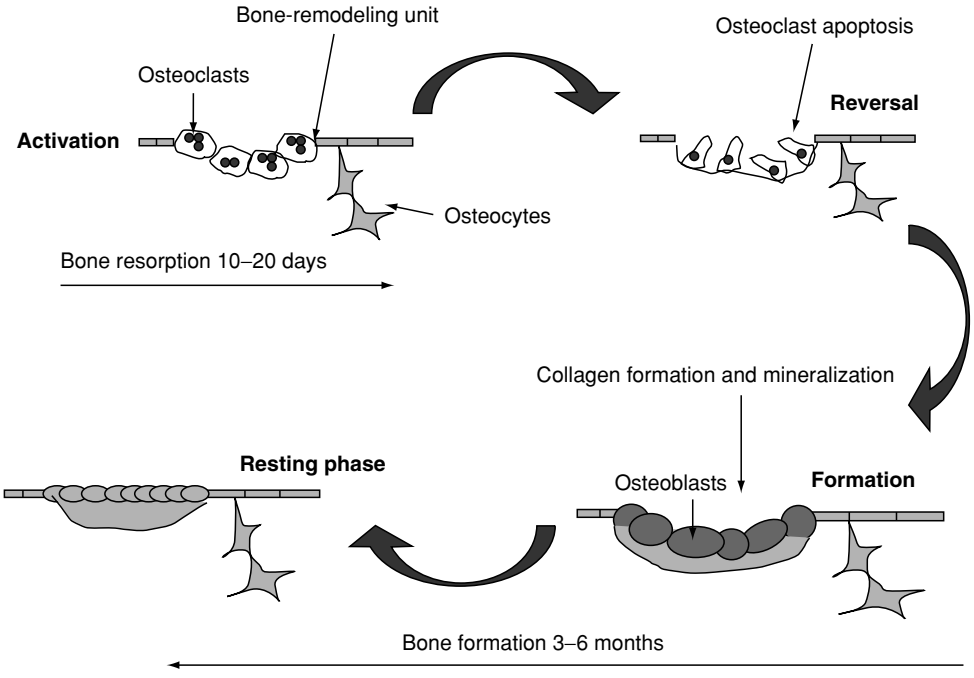

Figure 2 Bone-remodeling cycle.

events, is an important determinant of bone mass of an individual at any stage of the life cycle. In addition, all of the diseases of bone are superimposed on this normal cellular-remodeling sequence. In diseases such as primary hyperparathyroidism, hyperthyroidism, and Paget's disease, in which osteoclasts are activated, there is a compensatory and relatively balanced increase in the formation of new bone. In elderly patients with osteoporosis, there is a decrease in mean wall thickness, presumably reflecting the inability of osteoblasts to repair adequately the resorptive defects made during normal osteoclastic resorption.

Regulation of Bone Cell Activity

Bone remodeling is regulated by a variety of systemic hormones and by local regulatory factors (Table 2) that affect cells of the osteoclast and osteoblast lineage and exert their effects on: (1) the replication of undifferentiated cell; (2) the recruitment of cells; and (3) the differentiated function of cells.

Table 2 Systemic hormonal and local regulation of bone remodeling

Type of regulatory factor/name	*Effect(s)*
Systemic hormones	
Parathyroid hormone (PTH)	Stimulates differentiation of committed progenitors to form mature osteoclasts; activates preformed osteoclasts to resorb bone
Parathyroid hormone-related protein (PTHrP)	Effects identical to those of PTH on osteoclasts
1,25 $(OH)_2D_3$	Potent stimulator of osteoclastic bone resorption
Calcitonin (CT)	Potent inhibitor of osteoclastic bone resorption (transient effect); causes cytoplasmic contraction of the osteoclast cell membrane; causes dissolution of mature osteoclasts into mononuclear cells; it can also inhibit osteoclast formation, inhibiting both proliferation of the progenitors and differentiation of the committed precursors
Insulin	Stimulates bone matrix synthesis and cartilage formation; necessary for normal bone mineralization
Growth hormone (GH)	May regulate bone formation
Glucocorticoids	May regulate bone resorption
Sex steroids	Estrogen deficiency is associated with increased osteoclastic bone resorption (either via a direct or indirect mechanism)
Thyroid hormones	May stimulate osteoclastic bone resorption
Local factors	
Interleukin-1 (α, β)	Potent stimulators of osteoclasts; stimulates the proliferation of the progenitors and differentiation of committed precursors into mature cells; activation of mature multinucleated osteoclasts
Tumor necrosis factor (TNF)	Stimulates the proliferation of osteoclast progenitors, causes fusion of committed precursors to form multinucleated cells, and activates multinucleated cells to resorb bone.
Colony-stimulating factor 1	Mediates osteoclast formation
Interleukin-18	Inhibitor of osteoclast formation
Osteoclastogenesis-inducing differentiation factor (ODIF)	Mediator of osteoclastic bone resorption
Interleukin-6	Weak stimulator of osteoclast formation
Interferon-γ	Inhibitor of osteoclastic bone resorption; inhibits differentiation of committed precursors to mature cells
Transforming growth factor-β	Inhibits osteoclast formation by inhibiting both the proliferation and differentiation of osteoclast precursors; directly inhibits the activity of mature osteoclasts; stimulates osteoblast proliferation and synthesis of differentiated proteins; increased mineralized bone formation
Insulin-like growth factors (I, II)	May enhance bone collagen and matrix synthesis and stimulate the replication of cells of the osteoblast lineage
Fibroblast growth factors (1, 2)	Increases bone cell population capable of synthesizing bone collagen
Platelet-derived growth factors	Stimulates bone collagen synthesis
Retinoids	Stimulatory effect on osteoclasts
Prostaglandins	Complex and multiple effects on osteoclasts; prostaglandins of the E series may stimulate osteoclastic bone resorption; may act as mediators of pro-bone-resorptive growth factors
Leukotrienes	Linked to osteoclastic bone resorption

Adapted from Lian JB, Stein GS, Canalis E, Robey PG, and Boskey AL (1999) Bone formation: osteoblast lineage cells, growth factors, matrix proteins, and the mineralization process. In: Murray FJ (ed.) *Primer on the Metabolic Bone Diseases of Mineral Metabolism*, 4th edn, pp. 14–30. Philadelphia, USA: Lippincott/Williams & Wilkins.

Systemic regulation of bone turnover is controlled by numerous hormones, including the mineral homeostasis hormones (parathyroid hormone, calcitonin and 1,25-dihydroxvitamin D; (*See* **Calcium**: Physiology)), estrogen, growth hormone, thyroid hormone, and others (Table 2). The mineral homeostasis hormones ensure that the skeleton fulfills its metabolic function as a source of ions, by regulating osteoblast and osteoclast maturation and activity and thus ensuring that ions are released or retained by the skeleton as necessary. Circulating hormones may act on skeletal cells either directly or indirectly, modulating the synthesis, activation, receptor-binding, and binding proteins of a local growth factor, which in turn stimulates or inhibits bone formation and bone resorption. It is likely that hormones are important in the targeting of growth factors to tissue expressing specific hormonal receptors.

Growth factors may play a critical role in the coupling of bone formation to bone resorption, and possibly in the pathophysiology of bone disorders. The local factors are synthesized by skeletal cells and include growth factors, cytokines, and prostaglandins (Table 2). Growth factors are polypeptides that regulate the replication and differentiated function of cells. Growth factors have effects on cells of the same class (autocrine factors) or on cells of another class within the tissue (paracrine factors).

Bone Development and Growth

Bone is often described as developing by two different methods: intramembranous (in membrane) and endochrondral (in cartilage) ossification. The fundamental process is, however, similar. The osteoid is laid down by osteoblasts, and this then becomes calcified. The flat bones (such as the bones of the calvarium of the skull) are formed by intramembranous ossification, whereas the basal bones of the skull and the majority of bones of the skeleton, including the long bones, are formed by endochrondral ossification. The main difference between the processes is the presence of a cartilaginous phase in the latter.

Endochondral Ossification (Development of Long Bones)

Formation of a cartilage model Long bones begin as cartilaginous regions in the early embryo. Mesenchymal cells proliferate and differentiate into prochondroblasts and then into chrondroblasts. These cells secrete the cartilaginous matrix. Like the osteoblasts, the chrondoblasts become progressively embedded within their own matrix, where they lie within the lacunae; they are then called chrondocytes. Unlike the osteocytes, they continue to proliferate for some time, this being allowed in part by the gel-like consistency of cartilage. At the periphery of this cartilage (the perichrondium), the mesenchymal cells continue to proliferate and differentiate. They lay down a layer of osteoid, which immediately calcifies, so becoming a collar of periosteal bone directly in contact with the cartilaginous model. This is called appositional growth. Later on, the chrondocytes enlarge progressively, become hypertrophic, and undergo apoptosis.

Longitudinal growth, growth in diameter, and shape modification The embryonic cartilage is avascular. During its early development, a ring of woven bone is formed by intramembranous ossification in the future midshaft area under the perichondrium (which is then the periosteum). Just after the calcification of this woven bone, blood vessels (preceded by osteoclasts) penetrate the cartilage, bringing the blood supply that will form the hematopoietic bone marrow.

The growth plate in a growing long bone has a proliferative zone at the top, where chondroblasts divide actively, while their more mature descendants synthesize the matrix and enlarge, thereby producing longitudinal growth. Ultimately, the chondrocytes hypertrophy and calcify their matrix. Osteoclasts present in the marrow cavity invade this calcified cartilage, destroying the horizontal septa separating the chondrocytes. After osteoclastic resorption, osteoblasts differentiate and form a layer of woven bone on top of the cartilaginous remnants of the septa. This is the first remodeling sequence, and cartilage is replaced by woven bone. Still lower in the growth plate, this woven bone is subjected to further remodeling, in which the woven bone and the cartilaginous remnants are replaced with lamellar bone, representative of mature trabecular bone. Complete calcification of the growth plate at the end of puberty marks the end of longitudinal growth.

Growth in diameter of the shaft is the result of a deposition of new intramembranous bone beneath the periosteum that will continue throughout life. The midshaft is narrower than the metaphysis, and the growth of a long bone progressively destroys the lower part of the metaphysis and transforms it into a diaphysis, accomplished by continuous resorption by osteoclasts beneath the periosteum.

Intramembranous Ossification (Development of Flat Bones)

In intramembranous ossification, a group of mesenchymal cells within a highly vascularized area of the embryonic connective tissue proliferates and differentiates directly into preosteoblasts and then into osteoblasts. These cells synthesize and secrete osteoid which is calcified to become woven bone.

Blood vessels incorporated between the woven bone trabeculae will form the future hematopoietic bone marrow. Later, the woven bone is remodeled and is progressively replaced by mature lamellar bone. In early human fetal life, resorption and apposition begin to take place so that the cancellous bone occupies the center of the mass while a layer of cortical bone is formed on each surface by the continuous addition of new sheets of bone by active osteoblasts. Osteoclasts resorb bone from the inner surface to maintain proportional thickness and shape.

Age-Related Changes in Bone Mass

Bone mass in later life depends on the peak bone mass achieved during growth and the rate of subsequent age-related bone loss. Therefore, development of maximal bone mass during growth and reduction of loss of bone later in life are the two main strategies of preventing osteoporosis. Several factors are thought to influence bone mass. These can be broadly grouped into factors that cannot be modified, such as gender, age, body (frame) size, genetics, and ethnicity, and those factors that can be modified, such as hormonal status (especially sex and calciotropic hormone status), lifestyle factors, including physical activity levels, smoking and alcohol consumption patterns, and diet. The interaction of these genetic, hormonal, environmental, and nutritional factors influences both the development of bone to peak bone mass at maturity and its subsequent loss.

After the initial formation and development of bone, and during childhood and adolescence, there is a rapid linear and appositional skeletal growth, the former reaching a maximum between ages 15 and 20 years. Bone mass then continues to increase by appositional growth and the peak bone mass is probably attained during the third decade of life (Figure 3), although the exact timing is not certain and may vary between different regions of the skeleton. Peak bone mass and the subsequent rate of loss of bone are important determinants of risk of osteoporosis in later life. The regulation of peak bone mass is not fully understood but a number of factors have been identified. Of these, the most important are genetic influences; other determinants, which are potentially modifiable, include physical activity, nutritional factors, and hormonal status:

- Genetic factors – studies in twins show that 60–80% of peak bone mass is genetically determined; there is also some evidence that some aspects of bone architecture and geometry relevant to bone strength are inherited. The heritability of peak bone mass is believed to be polygenic (i.e., influenced by numerous genes) and there is currently a lot of interest in identifying these genes.
- Nutritional factors adequate intakes and status of a number of dietary components and nutrients are thought to be important in achieving optimal peak bone mass. These include calcium, phosphorus, magnesium, while high salt intakes may be detrimental.
- Physical activity – physical activity has important effects on bone growth and architecture during childhood and adolescence.
- Hormonal status – primary hypogonadism in either sex is associated with low bone mass, while secondary amenorrhea in women (due to anorexia nervosa, excessive exercise, or disease) results in low peak bone mass.

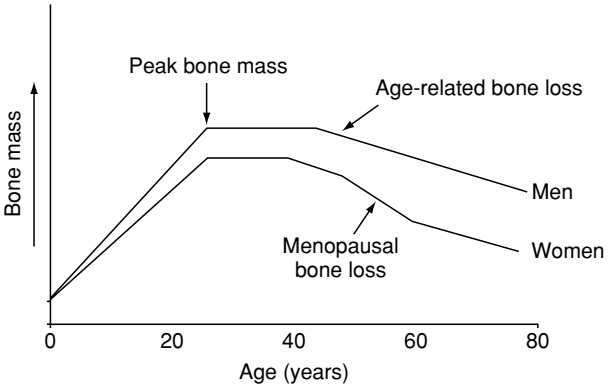

Figure 3 Age-related changes in bone mass in men and women.

Age-Related Bone Loss

After peak bone mass has been attained, there is a period of consolidation in which the transverse diameter of the long bones and vertebrae continues to increase by subperiosteal appositional growth. The age at which bone loss commences is uncertain but is believed to be around the age of 40 years in both men and women. Bone loss then continues throughout life, affecting both cortical and cancellous bone throughout the skeleton. In men, bone loss averages between 0.5 and 1.0% per annum. In women, there is an acceleration in the rate of bone loss around the time of the menopause to about 2%, although rates of bone loss vary widely, from less than 1% to 6% per annum. In the early postmenopausal years, bone loss from the spine exceeds that at other sites and overall it is estimated that, in women, approximately 35% and 50% of cortical and cancellous bone respectively are lost from the skeleton over the course of a lifetime.

The factors that contribute to age-related bone loss are incompletely understood. Potential contributory factors include:

- Hormonal factors – estrogen deficiency is an important determinant of menopausal bone loss. Both osteoclasts and osteoblasts possess estrogen receptors and thus may be influenced by estrogens. Declining production of sex hormones may also contribute to age-related bone loss in men, although this is less well documented than in women. Changes in the growth hormone–insulin-like growth factor I axis may contribute to age-related bone loss. The age-associated increase in parathyroid hormone is also thought to be a contributory factor.
- Nutritional factors have also been implicated; calcium deficiency due to an inadequate intake, reduced intestinal absorption, or increased renal deficiency may contribute to age-related bone loss. Vitamin D deficiency is common in many elderly populations and results in secondary hyperparathyroidism and increased bone turnover. Malnutrition, also common in some older individuals, may lead to acceleration of bone resorption, possibly as a result of reduced protein intake. Vitamin K-deficiency may contribute to an increased risk of osteoporotic fractures, although the pathogenesis of this condition has not been precisely delineated.
- Heritable factors – age-related bone loss can be very dramatic in certain individuals, and this decline cannot be attributed solely to hormonal or nutritional factors. This has led some researchers to hypothesize that genetic programming, when triggered, may lead to bone loss. However, the identity of genes involved in this process remains elusive.
- Environmental factors – decreasing physical activity with age is another likely contributor to age-related osteopenia, in both men and women. Similarly, smoking, alcohol, and some medications (such as glucocorticoids and anticonvulsants) may contribute to an excessive rate of bone loss in some elderly individuals.

Age-Related Fracture and Osteoporosis

Advancing age is a relatively strong risk factor for an osteoporotic fracture. Osteoporosis is defined as a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture. Fragility fractures are the hallmark of osteoporosis and are particularly common in the spine, hip, and distal forearm (Colles fracture), although they can occur throughout the skeleton. These fractures constitute a major public health problem. Osteoporosis can be classified into type I (or postmenopausal osteoporosis) and type II (or senile osteoporosis). A more indepth discussion on the etiology, treatment, and prevention of osteoporosis as well as its consequences for quality of life are discussed elsewhere in this encyclopedia. (*See* **Osteoporosis**.)

Other bone disease states result from nutritional deficiency, e.g., rickets/osteomalacia (*See* **Cholecalciferol**: Properties and Determination; Physiology), or from genetic defects, e.g., osteopetrosis (characterized by defective osteoclast function and a consequent failure of bone remodeling) or osteogenesis imperfecta (characterized by an osteopenia associated with recurrent fracture and skeletal deformity stemming from a qualitative or quantitative abnormality of type I collagen).

BORON

C D Hunt, Grand Forks Human Nutrition Research Center, Grand Forks, ND, USA

Background

Boron is a light, nonmetallic element known to be essential for all vascular plants and some lower plants and prokaryotes. The discovery of two classes of naturally occurring organoboron compounds has provided some insight into the biomolecular role of boron. Recent research findings indicate that boron is important for the embryological development of lower vertebrates. In human and subhuman animals, boron modifies, and possibly regulates, energy substrate and mineral metabolism, and immune function.

Boron Chemistry

Boron Structure and Bonding

Boron is the fifth element in the periodic table and the only nonmetal in Group III. Although boron has five electrons and a ground-state electronic configuration of $1s^2\ 2s^2\ 2p^1$, it is always trivalent; simple electron loss to form a cation does not occur in boron chemistry. Boron has a small atomic size; the first ionization potential of boron ($800.5\,kJ\,mol^{-1}$) is rather high, and the next two are much higher (2426.5 and $3658.7\,kJ\,mol^{-1}$). It requires less energy to promote one 2s electron and mix the remaining 2s electron with the resultant $2p_x$ and $2p_y$ electrons to form a hybridized valence state of the sp^2 type. The three resulting B–X σ-bonding electrons can be regarded as occupying three equivalent sp^2 hybrid orbitals. Thus, the characteristics of the boron atom dictate covalent rather than ionic bonding. BX_3 compounds have a trigonal–near planar configuration.

In geological systems, boron neither occurs free nor binds directly to any element other than oxygen except for trivial exceptions, e.g., $NaBF_4$ (ferrucite) and $(K,Cs)BF_4$ (avogadrite). Only organoboron compounds are apparently important in biological systems during normal physiological conditions, and they are defined for this discussion as those organic compounds that contain B–O bonds, i.e., the orthoborates $(B(OR)_3$, $(RO)B(OR')_2$ and $(RO)B(OR')(OR'')$, and orthoborates of polyhydric alcohols. Organoboron compounds include B–N compounds, because B–N is isoelectronic with C–C.

Boron Speciation

Boric acid is an exclusively monobasic acid and is not a proton donor, but rather accepts a hydroxyl ion (a Lewis acid) to form the tetrahedral anion $B(OH)_4^-$ (eqn (1)):

$$B(OH)_3 + 2H_2O \leftrightarrow H_3O^+ + B(OH)_4^- \qquad pK_a = 9.25(25°C). \qquad (1)$$

At typical physiological boron concentrations (6.0×10^{-7} – $\sim 9.0 \times 10^{-3}\,mol\,l^{-1}$) in plants, animals (Table 1), or humans, inorganic boron is essentially present only as the mononuclear species boric acid $B(OH)_3$ and as borate $B(OH)_4^-$. Within the normal pH range of the gut and kidney, $B(OH)_3$ would prevail as the dominant species (pH 1: ~100% $B(OH)_3$; pH 9.3: 50%; pH 11: ~0%). Undissociated (and uncharged) boric acid is very soluble in water ($B[OH]_3$-saturate solution at $20\,°C = 0.75\,mol\,l^{-1}$) and has a high lipid solubility of the same order as urea. Polyborate species can form near neutral physiological conditions (pH ~7.4) when borate concentrations exceed $\sim 0.025\,mol\,l^{-1}$, an unusually high boron concentration in biological systems, but still lower than that found in the snap bean leaf ($0.1\,mol\,l^{-1}$).

The speciation of boron in foods has not been determined, but if plant and animal boron absorption mechanisms are analogous, the organic forms of boron *per se* are probably unavailable. However, the strong association between boron and polyhydroxyl ligands (described below) is easily and rapidly reversed by dialysis, change in pH, heat, or the excess addition of another low-molecular-weight polyhydroxyl ligand. Thus, within the intestinal tract, most ingested boron is probably converted to $B(OH)_3$, the normal end product of hydrolysis of most boron compounds.

Boron Isotopes

The study of boron kinetics in biological systems is hampered because the radioisotopes ^8B, ^{12}B, and ^{13}B all have half-lives of less than 1 s. However, two stable boron isotopes, ^{10}B and ^{11}B, are distributed unequally in nature (19.8 and 80.2%, respectively). This phenomenon has been successfully exploited to determine boron translocation in plant species and boron kinetics in animal models of human physiology. The ^{10}boron has a very large cross-section for thermal-neutron capture, and this property has been

Table 1 Concentration of boron in selected foods (wet-weight)[a]

Food	*Micrograms per 100 g*
Animal products	
Milk, low fat, 2% milkfat	27.0 ± 3.0[b]
Chicken, fryer, light meat, cooked with meat and skin, flour, with added fat	12.0 ± 2.0
Beef, ground, cooked, pan-fried	9.0 ± 2.0
Butter, with salt	4.0 ± 0.0
Cereal grain products	
Cornbread, homemade-type	56.0 ± 4.0
Cereal, ready-to-eat, wheat, shredded	34.0 ± 2.0
Bread, white, enriched	17.0 ± 1.0
Rice, white, long-grain, instant, enriched	9.0 ± 0.0
Macaroni, cooked, enriched, with salt	8.0 ± 1.0
Sweeteners/catsup	
Jelly, grape	145.0 ± 8.0
Catsup	100.0 ± 14.0
Sugar, white, granulated	10.0 ± 1.0
Infant foods	
Fruit, prunes with tapioca	359.0 ± 8.0
Carrots and beef, strained	132.0 ± 9.0
Vegetable, corn, creamed, strained	19.0 ± 2.0
Infant formula, Gerber, with iron	12.0 ± 0.0
Fruits and fruit beverages	
Avocado, raw	14 300.0 ± 42.0
Grape juice, unsweetened	342.0 ± 2.0
Cherries, sweet, raw	228.0 ± 3.0
Pears, raw	227.0 ± 11.0
Apple, juice, bottled, unsweetened	190.0 ± 3.0
Peach, raw	171.0 ± 7.0
Orange juice, unsweetened, reconstituted from concentrate	81.0 ± 1.0
Pineapple juice, canned	78.0 ± 1.0
Vegetables	
Snacks, potato chips, plain, salted	228.0 ± 6.0
Squash, winter, cooked, baked	161.0 ± 10.0
Carrots, raw	130.0 ± 7.0
Radishes, raw	66.0 ± 11.0
Potato, boiled, cooked without skin	48.0 ± 2.0
Beverages	
Alcoholic beverage, wine, table, white	364.0 ± 3.0
Coffee, instant, regular, prepared with water	24.0 ± 0.0
Carbonated beverage, cola, contains caffeine	10.0 ± 0.0
Tea, leaf, brewed in a porous bag	6.0 ± 0.0
Water, spring, bottled	2.0 ± 0.0

[a]Data from Meacham and Hunt (1998).
[b]Mean ± standard deviation ($n = 3$) of values from a single package of a single lot of a single brand.

used in neutron capture therapy (NCT) for inoperable brain tumors. During NCT, a boronated compound, preferentially bound to the tumor cells, is irradiated with thermal neutrons. Following neutron capture, the energy is released as a γ ray, α particle and lithium nucleus, the latter two traveling 9 and 5 μm, respectively. Thus, heavily ionizing radiation is deposited in single targeted cells with minimal collateral damage.

Boron Biochemistry

Boron Esters

Boroester formation Boroesters result from reactions between boron oxo compounds and certain mono or polyhydroxy compounds to form specific organoboron complexes. Boroesters probably represent the most biologically relevant boron species because of the vast number of biomolecules that contain one or more hydroxy groups with suitable positions. Boric acid reacts with suitable dihydroxy compounds to form the corresponding boric acid monoesters ('partial' esterification) (e.g., Figure 1) that retain the trigonal–planar configuration and no charge.

A borate monoester ('partial' esterification; monocyclic) (Figure 2) with a tetrahedral configuration and a negative charge is created when borate forms a complex with a suitable dihydroxy compound. A compound of similar configuration and charge is also formed when a boric acid monoester forms a complex with an available hydroxyl group. These two types of boromonoesters can react with another dihydroxy compound to give a corresponding spirocyclic borodiester ('complete' esterification) that is a chelate complex with a tetrahedral configuration and negative charge (Figure 3). Boric acid and boric acid-like structures, instead of borate, are most likely the reactive species with biological ligands, because it is probably easier for a diol to substitute for a relatively loosely bound water molecule associated with boric acid or a boric acid-like structure than it is for the diol to substitute for a hydroxyl ion in borate or a borate-like structure.

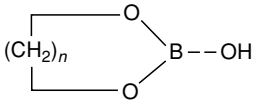

Figure 1 Structure I.

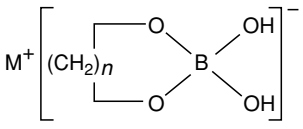

Figure 2 Structure II.

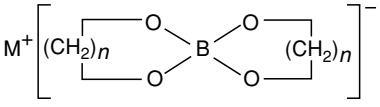

Figure 3 Structure III.

Ligand structure Ligands that contain adjacent and *cis* hydroxyl groups are those most likely to react with boron oxo compounds to give a boroester, and the reactivity of boric acid with the ligand generally increases as the number of these *cisoid* groups increases. The relevant *cis*-diol conformations for boron complexation are present in several biologically important sugars, their derivatives (sugar alcohols, -onic, and -uronic acids), and some polymers. Common examples include mannitol, ribose, erythrose, and glycerol. Sugars often form intramolecular hemiacetals in water where those with five-membered rings are called furanoses, and those with six-membered rings are called pyranoses. Compounds in a configuration where there are *cis*-diols on a furanoid ring (e.g., ribose, apiose, and erythritan) are rare in nature and form stronger complexes with boron than do compounds configured to have *cis*-diols predominately on a pyranoid ring (e.g., the pyranoid form of α-D-glucose). Glucose is virtually all in the pyranose form. The pyridine (e.g., NAD^+ or NADP) and flavin (e.g., FAD) nucleotides have received special attention, because they contain a ribose moiety with a *cisoid* diol conformation.

***p*K$_a$** Because borate complexes often have a much lower pK_a (e.g., boron-mannitol, 5.2) than free boric acid (9.25), the pK_a of many boron complexes is considerably below the physiological pH. This phenomenon has functional consequences and becomes the mechanism of action for some enzymatic activities. For example, boric acid is a competitive inhibitor of *Streptomyces griseus* Protease 3, and there is decreased affinity of the protein for boric acid below pH 7.0. This is directly attributable to the stability of the enzyme inhibitor complex, which is dependent on an ionizing group in the protein with an apparent pK_a of 6.6. This finding indicates that boric acid is an inhibitor of the enzyme at physiological pH by shifting the pK_a.

Boron–Nitrogen Compounds

The known ability of boron to form covalent bonds with the nitrogen atom of amine groups and the observation that boron binds near the coordinating iron site of hemerythrin (the nonheme iron-containing, oxygen transport protein of the sipunculid worm, *Golfingia gouldii*) suggest that a large array of biocompounds other than polyols can react with boron to form complexes. For example, there is experimental evidence to suggest that the mechanism for inhibition of a sub-subclass of enzymes (the serine proteases) by boron involves the formation of a covalent bond between boron and a specific nitrogen at the active site of these enzymes (Figure 4).

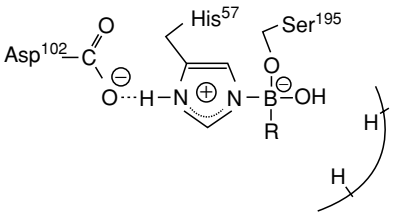

Figure 4 Structure IV.

Boron Occurrence in the Environment

Anthropogenic Sources

Each year, coal combustion is estimated to release between 28 000 and 330 000 tonnes of boron to the atmosphere and between 24 000 and 287 000 tonnes of boron go to landfill/soil. Also, approximately 300 000 tonnes of boron are recovered from extracted and refined deposits destined for five main product groups: insulation fiberglass/textile fiberglass/borosilicate glass (39%), ceramics (13%), detergents (19%), fertilizers (5%), cellulose insulation (2%), and other products (23%) including nuclear shielding, leather tanning, and catalysis. Boron, in the form of borax, has been used since Egyptian and Roman times for the preparation of hard (borosilicate) glasses. Boron leaches readily from most glassware, especially under conditions of alkalinity.

Soil

The largest single natural deposit of boron is located at Boron, California, an area of former volcanic activity and associated with the waters of former hot springs. Within geological boron deposits, boron is usually present as a borate mineral such as borax, $Na_2B_4O_5(OH)_4{\cdot}8H_2O$. A 1956 survey of US soils indicated an average total boron content of 30 μg g^{-1}. Less than 5% of the total soil boron is available for crop uptake and depends on release from soil minerals, mineralization from decomposed organic matter, artificial addition to soils by irrigation or fertilization, and subsequently distribution between the solid and liquid phases of the soil. Boron is easily leached out of soils by rainwater. Thus, plant boron deficiency is of concern in humid regions with light-textured, acid soils.

Water

Weathering of clay-rich sedimentary rock is the major source of total boron mobilized into the aquatic environment, although sewage effluent can be an important source of boron, especially in areas where boron compounds are major constituents of detergent products. Undissociated boric acid is the

predominant species of boron in most natural freshwater systems. The concentration of boron in surface water may vary substantially between geographic locations and water sources (values in $\mu g\,ml^{-1}$; in parentheses, $\mu mol\,ml^{-1}$): UK, 0.046–0.822 (0.004–0.077); Italy, 0.400–1.00 (0.037–0.093); the USA, 0.001–5.0 (0.00009–0.467). The concentration of boron in seawater is $4.5\,\mu g\,ml^{-1}$ ($0.42\,\mu mol\,ml^{-1}$), whereas the median boron concentration in USA drinking water is $0.031\,\mu g\,ml^{-1}$. Thus, the usual boron intake through drinking water is usually not high. For example, an adult consuming 2 l of water with the median concentration and ingesting 1.5 mg of boron in the diet would be exposed to < 1.6 mg or < 10% of the acceptable reference dose (18 mg of boron per day).

Foods

Boron is unequally distributed within Angiospermae, the class of plants most often utilized in human and animal diets. Most species within the subclass Dicotyledoneae, which includes fruits, vegetables, tubers and legumes, have much higher concentrations of boron than do species in the subclass Monocotyledoneae, especially gramineaceous species (the grasses), i.e., rice, corn, rice, and wheat (Table 1). Foods cooked in boiling water are quickly leached of boron content. Also, $B(OH)_3$ is volatile in steam. Boron loss could conceivably be further enhanced during pressure cooking with chlorinated or fluorinated water; boron–halogen compounds are extremely volatile at high temperatures.

Estimated daily intakes of boron vary with age and sex. Infants, toddlers, adolescent females and males, adult females and males, and senior females and males in the USA consume 0.545, 0.534, 0.590, 0.848, 0.698, 0.907, 0.731, and 0.863 mg of boron per day, respectively. The concentration of elemental boron in animal muscle and milk is relatively low. Because whole milk (0.29 µg of boron per gram) is consumed in such large quantities, it is the typical primary source of boron for infants, toddlers, and adolescents. Coffee is the primary source of boron for adult females and males, and senior females and males in the USA. There is a close relation between boron and vitamin intakes; a diet low in boron is typically low in vitamins, especially ascorbic acid.

Boron Essentiality and Function

The high affinity of boric acid for adjacent and *cis*-hydroxyl groups present on biomolecules may have exerted evolutionary pressure to select for carbohydrate energy sources with low percentages of the furanose forms described above. Conversely, there may have been selection for two natural sugars, apiose and ribose, because their physiological derivatives have a strongly borate-complexing furanose configuration and they serve as components of important structural or enzyme-related biomolecules, as described below.

Prokaryotes

Boron essentiality for the heterocystous Cyanobacteria, predominant organisms during the Middle Pre-Cambrian Period, indicates that boron was an essential element during the early evolution of life. Boromycin, an antibiotic from *Streptomyces antibioticus*, was the first well-defined boron-containing biological organic compound. Antibiotics with a similar structure are excreted by a marine isolate belonging to *Streptomyces griseus* (aplasmomycin) and from the myxobacterium *Sorangium cellulosum* (tartrolon B; Figure 5). These antibiotics are ionophoric macrolides and have four inward directed oxygen atoms (two *cis*-hydroxyl groups) that provide an ideal geometry for accommodation of the boron atom and thus formation of a stable borodiester.

Plants

Whether certain lower plants lack a boron requirement is being revisited. Findings in 1999 that boron stimulated growth in the fungus *Saccharomyces cerevisiae* (a yeast) supplanted findings in 1968 to the contrary. There is a demonstrated boron requirement for *Penicillium italicum* but apparently not for the fungi *Neurospora crassa* or *Aspergillus niger*. Boron stimulated penicillin production, but not growth, in *Penicillium chrysogenum*, and boron enhanced growth of *Chlorella vulgaris*, but no apparent boron requirement has been demonstrated among the many species of chlorophyta tested. At least 16 species of

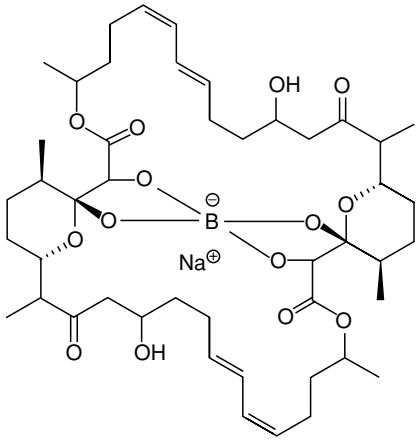

Figure 5 Structure V.

marine and eight species of freshwater diatoms and some species of marine algal flagellates have an absolute boron requirement.

All vascular plants have acquired a unique requirement for boron. However, the primary role and mode of action of boron remain controversial. Boron seems to be involved in such diverse cellular processes as sugar transport, cell-wall synthesis, lignification, cell-wall structure, carbohydrate metabolism, RNA metabolism, respiration, indole acetic acid metabolism, phenol metabolism, and membranes. Rhamnogalacturonan-II (RG-II) is a small, structurally complex polysaccharide of the pectic fraction of primary plant cell walls. It is present in at least 24 plant species and represents an extreme example of the evolutionary conservation of wall polysaccharide structure. RG-IIs contain the unusual monosaccharide apiose described above and an atom of boron that cross-links two RG-II dimers at the site of the apiose residues to form a borodiester (Figure 6). Knowledge that borate ester cross-linking of polysaccharides *in vitro* is pH-dependent has led to the suggestion that the boron cross-links in RG-II are the 'load-bearing,' acid-labile linkages that are hydrolyzed by a decrease in wall pH during auxin-induced cell expansion. However, graminaceous plants, with an absolute but low requirement for boron, have very low amounts of boron, pectin, and complexable polysaccharides in their cell walls, a finding that suggests unknown additional roles for the element.

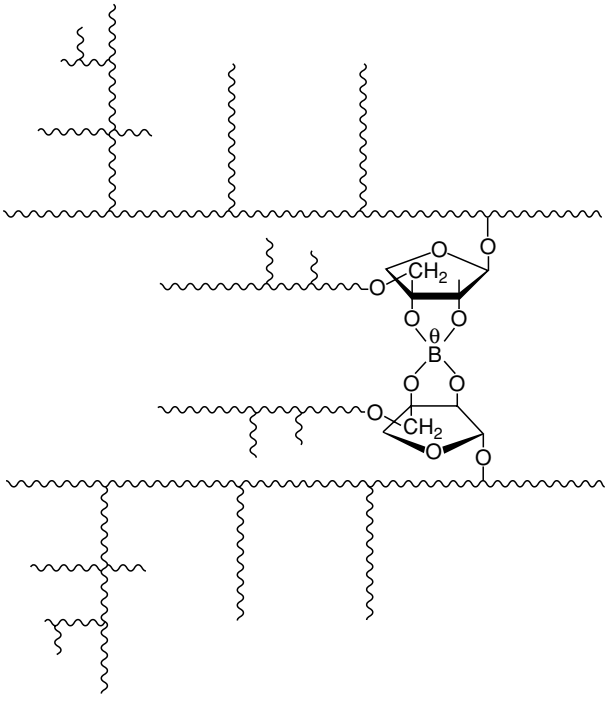

Figure 6 Structure VI.

Humans and Animal Models

Boron homeostatic control Gastrointestinal absorption of inorganic boron and subsequent urinary excretion are near 100%. In humans, a lack of boron accumulation and relatively small changes in blood boron values during a substantial increase in dietary boron support the concept of boron homeostasis. Female rats given water high in boron (9.25 mmol l^{-1}) for 21 days exhibited increased plasma boron concentrations, although some type of homeostatic mechanism concurrently eliminated any excess of boron from two examined organs, liver and brain, against their own concentration gradients. In cows, the percentage of filtered boron reabsorbed by the kidneys decreased significantly with increased boron intake, a finding that suggests physiologic regulation of the element.

Boron and reproduction Boron may be essential for embryological development in at least two separate vertebrate phylogenetic classes. In the South African clawed frog, *Xenopus laevis*, dietary boron deprivation (4.16 μmol kg^{-1}) causes a high proportion of necrotic eggs, fertilized eggs with a high frequency of abnormal gastrulation, and abnormal development of the gut, craniofacial region, and eye; visceral edema; and kinking of the tail musculature and notochord. In mated zebrafish (*Danio rerio*) fed boron-depleted brine shrimp and maintained in low-boron water (0.1 μmol l^{-1}), the boron content of the blastulas was only 5% of that in blastulas from boron-supplemented (45.0 μmol l^{-1}) parents. The early cleavage stage of development was the most sensitive to boron deficiency, although repletion of low-boron embryos during the first hour after fertilization rescued them from death.

Boron and cartilage and bone structure Interest in mammalian boron nutrition was renewed after a 36-year hiatus with the discovery that boron supplementation of a boron-low diet reduced gross bone abnormalities in the vitamin D-deficient chick model system. Other subsequent findings at the microscopic level indicated that physiologic amounts of boron (321 μmol kg^{-1}) function to modify mineral metabolism in vitamin D deficiency (3.13 μg kg^{-1}) by suppressing initiation of growth cartilage mineralization in magnesium deficiency and enhancing cartilage calcification in magnesium adequacy (see Figure 7). The effects of boron in this model on cartilage calcification apparently are beneficial in both magnesium deficiency and adequacy because the vitamin D deficiency-induced mortality was substantially reduced by dietary boron. Furthermore, supplemental boron

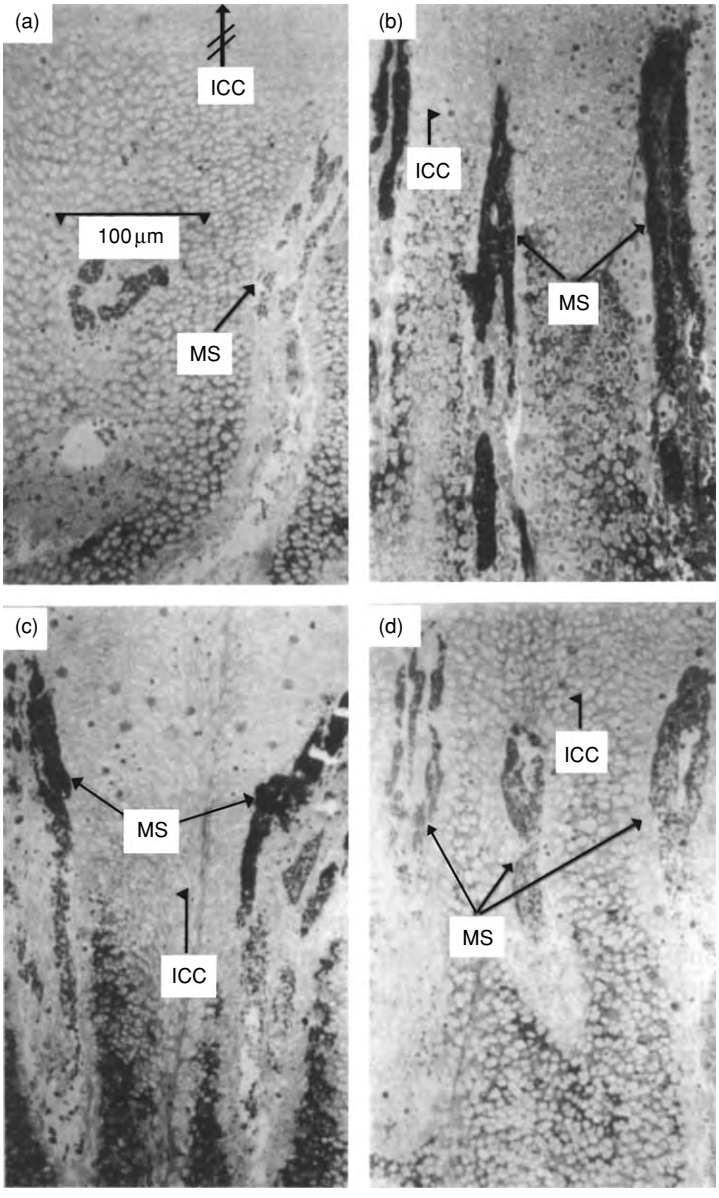

Figure 7 Microphotographs (all at same magnification) depicting marrow sprout (MS) orientation and initiation of cartilage calcification (ICC) in the chick proximal tibial epiphysial plate. ICC beyond a frame is denoted by slashed arrows. Boron supplementation corrected the cholecalciferol-deficiency-induced disorientation of the MS (compare a and b, and c and d). ICC is inhibited by boron in magnesium inadequacy (compare a and b), but enhanced in magnesium adequacy (compare c and d). Dietary supplements (milligrams of supplement per kilogram of diet): (a) B, 0; Mg, 300; (b) B, 3; Mg, 300; (c) B, 0; Mg, 500; (d) B, 3; Mg, 500. Data from Hunt (1989).

alleviated distortion of the marrow sprouts, a distortion characteristic of vitamin D deficiency.

Boron also has an apparent undefined role in metabolic events not directly related to extracellular matrix calcification. *In ovo* injections of boron (90 μmol) or 1-25-dihydroxycholecalciferol reduced the abnormal height of the growth plate of 1-day-old chicks hatched from vitamin D-deficient eggs. In addition, physiological supplements of boron (130 μmol kg^{-1}) to a boron-low diet (16 μmol kg^{-1}) increased chondrocyte density in the proliferative zone of the growth plate in vitamin D-deficient chicks.

Boron and mineral metabolism In postmenopausal volunteers fed marginal amounts of magnesium (4.5 mmol per day), boron supplementation (280 μmol per day) of the low-boron diet (33 μmol per day) significantly decreased the percentage of dietary calcium lost in the urine (1.4%) but significantly increased that percentage (2.5%) in volunteers fed

ample amounts of magnesium (14.0 mmol per day), a relation that may be important in understanding metabolic mineral disorders that perturb calcium balance. A similar phenomenon occurred in either free-living sedentary or athletic premenopausal women consuming self-selected typical Western diets not different in analyzed calcium content; boron supplementation (280 μmol per day) increased urinary calcium loss. In a different study of older volunteers fed a low-magnesium (4.73 μmmol 8330 kJ^{-1}), marginal copper (25.3 μmol 8330 kJ^{-1}) diet (men, and women on or not on estrogen therapy), boron repletion (300 μmol 8330 kJ^{-1}) after boron depletion (21.3 μmol 8330 kJ^{-1}) significantly decreased calcitonin and significantly increased ionized calcium, but not total calcium concentrations in serum in a manner similar to that caused by estrogen therapy. In the vitamin D-deficient rat model fed a low-boron diet, supplemental dietary boron enhanced the apparent absorption and retention of calcium and phosphorus and increased femur magnesium concentrations.

Boron and steroid metabolism There is clear evidence that dietary boron affects steroid metabolism. In particular, circulating concentrations of vitamin D metabolites are sensitive to boron nutriture. The number of vitamin D-deficient chicks with detectable serum concentrations of 25-hydroxycholecalciferol and the overall serum concentrations of 25-hydroxycholecalciferol increased when boron-deprived chicks (15 μmol B kg^{-1}) were supplemented with physiological amounts of boron (280 μmol kg^{-1}). In the same study, physiological supplements of boron improved growth, feed efficiency, leg conditions, and bone calcium, and serum ionized calcium in broiler chicks fed low amounts of vitamin D, but not in vitamin D-deprived or adequate chicks. These findings indicate that dietary boron enhances the efficacy of vitamin D but cannot substitute for the vitamin. Further research is needed to determine whether boron enhances vitamin D absorption or increases cholecalciferol hydroxylase activity. In volunteers (men, and women on or not on estrogen therapy), boron supplementation after consumption of a low boron diet increased serum 25-hydroxycholecalciferol (62.4 ± 7.5 vs. 44.9 ± 2.5 mmol l^{-1}, mean $\pm$ SEM), an effect that may be especially important during the winter months when those concentrations normally range between 35 and 105 mmol l^{-1}.

The circulating concentrations of 17β-estradiol also respond to boron nutriture. Perimenopausal women who excreted < 93 μmol of boron per day during the placebo period exhibited increased serum concentrations of estradiol after boron supplementation (231 μmol of boron per day) of self-selected diets. In a separate study, postmenopausal women on estrogen therapy, but neither men nor postmenopausal women not ingesting estrogen, also exhibited increased serum concentrations of estradiol after boron supplementation (280 μmol of boron per day) of a low boron diet (23 μmol of boron 8330 kJ^{-1}). However, plasma estradiol, but not testosterone, concentrations increased in young male volunteers when their self-selected diets were supplemented with ample amounts of boron (10 mg per day).

Boron and enzyme regulation Boron influences the activities of at least 26 enzymes examined (various oxidoreductases, transferases, hydrolases, and isomerases), most often in an inhibitory manner, by binding to cofactors (e.g., NAD) or substrates, or by unknown mechanisms. Reversible enzymatic inhibition as an essential role for an element is unusual. However, there is irrefutable evidence that boron serves to inhibit or dampen several metabolic pathways in higher plants. A serious outcome of boron deficiency in plants is starch accumulation, a condition thought to be caused by increased activity of an enzyme in that pathway, starch phosphorylase. Oxidoreductase enzymes that require pyridine (e.g., NAD^+ or NADP) or flavin (e.g., FAD) nucleotides (EC 1.1.1, 1.1.3, 1.2.1, 1.3.5, 1.6.2) are competitively inhibited by borate or its derivatives as boron competes for the NAD or flavin cofactor. The serine proteases (EC 3.4.21) represent one critical sub-subclass of hydrolases that have many essential regulatory roles including the blood coagulation system (e.g., coagulation Factor Xa). Boron reversibly inhibits the activity of these enzymes by serving as a transition-state analog. It is possible that boron acts as an unobtrusive metabolic regulator by quenching the activity of some enzymes and/or stabilizing reactive compounds to limit the hyperactivity of several physiological systems including the normal inflammatory response.

Boron and membrane function There are numerous indications that boron is important for membrane function. The esterification reaction that produces boromonoesters (e.g., **Figure 1** or **2**) is easily reversible, because these esters are completely hydrolyzed when transferred into water. Therefore, it is reasonable that boromonoesters in the hydrophobic environment of the lipid portion of the plasmalemma should have a prolonged functionality, because the absence of water in these environments shifts the equilibrium to the right (eqn (2)).

$$B(OH)_3 + 3ROH \leftrightarrow B(OR)_3 + 3H_2O. \qquad (2)$$

Heterocystous cyanobacteria may require boron interactions with polyhydroxy components of the

cellular membrane to maintain efficient conformation of cell membranes and thus preservation of the anaerobic environment of the heterocyst. Very early research on plant boron nutrition indicated that boron deficiency caused a reduction in ion uptake in *Impatiens balsamina*, and considerable evidence has accumulated since then that boron is involved in plasmalemma-bound transport processes for higher plants and diatomaceous species. Low-boron zebrafish zygotes began to die during the one-cell stage where blebbing of the cell and yolk-sac membranes marked the early stages of death followed by extrusion of cytoplasm and yolk-sac contents. In boron-deprived rats, increases in dietary potassium from marginally deficient to adequate to luxuriant induced increases in the transport of calcium into thrombin-activated platelets. However, physiological amounts of boron muted the effect of potassium on calcium transport. Boron may have reacted directly with thrombin to somehow modify platelet activation because thrombin is a serine protease inhibited by boron. However, these findings are similar to those expected for plasmalemma ion transport involving regulation of the voltage-dependent Ca^{2+} channel by boron through inhibition of NADPH or cAMP concentrations.

Boron and immune function There is evidence that dietary boron helps control the normal inflammatory process. The antigen-induced arthritis rat model exhibited reduced paw swelling and circulating neutrophil concentrations when fed with physiological amounts of boron ($190\,\mu mol\,kg^{-1}$). Commercial rat chow contains considerable higher amounts of boron ($\sim 1100\,\mu mol\,kg^{-1}$). Perimenopausal women excreted 110 and 304 μmol of boron per day during the placebo and boron supplementation periods, respectively, and exhibited an increased percentage of polymorphonuclear leukocytes during the boron supplementation period. Boron-containing rhamnogalacturonan-II from *Panax ginseng* leaves enhanced expression of the Fc receptor (that internalizes antigen–antibody complexes) and interleukin-6 (IL-6) production activity of mouse macrophages. Dietary boron may serve as a signal suppressor that downregulates specific enzymatic activities typically elevated during inflammation at the inflammation site. Suppression, but not elimination, of these enzyme activities by boron is hypothesized to reduce the incidence and severity of inflammatory disease.

Boron Toxicity

As with all other elements, boron produces toxicity in all tested biological organisms when excessive amounts are absorbed. The associated toxicity of boric acid when used as an antiseptic in lieu of antibiotics on abraded epithelium (i.e., surgical wounds and diaper rash) was overlooked for many years, even though signs of poisoning were reported soon after its introduction into clinical use. Boron is more of a bacteriostat than a bactericide and as such is not sufficient for most modern usage. The minimum lethal dose of boron for humans has not been established, although single doses of 18–20 g in adults have been fatal. Signs of acute boron toxicity, regardless of route of administration, include nausea, vomiting, headache, diarrhea, erythema, hypothermia, restlessness, weariness, desquamation, renal injury, and death from circulatory collapse and shock. Autopsy may reveal congestion and edema of brain, myocardium, lungs, and other organs, with fatty infiltration of the liver. Chronic boron toxicity symptoms include poor appetite, nausea, weight loss, decreased sexual activity, seminal volume, sperm count and motility and increased seminal fructose. At present, death from boron poisoning is exceptionally rare probably because of the emphasis placed on maintaining the electrolytic balance and supporting kidney function during the worst part of the illness. Depending upon boron blood levels, treatment ranges from observation to gastric lavage to dialysis.

BOVINE SPONGIFORM ENCEPHALOPATHY (BSE)

R Bradley, Private Consultant, UK

Introduction

Bovine spongiform encephalopathy (BSE) is a feed-related infectious disease of cattle, *par excellence*. It is a new disease first identified as a subacute spongiform encephalopathy (SE) in November 1986, though the earliest clinical case probably occurred in the UK in April 1985. BSE was later determined to be a transmissible SE (TSE) and a prion disease. Such diseases had previously been confined to humans (Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler–Scheinker (GSS) disease, and kuru), sheep and goats (scrapie), farmed mink (transmissible mink encephalopathy (TME)) and certain species of deer in North America (chronic wasting disease (CWD)). Of these, only TME was certainly contracted via feed. All these diseases, with the possible exception of scrapie and now BSE, are rare. For example, the annual incidence of CJD is between one and two cases per million per annum worldwide.

In the years following the discovery of BSE, a number of other species of the families Bovidae and Felidae became affected with similar diseases, almost certainly following feed exposure to the BSE agent. Finally, in March 1996 10 cases of a new variant form of CJD (vCJD) in the UK were announced. In the absence of any other plausible explanation, exposure to the BSE agent before 1989 was presumed to be the cause. In 1989 a specified bovine offals (SBO) ban had been put in place in the UK to protect public health to supplement the 1988 measure of removing all clinically suspect animals from all food and feed chains. SBO are the offals from cattle that were, on

scrapie evidence, likely to contain BSE infectivity. In fact, subsequent transmission studies from natural cases of BSE have only detected infectivity in the central nervous system. Other tissues, including blood, milk, and muscle meat, show no detectable infectivity. Subsequently it was shown that the agent causing BSE in cattle was indistinguishable biologically from the vCJD agent, i.e., the strain type was the same. Furthermore, the strain-type characteristics were different from the agents causing conventional forms of sporadic CJD and scrapie. Molecular analysis of the prion protein (PrP) from some of these species has also shown distinct similarities between them. In particular, that from vCJD cases has a unique molecular signature that distinguishes it from conventional sporadic and other forms of CJD.

The following is a brief account of the BSE epidemic in cattle, where it exists, how it is being eliminated, and how both public health and animal health are being protected.

The Cause of BSE

BSE is caused by the BSE agent. TSE agents can be biologically strain-typed in inbred strains of mice, a process that usually takes years. The BSE agent exists as a single major strain and is different from the agents that cause scrapie, TME, CWD and all forms of human TSE except vCJD.

The Nature of TSE Agents and Diagnostic Methods

The nature of TSE agents is disputed. They have been variously described as prions, virinos, and unconventional viruses. They are unlike bacteria and conventional viruses as they provoke no conventional immune response in infected hosts. Therefore there is no immunological test that can be used to identify an infected individual before the onset of clinical signs. TSE agents are the nearest things to indestructible forms of life. They can resist boiling, conventional autoclaving, dry heat to over 300 °C (and perhaps more) for an hour, ionizing and ultraviolet radiation, burial for up to 3 years, formaldehyde, and a range of chemicals that are effective against conventional bacteria and viruses. Nevertheless, several of these treatments do reduce the titer of infectivity, often substantially. Specified autoclave conditions and incineration, sodium hypochlorite, and sodium hydroxide are either effective or useful in practice.

The Prion Hypothesis and PrP Detection

The prion hypothesis, in its purest form, proposes that the agent is an infectious protein, an altered form of a host protein known as PrP. This protein is coded for by the *PrP* gene that exists in all cells of an individual. The gene is highly preserved in mammals and some other orders of animals. PrP is found in several tissues of mammals but is most abundant in nervous tissue and particularly nerve cells, where it is regarded as a neuronal membrane protein. The function of this protein is unknown though it may control programmed cell death. Mice appear to live successfully if the *PrP* gene is deleted (*PrP* knockout mice), though some models have shown altered circadian rhythm and others deficits in synaptic function.

The protein found in normal individuals is called PrP^{C}. In disease there is a post-translational conformational change that results in the formation of PrP^{Sc}. This involves a change in shape from mainly α helix to mainly β sheet. PrP^{C} is denatured by proteases such as proteinase K. PrP^{Sc}, on the other hand, is insoluble and partially protease-resistant. It is then known as PrP-res. These features have been exploited to develop diagnostic methods to identify the protein in infected tissues. Such methods include immunoblotting (Western blotting), dot blotting, and immunohistochemistry (the detection of PrP in tissue sections). Disease-associated PrP tends to aggregate in tissues. Diagnostic use is made of this phenomenon by detection of disease-specific fibrils (scrapie-associated fibrils or SAF) by electron microscopy. This is done on detergent extracts of brain or spinal cord, treated with proteinase K, and followed by electron-dense staining. More recently Rapid diagnostic tests have been developed for use in cattle and sheep to aid surveillance for the disease (active surveillance). All Rapid tests are based on the detection of PrP^{Sc} in central nervous tissue collected after death.

The Virino Hypothesis

There is no doubt that infectivity and PrP are closely associated and difficult to separate. However, doubt has been cast on the validity of the prion hypothesis. This is because some features of the transmissibility and dynamism of TSE agents, such as mutation and agent strain differences, for which there is abundant evidence, are not well explained by the basic 'protein-only' hypothesis. These observations have been made following transmission experiments between species. This has meant that various modifications to the prion hypothesis have been proposed over the years to explain the observations. One of these modifications is the proposition that 'protein X', an unidentified protein, is required for infectivity. This may act as a molecular chaperone. A second is that in some prion disease neurodegeneration occurs in the absence of PrP^{Sc}. Instead, it may be caused by a transmembrane form of PrP, called ^{Ctm}PrP.

Although the biological features of agents isolated from cattle with BSE and several other species with recently discovered, natural, or experimental TSE, including three human patients with vCJD, are indistinguishable (the biological strain type is the same), the primary PrP amino acid sequence from each is different. This feature, mutation, and strain variation in general can be more readily explained by conventional molecular theory, namely that the agent has a genome that is, perhaps, a small nucleic acid. The agent therefore is hypothesized to be a hybrid mixture of PrP and the agent genome. However, the weakness in the hypothesis is that this genome has remained undiscovered.

Unconventional Virus Hypothesis

There are generally fewer supporters of this hypothesis but most of them claim it has not been disproved. An infection-specific nucleic acid has not been identified.

Whatever is the structure of the causal agent it is clear that the PrP plays a central role and this must be accommodated in any hypothesis. Claims that BSE is an autoimmune disease or alternatively that organophosphorus compounds are a prime cause are not viable theories.

Epidemiology of BSE

Origin of BSE

The UK epidemic of BSE had an extended common source. The features were consistent either with an origin from sheep affected with a scrapie-like agent or from a cattle-adapted scrapie-like agent. They were not consistent with exposure to a mutant form of scrapie. The source of infection has been identified as concentrate feed and the vehicle is ruminant-derived protein in the form of meat-and-bone-meal (MBM). Bovine blood, fetal calf blood, components of blood, and bovine milk have shown no detectable infectivity following bioassay. Positive epidemiological evidence for transmission of BSE via milk is also absent. All authorities, including the World Health Organization (WHO), Office International des Epizooties (OIE), European Commission (EC), Food and Drug Administration (FDA), and Spongiform Encephalopathy Advisory Committee (SEAC), having reviewed the evidence conclude that bovine milk is a safe product in regard to TSE, for all purposes. This means that suckled cattle, not the offspring of a BSE case, reared entirely on milk and subsequently on grassland have a negligible risk of developing BSE. It also follows that unadulterated bovine blood and milk products can safely be used in pharmaceuticals, biologicals, and cosmetics. However, in the case of bovine blood an additional safeguard against contamination is to source the material from countries that are classified in the highest category of safety.

The genetic component in BSE is small. Thus, the disease can be considered as an infectious disease transmitted mainly via feed.

There is a possibility that maternal transmission may play a minor role in the transmission of BSE in the UK but, even if it does, it will not itself prevent the elimination of the disease.

It has not been possible to transmit BSE via embryos derived from clinical cases of BSE either to the offspring so derived, or to recipient dams after a 7-year period. Male or female reproductive tissue, including embryos, fluids used for flushing embryos from the uterus, placenta, and milk, have not revealed detectable infectivity following bioassay. Nevertheless a cohort study, confounded by accidentally feeding MBM to both cases and controls, provided some evidence that there was a risk of maternal transmission at a level around 10% in the study. The risk was highest for calves born whilst the dam was clinically affected but there was also a significant risk for calves born in the 6 months prior to onset of clinical signs in the dam. Subsequent experience of BSE in the UK as the epidemic declines and following detailed epidemiological study of a few BSE cases born after 1 August 1996, when the second feed ban was considered complete, has not supported such a high incidence of maternal transmission. Furthermore, no BSE has been reported in any offspring of dams with BSE in any other country, even though over 3000 cases or positive animals have occurred. In summary, maternal transmission cannot be entirely ruled out but evidence for it is meager and no plausible method has been proposed for its occurrence.

A recent review reports that, during the period 1970–88 (a ruminant feed ban was introduced in July 1988 in GB) feed manufacturers introduced MBM into rations for calves from the first or second week of age. Accordingly, in the UK, a high proportion of dairy cows and cross-bred suckler cows derived from dairy cows will have been fed MBM as calves. This was an important risk factor for BSE and accounted for most cases of BSE being in dairy cows or cows derived from the dairy herd.

Commercially and safety-stimulated changes in the processing of animal waste around 1980 in the UK apparently permitted an increase of BSE agent infectivity to enter the MBM, sufficient to cause detectable disease by 1985–86. Disease resulted after the mean 60-month incubation period was complete. Recycling BSE infection from cattle via MBM exacerbated the

epidemic, whether its origin was from sheep or cattle. Recycling commenced from infected tissues of incubating cattle, before BSE was even discovered, and resulted in a marked increase in incidence from mid-1989. MBM was probably also the source of infection for a small number of captive wild Bovidae that developed TSE during the late 1980s and early 1990s in the UK. The origin of TSE in captive wild Felidae was consumption of uncooked carcass material from fallen stock (animals that die on the farm or in transit) that contained central nervous system (CNS) tissue. It is these tissues that contain the highest levels of infectivity in clinically affected animals. The precise origin of feline spongiform encephalopathy (FSE) in domestic cats is less certain but was via feed.

The Scientific Steering Committee (SSC) of the EC has frequently been confronted with unresolved issues relating to the origin of BSE and with alternative hypotheses for the transmission of this disease other than via animal proteins and maternal transmission. They reviewed the evidence in 2001 provided in reports by the TSE/BSE ad hoc group and gave an opinion. They concluded that:

- Epidemiological studies, rendering studies, and the effect of feed bans in all countries with BSE very clearly support the hypothesis of infected mammalian protein in the form of MBM being the major vehicle for BSE transmission in cattle. It can enter the feed deliberately or accidentally by cross-contamination that can occur readily during feed preparation in feed mills, during transportation, or on the farm.
- Maternal transmission is theoretically a possible route of transmission, although it has not yet been demonstrated.
- Other infected materials, such as gelatin and/or fat, incorporated in feed represent another possibility of transmission.
- The PrP theory remains central to BSE and other TSE.
- It is wise at present to maintain an open mind on the nature of the BSE agent(s).
- A number of other hypotheses have been proposed on the nature of the responsible agent(s) of BSE (e.g., a toxin, a bacterium, alkaloidal glycosidase inhibitors, autoantibodies, and a single-stranded DNA), but for none of them is sufficient scientific evidence available and some are clearly implausible or very difficult to investigate.
- The origin of the BSE prion is not known. Many hypotheses have been suggested, including, for example, an origin from mammalian species other than cattle (a mutant form of scrapie agent, a natural TSE in Bovidae or Felidae or other wild animals whose carcasses were rendered into MBM, the existence of a form of sporadic TSE-like sporadic CJD of humans, a spontaneous mutation of normal bovine PrP into an infectious and protease-resistant TSE prion, etc.). For none of these hypotheses are there enough data either to substantiate or to reject it.
- In regard to routes of transmission other than those mentioned above (the so-called third route), not one of the many possibilities considered has been substantiated by scientific evidence so far.
- Factors that have been suggested as having a potential for affecting susceptibility of cattle to BSE include some metal ions (e.g., copper and manganese), organophosphorus compounds, and antioxidants. However, supporting data for all these hypotheses are very limited and do not allow any conclusions to be drawn.

Geographical Distribution of BSE and Related Diseases

Imported cases

In cattle BSE has occurred in a small number of cattle exported from countries with BSE (mostly the UK) to other countries. These countries are as far afield as Canada, the Falkland Islands, the Sultanate of Oman, and some European countries. In these countries, so long as cases occur only in imported animals, the surveillance for disease is sound, affected cattle are completely destroyed, infected cattle and their offspring are quarantined, and no infected organs are permitted to enter any food or feed chain, any residual risk is likely to be extremely small.

In other species FSE has been reported in a small number of cheetahs exported from the UK and imported into captivity in the Republic of Ireland, France, and Australia.

Cases in native-born animals

In cattle Up until June 2002, countries with BSE in native-born cattle, mostly dairy cattle, are (cumulative numbers of confirmed cases including cases found by active surveillance using 'rapid' tests): Austria (1), Belgium (81), Czech Republic (2), Denmark (8), Finland (1), France (567), Germany (163), Greece (1), Italy (54), Israel (1), Japan (3) Liechtenstein (2), Luxembourg (1), Netherlands (35), Northern Ireland (1977), Poland (1), Portugal (631), Republic of Ireland (953), Slovakia (5), Slovenia (1), Spain (137), Switzerland (416), UK (179 488) and other British Isles (1287). (Data courtesy of DEFRA and DARDNI for the UK and OIE/EC for other countries).

In other animal species A total of 37 cases of SE in captive wild Bovidae and Felidae and 90 cases of FSE in domestic cats have been confirmed in the UK to June 2002. One case each of FSE in domestic cats has been reported in Norway, Liechtenstein, and Switzerland. (Data courtesy of DEFRA, UK).

In humans Up until June 2002, there has been a total of 113 definite and probable cases of vCJD in the UK, four cases in France, and one each in the Republic of Ireland and Italy. Each of these countries has had BSE in native-born cattle. By contrast, in 2001 the total number of all forms of definite and probable CJD in the UK was 77 (sporadic 50, iatrogenic 3, familial 2, GSS 2 (all these completely separate from vCJD), and vCJD 20: data courtesy of Department of Health). Two or three further cases of vCJD have been confirmed in countries without BSE, but these are included in the UK total because the epidemiological evidence points to them having been exposed in the UK during residence there.

The SSC of the EC has classified a range of countries wishing to trade in bovine products with member states of the European Union (EU) and including all member states into one of four categories on the basis of an analysis of submitted dossiers containing relevant data. This analysis is called the Geographical BSE Risk (GBR) risk assessment. Although the list is dynamic, at the present time the UK and Portugal are in the highest risk category and countries like Argentina, Australia, and New Zealand that have reported no BSE and have good surveillance for the disease are in the lowest risk category. The OIE has defined five categories dependent upon the occurrence and incidence of BSE but has categorized no individual country. The two apparently different approaches are in fact very closely aligned and it is anticipated that eventually they will coincide. The EC is currently re-evaluating the GBR for over 80 countries to reflect the current situation more accurately and since BSE has been reported in widely separated regions of the world.

Processing of Waste Animal Tissues – Rendering

Epidemiological studies In the UK, MBM had been fed to cattle for decades before the first case of BSE was discovered in 1986, without any knowledge of a problem and despite the fact that scrapie-infected sheep tissues were in the starting material. At this time and until it was stopped many years later by EC decision, the starting material had included certain bovine TSE-risk byproducts from abattoirs. Also included were condemned materials and fallen stock. During the 1970s and early 1980s commercially motivated changes were occurring in the UK rendering industry.

First, there was a change from batch processing to continuous processing. But this did not result in an equivalent change in the processing parameters (such as processing at lower temperatures or for shorter times) that might reasonably have been associated with a reduced inactivation of a scrapie-like agent.

Second, there was a phasing-out of the hydrocarbon solvent extraction of tallow, particularly in the period of the putative first exposures to the BSE agent. This was believed to be critical. This change appears to have permitted an increased amount of TSE agent infectivity to escape inactivation, and this was sufficient to produce disease at a detectable incidence. However, subsequent laboratory inactivation studies using hydrocarbon solvents previously used to extract tallow, and the additional heat process used to recover the solvent, showed that these had little effect on TSE agent inactivation, though possibly just sufficient to restrict an effective oral dose being delivered. Nevertheless, some doubt was cast on the 'rendering' hypothesis, but no plausible alternative explanation has been proposed for the timing of the first effective exposures.

Experimental studies Experimental studies on animal waste processing, as conducted throughout the EU, showed that viable scrapie and BSE agents could survive some processes that were used in the countries where BSE occurred, thus supporting the notion that MBM was the vehicle of transmission. As a result of all these studies, the procedures adopted in the EU for processing mammalian waste now require the following parameters: a maximum particle size of 50 mm in the raw material, followed by processing (pressure cooking) at a minimum temperature of 133 °C at 3 bar pressure, for 20 min. However, laboratory studies suggest that no rendering process, including pressure-cooking, can guarantee complete inactivation of TSE agents.

A new European regulation to control animal waste is likely to become law by 2003 and covers all member states of the EU. Amongst other things, this determines that waste is divided into three categories of risk, each of which has a predetermined disposal method applied to it. The highest risk material would be incinerated and the lowest could only come from animals passed fit for human consumption and then be treated in approved ways before being permitted into animal feed or for other purposes. A major step forward was the earlier introduction, consolidated into the new regulation, of the rule whereby animal feed derived from animal byproducts can only use starting materials passed fit for human consumption

and processed by approved methods. Furthermore, within-species recycling of animal protein (other than milk and a few other exceptions) will not be permitted. Of course ruminants would not be permitted to receive protein from any animal species. In addition, there is a temporary ban on feeding animal protein to any food animal species, mainly to combat the problem of cross-contamination of ruminant feed and the occurrence of cases of BSE born after the feed ban was put in place.

Gelatin, Skull, and Vertebral Column

Gelatin is a product with a wide range of uses, including in food, confectionery, and medicines. The raw materials are animal bones or skin from pigs and cattle. The only starting material with which there is concern is bovine bone, not because of any inherent infectivity in it in clinically healthy animals, but rather because of the possible contamination with specified risk materials (SRM), particularly brain, spinal cord, and associated ganglia. Thus the bones most likely to be a risk are ruminant skull bones (that are SRM throughout the EU) and vertebral column, excluding the tail vertebrae. These, respectively, could easily retain residual brain and spinal cord and the vertebral column would certainly retain dorsal root ganglia in which TSE infectivity has been found in experimental BSE. Depending on the GBR category to which a country has been allocated by the EC, the risk bones are designated SRM and cannot be used for gelatin manufacture. In addition, the processing parameters must follow prescribed rules that have been shown experimentally to reduce the titer of spiked BSE material by substantial amounts. If this is done the residual TSE risk in gelatin is negligible.

Because of the same TSE concerns with the starting material (bovine skull and vertebral column) it is now prohibited to use ruminant bones in the EU to manufacture mechanically recovered meat that has been widely used in human food in the past and was thought by some to be a possible source of vCJD infection from cattle. All ruminant bones are now proscribed because it would be impossible otherwise to police the ban.

The Source of BSE Infection and Effect of the Removal of the Source

The coordinated epidemiological studies on BSE commenced in mid-1987 when there were fewer than 10 confirmed cases of the disease. By the end of the year, there had been almost 200 cases, sufficient to enable a working hypothesis for the origin to be drafted. Thus, the MBM hypothesis was established. The results from this study led to the introduction, in July 1988, of a major measure to control the disease, the ban on feeding ruminant protein to ruminant animals, with certain exceptions like milk protein.

Withdrawal of mammalian MBM from the rations of cattle and other Bovidae in 1988 effected a marked reduction in incidence of BSE and feed/BSE-related ruminant TSE in the UK, and strongly supports the hypothesis of an origin from TSE-infected raw material that somehow survived processing. The decline in incidence became clear from 1992–93 onwards; the delay was due to the mean 5 years' incubation period for BSE.

Descriptive Epidemiology

All breeds of cattle and both sexes appear to be equally susceptible; however, the disease affects mostly breeding dairy cows due to the methods of feeding the calves of these animals. Unlike beef breed calves that are suckled, dairy calves are removed from the dam after sucking colostrum. They are then fed artificial milk and later concentrates that, until 1988 in the UK, often contained MBM. Amongst dairy cattle in the UK, the incidence of disease between breeds is similar, but the number of confirmed cases by breed is directly proportional to the numerical size of the breed. Thus, most cases occur in Holstein-Friesian cattle and crosses with this breed, because they are the most abundant. Because of the widespread use of artificial insemination, bulls are much less numerous than cows and this largely explains why so few bulls (just under 500 in GB) have been affected by BSE compared with cows.

The risk of BSE occurrence in a herd increases with increase in herd size. This is attributed to the greater risk attached to purchasing an infected ration because in large herds more batches of feed would be bought. Of herds affected by BSE in the UK, nearly 35% have had only one case and over 80% have had seven or less. The mean within-herd incidence has remained more or less constant at less than 3% in any 6-month period, though it is now falling as the epidemic declines. Collectively these data and the results of a case-control study do not support contagion being important in BSE. Instead, it seems that infection and disease result from a random low-dose exposure to a common source of infection in MBM that is in 'packets' rather than being evenly distributed within feed, though this hypothesis is disputed by some workers.

Control and Elimination Measures

Animal Health Control Measures

The objective of member states of the EU and Switzerland is elimination of BSE from the territory.

A new regulation of the European Parliament and of the Council (EC no. 999/2001 of 22 May 2001) details the rules for the prevention, control, and eradication of TSE. Eradication (elimination of BSE from all countries in the world) is the eventual objective, but with several countries reporting BSE for the first time in the period 1999–2002, this task will not be achieved in the immediate future.

The main measures to protect ruminants from BSE are a ban on the inclusion of ruminant protein (subsequently mammalian MBM) in ruminant diets and the authorization only of the most effective rendering processes (pressure-cooking or methods giving equal or better inactivation of BSE and scrapie agents) where this is permitted for processing mammalian waste. Legislation to achieve the former has been adopted in the major cattle-rearing countries of Europe, North and South America, Australasia, and some other countries. Rendering process controls are in place throughout the EU.

In the UK a ban on the use of certain specified bovine offals (SBO) thought most likely to contain BSE infectivity in cattle incubating BSE, originally introduced to protect public health in 1989, was extended in 1990 to protect all species of animal and bird. More recently, the SRM ban was introduced in the UK to protect public and animal health. SRM include some tissues from sheep and goats. An EU-wide SRM ban was introduced in June 2000 and has subsequently been modified to improve its scope. SRM must be destroyed completely by approved processes.

The feed ban, introduced in its initial form in 1988 in the UK, has a sound scientific basis but was not completely effective in reducing exposure from feed sources, so that cases of BSE have occurred in animals born after the ban was introduced. Indeed, over 43 500 such 'born after the ban' or BAB cases have been reported in GB and most current cases of BSE in Europe have occurred in animals born after the date of feed bans applied in individual countries. In the UK, new exposures from feed in cattle born since 1 August 1996 should in theory be entirely prevented as a result of banning the use of mammalian MBM in the feed for any food animal species, including horses and fish. An even more extensive ban now applies throughout the EU and essentially prohibits the feeding of any animal protein, except milk protein, to food animals. The major stimulus to introduce these extended and strict bans is because cross-contamination of ruminant diets with MBM or diets for pigs and poultry containing MBM (nonruminant diets legitimately could, prior to the regulation, include MBM as a constituent) could not be prevented in feed mills, during transport, or on-farm. Research has shown that very small amounts (< 1 g) of brain material can carry a lethal infective oral dose for a cow.

The epidemics of BSE in the UK and Portugal are now declining towards elimination. It is hoped that Switzerland and all EU member states will follow as the extended bans become completely effective.

The OIE (World Organization for Animal Health) has produced an *International Animal Health Code* chapter on BSE that determines the requirements to facilitate safe trading in cattle and cattle products in regard to BSE throughout the world.

Public Health Control Measures

In addition to the SRM ban mentioned above, all cattle suspected of having BSE are compulsorily slaughtered and totally destroyed (since 1988 in the UK and 1990 in the EU) so they can enter no food or feed chain. This is now practiced in all countries and is endorsed by WHO that has also recommended global surveillance and diagnosis of all forms of CJD. The WHO collaborates with the OIE in recommending surveillance and monitoring for animal TSE, including BSE in all countries.

The UK BSE Situation Contrasted with that in other European Countries

It is clear that the total number of cases of BSE and the incidence of BSE in GB (> 179 000 to date) exceeds, by far, the number of cases and the incidence in other countries (collectively > 3000 to date). However, the annual number of suspect cases reported and confirmed in the UK has declined since 1992 and is still declining toward extinction and in line with predictions. As a result of passive surveillance, at the peak of the epidemic in GB in 1992 > 36 000 cases of BSE were confirmed. In 2001 only 781 were confirmed. There is greater than a 40% reduction in cases by year, though the epidemic is expected to have a long 'tail'. Furthermore, the residual risk to humans and animals is probably lower in the UK than anywhere else, because of the extensive interlocking measures applied and enforced to protect animal and human health. A significant measure applied after March 1996 in the UK is the scheme that prohibits the use for any purpose of products from cattle over 30 months (OTM) of age. A conditional exclusion is permitted for hides. This OTM scheme exists in no other country. However, cattle from herds in the UK beef assurance scheme may be slaughtered for human consumption up to 42 months of age. Because cattle in these closed herds are mainly grass-fed and have not received MBM in their diet, they present a low risk from BSE.

Some British and continental veterinarians have formally expressed in 1997 concern that there could be more cases of BSE occurring outside the UK than were being officially reported. Indeed, there have been studies into the expected incidence of BSE in cattle exported from the UK to other member states. It was concluded that it was likely that BSE cases had occurred in cattle in member states that had been imported from the UK. The (average) number of potential cases in animals imported between 1985 and 1989 was estimated to be 1642, a much higher number than had been officially reported to the EC or OIE. BSE cases in imported cattle could also have been the source of secondary cases of BSE. Such cases could have resulted from the recycling of infected cattle tissues through the rendering system (depending on the efficacy of the processing in the country in question) and then back to cattle via contaminated feed. These predictions have come true.

Following the announcement of 10 cases of vCJD in March 1996, several countries reported an increase in the number of BSE cases. For example, all three Benelux countries reported their first BSE cases in 1997 and Denmark, Germany, and Spain their first native-born case in 2000, and several other European countries followed suit during 2001 and 2002. BSE has now been reported in Japan and Israel. The number of confirmed cases currently being reported in these countries is small and less than the number currently being reported in the UK. However, the epidemics in most countries, as judged by the numbers of cases reported in successive years and identified by both passive and active surveillance, are increasing, whereas those in the UK and Portugal are declining. The occurrence of clinical cases refers back to exposures 5 years previously, so it is quite possible that new infections in most European countries are currently very low and will be reflected as a declining incidence in the coming years.

Feed Bans in other European Countries

It is only since 1994 that a uniform MBM feed ban (for ruminants) and rendering control has been determined by EC legislation. Switzerland (who alone adopted an SBO ban like the UK in 1990), Denmark, France, Ireland, the Netherlands and some other countries imposed a national ruminant feed ban from 1990. In at least one country, the ban was applied to cattle feed only, and not to other ruminant feed, thus potentially exposing sheep and other ruminants to infected MBM via feed until the law was changed some years later. All other member states with BSE in native-born cattle have had, like the UK, cases in animals born after the respective dates of the feed ban in their own country. Most agree that these probably result from cross-contamination of ruminant feed with infected MBM intended for monogastric species (mainly pigs and poultry). Mammalian MBM, including ruminant MBM, was permitted until 1 January 2001 for feeding to non-ruminant farm animals in all member states except the UK and Portugal.

Offal Bans in other European Countries

In 2000, uniform SRM controls in the EU were introduced, though several countries with BSE in native-born animals had some form of ban prior to this. However, some member states with no BSE in native-born animals until recently had no SRM ban at all, despite the known risks. This meant that it was possible that consumers of permitted but dangerous offals (SRM) in those countries had risked exposure to BSE if the offals were derived from incubating animals. Nowhere were the various offals/materials bans so extensive as in the UK. However, before 1996 in the UK, compliance with and enforcement of the ban were incomplete. There was leakage of some infected material, largely into waste destined for rendering, which was recycled to pigs and poultry via MBM. This contributed to an extension of the cattle epidemic because of accidental cross-contamination of ruminant diets with MBM intended only for non-ruminants. There is no clear indication that such bans, where they existed, were as rigorously enforced as they are now in the UK. The EU-wide SRM ban in place since 2000 will only be effective if it is completely and continuously enforced. However, Rapid tests applied to cattle over 24 or 30 months old in EU abattoirs and destruction of the whole carcasse of those that fail the test are added consumer safeguards.

Passive Surveillance

For the most part, the surveillance for BSE in all member states is passive, relying on the clinical identification of suspect animals by farmers and veterinarians. This is followed by compulsory slaughter and by microscopic examination of brains to confirm or deny a diagnosis of SE, according to standard criteria set down by the EC and the OIE. Such surveillance relies for its success on the vigilance of the observers and awareness of the clinical signs of the illness. Such surveillance is likely to underestimate the real number of cases and cannot detect preclinical cases (or, if they exist, subclinical cases) of BSE.

Active Surveillance

As a result of research into methods of detecting PrP in the brain or spinal cord of BSE-affected cattle, a number of confirmatory tests have been developed

and evaluated by the EC. Using one of these tests, in January 1999, the Swiss State Veterinary Service initiated a targeted, active surveillance system for three categories of cattle. These are fallen stock, cattle slaughtered in emergency, and a proportion of healthy cattle slaughtered for human consumption. Twelve out of 4868 tested fallen stock were positive and four out of 2274 tested emergency slaughter animals were positive. Two out of 4847 healthy slaughter animals were positive, probably because they were in the last few months of incubation. Thus, 18 additional cases of BSE that otherwise would not have been detected have been identified by this method before the end of 1999. This was about the same low number of cases detected by conventional passive surveillance in that period. The underreporting of BSE in 1999 in Switzerland was thus estimated to be about 50%.

Future Outlook

A successful EC-funded comparative evaluation of four Rapid tests for PrP using brain or spinal cord tissue for the postmortem confirmation of BSE in clinically affected cattle has been reported. The approved tests are now being used throughout the EU on fallen stock and cattle sent for emergency slaughter over 24 months of age and on all cattle for slaughter for human consumption over 30 months of age. Some countries test all animals for human consumption over 24 months of age. Any animals that fail the test must be completely destroyed. Application of several million tests has already identified several hundred additional animals with BSE infection that would otherwise have escaped detection. Results of tests must be regularly reported to the EC and are published. The true incidence of disease and the extent of underreporting are thus being revealed.

Though not currently validated for use in clinically healthy cattle, studies are in progress to determine how effective some of these tests are for detecting preclinical cases of BSE. This will be done by using CNS tissue derived from a study of the pathogenesis of experimental BSE in cattle. In contrast to the situation in scrapie-infected sheep, the distribution of infectivity in cattle with naturally occurring BSE is restricted to inaccessible tissues even in the clinical phase of disease, namely the brain spinal cord and the retina. In the experimental disease, infectivity has been detected in the distal ileum in the preclinical phase of disease, and in central ganglia and possibly in bone marrow during the clinical phase. Because none of these tissues is easily accessible, the prospect of a reliable and practical test being soon available to detect preclinical BSE in live cattle is remote.

Conclusions

The epidemic of BSE in the UK is clearly under control and heading for elimination, as predicted. It is probably similarly heading for elimination in Portugal. All products permitted for sale from cattle slaughtered in the UK in 2002 are as safe, if not safer in regard to the BSE risk, as those are from any other country with BSE. The situation in other countries is less certain but, provided all those countries at risk adopt the lessons learned in the UK, Portugal, and Switzerland, the future prospects for the elimination of BSE are also good. The critical issue is to insure that ruminant feed is not contaminated with infected MBM. This is a difficult task and interlocking and enforced measures are essential to success. Also essential is to conduct surveillance of targeted populations of cattle using the most sensitive and specific tests available.

Surveillance for all forms of CJD in humans is also vital. Of current concern is the future size and duration of the vCJD epidemics and of the possible occurrence of scrapie in sheep caused by the BSE agent. There is no evidence for the latter. In regard to the former, predictions are not possible due to several uncertainties, including the length of the incubation period, the number of humans exposed, and the precise source of infection. Concerns have been expressed about the possible transmission of vCJD from human to human, particularly via blood transfusion or surgical instruments. Currently, there is no evidence for transmission of vCJD by any means between humans, but nevertheless, strict risk management procedures have been put in place to reduce any possible risk.

Brandy

Regulations

European legislation (EC regulation no. 1576/89) distinguishes between wine spirits and brandy.

Wine spirits According to regulations, wine spirits is a spirit drink, obtained exclusively by distilling wine or 'winey' wine (vin viné) to 86% vol, or by redistilling wine distillates to less than 86% vol (wine distillates are halfway between spirits and ethyl alcohol; they must have retained the flavor and aroma of wine).

Wine spirits have a volatile substance content equal or superior to 125 g hl^{-1} of 100% vol alcohol (volatile substance content includes higher alcohols, esters, aldehydes, volatile acids, and furfural). Maximum methanol content is 200 g hl^{-1} of 100% vol alcohol. When aged, this beverage can continue to be marketed with the designation 'wine spirits' if the period of aging is equal or superior to the period provided for brandy.

According to this rule, general designations (20 different kinds of spirits) can be completed by geographical indications. The most famous French geographical designations are Cognac and Armagnac.

Brandy Brandy is a spirit drink which is obtained from wine spirits either blended or not with wine distillates distilled to less than 94.8% vol, on condition that such distillates do not exceed maximum 50% proof in the finished product.

Brandy is aged in oak containers for at least 1 year, or for a minimum period of 6 months if the capacity of the oak casks is less than 1000 l.

Brandy has a volatile substance content equal or superior to 125 g hl^{-1} of 100% vol alcohol resulting exclusively from the distillation or redistillation of the raw materials brought into play, and with a maximum methanol content of 200 g hl^{-1} of 100% vol alcohol.

Distillation

As a rule, brandies are distilled in columns containing several dozen plates. Old stills were made entirely of copper, but because the sulfur dioxide in the wine corrodes the stills and particularly the 'phlegm' collector plates, copper has gradually given way to stainless steel; today, copper is only used for the topmost parts of the rectifying columns (to draw the spirits).

Wine rectifiers For a long time, only phlegms were rectified, that is, the distillery carried out two successive operations: (1) wine distillation and recuperation of phlegms; (2) rectification of phlegms.

With advances in the conception and building of distilling equipment, continuous rectifiers now exist which process the fermented wine, making it possible to obtain 96.5 ° rectified alcohol in a single operation.

Wine rectifiers can be divided into three categories: indirect, direct, and semidirect appliances.

Indirect rectifiers (**Figure 1**). The term indirect means that rectification involves a traditional distillation process, except that phlegms are not cooled and

sent into trays but go directly into the continuous rectifier on the end of the column.

A is the distillation column producing the phlegm; while hot, phlegm is then extracted from the distillation column and sent directly to the purifying column (B) of the continuous phlegm rectifier.

The purifying column extracts the head foreshots, after which the purified phlegm is sent to the rectifying column (C) from which the drinkable pasteurized alcohol is drawn off; the unpasteurized alcohol, which is downgraded, and the low- and high-fusel oils are also extracted.

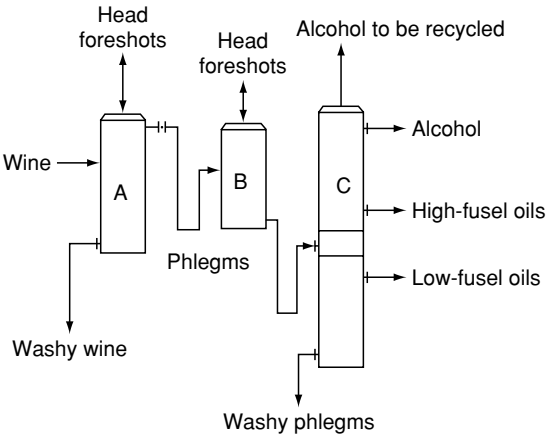

Figure 1 Indirect continuous wine rectifier. A, distillation column; B, purifying column; C, rectification column. Reproduced from Mariller C (1925) *Distillation et Rectification des Liquides Industriels*. Paris: Dunod, with permission.

Special devices have been added to the columns to recycle the most volatile substances which are of organoleptic interest (Figure 2).

This specific draw-off determines the final amount of tailings in the distillate.

For the subsequent production of wine spirits, only the higher alcohols are partially eliminated (high- and low-fusel oils) in order to recompose the distillate as desired. In this case, the resulting alcohol can only be called distillate and not 'spirits', because of the high percentage of alcohol – higher than 86% vol. – required for sorting heavy impurities.

Methanol is extracted on a special multiple-plate column (about 50 plates). This column has the disadvantage of eliminating not only the methanol but also volatile compounds of organoleptic interest; a small column can be added which separates the methanol and the volatile substances, and the latter are reintroduced into the distillate.

Batch rectification for the production of wine spirits or distillate This kind of still has a boiler similar to that of the Charente still or of cylindrical boiler stills. Primary spirits can be slightly oxidized before redistillation. This batch rectier comprises a steam-producing device, a 30-plate column, and cooler satellites and circuits. Head and tail products can be recycled in the boiler (Figure 3).

Composition of Brandies

Because of the nature of the raw material brought into play (usually red wine) and how they are made, brandies contain far fewer volatile substances than

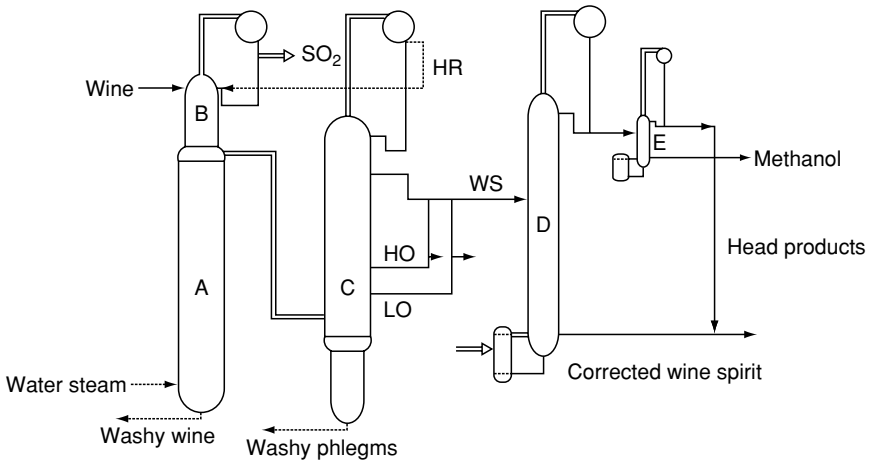

Figure 2 Continuous wine rectifier with head foreshot recuperation. Paris: Lavoisier-TEC & DOC, with permission.

Appellation d'Origine Contrôlée (AOC) spirits (Table 1); higher alcohols are rectified by specific fusel oil separation processes; head products lose most of their ethyl acetate and esters during the ethanal and sulfur dioxide elimination process.

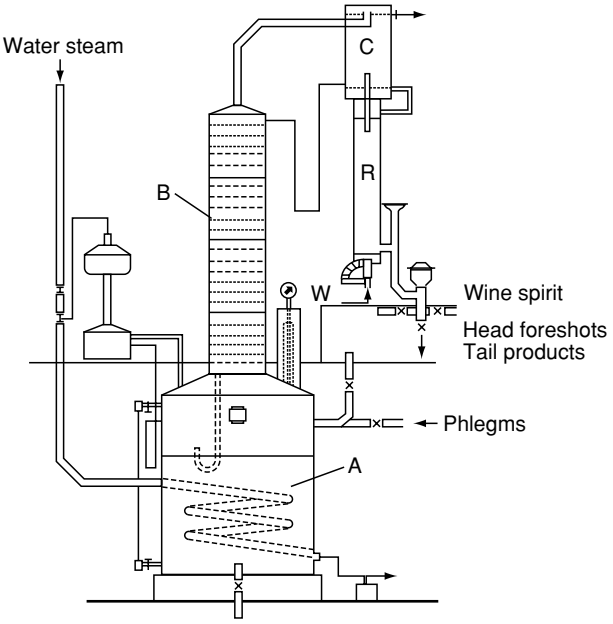

Figure 3 Batch rectifying still for the production of wine spirit or distillates. A, boiler; B, distillation column (30 plates); C, condenser; R, refrigerator (cooler); W, water. Reproduced from Guigon D and Cogat P (1991) Elimination des défauts dans les caux-de-vie de vin traditionelles. In: *Les Eaux-de-Vie Traditionelles d'Origine Viticole*, pp. 110–113. Paris: Lavoisier-TEC & DOC, with permission.

Making brandy is usually a way of salvaging defective wines or production surpluses. However, there are some good-quality brandies made from wines which are specially grown for the purpose and vinified with limited quantities of SO_2.

Gas chromatography is used to analyze volatile compounds. As an example, the chromatogram in Figure 4 shows some of the volatile alcohols, esters, acids, and various aromatic components contained in an ether-hexane extract of a brandy. Other analyses can be carried out by injecting the spirits directly into the chromatograph. The high levels of diethyl succinate indicate that the wine distilled was older than the wine used for Cognac and Armagnac.

Aging and Merchandising Preparations

As specified in the law, brandies are aged in wood containers (sous bois); different processing methods can be used: cold processing, ion exchange resins to eliminate sulfur dioxide, calcium, and copper cations; sugar, caramel, and boisé (infusions from oak shavings) may be added. Brandies are reduced with deionized water and must have a minimum 37.5% vol alcohometric titer.

The entire production of French brandy is exported.

Summary

Wine spirits of viticultural origin belong to French cultural heritage; they also constitute a major part of our economy.

Furthering our knowledge of their composition reveals that traditional wine spirits have exactly the

same composition as wine; only the heaviest and most polarized products are rectified (acetic acid, phenyl ethanol, polyols).

Major defects can only be eliminated with a distillation column, but at the cost of eliminating components which contribute to quality.

Good-quality wine spirits can only be made with good-quality wines; expensive aging in oak casks should be reserved for noble products.

Armagnac

Historical Background

According to scholars, Armagnac is the oldest known wine spirit; it has been produced without interruption since the early fifteenth century.

The name is the result of successive transformations of the word 'arminiacum,' meaning owned by or estate of Arminius. Arminius may be the latinized form of Hermann, a Saxon warrior and a companion of Clovis, the Frank king, who crossed the Rhine in 406 to wage war in the south-west of France. A Count of Armagnac is recorded in about 1032.

As in many other regions of France, the vineyards developed considerably under the Romans, until their expansion was temporarily interrupted by a decree of Emperor Domicien in 92 (in fact, half of the vines were pulled up and not planted again until 267, when Emperor Probus published an edict authorizing wine growing in Gaul). Vines continued to be planted all through the barbarian invasions and developed essentially around the monasteries. A tithe levied by the monks from the Abbey of Saint Mont (Gers) testifies that wine was being produced in the tenth century.

In 1254, Bayonne was actively trading with merchants from northern Europe; wines from Chalosse and probably from the west of Armagnac were shipped down the Adour. Wines from Haut Armagnac passed in transit on their way to Bordeaux, but, in 1241, the Bordeaux authorities decided to regulate, to their advantage, the Haut-Pays wines arriving in Bordeaux.

For a region so far removed from any natural outlet to the sea, distillation proved very early to be a reasonable solution, with smaller volumes to transport and without the quality of the wine deteriorating. This explains why the Comté of Armagnac became the first region of France to develop distillation. At the time, most of Aquitaine was English and wine growing was certainly favored by the flourishing trade between England and Northern Europe, as well as by the pilgrimage to Santiago de Compostela.

In 1411, the archives of the Haute-Garonne show that a distiller, M Antoine (aygua ardentarius), was producing a wine spirit, 'aygue de Bito,' in Toulouse; 28 years later, in 1439, the same source mentions other distillers: Jean Nouvel and his wife 'facientes aquam ardentum.' One document, dated 1461, mentions the levy of taxes, which testifies to the beginning of an Armagnac trade in Saint-Sever (Landes). In 1489, a document in the Gers archives mentions the presence of a still in Solomiac (Gers). By 1550, both Bordeaux and Bayonne were selling Armagnac to northern Europe.

Until the eighteenth century, wines were distilled in pot stills; these were simple devices similar to those described by Savonarole in 1440 in his treaty on distillation, 'Confidencia aquae vitae,' in which he describes the first copper still with a coil plunged in cold water. It was only toward the mid eighteenth century that distillation methods began to be improved. In 1761, with the help and advice of the chemist Chaptal, Menier invented a new process known as continuous distillation, and this process was patented by Adam in 1801.

This new distillation technique rapidly spread to the whole Armagnac area and is still the method used today, with few alterations. However, the type of still used in Charentes had to gain formal approval again in 1972.

The French Revolution boosted production: 50 000 hl of pure alcohol were produced in 1810, and over 100 000 hl in 1873, corresponding to 107 000 ha of vines. At that time, the Armagnac vineyard was one of the largest in France but in 1879 it was hit by phylloxera; 10 years later, alcohol production had been reduced by two-thirds. The vineyard was never to be entirely replanted and present-day production wavers between 20 000 and 50 000 hl per year as pure alcohol.

Appellation Areas, Soils, Climate, Vine stocks

The region of production covers about 12 000 ha, divided into three areas: Bas-Armagnac, Ténarèze, and Haut Armagnac (Figure 5).

Bas-Armagnac Bas-Armagnac is the most productive area – about 60% of the vineyard – with acid, predominantly sandy soils. Conversely, the soil in Haut-Armagnac is mainly composed of calcareous clay and has virtually ceased producing wine spirits. A blend of wine spirits from several minor appellations can only be called plain Armagnac.

Bas-Armagnac is a flat area, on the edge of the Landes forest, and the slightly acid, siliceous clay soil often contains iron oxides which endow it with a dark color – hence the name 'fawn sands.'

The annual mean temperature is 13 °C, with 7.5 °C in winter and 20 °C during the three summer months. Annual rainfall is 892 mm. The rain is well spread out over the year, with 1 mm minimum in July and 86 mm maximum in May.

Ténarèze The hilly landscape of the Ténarèze area consists of a variety of soils: sand, outcrops of calcareous clay, and boulbènes (a mixture of clay and fine sand) in the valleys. Being further away from the ocean, and especially from the Landes forest, the climate is a little more 'continental,' entailing atmospheric disturbances and more rainfall.

Mean annual rainfall is 804 mm, the main difference from Bas-Armagnac being the frequent thunderstorms in October.

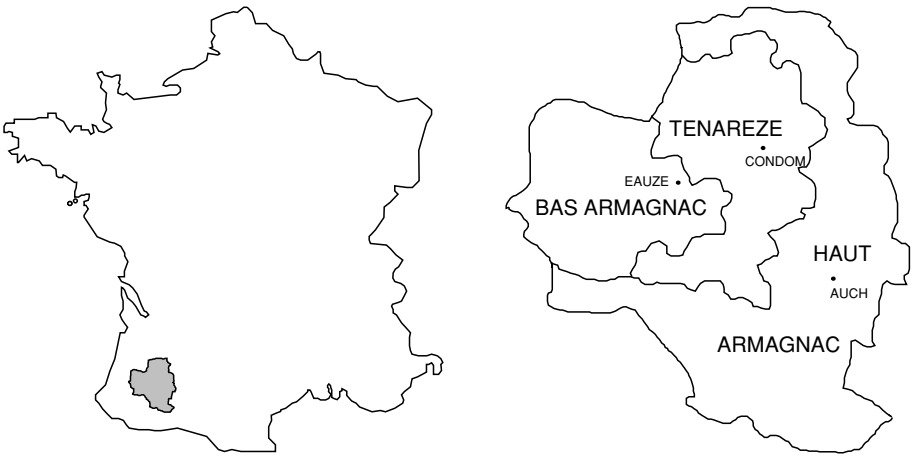

Figure 5 Armagnac in France and the three appellation areas.

Likewise, temperatures range between 7.2 °C in winter and 26 °C in summer. This difference is due to wind conditions; the area is still exposed to the east wind (vent d'Autan), which brings the end of summer droughts and storms.

Haut-Armagnac In Haut-Armagnac, soils are more calcareous and the climatic differences even more pronounced. The average period of sunshine in Auch is 1934 h, surprisingly, this is 5% less than in Bordeaux, perhaps because of a longer period of cloud cover.

The main different vine stocks allowed are Ugni blanc, Baco 22 A, Folle Blanche and Colombard.

Ugni blanc, an Italian vine stock related to Trebbiano, is rapidly gaining ground, as it offers the advantage of coming to maturity in the 'troisième époque' (45 days after Chasselas maturation), thus eliminating the problem of rot, and it produces low-alcohol wines suitable for distillation. Baco 22 A, which ranks second for making Armagnac, is a hybrid of Noah (*Vitis labrusca* × *V. riparia*) and Folle Blanche; it matures 30 days or more after Chasselas ('maturité de deuxième époque'), is very disease-hardy and does not require grafting thanks to the sandy soil of the Landes. This variety stands out as an exception among the vine stocks used for French AOCs. The Institut National des Appellations d'Origine des Vins et Eaux-de-Vie (INAO: French National Institute for Wine and Spirits Appellations of Origin) is planning to eliminate it from the Armagnac vineyard by 2010. The rather 'foxy' flavor of Baco wines, due to the presence of furaneol and methylic anthranilate ('*labrusca*' character), disappears during distillation and neither substance is detectable in the spirits.

The vineyards are of average size; pruning is managed according to the Guyot method in one or two stages; the vines are trellised and there are 4000–5000 vines per hectare.

Vinification

Most vinegrowers use a grape harvester to harvest the grapes and a continuous wine press to extract the juice; such methods, which are usually too brutal for immature grapes, have no particular drawbacks in this case as long as the dregs are not strained too much.

The temperature of alcoholic fermentation is rarely checked. Wines are not subjected to any enological process, and sulfur dioxide is strictly forbidden (Decree of 6 August 1936, modified 24 May 1956). The alcohol strength of the wine varies considerably, ranging between 8 and 11.5% vol or more; acidity is average (4–6.5 g l^{-1}, expressed as H_2SO_4). Malolactic fermentation usually occurs spontaneously just after alcoholic fermentation.

According to the Bureau Interprofessionnel de l'Armagnac (BNIA: French Interprofessional Office for Armagnac), 60 922 hl of pure alcohol were distilled in 1990, from 567 000 hl of wine. Production this year has been particularly good. The average annual production is about 20 000 hl 100% vol alcohol.

By law, wines have to be analyzed in an appointed laboratory to prove they are free of sulfur dioxide and of sufficient quality to be used to make Armagnac.

Distillation and Regulations

Wines have to be distilled in the appellation area. Two sorts of stills are used; the BNIA has listed the following ones which are in use:

1. 112 continuous stills: Armagnacais
2. 12 pot stills, producing less than 10% of the total volume of Armagnac.

The maximum distillation alcohometric titer allowed is 72% vol, the same as other French AOC wine spirits (Decree of 6 August 1936). The minimum alcohometric titer for white spirits (when they come out of the still) is set at 52% vol.

Wines are required to be distilled between the end of the harvest and 31 March of the following year (Decree of 15 March 1988, modified).

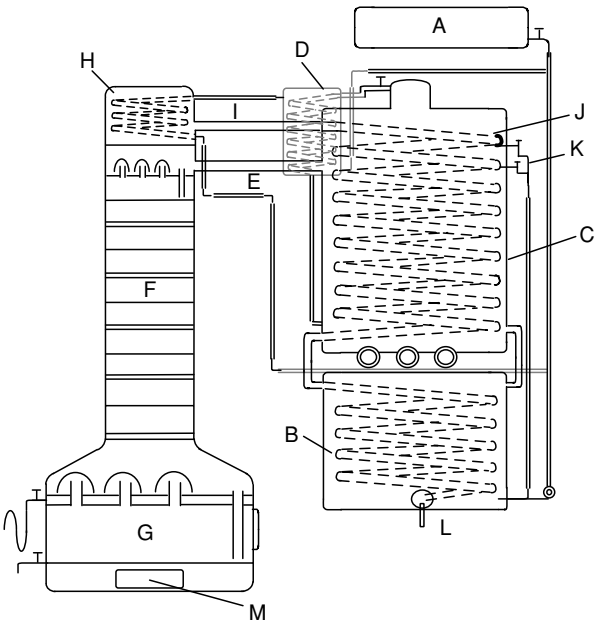
The continuous Armagnac still (Figure 6) The continuous still used in Armagnac is made entirely of annealed electrical-grade copper; it works very much like steam-powered distillation and plays an essential role in the specificity of armagnac.

The boilers, distillation columns, wine-heater, and cooler constitute the still's main parts.

The volume of the boiler ranges from 5 hl to a maximum of 35 hl; it is divided into two or three sections by separation plates. The total capacity of the boilers must be at least equal to that of the cooling unit, including the wine-heater and the cooler.

The column has five to 15 plates (the most recent stills have about 12 plates). These plates are fitted with different-shape bubble-through devices: bubble caps, bell-shaped tunnels or oil grooves. The plates above the wine arrival pipe are called dry plates and help reduce tailings while increasing the alcohometric titer.

The wine-heater is used to preheat the wine; the coil inside raises the temperature to 70 or 85 °C, which condenses the alcoholic vapors issuing from the column. The capacity of the wine-heater varies considerably (5–15 hl).



A: Head of wine, B: cooler, C: wine heater, D: head condenser,
E: wine arrival, F: column, G: boilers, H: head of column,
I: swan neck, J: coil, K: drawing and recycling of tailings
L: alcohometer holder, M: furnace.

Figure 6 Armagnac still.

The cooler, which is generally smaller (3–10 hl) than the wine-heater, is placed under the wine-heater. After going through the wine-heater, the coil goes into the cooler to achieve complete condensation and cooling of alcoholic vapors.

Sometimes, a head foreshot condenser system can be fitted to the still, above the wine-heater; more frequently, a tail product condenser is placed level with the alcoholic vapor pipe, between the column and the wine-heater. Tailings can also be collected in the first turns of the coil. The condensed fractions can be returned to the wine and recycled. A coil can be added to the head of the column, to circulate pre-heated wine in the head or tailings condensers; this also helps to condense the least volatile products and to increase the percentage of alcohol.

The wine from the loading vat goes into the still, at the bottom of the cooler, by force of gravity. The flow is regulated with a gate-valve equipped with a flowmeter. The spirits come out of the still through the alcohometer holder where the temperature and alcohometric titer of the distillate are measured. Washy wines are evacuated continuously through a syphon connected to the boiler.

The daily quantity produced cannot exceed one and a half times the capacity of the whole cooling system.

The wine is always heated over an open fire, usually propane gas, although wood is still frequently used to heat small stills.

Because of the way it works, Armagnac distillation is not only far more economical than two-stage distillation, but also three times as fast.

When it has been running for about 2 weeks, the still is turned off and cleaned. Sediments accumulated on the plates and residues prevent the copper from fixing the volatile acids and sulfurous compounds. Inadequate cleaning soon results in the appearance of an unpleasant flavor and a greasy rancid smell, like seconds.

To start the still, one proceeds as follows: first, the boiler and the column are filled with water; once the wine-heater and the cooler are full of wine, the fire is lit; when the water begins to distill, the wine inlet pipe is opened. As soon as the desired alcohometric titer is reached (60% vol, for instance), the spirits are recuperated.

With the Armagnac distillation method, the volatile substances are either entirely distilled (higher alcohols), or are more or less rectified (2-phenyl ethanol, ethyl lactate, 2,3-butanediol), according to their polarity. The fatty acid ethyl esters and fatty acids with a high molar weight are released by heating the yeasts, which means that the quantity of these acids depends on the the wine's yeast content; generally speaking, there are about four times fewer fatty acid ethyl esters with 8, 10, and 12 atoms of carbon in Armagnac than in Cognac. This leads connaisseurs to claim that the quality of Armagnac comes from the specific nature of its soils and the aromas of vines harvested at maturity and not only from their yeast ester content (Table 2).

Table 2 Distillation of volatile substances (average from 50 wines and their corresponding spirits)

	Wine ($mg\,l^{-1}$)	*Spirit* ($mg\,l^{-1}$)	*% Recovery*
Ethanol, (% vol)	11.1	59.7	
Higher alcohols	373	2043	102
Methanol	41.4	194	87
2-Phenyl ethanol	53	32	10
Higher alcohol acetates	2.61	12.7	90
Volatile acid ethyl esters	1.46	14	177
Ethyl acetate	41	207	94
Diacetyl	0.65	2.91	83
Volatile acids (C3 – iC5)	4.12	10.79	38
Volatile acids (C6 – C12)	11.2	34.2	56
Ethyl lactate	340	248	14
Acetic acid	400	118	5.5
Butane-2,3-diol	549	14.9	0.5

To modify the composition of the spirits, the distiller mainly controls two parameters: wine flow and heating.

How the still is adjusted plays an essential role in the composition of the spirits: lowering the heating or increasing the wine flow brings down the temperature at the head of the column and results in a higher alcohometric titer; in this case higher alcohol and ester concentrations correspond exactly to the percentage of alcohol, in other words, the quantity of these substances expressed in g hl^{-1} remains constant (Figure 7).

Conversely, the amount of substances called tailings, of which there is usually a surplus in Armagnac, decreases exponentially when the percentage of alcohol increases. For prolonged aging, a large quantity of tailings is an advantage because of the 'winey' character of their molecules; but if the Armagnac is to be marketed soon, it is preferable to make a high-proof distillate to limit the amount of such substances.

Two-stage pot stills These stills are used in the same way as for Cognac; however, in Armagnac, sediments are never reintroduced in suspension into the wine before distillation. Two-stage distillation has its advantages: the Armagnac ages more quickly and can thus be marketed much earlier, although it loses some of its specificity in the process.

Analysis

Two sorts of analysis are carried out on wine-spirits: (1) traditional analyses; and (2) analyses to improve knowledge of the products and establish correlations between their chemistry and organoleptic observations.

Traditional analyses Their purpose is to determine real and raw volume-percentages of alcohol (titration), dry extract, total acidity, and the ratio of non-alcoholic elements, i.e., volatile acidity, aldehydes, esters, furfural, and higher alcohols; methanol values are determined separately.

Table 1 shows mean values for Armagnac and Cognac, compared to brandy. The sum of volatile substances of brandy is noticeably lower than the others; this is due to the fact that it is elaborated in columns.

Conversely, brandy contains more methanol than Armagnac or Cognac, because it is made essentially with red wines.

Gas chromatography Gas chromatography is used to analyze volatile compounds. As an example, the chromatogram in Figure 8 shows some of the volatile alcohols, esters, acids, and various aromatic components contained in an ether-hexane extract of Very Special Old Pale (VSOP) Armagnac. Other analyses can be carried out by injecting the spirits directly into the chromatograph. The high levels of butanediol found in Armagnac show that it is rich in tail products.

A set of average values can be established from these analyses (Table 1).

Carbonyl compounds are currently being analyzed; long-chain aldehydes seem to be specific to Armagnac; methyl ketones, glyoxal, and methyl glyoxal levels increase with age. These carbonyl compounds contribute to the rancid character of old wine-spirits.

Different high-performance liquid chromatography (HPLC) analyses can also be carried out by absorption spectroscopy to measure the principal phenolic compounds extracted from wood which contribute to the vanilla flavor that develops with age.

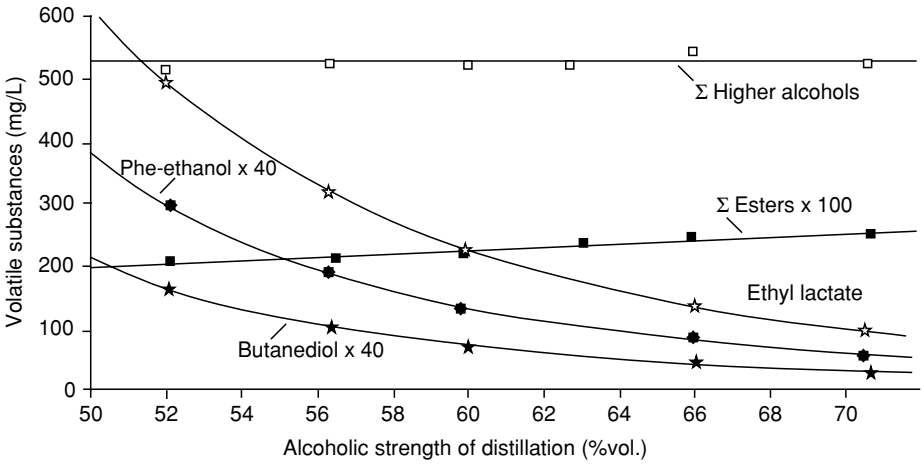


Figure 7 Relationship between alcoholic strength of distillation and content of volatile substances.

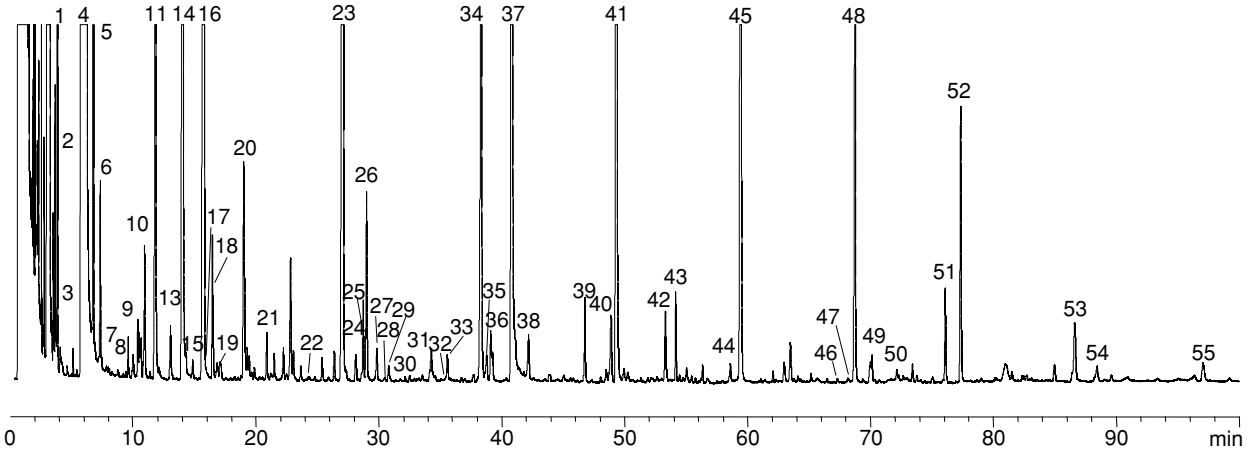

Figure 8 Chromatogram of the extract of an Armagnac by ether hexane (concentration about 3 times); column FFAP 50 m × 0.22 mm; injection according to splitless mode; temperature programmation from 40 to 200°C. Identification of the peaks: 1, Ethylbutyrate; 2, 2-methylpropan-1-ol; 3, isoamyl acetate; 4, isoamyl alcohols; 5, ethyl hexanoate; 6, hexyl acetate; 7, styrene; 8, acetoin; 9, ethyl heptanoate; 10, ethyl lactate; 11, hexan-1-ol; 12, trans-hex-3-en-1-ol; 13, cis-hex-3-en-1-ol; 14, octan-3-ol (internal standard 1); 15, trans-hex-2-en-1-ol; 16, ethyl octanoate; 17, trans-linalol oxide (furane); 18, cis-linalol oxide (furane), 19, acetic acid; 20, benzaldehyde; 21, linalol; 22, 2-methylpropionic acid; 23, ethyl decanoate; 24, butyric acid; 25, 3-methylbutyric acid; 26, diethyl succinate; 27, α-terpineol; 28, 1,1,6-trimethyl-l,2-dihydronaphtalene (TDN); 29, methionol; 30, inconnu; 31, inconnu; 32, damascenone; 33, phenylethyl acetate; 34, ethyl dodecanoate + hexanoic acid; 35, benzyl alcohol; 36, trans-whisky lactone; 37, 2-phenylethanol; 38; cis-whisky lactone; 39, 4-ethylgaiacol; 40, ethyl myristate; 41, octanoic acid; 42, 4-allylgaiacol (eugenol); 43, 4-ethylphenol; 44, ethyl palmitate; 45, decanoic acid; 46, ethyl stearate; 47, ethyl oleate; 48, dodecanoic acid; 49, ethyl linoleate; 50, ethyl linolenate; 51, inconnu; 52, myristic acid; 53, palmitic acid; 54, palmitoleic; 55, linoleic acid.

Sensory analyses Sensory analyses can also be carried out by experienced wine-tasters. Tasters fill in a multiple-choice question tasting-card, and tick off the boxes corresponding to their perceptions; there are also questions related to 'hedonistic' sensations. Since Armagnac comprises several hundreds of substances, it is extremely difficult to describe it accurately in just 20 questions (which is a maximum), but no other solution is forthcoming. Results are often computer-processed using multidimensional analysis methods; multiple correspondence factorial analysis is the best suited.

The main features of old Armagnac are its aroma of prunes, its 'rancio' taste, its complexity; it is vigorous and even rough, with a long-lasting palate.

Aging and Merchandising Preparations

Wine spirits are usually aged in oak casks. Coarse-grained wood is preferred (Gascony or Limousin) to fine-grained wood, as it is slightly more permeable to oxygen and yields more tannin.

At this stage, oxidation is of prime importance, not only for the development of the substances originating from the wood, but also for the distillate itself. Alcohol is oxidized into acetic acid, the quantity of which increases threefold in 20 years; pH, which is 5 in a young wine spirit, drops to 3.5; acids in turn partially become esters; and, in the end, only the higher alcohols remain relatively unchanged in relation to ethanol.

Oak consists of 40–45% cellulose, 20–25% hemicellulose, 25–30% lignin, and 8–15% tannins. The optimal alcohometric titer to extract these components with wine spirits is around 55% vol. Armagnac just out of the still lends itself perfectly to harmonious aging.

The amount of substances extracted from the wood depends on whether the cask is new or old; over a 12-year period, a new cask can produce three times as much as an old one.

Spirits with too much tannin (castalagin and vescalagin) can be harsh and astringent.

With time, lignin is transformed into aromatic aldehydes and phenolic acids.

Armagnac contains vanillin, syringaldehyde, coniferaldehyde, and sinapaldehyde, but only the vanillin is detectable at tasting.

Although there are a variety of aging methods, spirits are usually kept in new casks for 6 months to 1 year before being transferred to old casks.

Prior to being marketed, several wine spirits are blended and the alcohometric titer of the blend (the cut) is reduced to a minimum of 40% vol with distilled water. The naturally golden-yellow color can be enhanced with caramel. Sometimes, infusions or decoctions made from oak shavings are added to

Table 3 Major commercial designations of Appellation d'Origine Contrôlée (AOC) wine spirits

Category	*Minimum age (compte d'† ge)*	*Average age*
Three Stars	2	About 2 years
VO, VSOP	4	5 years
XO, Extra, Napoleon Vieille Réserve, Hors d'Age	5	6 years

VO, Very Old; VSOP, Very Special Old Pale; XO, extra old.

make the Armagnac more astringent, to give it more body; however, these preparations must be at least the same age as the youngest spirit used for the commercial designation of the final product. Sugar solutions are sometimes added to attenuate the 'burn' of the alcohol (about $6\,g\,l^{-1}$).

Finally, before being bottled, the spirits are cold-processed (usually 1 week at $-5\,^{\circ}C$) and passed through a cellulose filter to eliminate any possible cloudiness due to an excess of calcium or fatty acids.

Vintage spirits from a single harvest of a particular year are sometimes sold with no prior reduction of their natural alcohometric titer. Vintage Armagnacs constitute an exception among wine spirits; some of them are extremely valued and fetch high prices.

The various commercial designations are based on the youngest spirit in the blend (cut) the BNIA keeps updated registers listing the age (compte d'âge) and volume of all the different Armagnacs stored in any given storehouse (Table 3).

Cognac

The first distillation of wine for the production of Cognac took place in Charente in 1622. In fact it was in the province of Aunis that this distillation took place, but historically the development of the vine in this area of the south-west of France is related to the economic development of the old maritime province of Saintonge. This was much vaster and extended from the Sèvre Niortaise to Angoulème, the north of the Dordogne, and the Gironde river. But, it only really developed from 276 AD with the edict of the Roman emperor Probus who granted the privilege of cultivating the vine which had hitherto been granted only to Romans in 92 AD.

During the thirteenth century trade flourished, in particular with the shippers of the Nordic countries who came to buy not only the salt of the Saintonge salt-pan created by the Romans but also the wine of Ritsel (La Rochelle) and Saint Jean (d'Angély). Since demand perpetually increased, the wine of the 'haut pays' began to be traded as the small coastal rivers were navigable (Boutonne river which goes to Saint Jean d'Angély and especially the Charente river, navigable up to Saintes, Cognac, Jarnac, and Angouleme). Dutch sales representatives settled in Tonnay-Charente, then in Cognac, which was a 'tax stage' city between the provinces of Saintonge and Angoumois and which in the fifteenth century had an administrative infrastructure appreciated by the traders.

Another important event was the marriage of Eleanor of Aquitaine with Henri Plantagenet in 1152. This opened up an era of great prosperity for this province which could practise the trade of wine since it was now attached to England. The province then began to plant vines massively. At the end of the sixteenth century, when the Dutch became the masters of maritime trade, brandy gradually replaced wine and it was also used as a currency of exchange for spices, metals, and slaves. The Dutch stimulated the production of aquavits and brandevins which insured a perfect conservation of the distilled product and made it possible to reduce the volume to be transported. However, because of the proximity of the sea, the Dutch could distil the wine on their premises because the trip was not too long. This explains the relatively late appearance of distillation in Saintonge (two centuries later than in Armagnac).

At the beginning the stills were imported from Holland. They were manufactured with Swedish copper but the production of stills in Bordeaux and then in the Cognac area began about 1724. At that time there occurred a kind of wine revolution which led certain areas to increase their production, in order to have the greatest volume for the Dutch merchants. On the other hand, other areas preferred the production of high quality, thereby implying limited yields. Such was the case in particular for the wines of Bordeaux, Burgundy, Champagne, for the liqueur wines of Sauternes, Bergerac, and Borderies (area to the north-west of Cognac), and finally for Cognac brandies.

In fact, it seems that tax reasons encouraged the middle-class rich of the city of London to search for top-of-the-range products. Since taxation of wines and alcohols was very high from 1628, it was necessary to pay high prices, so the product had to be of excellent quality. By storing brandy in wood barrels, the English to some extent invented the aging that is now known to transform brandies into delicious, much more agreeable products for consumption. Moreover, the term 'Old Cognac Brandies' appeared in London in 1700. With the Augier family in 1943, the British, for example, Jean Martell (1715) and Richard Hennessy (1765), were partly responsible for setting up the true commercial structures which still remain today.

At that time, the trade in wines and brandies was of equal importance but thereafter, brandy production really came to the fore.

The production of Cognac began on the chalky slopes located to the south-east of Cognac, an area called 'Champagne' because of the nature of the grounds. The vineyards extended gradually to the surrounding wooded regions. Starting from 15 000 ha in 1600, the vineyard reached 100 000 ha in 1800 and 255 000 ha in 1878, just before the phylloxera epidemic which destroyed the Charentais vineyard.

Nevertheless, the multiple obstacles to trade of all types, in particular the wars, resulted in huge volumes of spirit being stored. In 1873 this was evaluated at 7 277 000 hl of Cognac. This made it possible to overcome the period of reorganization of the vineyard without losing important customers, in particular the English.

The Viala mission (1887) found an American vine in Texas, *Vitis berlandieri*, which was resistant to phylloxera and adaptable to the charentais soils which are very rich in limestone. This made it possible to create rootstocks which were not susceptible to chlorosis (when the leaves cannot synthesize chlorophyl owing to iron deficiency). Under the control of Alexis Millardet, the father of the bouillie bordelaise (copper sulfate + lime) used for treatment against mildew, research led to the 41 B rootstock, a hybrid of chasselas and *V. berlandieri*. This rootstock was used to reconstitute the vineyard, and gradually the old traditional type of vines like folle blanche or Colombard were replaced by the better-adapted white Ugni blanc cultivar. The average quality of brandies from Ugni blanc is higher than that of folle blanche brandies from the last century because the latter was subject to gray rot.

The Vineyard

Double Guyot pruning of the vine is practiced. Nowadays, the plants are 1 m 30 on the rows and 3 m between the rows. Pruning is done with two long branches arched downwards. The number of buds is 50 000–60 000 per hectare, i.e., 20–22 buds per foot. Normally the vine is trellised with five or six wires.

Blossoming (débourrement) of the buds take place between the end of March and beginning of April, flowering is about June 20–25, ripening (veraison) between August 25 and September 10, and harvesting generally begins about October 10.

The Climate

The climate is moderate and wet, rather similar to that of Bordeaux, with average temperatures + 6.5°C in winter and 21.7 °C in summer. Rainfall (800 mm of rain per year) is distributed over 130–150 days.

The Appellation Areas

There are six appellation areas (crus) (**Figure 9**) corresponding to particular soils, which may also be influenced by climate. For a long time tasters classified brandies according to the sectors. The decree fixing these areas was promulgated in 1909. The limits were modified in 1938.

1. The Grande Champagne comprises 27 communes of the Cognac district. The soils are clay-calcareous surmounting a friable calcareous layer of cretaceous soil which absorbs excess water and which, in dry periods, constitutes a reservoir locally, called the volant of quality. From a climatic point of view, this is both the hottest and driest area, with the nearby sea having relatively little influence.
2. The Petite Champagne is concentric in relation to Grande Champagne. Its characteristics are similar but slightly different brandies have produced. A mixture of grande and petite champagne is harmonious, and is called fine champagne.
3. Borderies, on the right of the Charente river, to the north-west of Cognac, has soil composed of sand and clay (instead of calcareous and clay in the other areas) on a calcareous base, and gives particular brandies which age with a typical bouquet.
4. The Fins Bois were formerly wooded areas (before the nineteenth century). The soils composed of hard stones are from Jurassic, and with a cretaceous calcareous base. They give brandies which are not as fine as the preceding ones but which age more quickly.
5. The bons bois soils contain less limestone, so may also be more influenced by the climate.
6. The bois ordinaires are primarily the north of maritime Charente and the islands. Here, the sea influence is more marked, and the wines and spirits may sometimes reflect this in taste.

Production

Between 1956 and 1973, the possible yield per hectare rose from 3 hl of pure alcohol (PA) to 11.5 hl PA. During the years 1967–1973 the average yield was approximately 7 hl. AP ha^{-1}. Nowadays it is about 9 hl ha^{-1}. For the 1999 vintage approximately 3 850 000 hl of white wine was distilled, giving 325 000 hl PA of Cognac (approximately the equivalent of 100 000 000 bottles of Cognac). The same quantity has been sold in 2000 with more than 90% for the export market.

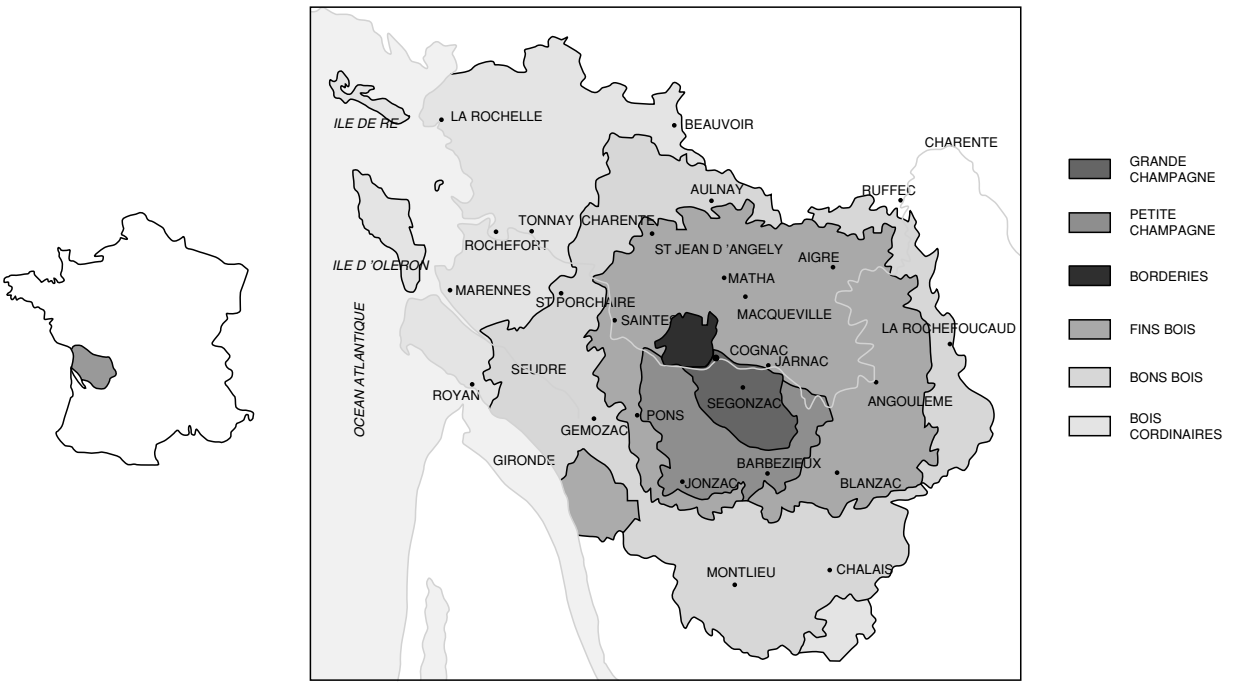

Figure 9 (see color plate 11) Cognac in France and the different appellation areas. See text for further details.

Wine Making

This is very rudimentary. The grape harvest takes place in the second fortnight of October. About 90% of the production is mechanically harvested. Then the grapes are pressed in horizontal presses. The continuous presses (called the Archimedes screw) are prohibited because they may induce herbaceous tastes. Sulfur dioxide is not used because it binds ethanal which is then released during distillation and tastes pungent. Nor is there any racking of the lees before fermentation (débourbage), and addition of sugar to the must to increase the potential alcoholic strength (chaptalization) is strictly prohibited.

Sometimes, alcoholic fermentation starts badly in cold and rainy years, but generally it is very fast (8 days for the first vat), then 3–5 days, when the wine material has been used and allows seeding of musts.

The wines are kept on the lees, and malolactic fermentation is conducted in the month following alcoholic fermentation, even if the pH is low, because absolutely no sulfur dioxide is used.

Distillation can immediately take place after the end of the fermentations, and the best brandies are those which are distilled first. Ethyl butyrate levels increase with time of conservation and especially when the temperature increases. This is explained by the total absence of disinfectants to protect the wine against oxidation and bacterial accidents. As long as the wine ferments, the medium is reduced (low oxidoreduction potential) and there is no risk. However, at the end of fermentation, the wine must be stored in full, hermetically closed vats. The most frequent accident is the browning of wine (casse brune) caused by an enzymatic oxidation of the phenols in quinones in years of rot. It seems that this has no effect on the quality of the spirits since the polyphenol does not distil.

The bacterial risks are the bacterial degradation of tartaric acid call tourne (which is far from frequent), and the problem of bitterness due to acrolein which arises from the decomposition of glycerol in propenal. This is not very frequent but is very harmful for the brandies, which then become undrinkable. Several cases occurred in the past when the tanks were situated under the ground; the wine cooled too slowly and lactic bacteria degraded the glycerol and butanediol. Since the use of disinfectants is prohibited, it is obviously necessary to work with perfectly clean wine-making equipment because of possible contamination. The screw of the press must be lubricated with paraffin oil because mineral oil could give a tainted taste to the Cognac.

Wines

The alcoholic strength is generally relatively low (8–10% vol). The wines are too acid for direct consumption at pH 3 or even less, and total acidity ranges

from 7 to 10 g l^{-1} (expressed as tartaric acid), even if malolactic fermentation has taken place. The acidity of the must reaches 15–20 g l^{-1}. This acidity makes it possible to some extent to compensate for the absence of sulfur dioxide. However, according to regulations, the wines must be distilled before the end of March because after that time heat would lead to inevitable deterioration caused by the growth of lactic bacteria. These wines contain only very little ethanal since sulfur dioxide is not used.

The flavor must be very neutral. When the specific fruitiness of the type of grape is too marked, it is not possible to obtain fine brandies. For example, muscadelle or sauvignon cultivars would not be suitable to obtain good Cognac. In contrast, with the very neutral Ugni blanc, the flavor comes from fermentation byproducts. This flavor is probably mainly due to higher alcohols which are present in high quantities, since fermentation occurs in the presence of the less of the must (see Table 1). The esters of fatty acids, ethyl caproate, caprylate, caprate, and laurate are also important because of a relatively low fermentation temperature (late grape harvest, low sugar content).

The herbaceous tastes in Cognac are due to carbonyl compounds with six carbons. They may occur when the harvested grapes contain too many leaves or when they are crushed too hard by the machines. Oily tastes are due to 1,1,6-trimethyl-1,2-dihydronaphtalene (TDN) for the same reasons. This chemical substance seems to be more or less specific to Ugni blanc, especially when it is not ripe enough.

Volatile acidity is generally very low (0.2–0.4 g l^{-1} expressed in acetic acid). Ethyl acetate levels are also generally low (30–60 mg l^{-1}). The dry extract varies between 15 and 24 g l^{-1}. The quantity of unfermented sugar is very low, and often nil (less than 50 mg l^{-1}).

Distillation

The charentais still (Figure 10) The charentais still is made of copper of electrolytic quality (no hydrogen bubbles in metal). Copper is essential since it is a good conductor, is not attacked by wine acids, and fixes the traces of H_2S arising from the late treatment of the vine with sulfur to combat oidium infection. Copper combines a part of the caprylic, caproic, and lauric fatty acids, whose odor resembles that of cheese, and long-chain fatty acids which could give insoluble soaps (eliminated by filtration). Distillation in a stainless-steel boiler gives poor-quality brandies. The process can be improved by adding turnings of copper or copper sulfate. The copper is rolled and hammered to increase its hardness and to make its surface smoother.

There are two shapes of stills according to the shape of the boiler, which is either straight or onion-shaped. The volume of the boiler is 30 hl maximum for the second distillation called the bonne chauffe; exceptionally, the volume of the boiler may be 150 hl but only for the distillation of the wine (first distillation).

The upper part is called the chapiteau (olive or onion form). Its volume represents 10% of the volume of the boiler and it is topped by the swan neck. A wine heater generally makes it possible to recover the calories provided by the alcoholic vapors. The temperature is about 50 °C before the boiler is filled. The serpentine, which is also made of copper, is about 30 m long. It is placed in the cooler, called

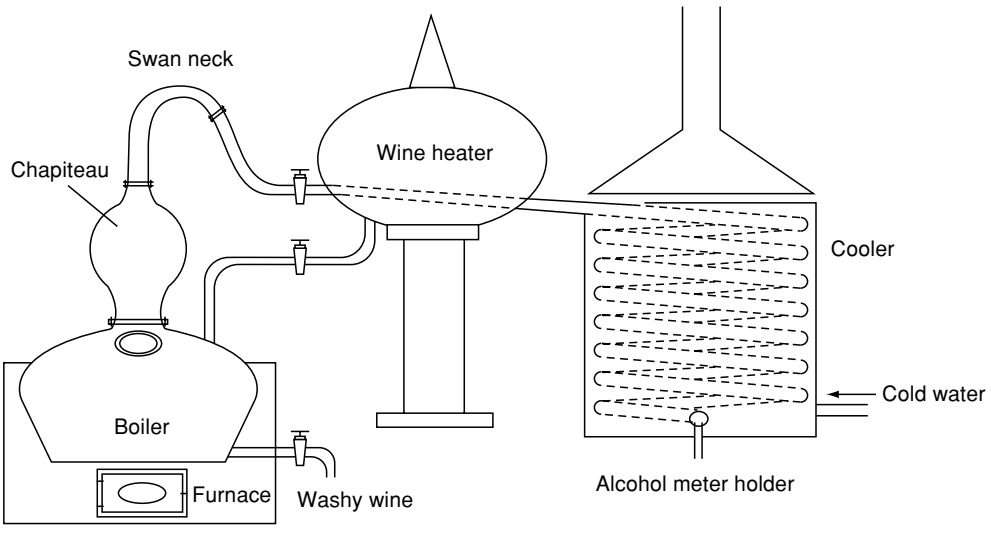

Figure 10 Charente still for the production of Cognac spirit.

la pipe, which is filled with water; its capacity is approximately twice that of the boiler.

The boiler is assembled on a solid mass of masonry. The boiler is heated by direct flame (no steam or electric heating). At the lower part is the furnace. On the sides of the boiler are what is known as the 'turns with fire' in which the gases from the hearth are burned before being evacuated towards the chimney. From 600 °C in the hearth, the evacuated gases drop to no more than 250 °C.

The liquid in the boiler is at boiling point (between 90 and 102 °C) and the temperature in the chapiteau is lower than 5–8 °C. Part of the vapor (3–5%) flows back, which makes it possible to obtain a slight rectification of the distillate. At 1 mm above the bottom of the boiler, there occurs an overheating of about 5 °C before boiling begins. Excessive overheating induces a certain bitterness of the spirit.

Formerly wood was used as fuel, then coal, and nowadays butane and generally propane. It is obviously necessary to use burners which work efficiently without overheating. The adjustments are similar to those of a central heating system.

Distillation method Traditionally the wines are distilled with their lees. However, in recent years only the finest lees (yeast) have been used, so it is possible to speak of wines with fine lees or even wines free of lees. This has repercussions on the ester content (Table 4).

Table 4 Effect of the lees of the wine on the composition of the distillate

	Few lees in the wine	*With lees in the wine*
Ethyl caproate	6.76	8.3
Ethyl caprylate	8.95	23.6
Ethyl caprate	13.8	63
Ethyl laurate	12.45	36.2
Ethyl myristate	5.4	9.8
Ethyl palmitate	9.77	13.2
Ethyl palmitoleate	1.44	1.8
Ethyl stearate	0.59	0.61
Ethyl oleate	1.19	1.22
Ethyl linoleate	7.69	9.2
Ethyl linolenate	1.86	2.58
Isoamyl caprylate	0.42	2.48
Isoamyl caprate	1.67	5.76
Isoamyl laurate	0.78	1.83
2-phenylethyl caprylate	Traces	1.2
2-phenylethyl caprate	0.25	1.55
Summ of aromatic esters	73.02	186.65 (+ 150%)

Results as $mg\,l^{-1}$ of the distillate at 70% vol.
Reproduced from Cantagrel R, Lurton L, Vidal JP and Galy B (1992) La distillation caharentaise pour L'obtention des eaux-de-vie de Cognac. In: Bertrand A (ed.) *Les Eaux-de-vie Traditionnelles d'Origine Viticole*, pp. 60–69. Paris: TEC & DOC, with permission.

First distillation or distillation of the wine, known as chauffe du brouillis The boiler is filled to 95% of its volume. The wine boils after 1.5 h of heating, and the distillate which runs out first contains 55–60% vol of alcohol. Distillation takes place until all alcohol is distilled and is stopped when the distillate contains 2% vol. The liquid thus collected is called the brouillis, its alcoholic strength ranges from 26 to 31% vol. It is obtained in approximately 12 h. The temperature of flowing distillate must be about 15 °C.

Second distillation, called the bonne chauffe This is carried out under the same conditions. After 1.5 h of heating, the distillate starts to run out. It contains 75–80% vol of alcohol: 1% of total volume collected constitutes the heads which are separated and mixed with wine or brouillis. The distillate is collected up to 60% vol of alcohol; this is the heart, whose average alcoholic strength is nearly 70% vol. The distillate which then runs out is called the seconds (which taste of fat); these seconds are mixed with wine or brouillis to be redistilled.

The temperature of the distillate which runs out of the cooler must be about 18 °C to obtain a good brandy. The rate of flow is $1\,l\,min^{-1}$.

The seconds can either be mixed with the wine and in this case the alcoholic strength is not of major importance (first principle, Figure 11), or they may be added to the brouillis, in which case the strength is 28% vol. Therefore, it may be necessary to reduce the distillation of the brouillis according to the alcoholic strength of the initial wine (second principle, Figure 12). In this case the seconds are redistilled only once, which increases the strength of the brouillis.

The second distillation is performed at a lower temperature, thus obtaining better rectification of the spirit. Here, the tails of the brouillis need to be cut.

There are also variants of these two methods. Varying the intensity of heating is important according to the strength of brouillis required. Slow distillation gives good rectification. An odorous fine brandy is obtained but with dryness that may be detected on tasting due to the lack of certain products of tail distillation (e.g., ethyl lactate, diethyl succinate). In contrast, fast heating involves the formation of a marrowy brandy with little bouquet. Excessive heating results in a heavy taste.

Aging

The cognac ages in barrels of between 200 and 600 l. The barrels must be in oak of special quality. Traditionally these oaks came from the forests of Tronçais, Allier, Limousin, and the Vosges in France. The stave woods, i.e., pieces of wood used to make the barrels,

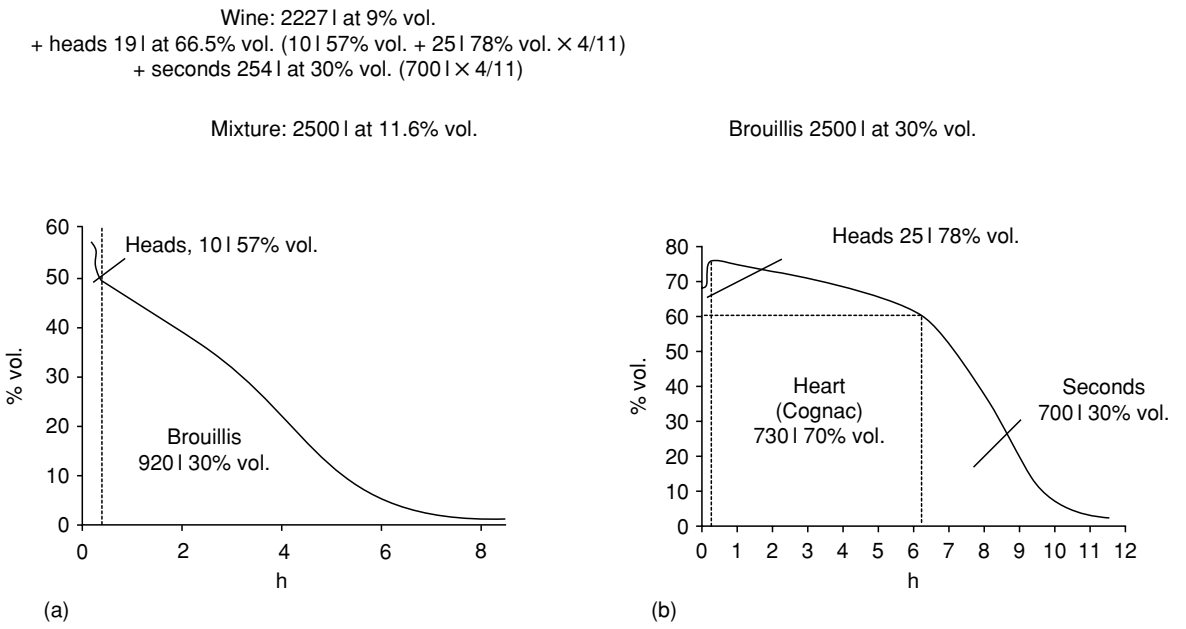

Figure 11 Distillation of the cognac, first principle. (a) First distillation of the wine, to obtain the broiullis; (b) second distillation, bonne chauffe. Eleven brouillis must be distilled to give four bonnes chauffes.

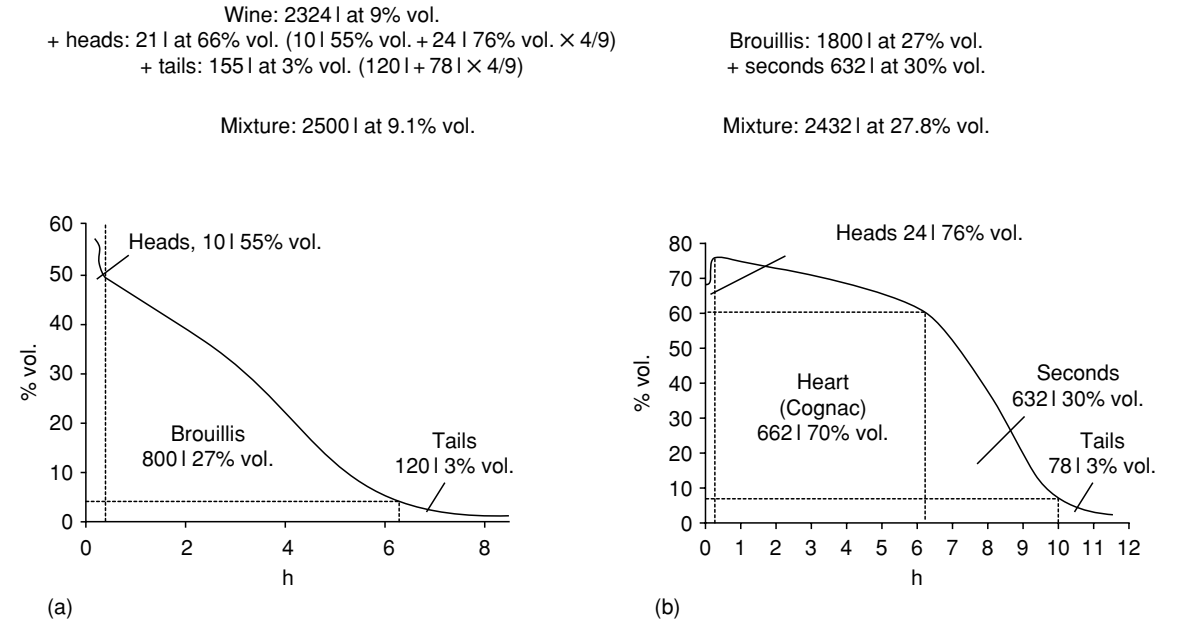

Figure 12 Distillation of the cognac, second principle. (a) First distillation of the wine to obtain the brouillis; (b) second distillation, bonne chauffe. Nine brouillis must be distilled to give four bonnes chauffes, and all the tails are mixed with the wine.

must be stored for 3 years outside so that the bitter substances that they contain are transformed by enzymatic reaction. The meta-digallic acid is hydrolyzed into the less aggressive gallic acid. The same occurs with aesculine and scopoline, glucosides that are transformed into aesculetine and scopoletine, which are less bitter. The transformations can take place only with time; fast drying obtained by stoving (heating) is not sufficient and the brandies placed in such barrels are bitter.

During aging the brandy is oxidized slowly. Its acidity grows by oxidation of alcohol into volatile

acids and by dissolution of the acid substances in the wood. Moreover, acetals are formed, and their odors are softer than those of aldehydes. The odor characteristic of young brandy becomes blurred, and eventually disappears, to be replaced by a vanilla odor induced by vanillic aldehyde, together with other phenolic aldehydes and acids arising from the alcoholysis of lignin in oak wood. The color becomes brown by dissolution of tannin. Moreover, the taste softens with the appearance of sugars arising from the hydrolysis of wood hemicelluloses.

There is also the appearance of a rancid taste by oxidation of fatty acids. Several stages in aging may be distinguished:

- From 1.5 to 5 years the main process is dissolution of substances in the wood.
- By 5–10 years astringency decreases and the brandy becomes rounder.
- From 10 to 35 years a rancio taste appears.
- After 40 years one should no longer keep brandies out of the barrel.

A barrel can yield substances to the cognac for about 40 years.

During aging, there is a loss of volume known as 'the angels' share.' This represents 3% on average per year, with a 1% vol reduction in the alcoholic strength.

During conservation there is little evolution of the volatile substances. The alcohols concentrate, the esters are slightly hydrolyzed, and the unsaturated fatty acids oxidize, which gives the rancio taste. The Cognac ages by slow oxidation in barrels. In bottles there is no further evolution.

Analysis

Traditional analyses Their purpose is to determine real and raw volume percentages of alcohol (titration), dry extract, total acidity, and the ratio of non-alcoholic elements, i.e., volatile acidity, aldehydes, esters, furfural, and higher alcohols; methanol values are determined separately.

Table 1 shows values for Cognac compared to those of brandy and Armagnac. The sum of volatile substances of Cognac is very high because the distillation process does not eliminate higher alcohols; however some tail products such as volatile acidity are noticeably lower than in Armagnac.

Gas chromatography Gas chromatography is used to analyze volatile compounds. As an example, the chromatogram in Figure 13 shows some of the volatile alcohols, esters, acids, and various aromatic components contained in an ether-hexane extract of VSOP cognac. Other analyses can be carried out by injecting the spirits directly into the chromatograph.

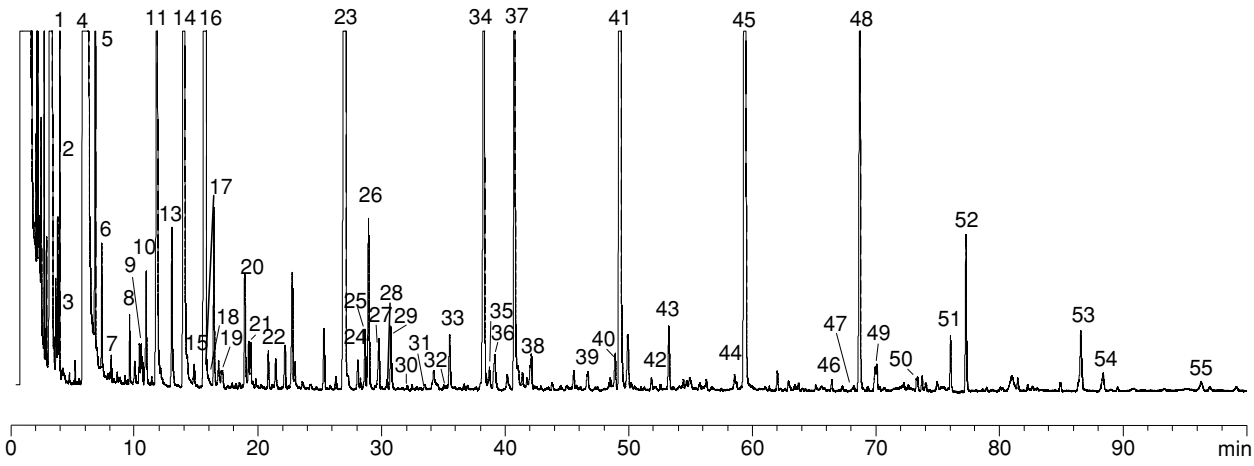

Figure 13 Chromatogram of the extract of a Cognac by ether hexane (concentration about three times); column FFAP 50 m × 0.22 mm; injection according to splitless mode; temperature programming from 40 to 200 °C. Identification of the peaks: 1, Ethyl butyrate; 2, 2-methylpropan-1-ol; 3, isoamyl acetate; 4, isoamyl alcohols; 5, ethyl hexanoate; 6, hexyl acetate; 7, styrene; 8, acetoin; 9, ethyl heptanoate; 10, ethyl lactate; 11, hexan-1-ol; 12, *trans*-hex-3-en-1-ol; 13, *cis*-hex-3-en-1-ol; 14, octan-3-ol (internal standard 1); 15, *trans*-hex-2-en-1-ol; 16, ethyl octanoate; 17, *trans*-linalol oxide (furane); 18, furfural, 19, acetic acid; 20, benzaldehyde; 21, vitispirane; 22, linalol; 23, ethyl decanoate; 24, butyric acid; 25, 3-methylbutyric acid; 26, diethyl succinate; 27, α-terpineol; 28, 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN); 29, methionol; 30, unknown; 31, unknown; 32, damascenone; 33, phenylethyl acetate; 34, ethyl dodecanoate + hexanoic acid; 35, benzyl alcohol 36, *trans*-whisky lactone; 37, 2-phenylethanol; 38; *cis*-whisky lactone; 39, 4-ethylgaiacol; 40, nerolidol + ethyl myristate; 41, octanoic acid; 42, 4-allylgaiacol (eugenol); 43, 4-ethylphenol; 44, ethyl palmitate; 45, decanoic acid; 46, ethyl stearate; 47, ethyl oleate; 48, dodecanoic acid; 49, ethyl linoleate; 50, ethyl linolenate; 51, unknown; 52, myristic acid; 53, palmitic acid; 54, palmitoleic; 55, linoleic acid.

The high levels of esters and fatty acids indicate that wine is distilled with lees (yeast).

Disturbances and Deposits

These can be:

- of organic nature: insolubilization of certain substances when the temperature decreases; to avoid this accident the brandies are filtered cold after cooling at $-5\,^{\circ}C$.
- of mineral origin due to calcium arising from the barrels (1–1.5 mg in 15 years' storage) or from the filter plates, thus requiring the use of plates without $CaCO_3$. Beyond $3\,mg\,l^{-1}$ the brandy deposits at cold temperature. Certain treatments by ion exchange resins could be used to eliminate the excess of calcium and copper.

Preparation for Commercialization

During aging, once a year, the cognac is racked and all the barrels of the same production are mixed together. The alcoholic strength is gradually diminished by adding demineralized water to finally obtain an alcoholic strength of 40.0% vol in commercialized bottles (never less). During aging it is common to mix spirits of different origins, quality and age in order always to obtain the same odor and taste for a given brand name. For instance, some Cognac firms use up to 60 different brandies to prepare their blend but the brand name (i.e., ***, VSOP) must consider only the youngest spirit of the blend.

The color can be adjusted with the addition of caramel. The taste can be adjusted with the addition of woody water extract obtained from small pieces of oak wood to give more body to the spirit, more astringency, and a little bitterness. On the other hand, excessive hardness can be diminished by the addition of sucrose syrup, generally less than $8\,g\,l^{-1}$. Generally, all these procedures should be carried out at least 2 or 3 months before bottling.

Tasting

Just as for wines, the length of a brandy can be measured by taking it into the mouth, spitting it out, and counting the number of seconds during which an intense aromatic persistence may be perceived, just before the appearance of a certain dryness. The word 'caudalies' is used to indicate the number of seconds elapsed. For a Grande Champagne Cognac the sensation lasts 7–12 s; for Bois ordinaire Cognac it is only 2 s.

The Grande Champagne In addition to the length of aromatic persistence, this brandy is characterized by a bouquet of great smoothness and distinction, odors of vine flower, dried lime, flowers and dry vine shoots.

The Petite Champagne The same characters are found but are less accentuated.

Borderies The persistence is the same as in Petite Champagne. These brandies have a developed odor which is more suave than that of the champagnes. At the time of the folle blanche before 1880, brandies had an odor of violet. Unlike in Armagnac, this is not considered a quality in Cognac spirits. They are less light than the Champagnes.

Fins bois The fins Bois brandies are rounder than the Champagnes. They are more marrowy but have a heavier odor more reminiscent of the fruit than the flower. From the point of view of character, the length decreases. They age faster, so together with the bons bois producting *** and VSOP Cognac, they constitute the most readily available of the Cognacs.

Acknowledgments

Chemical Composition and Analysis of Cognac

R Cantagrel, Bureau National Interprofessionnel du Cognac (BNIC), Cognac, France

Introduction

Cognac is one of the most prestigious products in the world. It has received an 'Appellation d'Origine Contrôlée' or registered designation of origin, and the term 'Cognac' must only be used for spirits from Cognac or the Charente region. It is subject to strict production regulations to guarantee origin and quality.

Cognac is characterized by a rich aroma and flavor, which distinguishes it from other spirits distilled from wine, the production of which is not governed by such strict regulations.

Chemical Composition and Sources of Variations

The aroma of Cognac is the result of the characteristic aromas of many of its constituents, enhanced or modified by synergistic or masking effects. More than 500 substances have been detected in spirits; they belong to a large number of chemical classes: alcohols (ethanol, methanol, higher alcohols, etc.), aldehydes, esters, volatile acids (acetic acid, fatty acids, etc.), ketones, acetals, nitrogen-, oxygen- and sulfur-containing heterocyclic compounds, phenolic acids, and aldehydes. These different aromatic constituents are contributed by:

- the grape (primary aromas);
- wine-making (fermentation aromas);
- distillation (specific aromas produced by the heating process);
- aging (aromas imparted by the oak wood).

The main aim in the production of a spirit is to form pleasant, distinctive flavors and fragrances to be conveyed by the alcohol. (*See* **Wines**: Production of Table Wines.)

The quality of a given Cognac depends on a number of factors:

1. In the production process, variations can be due to:
   - the weather conditions, which may vary from year to year, causing differences in the chemical composition of the resulting wines and spirits;
   - the diversity of grape producers;
   - the different 'crus' or growth regions within the area of designated origin;
   - the several hundered distillers;
   - the several types of stills used with different distillation methods.
2. In the aging process, variations can be due to:
   - the origin of the oak wood used for the barrels or casks;
   - cask-making techniques;
   - the layout and geographical location of the cellar (chai) where the spirits are aged;
   - the length of the aging period.

Variability of the Raw Material

The wines used in producing Cognac spirits are made essentially from the Ugni-blanc grape variety, which

produces wine with a relatively low alcohol content (generally 8–10% v/v) and a fairly high acidity (6–12 g of sulfuric acid per liter). This high degree of acidity ensures good conservation before distillation. Most of the constituents that make up a Cognac are present in the wine and lees used in the distillation.

Weather conditions are never the same from one year to the next. They determine the size of the grape harvest and the different qualities of wine produced by the vineyard. For example, the average alcoholic strengths (v/v) of wines over the last 12 years in Cognac were:

- 1987, 7.5%;
- 1988, 9.6%;
- 1989, 10.9%;
- 1990, 9.8%;
- 1991, 9.6%;
- 1992, 8.0%;
- 1993, 7.8%;
- 1994, 8.6%;
- 1995, 9.7%;
- 1996, 9.8%;
- 1997, 10.3%;
- 1998, 9.2%.

As a result, the chemical composition of the resulting spirits varies from year to year.

The figures below illustrate the diversity of the raw material obtained:

- the total area of the registered designation region is 80 000 ha, comprising six growth zones ('crus') within the designation region;
- the number of grape growers producing the white wine sold for Cognac is 8000;
- the number of producers with vineyards larger than 3 ha is 5000;
- the number of industrial-scale distillers is 150;
- the number of growers distilling on their own premises is 2500.

Cognac is an internationally recognized product, highly specific, and yet obtained from a number of different sources.

During the distillation period (about 5 months), the composition of the wines varies (see Table 1). The higher alcohol and polyol content does not change, but there is a significant decrease in the content of esters with aromatic properties of interest (isoamyl, hexyl and phenylethyl acetates, ethyl caproate, caprylate, caprate and laurate) and an increase in ethyl acetate, ethyl lactate, diethyl succinate, acetaldehyde (ethanal) and acetic acid. For this reason, the distillation is not performed in the same way in November, when the fermentation is completed, as in March.

Table 1 Variations in the concentration of wine constituents during storage for 5 months

Constituents		*Variation (%)*
Ethyl acetate		+24.1
Isoamyl acetate	1[a]	−55.7
Hexyl acetate	2[a]	−60.7
Phenylethyl acetate	3[a]	−62.1
Ethyl caproate	4[a]	−22.0
Ethyl caprylate	5[a]	−14.2
Ethyl caprate	6[a]	−18.9
Ethyl laurate	7[a]	−52.0
Total esters	1–7[a]	−25.8
Ethyl lactate		+49.1
Diethyl succinate		+226
Acetaldehyde (ethanal)		+117
Acetic acid		+18.8

[a]Organoleptically aromatic esters present in wine in low quantities. Ethyl acetate and ethyl lactate concentrations are much higher.

Charente Distillation Method

The distillation period in Charente begins as soon as the alcohol fermentation ends (generally the beginning of November) and continues until March 31.

The Charente method of distillation is performed in two stages. From the first distillation stage, the brouillis (27–30% (v/v) alcohol) is obtained; the second distillation stage yields the bonne chauffe (70% (v/v) alcohol). The purpose of this is threefold:

1. To extract the volatile compounds contained in the wines used. Besides water and alcohol (ethanol), other compounds contribute more through their intense characteristics rather than their quantities; they represent 0.3–1% (v/v) of the alcohol.
2. To select (rectification) from among the volatile substances present with the alcohol. Certain highly volatile products are undesirable at high doses (ethanal, ethyl acetate, acetal, etc.).
3. To perform certain chemical transformations favorable to the quality of the spirit. The heating time has a decisive influence on the combination and decomposition of compounds.

This reactive function of the Charente pot still is the source of chemical reactions such as:

Esterification/hydrolysis:

$$\text{Acid} + \text{Alcohol} \rightleftharpoons \text{Ester} + \text{Water}.$$

Acetal formation:

$$\text{Aldehyde} + \text{Alcohol} \rightleftharpoons \text{Acetal} + \text{Water}.$$

Maillard reaction:

$$\text{Sugar} + \text{Amino acid} \rightarrow \text{Pyrazine, Furans (cocoa flavors)}.$$

Table 2 Effect of lees on ester contents (mg l^{-1} spirit at 70% vol.)

	Distillation	
Constituents	*With few lees*	*With lees*
Ethyl caproate	6.76	8.3
Ethyl caprylate	8.95	23.6
Ethyl caprate	13.8	63.0
Ethyl laurate	12.45	36.2
Ethyl myristate	5.4	9.8
Ethyl palmitate	9.77	13.2
Ethyl palmitoleate	1.44	1.8
Ethyl stearate	0.59	0.61
Ethyl oleate	1.19	1.22
Ethyl linoleate	7.69	9.52
Ethyl linolenate	1.86	2.58
Isoamyl caprylate	0.42	2.48
Isoamyl caprate	1.67	5.76
Isoamyl laurate	0.78	1.83
2-Phenylethyl caprylate	Trace	1.20
2-Phenylethyl caprate	0.25	1.55
Total aromatic esters	73.02	182.65 (= + 150%)

Strecker degradation:

$$\alpha\text{-Amino acid} \rightarrow \text{Aldehydes} \rightarrow \text{Acetals}.$$

In order to prevent a coarse character appearing in the spirits, the wines are generally racked in order to leave only part of the lees. In keeping with tradition and local custom, the natural wine is distilled on fine lees. But of course, each firm gives its distillers specific instructions in order to obtain products in keeping with the distinctive types they each market. These instructions concern in particular the proportion of fine lees that must be kept in the wines used. Obviously, as a result, there are considerable analytical differences among the various finished products. The presence of lees results in a greater quantity of aromatic esters, which have a high sensory impact, and produces spirits higher in floral aromas (Table 2). Care must be taken that the lees are of good quality; if not, they are a major source of defects.

Given the very high number of chemical classes present in wines, all wine aromas that are volatile or carried over by water–alcohol vapors do not pass over with the same speed during distillation.

Obtaining a good-quality spirit necessarily implies a harmonious balance of all the constituents: the distiller's entire art is required to achieve this balance.

Aging Cognac

The Contribution to Product Diversity

Aging is a basic factor in the quality of Cognacs; it is also the most costly. Cognac can be kept for many years in oak barrels; the longer the aging, the more the intrinsic quality is enhanced. In order to maintain this quality, the producer is very careful in producing and aging the product.

Aging is an active process, and there are several parameters that must be controlled:

- the cellar or chai;
- the humidity;
- the temperature;
- the type of container used for aging.

The cellar may have an earthen floor, which provides good humidity, or it may be made of cement, in which case, the humidity is lower. The degree of humidity influences the evaporation rate. In a dry cellar, evaporation will consist mainly of water loss. In a very humid cellar, evaporation will affect mainly the alcoholic strength as alcohol is lost; Cognacs will then be smoother and mellower, and have a greater 'rancio' taste.

Difference in Cognac temperature from 7 °C on average in winter to 22 °C in summer are reasonable. This is one of the factors in the ability of a cellar to age spirits. Chemical reactions occurring during aging depend on the temperature (esterification, for example).

There are several types of containers. There are 1000- and 50 000-l barrels (for delivery of Cognac and blends) and casks of 100, 270, 350, 400, and 550 l (aging). Currently, most casks are of the 350-l type manufactured by coopers (cask makers). The cask performs several functions during aging. (*See* **Barrels**: Wines, Spirits, and Other Beverages.)

Quality Factors

The oak imparts aromatic elements to the Cognac in greater or lesser amounts according to:

- the choice of oak – coarse grain oak imparts tannins more easily than fine grain;
- the amount of time the staves are allowed to dry and their thickness;
- the method of heating when bending the staves to make the casks;
- the alcoholic strength of the spirits during aging;
- the age of the cask or barrel;
- the grape production zone ('crus') and the distillation method.

Oak wood consists of cellulose (wood fiber), hemicelluloses, lignin, and tannins. Tannins are highly soluble in spirits.

The first notable modification during aging is the change in color. This phenomenon is directly linked to the extraction and oxidation of tannins. As a direct result, a young Cognac in a new cask will color

quickly, even excessively, if kept there for a long time, whereas a young Cognac in an old cask will change color more slowly, remaining clear even after several years. Excess tannin (bitter taste) is often associated with a very high degree of extracted colour. (*See* **Tannins and Polyphenols**.)

The aromatic aldehydes, mainly vanillin, appear when the lignin breaks down. They are produced by aging and are very important for the bouquet of Cognac. Different types of casks result in substantial variations to their contents of these substances. These aldehydes, predominantly vanillin, contribute a vanilla note, which is not too heavy and is greatly appreciated.

The stave acts as a selective membrane enabling exchanges to take place between the Cognac within the cask and the air in the cellar by way of the evaporation of the most volatile and smallest molecules, a phenomenon that contributes to oxidation.

The quality of a Cognac's aging is measured by its 'rancio taste' (hydrolyses of fatty acid esters together with oxidation and transformation into ketones). The formation of the rancio taste during aging is accompanied by the continual extraction of tannins, slow oxidation, and various chemical reactions. (*See* **Fatty Acids**: Properties.)

The conditions necessary to make a good cask container are:

- the use of good-quality wood;
- the use of wood dried in the open air, exposed to inclement weather for at least 3 years;
- the careful preparation of a new cask and the judicious racking into older casks after proper storage of the recently distilled Cognac in new casks.

Important research work on the aging of Cognac spirits has been a major contribution in identifying the molecules extracted from the oak by the spirits and in understanding the reaction mechanisms underlying the aging process.

The development of gas–liquid chromatography (GLC) and high-performance liquid chromatography (HPLC) techniques has enabled the analytical changes noted during aging to be quantified with greater detail. Several aspects of variations observed in the aging of Cognacs are shown in Tables 3 and 4 by way of example. The extraction of gallic acid is much greater in a cask made of coarse grain oak, $35.7\,mg\,l^{-1}$ compared with $14.5\,mg\,l^{-1}$ in a cask made of fine grain wood. In an old cask, the extration of phenolic compounds is less (Table 3), but the oxidation and exchange with the atmosphere continue to occur. (*See* **Pesticides and Herbicides**: Types, Uses, and Determination of Herbicides; **Phenolic Compounds**.)

Table 3 Effect of cask on a spirit aged 13 years

	Concentrations ($mg\,l^{-1}$)	
Constituent	*New cask*	*Old cask*
Gallic acid	15.3	5.4
Vanillic acid	2.8	1.0
Syringic acid	7.0	2.2
5-Hydroxymethylfurfural	6.3	1.8
Furfural	21.3	10.8
5-Methylfurfural	1.6	0.2
Vanillin	8.8	2.9
Syringaldehyde	17.6	4.6
Coniferaldehyde	6.7	0.6
Sinapaldehyde	17.0	1.7

Table 4 Effect of length of aging period

	Concentrations ($mg\,l^{-1}$)		
Constituent	*0.7 years*	*5 years*	*13 years*
Gallic acid	4.6	9.0	15.3
Vanillic acid	0.3	1.4	2.8
Syringic acid	0.6	2.6	7.0
5-Hydroxymethylfurfural	4.2	4.2	6.3
Furfural	26.8	24.7	21.3
5-Methylfurfural	1.5	1.4	1.6
Vanillin	0.9	4.4	8.8
Syringaldehyde	2.25	8.9	17.6
Coniferaldehyde	3.65	5.9	6.7
Sinapaldehyde	9.45	17.8	17.0

Cognac is sold throughout the world mainly under commercial designations; among those currently in use are ☆☆☆, VSOP, Napoleon, and X.O. These commercial qualities correspond with products of different ages. The price increases with age. These commercial products are obtained through blends (also called 'coupes') of different cognacs. Each dealer has their own blending technique and style. The blend of different Cognacs is above all a subjective choice. It enables a representative product of constant and reproducible quality to be obtained. Blending is therefore an important step in the production of Cognac, since it is the key link between production and marketing.

Sensory Analysis

Cognac spirits are obtained from different 'crus' or growth zones within the area of designated origin: Grande Champagne, Petite Champagne, Borderies, Fins Bois, Bons Bois, and Bois Ordinaires. They show major sensory differences (see Table 5). The blending of several crus influences the quality of the product. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.)

Table 5 Main organoleptic characteristics of spirits from different Cognac crus

Crus	*Sensory characteristics*
Grande Champagne (GC)	Subtle fragrance, finish floral, fruity, persistent aromas, slightly viney
Petite Champagne (PC)	Elegant, added distinction with aging, slightly heavier than GC, stronger alcoholic aroma, supple
Borderies	Discreet violet aroma, ages more rapidly than the GC and PC 'crus', floral aromas + vinosity, fine, elegant
Fins Bois	Powerful, rich and well balanced, vinous, fruity grapey aromas, heavier alcohol aromas
Bons Bois	Less elegant than Fins Bois, heavier, rough, less persistent aromas
Bois Ordinaries	Alcoholic aroma, heaviness, vinosity, rough

During aging, the differences are increased with regard to both the quality of the flavors and the length of the aging. A fins bois spirit is aged over a maximum period of 30 years, whereas a Grande Champagne spirit can be aged in casks over 60 years. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Initial blending of new spirits provides more uniform batches.

Product Authenticity

The production of cognac spirits is subjected to very strict regulations with regard to both production and marketing. Regulations deriving from the Decrees of 15 May 1936 and 13 January 1938 are supplemented by genuine and consistent application of local custom for the area, based on several parameters:

- the area of registered origin;
- the choice of grape varieties;
- the materials used in the wine-making;
- the distillation method;
- the containers for the spirits;
- the minimum period of aging for each of the commercial designations.

Various governmental authorities are responsible for ensuring that these regulations are followed:

- the Institut National des Appellations d'Origines (INAO);
- the French internal revenue service (Direction Générale des Impôts, or DGI);
- the Directorate-General for Consumer Affairs, Competition and Fraud (Direction Générale de la consommation, de la Concurrence et de la Répression des Fraudes, or DGCCRF);
- Customs Administration.

The Bureau National Interprofessionnel du Cognac (BNIC) carries out inspections for age and issues certificates for age, designation of origin, and analysis, certifying the authenticity of the products placed on the market.

BRASSICAS

J W Fahey, Johns Hopkins University, Baltimore, MD, USA

Background

The brassicas comprise a large and diverse group of widely consumed vegetables. Brassica is the Latin name of a genus that is taxonomically placed within the Brassicaceae (Cruciferae), which is one of the 10 most economically important plant families in the world. The genus *Brassica* includes, but is not limited to, the following vegetables: bok choy, broccoli (calabrese, sprouting broccoli), Brussels sprouts, cabbage, cauliflower, Chinese cabbage, kale, kohlrabi, mizuna, swede (rutabaga), and turnips. Rapeseed or canola, one of the world's most widely grown oilseed crops, is also a nonvegetable *Brassica* species and is discussed elsewhere. Other, closely related vegetables within the Brassicaceae family (also known as brassica or cruciferous vegetables, crucifers, cole crops, or mustards) include radish (*Raphanus sativus*), watercress (*Nasturtium officinale*), arugula (*Eruca sativa*), horseradish (*Armoracia rusticana*), maca (*Lepidium meyenni*), mashua (*Tropaeolum tuberosum*), wasabi (*Wasabia japonica*), and cress (*Lepidium sativum*). One of the common characteristics of brassica vegetables is that they all contain glucosinolates, sulfur-containing compounds that are hydrolyzed to produce so-called mustard oils, which impart characteristic tastes and odors to these vegetables.

Vegetables are considered to be an essential part of a balanced diet. The brassica vegetables in particular, add considerable visual or esthetic appeal to a meal, since many of them are leafy and green. They are rich sources of dietary fiber, any many are good sources of calcium, provitamin A, vitamin C, and certain beneficial phytochemicals. They also have distinctive flavors and textures, which enhance palatability in the eyes of many consumers, though they evoke quite violent negative emotions in others, prodding them to wax poetic:

> Lurking in basement kitchens, consorting with boiled beef, tripe, watery-fleshed German cooks, and roaches, the kohlrabi, with darkened eyes, has designs upon the very young. Bilious whitey-green, pretending that its thickened basal part is a vegetable, it awaits the pink mouths of children, corrupting thick-witted kitchen help in their seduction.
>
> Oh, it is the whole puddle and sink of all sins against God and man, the kohlrabi.
>
> Think of it, hiding in vegetable bins like Nazis in Argentina.
>
> Noxious white root, it is the very nose and vegetable essence of Andy Warhol, silk-screened on pale velvet and hawked along the highways of America.
>
> The Kohlrabi, by William A. Fahey

Historical Origins of Modern Brassica Vegetables

Most scholars place the wild cabbage at the head of the family tree that has led to the development of the 400 or so varieties of *Brassica oleracea*. Although there is still considerable disagreement among scientists as to precisely how all of the modern brassica vegetables arose, there are widespread references to these vegetables in writings dating back many centuries. Their taxonomy, too, is a subject of considerable debate and should be regarded as being in a state of flux. Genus, species, variety, subvariety, subspecies, botanical group, and cultivar designations are frequently interchanged in the descriptive literature. Commonly recognized taxonomic designations are used herein, wherever possible.

It is widely agreed that there are six major vegetable *Brassica* species. Three are monogenomic, and three are amphidiploid (being diploid for two genomes, each originally contributed by a different species). These major categories are thus commonly designated as having A, B, or C genomic compositions, and their relationships are shown in Table 1.

The ancestral wild cabbage was almost certainly a seaside plant of northern European or Mediterranean origin. All of the wild brassicas today occur in cliffs and rocky islets in fairly isolated places. Wild *Brassica oleracea* varieties still grow as perennials along the coasts of northern Spain, western France, and southern and southwestern Britain. Over time, some 400 varieties have been created, which include cabbages, kohlrabi, oilseed rape, Brussels sprouts, cauliflower, and broccoli. Cabbages were not eaten by the Hebrews or the Egyptians. None of the crucifers are mentioned in the Old Testament, and the only crucifer mentioned in the New Testament (Mark 4:30–32) is mustardseed. The ancient Romans and Greeks, however, were quite familiar with cabbages and cauliflower, and believed that eating cabbage during a banquet would prevent one from becoming drunk. Dietary cabbage intake was discussed in the writings of Pythagoras, Diogenes, and Cato, to name a few. Cato, for example, recommended cabbage in the diet to prevent disease and prolong life, and claimed to owe the existence of his 28 sons to cabbage. In the Middle Ages, cabbage plasters were used for medicinal purposes, and cabbage was used for cough syrup and wound dressings. In the 1700s, they were used aboard ships for their vitamin C content and were used as dressings to combat gangrene.

Broccoli (from the Italian 'brocco,' arm or branch) is widely presumed to have developed from the wild cabbage that was native to coastal Europe and spread through the Near East to the Orient between 2000 and 2500 years ago. Some authorities consider that sprouting broccoli (something resembling modern-day broccoli) was first domesticated and cultivated in Italy during ancient Roman times. A vegetable that was probably broccoli was described by the Roman botanist Pliny (first century CE). There is no consensus, however, on the translation of the early name 'cyma,' and there is concern that the writings of early botanists may have confused 'broccoli' and 'cauliflower' as we know them today. Others maintain that early selection and domestication of broccoli may have been made in Asia Minor, with a cultivated form being brought to Italy by early traders in the 1500s. What is certain, however, is that broccoli (also known at that time as Italian asparagus or sprouting broccoli), was introduced to England around the 1720s. The following passage from Stephen Switzer's *The Practical Kitchen Gardiner* (1727) illustrates the point:

> As for the broccoli, there are three kinds of it, one of which yields sprouts button'd at their points, or headed like small collyflowers; another sort with curl'd leaves, which produce sprouts button'd on the points like asparagus; and a third with curl'd leaves of a pale green colour, which yield sprouts like the red kind; the two are to be had at several places about London; but the first is very rare to be had, but from some few gentlemen that have them yearly from Italy…

By the late 1700s, broccoli was introduced to the American colonies, where it was grown by Italian immigrants on the east coast of the USA but was otherwise little known until the 1920s. In 1912, the Stokes seed company brought broccoli seed into the USA and started selling to growers in 1918. In 1923, the D'Arrigo Brothers Company initiated field trials in California and, by 1925, was shipping ice-pak freight car loads of broccoli back to the east coast.

Commonly Cultivated Brassica Vegetables

Broccoli, Including Broccoli Sprouts (*Brassica oleracea* var. *italica*)

This is also known as calabrese or sprouting broccoli. The most valued portions of broccoli plants are the heads, which are inflorescences consisting of immature fully differentiated flower buds and tender upper stems. Both primary and secondary inflorescences are eaten, and lower stems are eaten, too but are not as prized due to their tough outer 'rind.' Broccoli is available commercially as fresh or frozen florets and is used raw in salads or as vegetable crudités. It is also frequently cooked and served by itself as well as being a component of many cooked and stir-fried dishes. There are over 100 commercial hybrid cultivars of broccoli, derived from a limited number of landraces or open pollinated cultivars that include purple sprouting, purple cape, purple Sicilian, white sprouting, and calabrese or green sprouting broccoli. Cut broccoli shoots or florets are very perishable and must thus be cooled (e.g., vacuum cooling) very soon after picking. Crushed ice or an ice slurry is typically blown into cartons of broccoli within a few hours of their being picked. California and Mexico in North America, and Italy, France, and Spain in Europe are the major production areas. Consumption of broccoli in the USA has been steadily climbing since about 1970. In 1970, the total per-capita consumption was about 0.7 kg and is presently about 3.6 kg. The development of hybrids in the late 1970s and their subsequent marketing by the vegetable seed companies

[b]Data from USDA-NCC Carotenoid Database for U. S. Foods – 1998; (not all vegetables have been analyzed for all carotenoids).

[c]Refuse is some combination of the total biomass, which is typically not used in food preparation, e.g. stems; crowns; spoiled, damaged croute leaves; leaf stalks; cores; trimmings; or root bases.

were responsible for much of the increased consumption in the 1970s and 1980s. Impetus for the dramatic increase in consumption over the past 10 or so years has come from the health aura which broccoli has recently enjoyed. It is regularly identified as the vegetable eaten most often for health reasons, including cancer prevention, high fiber, vitamin C, folate, and calcium content.

Broccoli raab (*Brassica rapa* var. *rapa*)

Also known as broccoli rabe, broccoli babe, rapini, broccoletti di rape, brocoletto, turnip broccoli, cima di rapa, Italian turnip, sparachetti, taitcat. Broccoli raab has also been classified botanically as *B. campestris* or *B. ruvo*. It is a bitter tasting vegetable similar in appearance to Chinese kale, but nonheading and with thinner stems and smaller flowers than broccoli. It is long been considered a delicacy in Italy, typically lightly sautéd with garlic. It has recently gained interest in the USA and is considered a 'new' vegetable by some.

Brussels sprouts (*Brassica oleracea* var. *gemmifera*)

Brussels sprouts are a relatively young member of the Brassica family. They originated in Belgium in the 1500s and by the 1700s were appearing on tables around the world. Brussels sprouts grow as a tall (*c.*1 m) single stem biennial from which the axillary buds, resembling miniature cabbage heads, are harvested. They are generally eaten after cooking (steaming or boiling) and are available commercially either fresh or frozen. Brussels sprouts require a long growing season, and vegetable quality is adversely affected by warm weather.

Cabbage (*Brassica oleracea* var. *capitata*)

Cabbage has been cultivated, and even revered, as a vegetable by the ancient Greeks as far back as 2600 years ago, and it has also had a long history of medicinal use. There are scores of references to its use for such diverse purposes as the prevention of drunkenness, headache, stomach ailments, and even cancer. Cabbage leaves have long been used as poultices for application to tumors, and even in modern times, they have been under investigation as a means for preventing or treating breast engorgement in nursing mothers.

All cabbages have heads formed from tightly packed leaves. There are many distinct head types, the most common being: Wakefield (with small, early, white, pointed heads; for fresh market), Red (leaf surfaces are pigmented, medium very firm, round heads; for fresh market and storage); Ballhead or Danish (round, very firm heads, light green leaves; for fresh market and storage); Savoy (some authorities designate this *Brassica oleracea* var. *sabauda*) (round, loose heads with crinkled or blistered leaves; for fresh market and storage). Cabbage is typically eaten fresh, processed into a salad-like dish called coleslaw, boiled, or as a fermented and pickled product called sauerkraut. Cabbages are important as a fresh market crop as well as a processing crop in most parts of the world and rank in the top 10 vegetables in both sales and volume in North America and much of Europe.

Cauliflower (*Brassica oleracea* var. *botrytis*)

The edible portion or head of cauliflower is composed of curds. In contrast to the head of broccoli, cauliflower heads consist of tightly clumped, undifferentiated shoot apices on top of hypertrophied, highly branched fleshy stem tissue. Referred to by Mark Twain as 'nothing but a cabbage with a college education,' cauliflower curds are actually degenerate shoot tips which are most frequently white in color (lacking chlorophyl), although purple, green, and orange cultivars now exist. Cauliflower is not as cold-tolerant as many other brassica vegetables. It is grown commercially in France, Italy, the UK, and North America, and it is eaten in the same manner as broccoli as well as being pickled. It is available commercially as fresh or frozen curds.

Charlock (*Brassica kaber*, also *Brassica arvensis*, *Sinapis arvensis*)

Charlock is also known as kaber. The seeds of this plant, likely of Mediterranean origin, are used as a condiment, and the leaves are eaten as a potherb. The seeds are not as pungent as those of other mustards.

Chinese Cabbage (*Brassica rapa* var. *pekinensis*)

Also known as napa, napa cabbage, pe-tsai, wongbok, chihli. This is a vegetable of major importance in China (over 300 000 ha grown), Korea, Taiwan, and Japan. Grown as an annual crop, most cultivars are biennial and produce tight, compact, cylindrical heads. This vegetable has been cultivated in China for over 1600 years and accounts for a major fraction of the total vegetable consumption in certain (northern) areas of the country. In Korea, it is is fermented to produce (preserved) Kimchi, which is thus a yearlong, ubiquitous commodity in that country.

Chinese Kale (*Brassica oleracea* var. *alboglabra*)

This is also known as gai lan, Chinese broccoli, gai lon, gai larn, kai laan, white-flowered broccoli, fatshan. Compared to broccoli, Chinese kale has more,

slender, dark green leaves, longer stems, and very few florets, which are similar to those of broccoli. Flower buds, flower stalks, and young leaves are consumed, primarily in salads and stir fries. Relatively new to Japan, Western Europe and US cuisines, but extensively grown in Taiwan, South-east Asia and China, Chinese kale is relatively fast growing and heat-tolerant.

Chinese Mustards (*Brassica rapa* ssp. *chinensis*)

These include bok choy, pak choy, choi sum, Shantung cabbage and are also known as Chinese white cabbage and celery mustard. Pak choi and bok choy are sometimes errantly referred to as Chinese cabbages. *Brassica rapa* ssp. *parachinesis*, also known as mock pak choy, choy sum, cai tai, saishin, has been cultivated since the fifth century CE in Asia and continue to be very important vegetables, especially in China. Pak choy is the more leafy cultivar, and bok choy is notable for its massive leaf midribs, which are white and fleshy. This subspecies is a biennial, which is grown as an annual for its edible leaves. Plants can reach 0.6 m tall and can weigh over 2 kg. Leaves are usually consumed fresh but are also dried after blanching, for use through periods when fresh vegetables are not plentiful.

Collards (*Brassica oleracea* var. *sabellica*)

Available commercially as fresh, canned, or frozen leaves, collard greens are popular in the southern USA, where they are grown along the eastern portion of the country. As such, it is a much more heat tolerant crop than its close relative, kale. The plants are nonheading and up to 1.25 m tall, and broad, flat, or slightly furrowed leaves form as a rosette on a minimal stem.

Colza (*Brassica napus* var. *napus*)

Colza is also known as vegetable rape, xi yang you cal, and chou navet. Colza oil (expressed from seeds) is commonly consumed in India and China. Foliage and sprouted seeds are eaten in salads or as a potherb; inflorescences are prepared like broccoli.

Kale (*Brassica oleracea* var. *acephala*)

There are many 'kales,' some of which are classified taxonomically into other *Brassica* species or varieties. Kale includes kitchen kale, green kale, dwarf Siberian kale, marrow stem kale, tronchuda kale, curly leaf kale, Scotch kale, tree kale, and borecole. Although highly variable, kale is characterized by a nonheading rosette-like whorl of foliage, a short, erect stem, and large, upright, curly leaves. They are used mainly for their edible foliage and are generally eaten cooked, but are sold fresh, canned, and frozen, or used as garnish. Among the commonly grown kales are:

- Branching bush kales (sometimes classified as *Brassica oleracea* var. *fruticosa*): also known as cow-kale, borecole (sometimes classified as *B. oleracea* var. *selenesia*), these were often cultivated in the past for their edible foliage and have been used extensively for animal fodder.
- Thousand-headed kale (*Brassica oleracea* var. *ramosa* or *B. oleracea* var. *millecapitata*).
- Inflorescence kales (a term used by some to describe cauliflower, broccoli, and related brassica vegetables).
- Galega kale (also known as couve galega): a traditional and widely grown Portugese nonheading kale with long petioles, large midribbed leaves, and an elongated stem that can reach 3 m; leaves are picked one by one and used for traditional soups or for animal feed.
- Marrow stem kale (*Brassica oleracea* var. *medullosa*): a particularly prolific type of kale used exclusively for animal feed.
- Siberian kale (also classified as *Brassica napus* var. *pabularia*): also known as Hanover salad; a leafy vegetable, similar to collards, which is used fresh in salads and cooked as a potherb.

Kohlrabi (*Brassica oleracea* var. *gongylodes*)

This is also known as knol khol or turnip cabbage. The edible portion of kohlrabi is the fleshy, swollen, tuber-like enlargement of the short, unbranched stem, which may be white, green, or purple and develops just above the surface of the soil. This vegetable developed in northern Europe about five centuries ago. It resembles turnip and rutabaga in flavor and texture but becomes highly fibrous if not harvested at peak maturity.

Mizuna (*Brassica rapa* ssp. *japonica*)

Also known as mibuna, curled mustard, or Japanese greens, mizuna is a cool-tolerant relative of the leafy turnips that has recently been introduced to the West.

Mustard (Various Latin Binomials)

Plants from this diverse group have been used worldwide for centuries as a condiment (mustardseed; also known as black mustard, brown mustard, *Brassica nigra*) and as a vegetable (mustard greens; *Brassica juncea*). Most well-known among the mustards are:

- white or yellow mustard (*Brassica hirta*, *Brassica alba*, *Sinapis alba*);
- chinese mustard (*Brassica japonica*);
- black mustard (*Brassica nigra*, *Sinapis nigra*);

- field mustard (*Brassica campestris*);
- Ethiopian mustard; Abyssinian mustard (*Brassica carinata*).

Many of the so-called brown mustards (*Brassica juncea*) have been assigned unique variety names. Common English and Chinese names are as follows:

- *B. juncea* var. *capitata* (capitata mustard, jie qiu jie);
- *B. juncea* var. *crassicaulis* (bamboo shoot mustard, sun zi jie);
- *B. juncea* var. *crispifolla* (cut leaf mustard, curled mustard, mi tuo jie);
- *B. juncea* var. *foliosa* (small leaf mustard, xiao ye jie);
- *B. juncea* var. *gemmifera* (gemmiferous mustard, bao zi jie);
- *B. juncea* var. *involuta* (involute mustard, juan xin jie);
- *B. juncea* var. *latipa* (wide petiole mustard, kuan bing jie);
- *B. juncea* var. *leucanthus* (white flowered mustard, bao hua jie);
- *B. juncea* var. *linearifolia* (line mustard, feng wei jie);
- *B. juncea* var. *longepetiolata* (long petiole mustard, chang bing jie);
- *B. juncea* var. *megarrhiza* (tuberous-rooted mustard, dal tou jie);
- *B. juncea* var. *multiceps* (tillered mustard, fen nie jie);
- *B. juncea* var. *multisecta* (flower-like leaf mustard, hua ye jie);
- *B. juncea* var. *rugosa* (large leaf, brown mustard, Indian mustard, mustard greens, rai, dai ye jie);
- *B. juncea* var. *strumata* (strumous mustard, tsatsai, zha cai);
- *B. juncea* var. *tumida* (swollen stem mustard, jing liu jie);
- *B. juncea* var. *utilis* (peduncled mustard, tai jie);
- *B. rapa* var. *narinosa* (broad beaked mustard, wu ta cai, taasai).

Swede (*Brassica napus* var. *napobrassica*)

Also known as rutabaga in the USA, swede is considered a root crop, though, technically, this is not accurate. It is an annual crop grown as animal fodder and consumed by human beings after cooking or pickling. It has been grown for about three centuries, originating in Sweden and spreading throughout Europe. The flesh is white or orange and similar in flavor and texture to turnips with equivalent, excellent storage characteristics but low commercial value. Swede is much hardier than the turnip but also takes much longer to mature. The leaves are used as a potherb.

Tendergreen (*Brassica rapa* ssp. *perviridis*)

Also known as spinach mustard, mustard spinach or komatsu-na, this leafy relative of the turnip is reasonably cold-tolerant, surviving temperatures as low as $-15\,^{\circ}C$. It has large, dark green, mild-flavored foliage, which is eaten fresh and pickled, primarily in Korea, Taiwan, and Japan.

Texsel greens (*Brassica carinata*)

Of Ethiopian origin, the early growth of this plant is valued for its high protein and vitamin C content and is eaten raw in salads or lightly boiled as a spinach substitute. It has a milder flavor than collards or mustard greens.

Tronchuda cabbage (*Brassica oleracea* var. *costata*)

Also known as Portugese cabbage, Couve Tronchuda, Galician cabbage, braganza, or sea-kale cabbage, these are loose-headed cabbages that have large leaves with succulent midribs. It is believed that the many landraces of this vegetable arose from an initial hybridization of cabbage and kale.

Turnip (*Brassica rapa* var. *rapifera*)

Turnip is very similar to rutabaga in that it is a root crop (technically incorrect) that produces high amounts of biomass per hectare, is high in starch content, and has very favorable storage characteristics. It appears to have been around for about 4000 years, originating in eastern Europe and Siberia and gradually spreading across Europe. As with swedes, turnips are generally eaten after cooking and can also be processed for use in pickled or mixed vegetables. Turnip greens are eaten in-season as a fresh leafy green vegetable.

Turnip rape (*Brassica campestris* var. *oleifera*)

The seeds of this plant produce an oil that is sometimes used in cooking, and it has relatively high levels of unsaturated lipids. It is becoming more popular as an oilseed but is distinct from the very widely grown oilseed rape (*B. napus* var. *oleifera*). The foliage of the plant is used as a potherb and garnish.

'New' Brassica Vegetables

A number of 'new' brassica vegetables have been produced under trade names, primarily by cross-hybridization between existing taxa. These include:

- broccolini: a cross between Chinese kale and broccoli trademarked by Mann Packing Co. (California, USA);
- asparation: a cross between Chinese kale and broccoli trademarked by Sakata Seed Inc. (California, USA);
- broccoflower (*Brassica oleracea* var. *botrytis*): a bright green cauliflower originating in Holland, and trademarked by T & A (Tanimura & Antle, California, USA) about a decade ago.

Regional Preferences

Brassica vegetables are a large group of primarily herbaceous plants that includes a number of the world's most commonly cultivated vegetables. Though the progenitor species likely originated in the Mediterranean region, the cultivated brassica vegetables are of cosmopolitan distribution. Cultivars have been adapted for worldwide production, from the tropics to the Arctic Circle. The largest cabbages in the world have, in fact, been grown near Fairbanks, Alaska, USA.

Brassica vegetables include a large number of taxonomically closely related, but morphologically and organoleptically diverse, plants. These species have been cultivated for many centuries and have been extensively crossed and hybridized. Many cultivars have been developed in microenvironments or very small geographical regions where they have remained essentially isolated for decades, even centuries. For example, certain small villages or regions in Italy have their own very distinctive broccoli cultivars. Since these vegetable gene pools have remained isolated for hundreds of generations of selection, there has been considerable development of phenotypes that diverge from a common ancestor. The relationships of some of the more common brassicas are detailed in Figure 1.

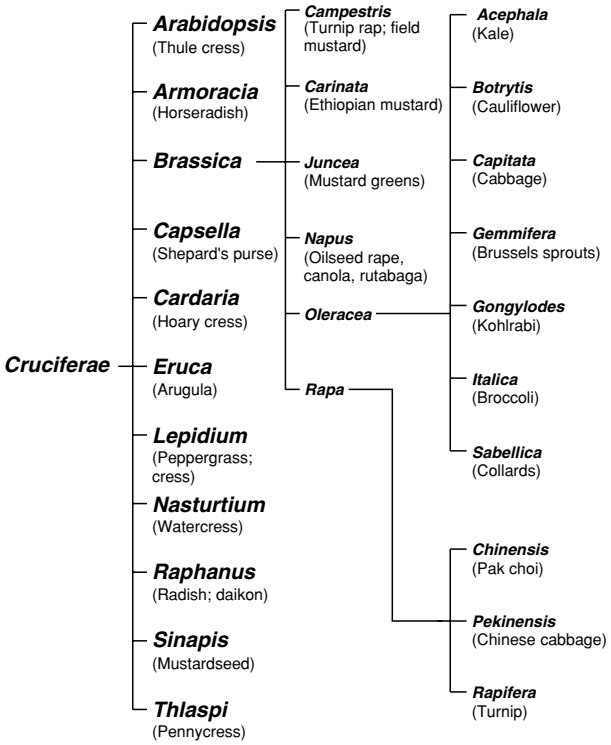

Figure 1

Dietary and Commercial Importance

From a nutritional standpoint, these vegetables are perhaps best recognized as excellent sources of vitamin C, fiber, calcium, and certain phytochemicals such as carotenoids (provitamin A) and glucosinolates (which have been the source of considerable recent scientific research as cancer protective agents). The contents of vitamins, minerals, and phytochemicals are, however, highly dependent on both genetic and environmental variables. Plant cultivar or variety, the environment in which the plant is grown (e.g., amount of sunlight, drought stress, temperature), the conditions under which it is harvested, stored, and transported to market, and the way in which it is prepared for the table and consumed all play key roles in the ultimate nutritional value of that vegetable. Water-soluble components such as vitamin C and glucosinolates (see below) are easily leached out in the pot liquor during cooking. These and other beneficial chemicals can exhibit a tremendous gradient from one portion of the plant to another, and it is often quite difficult to assess these differences without performing sophisticated chemical analyses. Nonetheless, the brassica vegetables remain among the best sources of the dietary components mentioned above and should be consumed regularly as part of a diet rich in fruit and vegetables.

In the West, broccoli, Brussels sprouts, cauliflower, cabbage, and kale are the most significant brassica components of the diet. In the East, the so-called oriental brassicas (Chinese cabbage, tendergreen (spinach mustard), bok choy, pak choy, mizuna, celery mustard, and Chinese mustard) as well as spinach mustard and mizuna greens, Chinese kale (Chinese broccoli), and daikon (Japanese radish – a cruciferous root crop) are the main brassica vegetables of commercial and dietary importance.

Cultivation and Postharvest

The brassica vegetables are hardy, cool-season vegetables that grow best in temperatures in the range of

15–20 °C and have similar cultural requirements. Cabbage plants that have been hardened off can tolerate temperatures as low as −4 °C for short bursts, and broccoli and cauliflower plants thrive in light frosts. Almost all cole crops decline in quality when temperatures are in excess of 26–27 °C. Under irrigation (guaranteed water supply), broccoli crops can be harvested in 10–15 weeks from direct seeding, cabbage crops in 13–17 weeks, and cauliflower crops in about 13–16 weeks, depending on the temperature and climate. Brassica vegetables can be grown on a wide range of soil types, and in addition to direct seeding, many crops are now grown from glasshouse transplants. All brassica vegetables are more or less susceptible to the same diseases and insect pests. More specific agronomic advice is beyond the scope of this article.

Although some brassica crops do not need cooling after harvest, broccoli and cauliflower require immediate prechilling to 4 °C. These crops are typically hydrocooled or immersed in an ice-slurry. They must be refrigerated for transport and storage and have a storage life of about 2 weeks (broccoli), to 4 weeks (cauliflower), to as much as 6 months for some cabbage varieties grown in cooler climates.

Nutritional Value and Chemical Composition

Table 2 summarizes the nutritional value and chemical composition of broccoli, Brussels sprouts, cabbage, red cabbage, savoy cabbage, Chinese cabbage, cauliflower, collards, cress, kale, kohlrhabi, mustard greens, tendergreen, and swede.

Vitamin A, Vitamin C, Selenium, Calcium, and Fiber

The brassica vegetables are excellent sources of calcium, fiber, vitamin A (in the form of β-carotene, or provitamin A, and vitamin C (especially broccoli, kale, and tendergreen). The element selenium can be incorporated into the tissues of brassica vegetables (in particular, broccoli), where it can reach rather high levels, and the vegetable may be of therapeutic value as a source of this antioxidant element due to its special availability from such tissues.

Table 2 Haploid chromosome number and genomic compositions of the six major *Brassica* species

Species	*Haploid chromosome number*	*Genome*
B. rapa	10	A
B. nigra	8	B
B. oleracea	9	C
B. juncea	18	AB
B. napus	19	AC
B. carinata	17	BC

Phytochemical Attributes (e.g., Glucosinolates/isothiocyanates, Carotenoids, and Flavonoids)

All of the brassica vegetables contain glucosinolates, at concentrations of up to 3% by weight in the seeds of some plants. These sulfur-containing compounds and their breakdown products have long been known for their fungicidal, bactericidal, nematocidal, and allelopathic properties, as well as for the goitrogenic or antinutritional glucosinolates in the protein-rich, defatted meal from widely grown oilseed crops (e.g., rapeseed) and in some domesticated brassica vegetables (e.g., Brussels sprouts). When used as animal feed, rapeseed meal can have pronounced deleterious health consequences on livestock due to ingestion of excessive quantities of 'progoitrin'; (e.g., when livestock are fed a meal produced from defatted rapeseed containing the progoitrin, which may interfere with thyroxine production, drastically reducing iodine supply to the thyroid gland, and resulting in the development of goiter and other associated problems. Recently, however, other members of this large group of compounds (e.g., glucoraphanin, sulforaphane, phenethyl isothiocyanate, benzyl isothiocyanate, crambene, and indole-3-carbinol) have attracted intense research interest because of their cancer chemoprotective and antioxidant attributes. Certain compounds (e.g., sulforaphane) have been shown to be potent inducers of mammalian detoxication enzymes, which facilitate the deactivation and excretion of many carcinogens from the body. The use of a number of these compounds in a dietary strategy for cancer prevention is now being investigated in clinical trials worldwide.

The brassica vegetables are generally very rich sources of the antioxidant and provitamin A carotenoids (e.g., lutein, zeaxanthin, and β-carotene). These compounds are long-chain, fat-soluble substituted hydrocarbons which are the light-gathering accessory pigments typically found in the leaves, stems, and inflorescences of most plants. Since these are typically the plant organs which are eaten, they can be regarded as typical 'dark green leafy vegetables' and good sources of such compounds (Table 2). Certain brassica vegetables, such as kale and broccoli, are particularly rich in these compounds, and the edible head of cauliflower is particularly devoid of them. A mutant, orange cauliflower plant was found growing in a Canadian field about 30 years ago, however, which is currently being investigated as a very potent source of β-carotene and a very useful system for scientists to unravel some of the biochemical and molecular mysteries still surrounding carotenoid production in

plants. Though an orange cauliflower is now being marketed, the application of this research may result ultimately in the introduction of higher-carotenoid varieties of some of the world's staple crops and a reduced incidence of vitamin A deficiency (which can be reduced by ingestion of β-carotene-rich foods).

The brassica vegetables, though not unique in this respect, are also good sources of various flavonoids and their conjugates to which significant antioxidant activity has been ascribed. For example, the prevention of lipid peroxidation for which these compounds appear to be reasonably well suited may be an important mechanism for reducing the severity of age-related degenerative diseases such as arthritis, cardiovascular disease, and cancer.

BRAZIL NUTS

G T Prance, University of Reading, Reading, UK

Background

Brazil nuts are produced in the crown of one of the tallest trees of the Amazonian rainforest. An important dietary item of the indigenous Indian and local populations, the Brazil nut later entered into commerce and is a major export of the Amazonian countries, Bolivia, Brazil, and Peru. The nuts (**Figure 1**) are harvested almost exclusively from wild trees in the forest, rather than from plantations. They are high in protein and oils and are also a useful source of thiamin (vitamin B_1). (*See* **Thiamin**: Properties and Determination.)

Description and Taxonomy

The Brazil nut comes from the species *Bertholletia excelsa* Humb. & Bonpl., the only species in this genus of the Brazil nut family, Lecythidaceae. Several other species of the family have edible seeds, the best known being the sapucaia nut or monkey pot (*Lecythis pisonis* Cambess.). However, the sapucaia fruits open at maturity on the trees, and the seeds are removed by bats, rendering large-scale harvesting almost impossible. The Brazil nuts are produced in large, woody, round fruits that are slightly larger than

Figure 1 Brazil nuts. Reproduced from Brazil Nuts, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds.), 1993, Academic Press.

a baseball. These fruits, or pyxidia as they are termed, drop to the ground intact when they are mature, 14 months after flowering has taken place. Between 10 and 25 seeds, or nuts, as they are incorrectly called according to the botanical definition of a nut, are arranged rather like the segments of an orange inside the pyxidium. This explains their characteristic flattened triangular shape. In nature, a large terrestrial rodent, the agouti (*Dasyprocta*), or squirrels open the pyxidium and bury the nuts in caches some distance from the parent tree; this is the means of seed dispersal for this species. Brazil nut gatherers go to the trees in January to March, when the fruits are falling and before the rodents have removed all the nuts. The fruits are generally gathered in the morning, because there is less danger of injury from fruit fall. The fruits weigh 0.5–2.5 kg and fall from a height of 40–50 m, and injury and deaths have been reported of collectors struck by falling fruits. The gatherers open the pyxidia skillfully with machetes (see **Figure 2**) and pour out the nuts into their baskets. They trade their

Figure 2 Brazil nut gatherer opening nuts. Reproduced from Brazil Nuts, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds.), 1993, Academic Press.

harvest for goods, and the nuts are shipped to factories for processing. Before exportation, they are pasteurized with steam to kill toxic fungi, and in many cases, they are also shelled and canned.

Distribution and Ecology

Brazil nuts grow in nonflooded rainforests of the Guianas and Amazonian Colombia, Venezuela, Peru, Bolivia, and Brazil. They tend to grow in natural clusters or stands of 50–100 trees. These stands are known as *manchales* in Peru and *castanhais* in Brazil. Usually, there are one or less trees per hectare, but stands of 15–20 trees per hectare have been reported in Madre de Dios, Peru. Some of the clustering may be the result of planting by Indians who formerly occupied the area. Brazil nuts grow in forests with an annual rainfall of 1400–2800 mm and do better where there is at least a short, dry season. The trees are light-demanding, i.e., they need gaps in the forest before they can grow to adult size.

Flowering and Pollination

Flowering occurs in the dry season, which begins in September and can extend until February. The peak of flowering is September and October throughout most of central and eastern Amazonia, and slightly earlier to the west. After flowering and pollination, the fruits take approximately 14 months to mature and fall off in January and February.

The flowers have a complicated androecium structure, which forms a closed hood over the top of the flower. Nectar is produced inside the hood. Large bees are the only insects that have the strength to force open the flower to reach the nectar. As the bees force open the springed hood, their backs are forced against the pollen-bearing stamens and the stigmatic surface where pollen is deposited. The bees therefore carry the pollen from flower to flower. Bees that have been found visiting Brazil nut flowers are from the genera *Bombus*, *Centris*, *Epicharis*, and *Eulaema*. The Brazil nut is largely self-incompatible, i.e., the tree requires pollen from another tree in order for seed set to take place. Low seed set has been found in trees that are isolated in forest clearings and in areas of disturbance. The maintenance of the pollination system is essential for the production of Brazil nuts. Therefore, plantations that are surrounded by forest where the pollinators thrive are much more likely to be productive than plantations that cover larger open areas away from the forest.

Chemistry

The Brazil nut is rich in oil and protein (see Table 1). The oil extracted from the seed is bright yellow, almost odorless, and with a pleasant nutty taste. It has a specific gravity of 0.9165 at 15 °C, solidifies at −4 °C and does not become rancid easily. The first extraction of oil from the seeds yields an excellent cooking oil, and the second extraction produces an oil suitable for making soap and burning in lamps. Hence, it furnished many of the needs of the Indian population of Amazonia. The residue left after pressing the seeds can be used as an animal feed. The average protein content of defatted Brazil nut flour is about 46% and contains all the essential amino acids, making both the nut and the flour highly nutritious. The principal amino acid content of the nuts is given in Table 2, which shows them to be rich in leucine. The nuts also contain vitamin A, vitamin B_1 (thiamin), vitamin B_2 (riboflavin), and niacin, being a particularly good source of thiamin and niacin.

Brazil nuts contain selenium, a powerful antioxidant. The amount in a Brazil nut (16–30 $\mu g\,g^{-1}$) exceeds the US recommended daily dose. Some people consume a Brazil nut a day to achieve the recommended dose. Brazil nuts can cause hair loss if consumed in large quantities owing to their selenium content. Brazil nuts accumulate selenium because of the similarity of this element to sulfur. There is often a sulfur deficiency in Amazonian soil, especially after long-term harvesting of the nuts. If the soil is selenium-rich, this is used by the plant as a substitute for sulfur. When sulfur fertilization is used, the selenium content of the nuts is reduced. Brazil nuts are rich in the sulfur amino acids methionine and cysteine. (*See* **Amino Acids**: Properties and Occurrence; **Niacin**: Properties and Determination; **Retinol**: Properties and Determination; **Riboflavin**: Properties and Determination; **Thiamin**: Physiology.)

Table 2 Principal amino acids found in the Brazil nut[a]

	Amino acid content (mg per kilogram fresh weight)
Lysine	4313
Threonine	3263
Valine	4888
Methionine	4088
Leucine	9250
Isoleucine	3450
Phenylalanine	4385
Tryptophan	1400

Economic Botany

Until recently, Brazil nut seeds were second only to rubber as an export crop from Amazonian Brazil. The production from 1933 to 1986 has ranged from a low of 3557 tonnes in 1944 to 104 487 tonnes in 1970 (Figure 3). The production in 1986 was 36 136 tonnes. The low of 1944 was caused by World War II. In the Department of Madre de Dios in Peru, 20% of the forests are rich in Brazil nuts, and it is estimated that two-thirds of the population are engaged in Brazil nut extraction and processing. The annual production of nuts from the state of Pando in Bolivia is estimated to be between 10 and 12 000 tonnes. Most of the seeds are exported to France, the UK, the USA, and Germany. Very little on the crop is consumed domestically in either Brazil or Peru. Recent price fluctuations of Brazil nuts on the commodity market have made it harder for the producers. The nuts are exported intact or with the seed coat removed. In the latter case, the seeds are soaked for 8–10 h in a tank of water, after which they are submerged in boiling water for 1–2 min. The seeds are dried to make the embryo shrink away from the seed coat; this facilitates the removal of the seed without breakage. Broken seeds have a lower export value and are often used locally for oil extraction and in the soap industry. The dried seeds are placed in a manual press, and pressure is applied at both ends to crack open the seed coat (see Figure 4). The seeds are canned for export. Brazil nuts can be eaten raw or roasted, and are used in confectionery.

Brazil nut oil is often used in soaps, shampoo, and hair and skin conditioning products. It is a good moisturizer for the skin and provides antioxidant benefits. Brazil nuts require careful handling and steam sterilization, because they are highly susceptible to bruising and molding, which can cause the accumulation of aflatoxins. Sometimes, whole batches of nuts exported in their shells have to be rejected because of the danger of aflatoxins. This is rare in properly prepared and packaged nuts.

Figure 4 Cracking Brazil nuts in a processing factory, Óbidos, Brazil. Reproduced from Brazil Nuts, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

In addition to producing the nut, Brazil nut trees yield excellent timber. Although it is against the law to fell Brazil nut trees in Brazil, there is still a clandestine market for its timber. The timber is also used in Peru. The fibrous bark of the tree is used for caulking boats, and in folk medicine, a bark tea is used as a cure for liver ailments. The empty fruit cases are used for fuel and for making a vast array of tourist souvenirs. The world-wide Brazil nut market in 1999 was estimated to be $35 million.

Dough Mixing and Testing Operations

S D Deshpande, Central Institute of Agricultural Engineering, Bhopal, India

Dough Mixing

One of the most important operations in a bakery is the accurate and thorough mixing of ingredients. Mixing reduces nonuniformities of gredients in composition, properties, or temperature of bulk materials or products in and out of a reactor, and was defined by Quillen as the 'intermingling of two or more dissimilar portions of a material, resulting in the attainment of a desired level of uniformity, either physical or chemical, in the final product.' The term 'mixing' includes more than just the mechanical actions that blend ingredients to a homogeneous mass. There may also be an incorporation of air and the formation of minute bubbles in a fat/water phase, a development of hydrated flour proteins into an elastic mass known as gluten, and an increase of temperature by a build up of mechanical heat. There is no fundamental basis for classifying the gluten proteins on the basis of aqueous alcohol extractability, although such a classification does have technological significance. Gliadin and glutenin are known to impart entirely different physical properties to the gluten network in a wheat-flour dough. Gliadin behaves mainly as a viscous liquid, when hydrated, and confers extensibility, allowing the dough to rise during fermentation, whereas glutenin provides elasticity and strength, preventing the dough from being overextended and collapsing either during fermentation or in baking. This article discusses the purpose of kneading of dough, types of mixers for dough, dough mixing and dough development, and empirical methods in physical dough testing.

Purpose of Dough Mixing

The dough is kneaded before it is allowed to ferment, and again before it is molded into the desired shapes. The purpose of kneading is to remove some of the excess carbon dioxide in order to prevent overstretching of the gluten strands, and to distribute the yeast cells throughout the dough. Kneading also tends to keep the dough at a uniform temperature. The dough is kneaded sufficiently when it has a smooth, 'satiny' surface, and small bubbles appear under the surface.

Mixing of Dough – Dimensional Analysis

Dough mixing is the most common unit operation in the food industry, finding widespread application in the bakery, snack food, and breakfast cereal industries. Dimensional analysis of this operation reveals how potential scale-up problems can be diagnosed before any experimentation is initiated.

Consider the schematic representation of a dough mixer that is shown in Figure 1. Cereal chemists generally consider the specific energy input as being indicative of the degree of 'development' of the dough. Specific energy is defined as the total energy dissipation per kilogram of dough. Assuming that the dough is Newtonian, one can perform a dimensional analysis for the power consumed by a dough mixer. The key variables used are given in Table 1.

By inspection, the dimensionless relationship that is sought is

$$\frac{P}{\rho N^3 D^4 L} = f\left(\frac{ND^2\rho}{\mu}, \frac{d}{D}, \frac{F}{D^3}, \frac{h}{D}, \frac{t}{D}\right). \qquad (1)$$

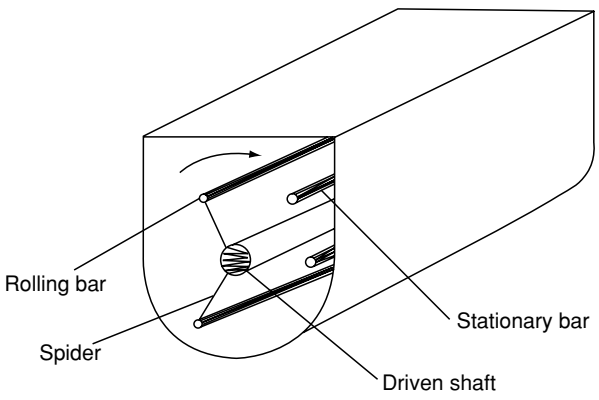

Figure 1 Schematic representation of a dough mixer. From Valentas KJ, Leuine L and Clark JP (1991). Dimensional analysis – mixing and sheeting of doughs. In: *Food Processing Operations and Scale-up*, pp. 359–361. New York: Marcel Dekker, with permission.

Table 1 Key variables used in the text

Variable	*Description*	*Units*
P	Power	ML/T^3
ρ	Density	M/L^3
μ	Viscosity	M / LT
N	Rotational speed	1 / T
F	Volumetric charge	L^3
d	Roller diameter	L
b	Breaker bar diameter	L
D	Mixer diameter	L
h	Clearance between rollers and wall	L
t	Clearance between breaker and rollers	L
L	Length of mixer	L

Solving for power and making use of the general rule that in laminar flow, the power is proportional to the velocity squared, it can be shown that

$$P\alpha\mu N^2 D^2 L g\left(\frac{d}{D}, \frac{F}{D^3}, \frac{h}{D}, \frac{t}{D}\right). \qquad (2)$$

The specific energy is simply the power dissipation multiplied by the mixing time divided by the mass of dough in the mixer. Then, the required time of mixing is given by

$$t = \frac{\omega}{P} \qquad (3)$$

where ω = specific energy input. If the scaled-up mixer is geometrically similar to the pilot mixer, this simplifies to

$$t\alpha\frac{1}{N^2}. \qquad (4)$$

A conclusion can be drawn from eqn (4). If the plant mixer operates at the same speed as the pilot plant mixer, the times required for developing the dough are identical. This provides the designer with a clear-cut direction as to how to design the scaled-up mixer. Unfortunately, for most actual applications, geometric similarity is not maintained when scaling up bakery mixers.

How does one handle a real dough with non-Newtonian properties? Complete analysis is impossible since the dough exhibits very complicated, time-dependent behavior. However, one can draw some useful inferences from the non-Newtonian analyses that follow.

If the dough were a simple power law fluid, the viscosity in the list of variables would be replaced by the flow consistency and the flow index. The result of the dimensional analysis would be

$$\frac{P}{\rho N^3 D^4 L} = f\left(\frac{N^{2-n}D^2\rho}{m}, \ldots, n\right). \qquad (5)$$

The time required to mix the dough is then

$$t\alpha\frac{1}{N^{1+n}}. \tag{6}$$

As before, if geometric similarity is maintained, the time required to mix the dough is held constant on scale-up if the speed of the mixer is held constant.

For a viscoelastic dough, which can be approximated as a Maxwell body, the variable list would have the relaxation time added. The new dimensionless group that appears to incorporate this new term is the Weissenberg (Deborah) number. The result is

$$\frac{P}{\rho N^3 D^4 L} = h\left(\frac{ND^2\rho}{\mu}, \theta_R N\right), \tag{7}$$

where θ_R is the relaxation time of the dough. The conclusions are unchanged. No matter how complicated a model, even a model containing an infinite number of relaxation times, the conclusion is the same.

Types of Mixers for Dough

Mixers and kneaders are necessary for the proper blending or mixing of the various ingredients. Liquids can be easily blended using propeller-type agitators in a tank. For blending of premixes or preparation of adjuncts, ribbon blenders, twin-cone, and V-shell blenders are usually employed when dry ingredients are to be mixed.

Dough mixing can be carried out using horizontal, vertical, reciprocating, or continuous mixers as required. The horizontal type may have a fixed or tilting bowl, while the vertical mixer may be a planetary or fixed spindle type. The continuous mixers may be of the agitator-in-tube type, or the rotor and stator head type.

Horizontal Dough Mixers

These mixers can be used to mix various mixtures ranging in consistency from thin batters to tough doughs. They must be used when gluten development is desirable, e.g., in breadmaking. These mixers have a horizontal U-shaped bowl mounted on a rigid frame with a drive motor. Their capacities range from 10 kg upwards. Bowls are usually made of stainless steel or stainless steel-clad mild steel. Bowls are sometimes provided with jackets for the circulation of cold or hot water.

High-speed mixers for gluten development usually contain a single axle on which two or more arms parallel to the front of the mixer are mounted. The limited clearance between the jacket wall and the agitator bars causes the dough to be repeatedly stretched and kneaded, resulting in quick gluten development. These mixers can usually be operated in two speed ranges, namely 30–60 and 40–80 r.p.m. In the slow-speed mixers, agitators of various forms, e.g., eight-arm, Z, etc., are employed on one or two axles.

The agitator configuration and its speed affect the action. Slow-speed Z or eight-arm mixers have a speed range of 14–60 r.p.m. (25 r.p.m. on an average).

The high-speed horizontal mixers are also called kneaders, and may contain bars projecting from the axle at right angles, while the bowl has radical bars intermeshing with axle bars. This construction gives very efficient dough kneading, and is particularly suitable for tough doughs.

The dough is discharged from these mixers by tilting the bowl so that the top is brought to a forward-facing position. In some models, the front of the bowl consists of a tightly fitting door, which can be raised and lowered independently of the immobile section of the bowl, and the dough is discharged through this door. The bowl-tilting mechanism may be hand-operated or it may be operated by a separate motor.

Vertical Mixers

Vertical mixers consist of a movable bowl or trough with one or two vertical shafts that may be stationary or may have planetary movement. The agitators themselves may be of various sizes and configurations. The most important design in the vertical mixer is the planetary mixer, which is particularly suitable for mixing batters or adjuncts such as icings. The agitator is called 'planetary' as it, apart from revolving around its own vertical axis at a relatively high speed, also moves in circles as it rotates around the bowl. This motion ensures 'beater' action throughout the bowl contents. The agitator may be provided with a variable-speed mechanism, and the bowl can be raised and lowered by a separate drive. The agitator may be of any of the various types available, e.g., simple, curved single-arm, wire meshing, or paddle gate.

The hook-type agitator gives a good kneading action to the dough, resulting in development of the gluten with a minimum of tearing. The wire-mesh type agitator gives a good 'beater' action with maximum air incorporation. The paddle-type agitator ensures good mixing coupled with scraping of the bowl sides. Bowls are usually provided with covers to prevent splashing or dusting. Capacities range from 10 kg upwards.

Spindle-type mixers are used mainly for biscuit doughs. Their special advantage is with saltine doughs, in which case they are adapted for mixing

in special mobile troughs used for fermentation. Thus, sponges and doughs need not be transferred in and out of the mixer between the various stages. The spindle speed is usually low, and spindles can be raised to allow the trough to be rolled into place under them. The mixer blades are so designed as to give a cutting action rather than a kneading or stretching action to the mix, thus a toughening effect on the cracker or biscuit doughs is avoided. (*See* **Biscuits, Cookies, and Crackers**: Methods of Manufacture.)

In reciprocating agitator or revolving bowl mixers, a pair of agitator arms travels through intersecting elliptical paths in a shallow, slowly revolving bowl. These mixers are useful for mixing temperature-sensitive doughs, and also where nuts and raisins in the mix are to be kept unbroken. Their output is usually low compared with horizontal mixers, and they are particularly suitable for pie doughs and puff pastry.

Dough Mixing and Dough Development

Dough Properties and Mixing Behavior

It is generally agreed that the uniqueness of wheat is due to its breadmaking quality. Among plant crops, only wheat flour and, to a limited extent, rye flour have the ability to form a dough that retains gases and produces a baked product, particularly leavened bread, with the desired eating qualities. Wheat-flour doughs exhibit a wide range of properties when different flour samples are compared. Dough properties influence both the efficiency of throughput in the manufacturing plant and the quality of the final baked product. In discussing the state of dough prior to baking, we need to differentiate between the contributions from the individual flour and those from the various treatments, which include added ingredients, mixing, and intermediate punching, and molding steps. Dough is a complex material from a rheological point of view. Knowledge about its structure comes from fundamental rheological studies, from standard physical dough testing, including mixing, and from microscopy.

Because of the trend towards greater use of baking processes involving intensive mixing and short fermentation times, much more attention has been given to basic studies of dough mixing in recent years. These studies have highlighted the sensitivity of dough structure to the conditions to which the dough has been subjected during its development. It is clear that meaningful interpretations of rheological measurements can be made only if the state of dough development is well understood.

Factors Affecting Dough Development

The first step in converting flour into bread is the mixing of flour, water, and other additives. Specific additives have been incorporated as improvers to wheat flour. The effects of addition of sodium alginate at 0.1–0.5% levels to wheat flour have been studied, and it has been observed that sodium alginate can improve the gas formation/retention power of dough, thus making it suitable for producing better bread. As mixing proceeds, the initially incoherent dough mass develops viscoelastic properties and finally acquires a sheen, this stage being termed 'clearing.' Prolonged mixing past this point causes the dough to lose its strength and become plastic and very sticky to the touch. If the torque on the pins, blades, or arm of the mixer is monitored against time, the trace rises, reaches a maximum, and then falls steadily. This is illustrated in Figure 2 for doughs mixed in a mixograph. Optimum bread-baking performance is usually achieved in a region at, or slightly past, the peak development point.

Critical mixing intensity and critical work input Two parameters are critical for optimum development and hence best performance. These are that

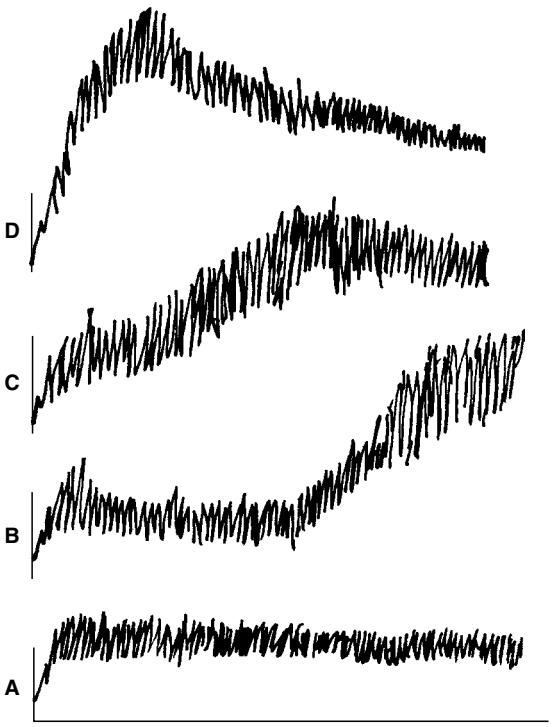

Figure 2 Mixogram traces. The sequence from A through D may be used to represent either doughs of increasing mixing requirements mixed at a fixed intensity, one dough mixed at increasing intensities or one dough mixed at a fixed intensity but containing increasing additions of cysteine.

(1) the mixing intensity must be above a minimum critical value, and (2) the total work imparted to the dough must be above a certain minimum value. Both parameters vary according to the flour used. Before discussing these requirements more fully, it is useful to consider the mechanical and mixing efficiencies of different dough mixers. The distinction between these two quantities is illustrated in Figure 3. A percentage of the total energy consumed by the mixer motor is available for performing mechanical work on the dough. This is called the mechanical efficiency. However, not all of this energy is utilized for mechanical development of the dough but that portion which is utilized is denoted the 'mixing efficiency' of the mixer.

Mixing requirements of flours vary widely, and Figure 2 illustrates the mixing behavior of four flour types. The mixing curves are for doughs that have been mixed at a constant and moderate speed. Flour A has high mixing requirements, and the rate of mixing used is insufficient to develop the dough; such a dough would be a failure in a baking test. Flour B is a moderately strong flour that does develop at this mixing speed, although there is an initial induction period before the dough begins to exert any appreciable torque on the mixer. Flour C is of medium strength, and flour D is a comparatively weak flour that develops quickly. We may also make use of Figure 2 to illustrate the effect of varying the mixing intensity (i.e., mixing speed) on the mixing curve of a given dough. At a low speed, the dough does not develop (trace A). As the mixing speed is increased, the dough develops after a lag phase (trace B) and thereafter develops more easily (traces C and D). With increasing speed, and providing the amount of work applied to the dough is above a certain level (corresponding to a point at, or slightly past, the peak in the trace), the baked loaf volume increases up to a critical mixing speed, above which it plateaus.

For every dough, there exists a critical mixing speed (which may vary for each mixer) below which dough handling properties and baked loaf characteristics are unsatisfactory. In addition, it is necessary to have imparted a minimum level of work input to the dough in order to bring it to an optimal developed state. If the mixing speed or work input level is below the critical values, unsatisfactory baking results are obtained. Baking results are less affected by exceeding the critical values than when these values are not reached. However, dough-handling properties deteriorate, and doughs become sticky; weaker flours are more sensitive to overmixing.

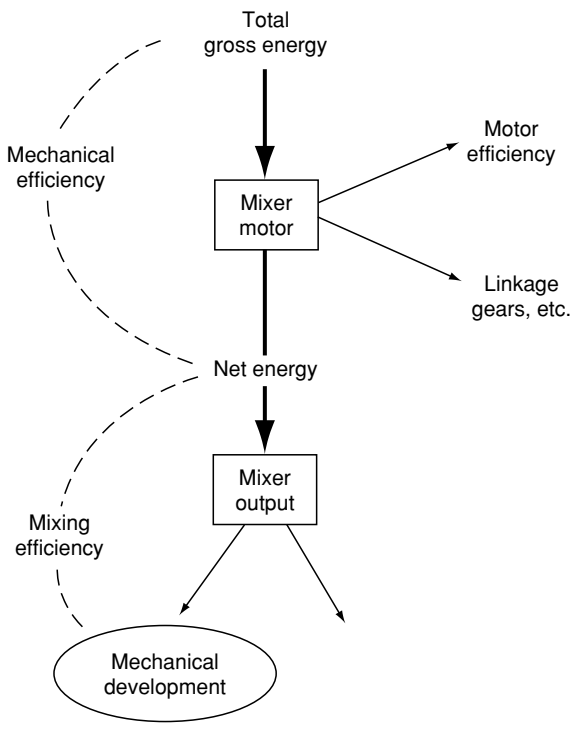

Figure 3 Diagram illustrating the distinction between mechanical and mixing efficiencies. From Kilborn RH and Tipples KH (1972) Factors affecting mechanical dough development. I. Effect of mixing intensity and work input. *Cereal Chemistry* 49: 34–47, with permission.

Activated dough development Because some flours have very long mixing requirements or have critical mixing speeds that exceed the capacity of many dough mixers, methods of overcoming these limitations have been devised. One method involves the addition of reducing agents, particularly sodium metabisulfite (SMS) and L-cysteine hydrochloride (cysteine), to doughs. Cysteine reduces the energy level required to achieve peak dough development, and also the critical mixing speed necessary to produce bread of satisfactory loaf volume. We may again make use of Figure 2 to illustrate the effect of increasing additions of cysteine in altering the mixing characteristics of a strong dough. As the amount of added cysteine is increased, the nature of the mixing curve changes from A through D. Cysteine also slightly increases the rate of energy input at a given mixing speed and increases the tolerance to undermixing, i.e., enables satisfactory bread to be produced with energy levels less than those required to achieve peak dough development. There is an optimum level of cysteine addition, and too high a level causes deterioration of loaf characteristics.

Intelligent Mixer for Bread Dough

To detect 'dough development' through digital signal processings of the mixer's torque and control mixing without an ordinary mathematical model, intelligent

mixer (speed variable farinograph, robots for flour–water addition) was developed.

A smoothed farinogram was obtained at constant mixing intensity, which has a linear part and a maximum point. Dough at the maximum point was judged to be fully developed by experienced mixing operators and was confirmed by the baking test. An empirical equation about torque mixing and fuzzy rules to correct nonlinear effects by three parameters (water content, temperature, and mixing speed) were obtained. Applying the equation gave a good statistical relation between 'torque increasing rate' and maximum torque value. This statistical relation led to regulation of the maximum torque value (a good indicator of dough properties) through flour (or water) addition by robots. Addition of flour or water in the early mixing stage caused no apparent influence on developed dough and baked products. The wave form of oscillating components, though there seemed a lot of background noise, had a good correlation with the degree of dough development. Combining wave-form analysis with step-wise change of mixing intensity, it was easy to find the optimum mixing intensity at each mixing stage. Applying these results, the intelligent mixer produced a dough with the desired maximum torque (a good indicator of dough properties) in a short time.

Empirical Methods in Physical Dough Testing

A great variety of commercial testing instruments are used in routine physical tests on dough, either in quality control or in research work. The deformation to which dough is subjected in these instruments is so complicated that it does not allow the evaluation of the properties of the material in simple physical terms. Though the results are evaluated more on an empirical basis than through theoretical analysis, they provide valuable information on the baking characteristics of the tested material and are a useful tool.

Over the years, a physical testing system has been developed on the basis of the 'three-phase concept of breadbaking.' The system has been generally accepted and is used in many commercial milling and baking operations. It applies three principles of testing: dough mixing, dough stretching (load–extension), and viscosity measurements on buffered flour suspensions at elevated temperatures.

Mixing Tests

The two most common instruments used for testing wheat flour and wheat-flour dough during the mixing operation are the Brabender farinograph and National Recording Dough Mixer (mixograph).

The Brabender farinograph is essentially a torque-measuring dough mixer that measures the plasticity and mobility of dough upon a relatively gentle mixing at constant temperature. The resistance of the dough to Z-shaped mixing blades is transmitted to a dynamometer connected to a mechanical recording system, which records a curve (farinogram) on a kymograph chart. Farinograms provide information on optimum mixing time and dough stability on prolonged mixing (Figure 4). Doughs are tested at a standard water content known as the 'farinograph water absorption' value. This value has to be determined by 'titration' of flour with water, and is the amount of water needed for a standard optimum consistency of the dough of 500 Brabender units. 'Forinograph water absorption,' dough development time, and dough stability are useful parameters for the evaluation of the strength of a flour. In general, the higher the value of these parameters, the stronger the flour. To express the strength of a flour on the basis of farinograph data as a single score, the 'valorimetric value' may be determined by the dough development time and the decreasing slope of the curve (degree of softening) – the higher the value, the stronger the flour.

The National Recording Dough Mixer is another widely used instrument for flour testing. Like the farinograph method, the mixograph method has become a standard physical dough test. The resistance offered by the dough to four vertical pins revolving around three stationary pins in a mixing bowl creates a force that deviates the mixing bowl from its original position. The torque is proportional to the shear strength and elasticity of the dough, and may be used as an index of the dough strength. Both Brabender farinographs and National Recording Dough Mixers may be modified by replacing the mechanical recording device by an electronic strain-gauge system. Electronic strain-gauge recording offers several advantages: ease of calibration in terms of physical units, greater accuracy because of the elimination of friction from the torque measuring system, a wide range of sensitivity, and a record on rectangular coordinates.

For testing the mixing characteristics of dough under conditions more closely related to those during mechanical development, a variant of the farinograph, known as the Brabender Do-Corder, was developed. This has a nearly closed mixing bowl with heavier mixing blades. The dough can be mixed at higher rates than in the standard farinograph. A more recent development is the Brabender resistograph. The instrument was developed to meet the needs of modern bread-baking technology in which high-speed mixers subject the dough to both kneading and stretching. The characteristics of doughs mixed

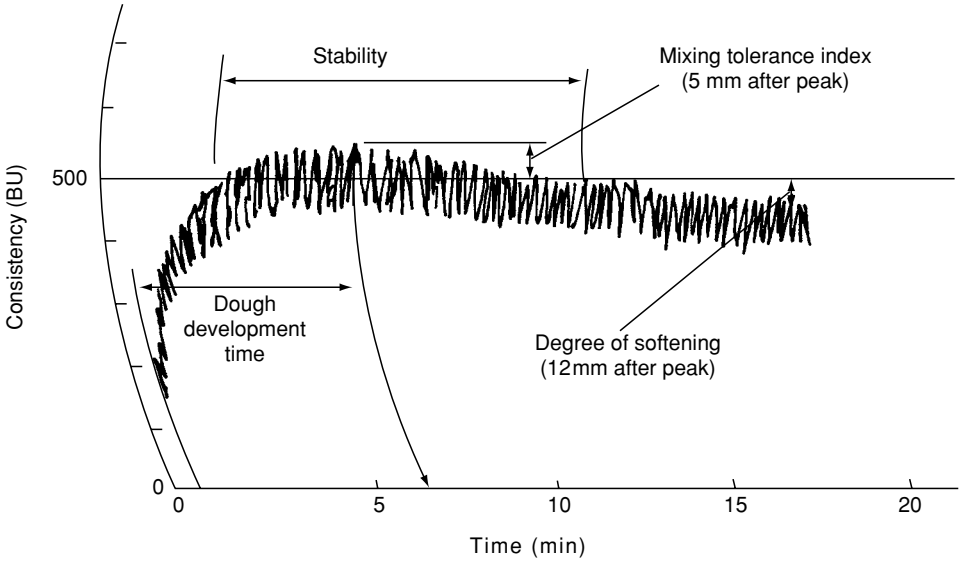

Figure 4 Representative farinogram showing the most commonly measured parameters. Brabender units (Bu) are a measure of optimum consistency of the dough. From Bloksma AH (1971) Rheology and chemistry of dough. In: *Wheat Chemistry and Technology*. St. Paul, MN: American Association of Cereal Chemists, with permission.

under these conditions differ from those produced by conventional mixers, where mixing is accomplished more by pressure than stretching. The resistograph has a mixing head that combines blending with stretching, pressing, and kneading. It imparts a high work input to the dough and can be used for the evaluation of dough response to high-speed mixing. Strong flours show a sharp increase in mixing resistance, and broadening and narrowing of the band. The resistograms of medium strength and weak flours are characterized by two pronounced maxima. The first is related to waterbonding and dough development and indicates the dough development time. The second measures the stickiness and extensibility at breakdown of the dough; the time to reach this point is most important in testing medium and weak flours. Both optimum and breaking points are reached when the blades of the mixer are completely covered with dough.

Load–Extension Tests

Several commercial instruments are available for the routine testing of dough at large elongations. From the recorded curves, various characteristics, such as resistance to deformation, extensibility, and energy needed to rupture the dough, can be computed. Among these instruments, the Brabender extensigraph is the most common. It was developed in about 1936 as a supplement to the farinograph, and has become particularly useful in the study of the effect of various chemical improvers on the rheological properties of dough. The extensigraph data (Figure 5) reported for control purposes are usually the curve length in centimeters (extensibility), the curve height in extensigraph units either at the maximum or 5 cm from the start of the curve (resistance), the area under the curve in square centimeters (strength value), and the quotient of height over length – the greater this quotient, the stronger the dough. Several attempts have been made to use the extensigraph for more fundamental studies, and to transform extensigraph data into rheological terms. The main problem in these transformations is the calculation of the actual cross-sectional area based on the 'effective mass' of the dough, i.e., the mass between the edges of the cradle supporting the dough. The effective mass progressively increases during stretching because some dough is pulled out from the cradle due to its resistance to extension. The effective mass and the actual cross-sectional area of the dough can be calculated from multiple regression equations. The coefficient in these equations, however, change with the type of dough and have to be determined experimentally.

A higher sensitivity and wider applicability of the Brabender extensigraph may be achieved by replacing the mechanical recording device by an electronic strain gauge system.

Another load–extension meter used in cereal laboratories is the research extensometer (Halton extensigraph) designed by Halton and associates. While the actual extensometer works on a similar principle to the Brabender extensigraph, the required water content for dough preparation is measured on

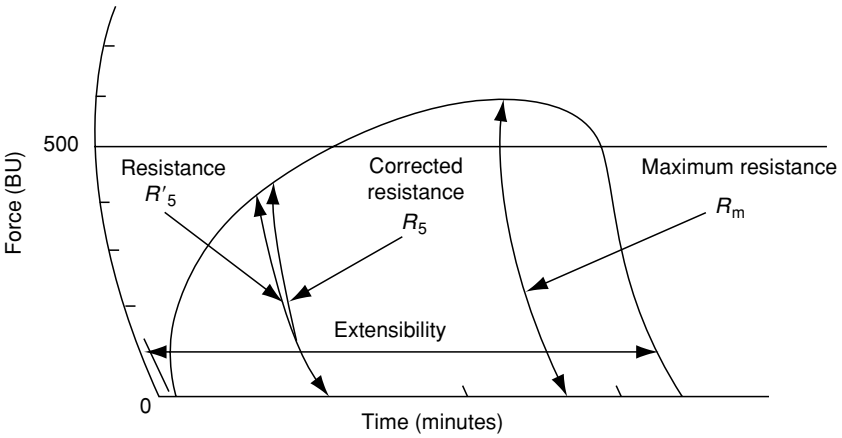

Figure 5 Representative extensigram showing the most commonly measured parameters. From Bloksma AH (1971) Rheology and chemistry of dough. In: *Wheat Chemistry and Technology*. St. Paul, MN: American Association of Cereal Chemists, with permission.

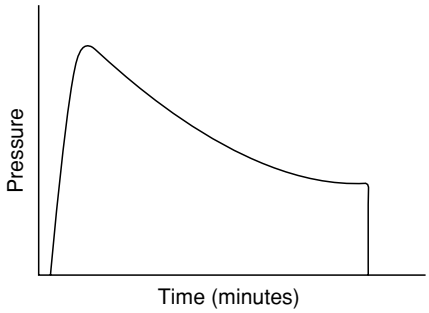

Figure 6 Representative alveogram. From Bloksma AH (1971) Rheology and Chemistry of dough. In: *Wheat Chemistry and Technology*. St. Paul, MN: American Association of Cereal Chemists, with permission.

the principle of extrusion by means of a special water-absorption meter, which, together with a mixer/shaper, belongs to the three-unit extensometer. The interpretation of the curves is the same as with Brabender extensigrams. A great advantage of this instrument lies in its applicability to fermenting doughs.

The Chopin alveograph is more popular in Europe than in North America. The instrument consists of three parts: mixer, bubble blower, and a recording manometer. The procedure involves using air pressure to blow a bubble from a disk of sheeted dough until it reaches its breaking point. A recording manometer records the presure of the air in the bubble as a function of time. The manometer records a curve (Figure 6) from which three basic measurements are taken: the height and the length of the curve, and the area under the curve. The area under the curve is proportional to the work of deformation.

Viscosity Measurements

The third step in the process of the physical testing of flour or dough, based on the 'three-phase concept of bread baking,' is the measurement of changes in flour-paste viscosities at temperatures above the gelatinization temperature of starch present in flour. The data obtained by these measurements are not only related to the gelatinization characteristics of the crumb in the baking oven, but also a good indicator of the diastatic activity of the flour. These measurements do not fall into the category of dough rheology, because all tests are done on flour slurries only. However, they help to evaluate factors that considerably affect the consistency of dough as well as the texture of bread crumb, its color, general appearance, and shelf-life. The most common instrument used for these tests is the Brabender amylograph. It is a torsion viscometer that provides a continuous record of changes in viscosity of the flour slurry at a uniform rate of temperature increase (decrease) of 1.5 °C min^{-1} under constant stirring. Although the instrument was originally developed for testing rye-flour pastes, the amylographic method has become a standard method for controlling α-amylase activity in wheat flour. The higher the activity, the lower the hot paste viscosity due to the liquefying effect of the enzyme. The effect of other amylolytic enzymes present is also reflected in the amylogram.

Breadmaking Processes

M Collado-Fernández, University of Burgos, Burgos, Spain

Background

Bread is one of the most consumed food products known to humans, and for some people, it is the principal source of nutrition. Bread is an inexpensive source of energy: it contains carbohydrates, lipids, and proteins, and it is important as a source of essential vitamins of the B complex and of vitamin E, minerals and trace elements.

The history of bread can be traced back about six millennia. Breadmaking is an ancient art that is closely connected with the development of the human race and civilization, but the development of the baking oven, the industrial production of baker's yeast in the nineteenth century, was decisive for the technology of breadmaking. The twentieth century led to technical advances and the rationalization of bread production. Some of these advances in breadmaking include knowledge about physical–chemical changes in dough, the rheology of flour and dough, and the development of different instrumentations of rheology. Research into breadmaking is currently concerned with staling, the influence of the different additives on the breadmaking process, and the rheological properties of flour, dough, and bread, in order to improve its quality.

There are numerous variations of the breadmaking process. The choice of one or another is related to: tradition, cost, the kind of energy available, the kind of flour, the kind of bread required, and the time between baking and consumption of bread.

Bread

The basic formulation of bread is wheat flour, yeast, salt and potable water. Optional ingredients are nonwheat flours, shortening, nutritive carbohydrate sweeteners, skim-milk powder, enzyme active preparations, dough conditioners, and so on. The Food and Drug Administration legally defined the specified amounts of these optional ingredients in the production of various standardized bread products. (*See* **Legislation**: Additives.)

Bread is the food produced by baking a dough obtained by mixing wheat flour, salt, and potable water, leavened to specific microorganisms of bread fermentation, as *Saccharomyces cerevisiae*. Each country has many different kinds of bread, and these differ from one country to another (bread, rolls, pan

bread, pita bread, French bread, toast bread, baguette, etc.).

The breadmaking process changes the rheological and organoleptic properties of bread; this also changes the quality. In each country, the definition of quality may also change according to specific consumer preferences. However, the term 'bread' describes a range of products of different shapes, sizes, textures, crust, colors, softness, eating qualities, and flavors. For this reason, we will consider only the influence of the breadmaking process on the organoleptic properties of bread, and not if this bread is of a good or bad quality. The principal attributes of bread are as follows: loaf volume, crumb softness, grain uniformity, silkiness of texture, crust color, flavor and aroma, softness retention, and nutritive value. Although the breadmaking process influences the end product, the bread, the principal influence is the quality of different ingredients and especially the kind of flour used.

Principal ingredients

Flour

The breadmaking quality of flour depends on the variety of the grain, all agricultural and climatic conditions, including the harvest, and the milling process. Flour is the major ingredient in most formulations. The most important characteristics of flour are as follows: the protein content, especially the quantity and quality of gluten, the water absorption capacity, and the diastatic activity. The kneading of the flour and water gives the dough a cohesive, viscoelastic mass that retains the gas formed during fermentation. Thus, flour is responsible for the structure of bread. (*See* **Flour**: Analysis of Wheat Flours.)

Yeast

The principal function of yeast is the conversion of the simple sugars into carbon dioxide and ethanol. The production of gas causes the expansion of dough. Yeast also has an important role in the rheological properties of dough. (*See* **Bread**: Dough Fermentation.)

Salt

Salt is used in all baked goods to provide flavor, and because of its effect on the breadmaking process, salt has an influence on the rheological properties of dough. Salt inhibits the hydration of gluten; the gluten shrinks, the dough does not collapse, and gas retention is improved. Higher concentrations of salt inhibit enzymatic reactions and also inhibit the fermentation activity of yeast. In general, the proportion of salt used is 1–2% (based on flour weight).

Water

Only potable water may be used for the production of bread, and its quality is very important in breadmaking. Mineral constituents of the dough water (mainly carbonates and sulfates) give a firmer, more resistant gluten; the doughs do not collapse during fermentation, the gas retention is improved, and with a normal volume, the grain is finer and more elastic.

Optional Ingredients

Fat

The use of fats is essential to be able to keep the bread in storage. The functions of fats are as follows: fat increases the shelf-life, produces a finer grain, and, if used in small concentrations, yields a greater volume of baked foods (10%). The crust is more elastic and softer. The shortening effect is due to the formation of a film between the starch and protein layers of the flour. Surface-active materials, such as mono and diglycerides or lecithin, promote the formation of this film of fat and have a fat-sparing effect. The shortening effect is greater for fat with a lower melting point than for harder fats. The best fats are hydrogenated vegetable fats with a solidifying point between 30 and 40 °C. Fat produces a dough with more plasticity, so the use of fat requires less water in the formulation.

Sugar

Sugar promotes fermentation, browning of the crust, and a sweeter taste. In addition, it makes the dough more stable, more elastic, and shorter, and the baked goods more tender. For increasing additions of sugar and fat, the amount of added liquids must be reduced for a given dough consistency.

Milk and Dairy Products

These include milk (usually skim-milk powder) and whey containing lactose, which promotes browning, a softer crust, and a longer shelf-life.

Oxidants

The function of oxidants is the oxidation of -SH groups of protein to -SS-groups, resulting in an improvement in rheological properties of dough and of gas retention. The disulfide bonds thus established within and between protein chains lead to a firmer gluten structure. The time of dough maturation is shorter, the oven spring is greater, the volume is large, and the quality of the grain is better. The oxidant commonly used is ascorbic acid (E300). (*See* **Legislation**: Additives.)

Enzyme Active Preparations

Flours with a low enzyme activity produce breads that do not brown well, have a crumbly crumb, and stale rapidly. Such flours must have fermentable sugars or enzyme active preparations added (malted flour, malt extract, and bacterial or fungal α-amylases). The addition of malted flour increases bread volume slightly; the texture is better and decreases the keyholing (especially of pan breads). The addition of α-amylases is most important to start the hydrolysis of starch and to form the substrate for β-amylase action. The addition of fungal or bacterial α-amylases makes a difference to the thermal stability. The heat stability of bacterial α-amylases is higher. These amylases often remain active after baking and may cause some problems (moist and slim crumb) in the final product. (*See* **Enzymes**: Functions and Characteristics.)

Emulsifying Agents

Emulsifying agents or shortening or tensoactive agents are used to make bread softer during storage, especially pan bread. The effect of emulsifying agents on dough and baked products is based on their reaction with the starch–protein–fat–water system. The dough improves the strength of the gluten structure and improves the handling characteristics of dough as well as gas retention, and staling is delayed. Some of the emulsifiers in use are monoglycerides (E471), esters from monoglycerides and diacetyltartaric acid (DATA esters; E472e), sodium or calcium stearoyl-2-lactylate (SSL, E481 or E482), lecithin (E322), and other ingredients that perform a similar function. (*See* **Fats**: Uses in the Food Industry; **Legislation**: Additives.)

Preservatives

Preservatives are used in bread with a higher moisture content (40%) and packed hermetically because these breads are more sensitive to mold growth. The most important preservatives are calcium propionate (E282), sorbic acid (E200), and vinegar to prevent mold growth or rope. Calcium propionate also affects the fermentation process. More yeast can be added to compensate for this effect. (*See* **Legislation**: Additives.)

Breadmaking Process

The elaboration of bread may be divided into three principal stages:

1. Kneading of Dough (Dough formation): This stage marks the difference between all the breadmaking processes. In general, the kneading of dough involves the thorough mixing of ingredients. Some ingredients such as gluten and starch are hydrated; others are dissolved in water. The mechanical work produced by mixers contributes energy to the development of a gluten, incorporates air bubbles within the dough, and produces a dough with the rheological properties required, such as viscosity, elasticity, extensibility, gas retention, etc.
2. Fermentation, Proofing, or Proving: Fermentation is the action of the yeast on fermentable sugars to produce carbon dioxide (CO_2) and ethanol (which has a neutral taste). The gas is retained by dough and increases its volume. The production of gas and gas retention depends on the quality of the flour. The modifications of this stage are controlled fermentation and ultrafrozen dough.
3. Baking: This is the last stage, where, by the action of heat, the dough is converted into the final baked products by firming (stabilization of the structure) and by the formation of the characteristic aromatic substances. A modification of this stage is prebaked bread.

The different steps in breadmaking are as follows (Figure 1):

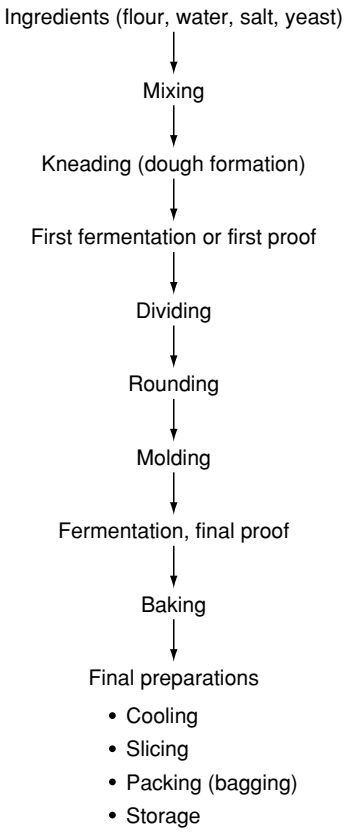

Figure 1 Different steps in the breadmaking process.

- *Ingredients*: Depending on the kind of bread required (flour, water, salt, yeast). (*See* **Flour**: Analysis of Wheat Flours.)
  - *Kneading*: This stage makes the greatest difference between all the breadmaking processes. (*See* **Bread**: Dough Mixing and Testing Operations.)
  - *First Fermentation or First Proof*: Dough has a resting period (floortime) in bulk after mixing and before dividing. In general, this stage tends to be substituted by intensive kneading or by other methods. Its function is to adapt the fermentation agent to the medium, production of dioxide carbon and other components, and the physical transformation of dough. The duration of this stage depends on the kind of process and equipment. The temperature conditions are 27 °C, relative humidity 75% (to avoid dried surfaces), and draught-free.
- *Dividing*: Dough may be divided by weighting or volumetrically (which is more common). At this stage, dough must be fluid, and have plegability and extensibility. After dividing, the dough is degassed and has an irregular form, the surface of dough has a higher viscosity, the structure of gluten has been damaged and the surface does not retain gas, and the dough has less plegability. For this reason, dough needs to undergo the next operation, rounding.
- *Rounding*: Dough with a rotary motion produces a ball-shaped piece with smooth skin. The alveolar structure is redistributed and improves the retention of gas. Dough is less viscous. After rounding, dough needs a floortime (between 2 and 20 min) in order to increase the plegability. The temperature conditions are 27–29 °C. If the temperature increases, dough becomes stale, decreases the retention of gas, and becomes more sticky; if the temperature decreases, dough becomes colder, and the fermentation time is greater. The relative humidity is 75%; if the relative humidity increases, this also increases the stickiness of dough.
- *Molding*: Two successive steps are responsible for the final shape of dough: laminated and curled. The molded dough is placed either in tins or on a baking tray and kept in a proofing cabinet to continue fermentation (final proof). This step is necessary to work the fermented dough, divide the alveolus, and provide a uniform redistribution.
- *Fermentation, Final Proof, or Proving*: During fermentation, starch is converted into sugars by enzyme action. The sugars feed the yeast, and the breakdown products are carbon dioxide and ethanol. As carbon dioxide is produced, the dough expands and retains it, and it is important that the skin remains flexible. There is a relationship between produced and retained gas that depends on the quality of the gluten structure. The more retained gas, the more bread volume. The temperature used depends on the kind of bread and the breadmaking process (28–30 °C): the lower the temperature, the longer fermentation time (2–4 h or 1–1.30 h). The relative humidity is between 60 and 90%, depending on the formulations and fermentation temperature. There is a variation of *P/L* during fermentation; dough has less tenacity (*P*) and more energy (*w*). (*See* **Bread**: Chemistry of

Baking; Dough Mixing and Testing Operations; Dough Fermentation; **Sensory Evaluation**: Aroma.)

- *Baking*: Baking is the final operation. There are physical, chemical, and biological transformations in dough that allow a stable product to be obtained, with excellent organoleptic and nutritive characteristics, the bread. (*See* **Bread**: Dough Mixing and Testing Operations; **Sensory Evaluation**: Aroma.)
- *Final Preparations*: Different steps for retention of quality: cooling, slicing, and packing.

- *Cooling*: During cooling, the moisture of the crumb goes to crust. It is necessary to reduce the temperature gradually to maintain the bread quality, and to take into account the relative humidity and temperature. If the relative humidity is low, the bread will lose too much moisture and may have no uniform crust. If the relative humidity is high, the crust of the bread will not be crunchy. This step is very important to maintain the bread quality when bread needs to be sliced and packed.
- *Slicing*: The bread must be cold for slicing; if not, it will crumble.
- *Packing*: Packing maintains the product quality by reducing crumb drying, minimizes the risk of contamination, and gives an appealing and informative package to the consumer.

Description of Breadmaking Processes

The different breadmaking systems are related to the diverse methods for making the dough. Although there are numerous variations, the major processing methodologies or breadmaking process are as follows:

Straight Dough Method

Flour, water, yeast, salt, and all other ingredients are added at the same time by single-stage mixing into a dough of optimum physical properties (i.e., the softness and appearance required, as well as the elasticity). The amount of water required depends on the water adsorption capacity of the flour determined by the farinograph. Usually, the amount of water is about 55–60% of the flour weight. (*See* **Bread**: Dough Mixing and Testing Operations.)

The kneading time depends on the speed and type of mixers used as well as the flour characteristics. Strong flours need more kneading time than soft flours. The speed differs, and energy imparted to the dough has repercussions on the efficiency of mixing of ingredients. (*See* **Bread**: Dough Mixing and Testing Operations.)

The dough is removed from the mixer, which may have a temperature between 26 and 28 °C, and is kept in the proof cabinet to ferment for 2–4 h, depending on the concentration of the yeast used. Afterwards, the dough is divided, rounded, molded, fermented (final proof), and baked.

- Advantage: It requires less processing time, labor, power, and equipment. Fermentation losses are smaller than with other processes.
- Disadvantage: Relatively small variations in processing may lead to noticeable variations in the final quality of breads. It is less flexible than the sponge dough, requires limited fermentation time, and does not permit correction of overfermentation.

Straight dough breads have a blander flavor than sponge dough breads. They do not have a soft texture, and the bread volume is lower, but this depends on the quantity of additives used.

Sponge and Dough Process

This method is the most common manufacturing commercial process used in the USA. In this indirect process, the flour, water, and a portion of the yeast are first mixed into a sponge or predough (temperature 25 °C). When the predough has fully fermented, it is mixed with the remaining flour, water, and other ingredients to make the final dough (temperature 26–28 °C), which is then given a short fermentation. Afterwards, the dough is divided, rounded, molded, fermented (final proof), and baked. (*See* **Bread**: Sourdough Bread.)

This method permits the use of strong and soft (weak) flour, using the strong flour to make the sponge and the soft in the final dough. Usually, the amount of strong flour is about 50%.

For rich dough high in fat or sugar, the fermentation time is often only 20–30 min. In this case, all the yeast is used with one-fourth to one-third of the flour and water to form a warm, soft predough. This causes better swelling and acclimatizes the yeast to the conditions of the dough.

- Advantage: It permits greater variations in the operations of the process and improves the volume, texture, and shelf-life of the bread. In addition, the longer fermentation time improves the aroma.
- Disadvantage: It requires more fermentation time and labor than the straight dough method, and it is more difficult to control. Sometimes, the dough has more tenacity, and it is difficult to divide, laminate, and mold.

Liquid Fermentation Process (Poolish)

The principle of this process is essentially the same as the sponge and dough method, except that it uses a

liquid instead of solid sponge. Its origin is Poland, hence the name Poolish, or liquid sponge. This method has been used since the 1920s with some variation in Vienna (for the production of Viennese bread); and in France (for the production of French bread). It has been used in American bakeries since the 1950s. (*See* **Bread**: Sourdough Bread.)

These preferments contain flour, water, and yeast. Usually, the amount of water is 1 l per kilogram of flour, and the amount of yeast depends on the fermentation time (12–15 g of yeast to 3 h; 7–8 g of yeast to 6 h; and 5 g of yeast to 8 h). The temperature of fermentation is 23–31 °C. The fermented liquid is stirred slowly to prevent foaming. After the desired fermentation time (the liquid triples its volume), the liquid is cooled by a heat exchanger to 8–10 °C and kept in a refrigerated storage tank until used. It may be stored for a 24-h period without any loss of activity.

The second step is the addition to this preferment liquid of the remainder of the flour, water, and salt (1%) and the other ingredients in the formulation. Afterwards, the final dough is fermented for 1 h, and then the remaining operations in the breadmaking process continue: dividing, rounding, molding, fermentation (1 h), and baking.

- Advantage: The same as the sponge and dough process, and also the consistency of the liquid sponge permits its transfer by pumping and better control of the production process. It permits work with weak flours, increasing its energy and elasticity, a cause of better starch gelatinization, and it has a good machinability. It requires less pressed yeast, and a single preferment may be used for the production of a variety of breads and baked goods.
- Disadvantage: It requires more fermentation time and labor than the straight dough method.

Continuous Bread Process

The development of continuous mix processes started in 1926 with the observation that the enzymatic and oxidative changes in dough structure during fermentation may be replaced by intensive mixing of dough at a high rpm. This process, introduced in the USA in the 1950s, was represented by two systems: the 'Do-Maker' process, based on patents granted to John C. Baker, and the 'Amflow' process, introduced by the American Machine and Foundry Co. It was observed that high-speed mixing could not replace the development of CO_2 and the aroma substances during fermentation. High-speed mixing was used with a liquid preferment to insure a desirable aroma in the final bread.

Do-Maker system (preferment liquid without flour) All operations are automatic. The first phase consists of preparations of the preferment liquid, which is a solution with all ingredients except the flour and shortenings (sugar, yeast, and nutrients to yeast and water). The development of the dough is due to the high degree of mechanical work, and not to floortime. It is also necessary to add higher levels of oxidants. The fermentation requires 1–4 h (usually 2.5 h) at 30–32 °C, with constant slow stirring in a vertical tank. The liquid preferment is then cooled (4 °C) and can be stored for a long time. During the fermentation, the pH decreases, so liquid preferment buffer substances like soya flour and powdered milk are added.

The second phase involves mixing the liquid preferment with the flour, shortening, and oxidants for 30–60 s and then pumping it to the developer. Usually, the rate of addition of the ingredients is 18–19 kg min^{-1} for flour and 14 kg min^{-1} for the preferment. The dwell time in the developer is only about 60 s. It is then extruded into pans.

- Advantages: The bread has a very uniform and fine grain, with a very soft crumb and a thin crust. It requires less time than the other systems with bulk fermentation.
- Disadvantages: The taste of the bread is different from that of the conventional sponge and dough bread.

Amflow system (liquid preferment with flour) This system is similar to the Do-Maker, except that the preferment is formed with flour, and the tank is horizontal.

Obtaining the preferment is a double step. In the first step, water, yeast, yeast nutrient, and a portion of sugar are mixed and kept in a holding tank to ferment for 1 h, and the aroma is developed. In the second step, salt, skim-milk powder, additional sugar, and 12% of flour are added. This viscous liquid is pumped to another tank for a second fermentation for 1 h with slow stirring at 30–32 °C. Finally, the preferment (sponge liquid) is pumped into a horizontal tank and cooled. The sponge liquid is pumped into the premixer, where the remaining ingredients (flour, water, sugar, fat, and oxidant) are mixed. This mixture is then developed in the mixer-developer. It is necessary to decrease the pressure created in the dough in order to avoid excess air, and directly extrude into baking pan. The bread has a very fine grain.

No-time Doughs (Short-time Doughs)

Dough fermentation and dough maturing may be accelerated by the addition of reducing and oxidant

substances. This has led to the development of 'no time dough' in which dough maturation is obtained by mechanically and chemically decreasing the fermentation stage.

Chorleywood process This system is also known as 'mechanical dough development' and 'intensive kneading.' This process originated in the UK and is used extensively throughout the world. The characteristic of this process is mixing of the dough intensively in a batch, high-speed mixer (Tweedy kneader) for 3–5 min with a controlled energy input. The optimum work input is 11 Watt-hours per kilogram of dough ($40\,J\,g^{-1}$). However, the energy requirements differ for flours of varying quality (soft flour needs less energy than strong flour) and the type of bread. This energy is five to eight times the energy used in conventional kneading. The mixing is generally done under vacuum, so the dough must contain ascorbic acid (75 p.p.m.). In this process, it is necessary to add high-melting-point fat (0.7% of flour), more water (3.5%) to soften the dough, since it has to support excessive mechanical work, and more yeast (50–100%).

- Advantages: This process saves time and space. The bread may be ready in 1.30 h. The production of bread is increased through the addition of extra water, and wastage is reduced by absence of bulk fermentation. Less, but more skilled, labor is necessary. More conservation and less staling of bread and soft flour may be used.
- Disadvantages: There is a reduction in the crumb of bread, flavor, and aroma because of the shorter processing times. For this reason, preferments may be added.

Activated dough development (ADD) This system was developed after research carried out on the Chorleywood system. It was found that good bread could be made with classic kneading, with a low-speed kneader, and a similar time to kneading but with the addition of chemical substances to eliminate the first fermentation or bulk fermentation. In this system, it is necessary to use fat and greater quantities of yeast and water.

Chemicals must be added before kneading, and are as follows: L-cysteine hydrochloride (35 p.p.m. based on flour) with ascorbic acid (35 p.p.m.) and potassium bromate (25 p.p.m.). Some legislation does not permit these oxidants. (*See* **Legislation**: Additives.)

- Advantages: This system is similar to the Chorleywood system, with the additional advantage of not requiring a high-speed mixer. The cost of chemicals is similar to the cost of the supplementary energy of the high-speed mixer.
- Disadvantages: The bread ADD crumb flavor and aroma are worse than that of traditional bread (straight dough) or Chorleywood bread.

In relation to fermentation, recent work has sought to control fermentation, which permits the regulation of bread production, and ultrafrozen dough. Controlled fermentation is one of the new techniques used to apply cold to stop or to decrease the extent of fermentation. (*See* **Bread**: Dough Fermentation.)

In ultrafrozen dough, the fermentation is interrupted for some time to renew it afterwards. The prefermentation time must not be more than 15 min, so as to avoid any type of fermentation. After molding, the dough is ultrafrozen (−35 to −40 °C), packed to avoid dry surface during conservation, and stored at −20 or −18 °C, until it is defrosted to go on to fermentation and baking.

In relation to baking, recent research has investigated prebaked bread. Prebaked bread is bread for which baking has been interrupted and may be continued afterwards. The baking is divided into two steps. The dough is prepared by the traditional method and is placed into an oven for 10 or 15 min until the starch has coagulated and the bread has gained structure, and then the bread is taken out of

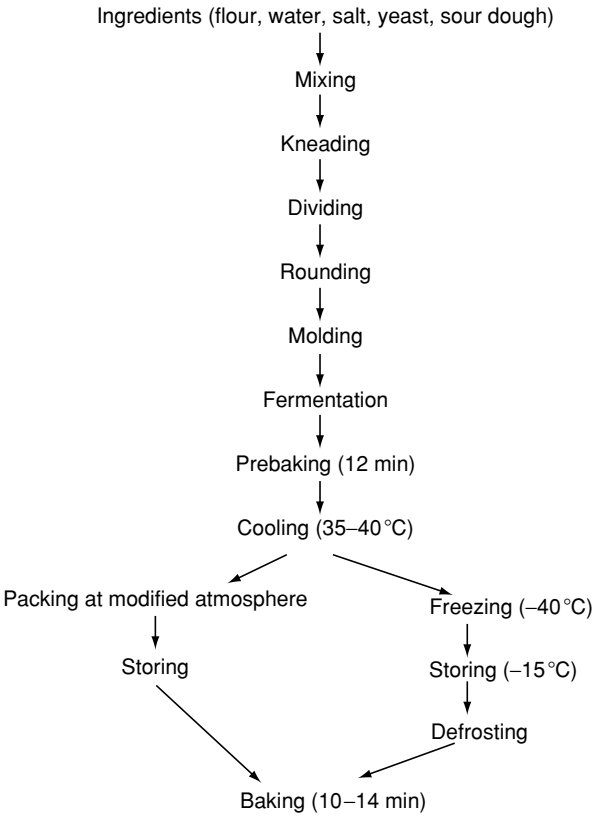

Figure 2 Different steps in the prebaked bread process.

the oven. After prebaking, the bread must be cooled down for an hour to a temperature of 35–40 °C, without any draughts so as to avoid cracking the crust, and packed in a modified atmosphere or frozen. This bread has a white color, contains more moisture, and is denser. The second phase is to finish the baking, and then the bread looks exactly like traditional bread.

- Advantages: Fresh bread can be obtained in a few minutes without having to ferment previously.
- Disadvantages: The bread has less volume, the crust is rougher and the crumb denser, and it stales more rapidly compared with the traditional system (straight dough).

Chemistry of Baking

M Collado-Fernández, University of Burgos, Burgos, Spain

Background

Baking is the last stage of the breadmaking process, in which there are several physical–chemical and biological changes as the result of the action of heat. These changes transform the dough into an edible final product with excellent organoleptic and nutritive characteristics – bread.

At this stage of baking, it is very important to control the baking temperature and time, which depend on the type of oven used, as well as the size of pieces and the kind of bread desired (the formulation used). All these possible variations may have repercussions on the different quality of bread depending on the bakery. The transfer of heat to dough may be by conduction, convection, and radiation. The different temperatures reached inside and outside the dough cause the formation of the crust and crumb of bread. The different phases during baking are as follows: oven spring (enzyme active zone), gelatinization of starch, and browning and aroma formation.

Baking

Working Conditions

During baking, the following highly correlated factors need to be controlled: the temperature of baking, the type of baking oven, the relative humidity, and the duration of baking.

Temperature of Baking

Usually, the baking temperature of 200–275 °C is a function of the type of baking oven, the duration of baking, and the size and type of bread desired (formulation used). Generally, the small items require a higher temperature and a shorter time, whereas large items need a lower temperature and a longer time.

This is also limited by the consistency of the dough; soft dough (low consistency) requires a higher temperature than hard dough (high consistency). In hard dough, where there is less water to evaporate, high temperatures produce cracks because dehydration is too rapid. If the temperature is too high, an overdone thick crust and, unbaked crumb result.

Depending on the type of bread, the temperature during baking will be uniform or will be higher at the beginning of the baking process with a slowly decreasing temperature afterwards.

Duration of Baking

The duration of baking depends on the temperature used. During baking, the following changes take place: gelatinization of the starch, denaturation of the protein, and the formation of aromatic substances. Thus, the duration of baking is limited, on the one hand, to a minimum in which all these changes are produced and, on the other hand, to a maximum limited by the loss of vitamins, excess evaporation of water, and also economic considerations.

Relative Humidity

The injection of water vapor into the oven favors the increase in relative humidity. The dough is covered with a fine surface layer of water, which keeps it moist and elastic for some time. This presents the following advantages: it avoids the immediate formation of crust, increases the volume (with a satisfactory oven spring), improves the color and shine, and produces a fine crust. Any excess water leads to the formation of drops of water on the surface of dough that give rise to bubbles on the bread.

Type of Oven

Heat is transferred by conduction, convection, and radiation. Coal, oil, or electricity may be used to heat the oven. There are several different types of oven, the most common being the hot air oven, in which the air is heated in a closed system and introduced into the oven by forced convection. Other types include the rotary hearth oven, the reel oven, the pan rack oven, and a continuous belt or tunnel oven.

Baking Process

The dough is placed into the oven when it reaches its optimum fermentation. If the fermentation is too short, the dough has not matured enough (underoxidized or green dough), and when it is placed into the oven, it does not support the increase (oven spring), resulting in a flat bread. If there is overfermentation (overoxidized dough), the crumb is very rough. To make bread with a crunchy crust, a cut is made on the dough before placing it into the oven. The cut should be oblique so that some of the wet zones are protected, thus achieving a greater volume of bread, because it can support the pressure better; if the cut is vertical, the bread opens and dries.

Transfer of heat Once placed into the oven, the dough increases its volume, reaching a maximum volume after some 5–10 min, depending on the weight, size, and quality of the dough. This increase in dough volume is due to the heat in the oven. Convection and radiation from the walls of the oven heat the dough, which comes into contact with the hot air. Dough on the baking pan is heated by conduction. The heat is transferred by conduction from the outside to the core of the dough, so the dough reaches different temperatures, leading to the formation of a crust on the surface ($> 100\,^{\circ}C$) and the crumb inside ($< 100\,^{\circ}C$) the bread.

Evaporation of water When the dough reaches $100\,^{\circ}C$, water inside evaporates. This process occurs superficially and water moves from the inside to the outside. When the migration of water is slow, the crust begins to form, the thickness of which depends on the duration of baking. At the beginning of baking, steam is added to help development and increase the bread volume. Later, the bread itself produces the steam, which condenses on the surface of the dough. The dough thus remains moist for longer, acquiring a satisfactory oven spring, and the surface is prevented from drying too rapidly. The resulting bread has a good external quality, color and shine, with a thick, crunchy crust.

Vaporization of aromatic substances During baking, together with the evaporation of water, there is also vaporization of all compounds that have a boiling point of less than $100\,^{\circ}C$, particularly ethanol, carbon dioxide, and some aromatic compounds formed during fermentation and baking (e.g., aldehydes, esters, and volatile acids). The vaporization depends not only on the concentration of these substances in dough but also on the capacity of gas retention in the dough and the permeability and elasticity of the network.

Cooling It is very important to cool the bread correctly after baking, otherwise the bread will crumble upon slicing. Cooling is also very important if the bread needs to be packed. The moisture of the crumb becomes crust during cooling. Depending on the relative humidity of the environment, the bread will lose or take up excessive moisture, and this will affect the quality of the bread.

Physical–Chemical Changes During Baking

Baking converts the dough into the final baked product by firming (stabilization of the structure) and by the formation of characteristic aroma substances. There are three phases depending on the temperature the dough reaches:

1. oven spring (enzyme active zone) (from 30 to 60 or 70 °C);
2. gelatinization of starch (55–60 °C) to no higher than 90 °C;
3. browning and aroma formation above 100 °C

Oven Spring

In this stage, the dough temperature reaches about 50 °C. There is very intensive fermentation because yeast activity continues until the dough reaches about 50 °C. Enzymatic activity is also very high because of the high temperatures, with a maximum at about 60 °C, and causes the conversion of starch to sugars. There is a liquefaction of dough and decrease in viscosity. The enzymatic activity continues until the dough reaches about 80 °C. There is an increase in the production of carbon dioxide from the conversion of sugar by the action of yeast. The solubility of carbon dioxide decreases with increasing temperature, and the production of carbon dioxide ceases when the yeast dies.

With the action of heat, the gas pressure increases. There is an inverse relationship between the size of the gas bubbles and gas pressure: the smaller the gas bubble, the higher the gas pressure. If the flour is of a poor quality, the gas bubbles cannot withstand the pressure and widen; then, the pressure decreases, and the resulting bread is flat (the bread deflates).

Enzymatic activity has an influence on the structure, crumb quality, and volume of the bread. If there is little enzymatic activity, the bread is small because the structure of the starch becomes rigid too soon, whereas too much activity leads to a structure that is too fluid, and the bread collapses completely.

Gelatinization of Starch

Dough undergoes increases in temperature from 50–60 °C to 90 °C. This promotes the gelatinization of starch and the denaturation of protein with the coagulation of gluten. The denaturation of protein begins at about 70 °C and is important for a stable bread structure. During kneading, the proteins are hydrated by the absorption of water, and during baking, water is transferred from gluten to starch, which swells. This dehydration of gluten continues until the increase in temperature leads to gluten coagulation. The denaturation of protein is more intensive on the crust than in the crumb of the bread because of the high temperature on the crust.

The capacity of starch to absorb water depends on the quantity of starch damaged during milling. First, starch absorbs the free water in the dough. It swells, and in the oven, the starch begins to gelatinize due to the high temperature. During baking, the gluten gives up water to starch, and the gelatinization is complete. The starch undergoes several changes such as loss of birefringence, increase in viscosity, and exudation of amylose (very important during staling). Dough undergoes an increase in viscosity by gelatinization of starch, and the dough becomes more consistent. The plasticity decreases, and the rigidity of the dough increases. When the gluten collapses, starch supports the structure of dough. During cooling, starch crystallizes, contributing to the firmness of bread. These changes in starch brought about by the action of heat may be measured using an amylograph, which gives an idea of the behavior of the flour in breadmaking and the retrogradation of starch, associated with staling. (*See* **Starch**: Functional Properties.)

Browning and Aroma Formation

The reaction of starch is different inside and outside the dough due to the different temperatures. The temperature outside the dough is more than 100 °C, there is a high degree of evaporation of water on the surface, and crust formation and coloration begin. The temperature inside the dough is less than 100 °C, which leads to crumb formation. The crumb in the center of the dough and the crumb near crust are different.

Color develops on the crust, as a result of the temperatures reached in the oven. Thus, the temperature and the time in the oven affect the color of the crust and the aroma of the bread. There are two different reactions: browning (or the Maillard reaction) and sugar caramelization. The formation of different aromatic compounds influences the color, aroma, and flavor of bread. Different dough ingredients, especially salt and sugar, also influence the flavor. The Maillard reaction is the reaction between reducing sugars (glucose, fructose) and the amino group of proteins to form dark brown melanoidins and other intermediate compounds such as maltol, isomaltol, and α-dicarboniles. Sugar caramelization is brought about by dehydration of sugar, as a result of the high temperatures, to form very reactive aldehydes (furfural aldehydes) and other dark compounds, which may form the polymers or react with the amino compounds, furan derivates, and isomaltol.

It is principally the quantity of the aromatic compounds formed during fermentation that determines the aroma of bread, but the compounds formed during baking as a result of browning reactions and formation of melanoidins and caramel polymers also have some influence. Some of the aroma components detected include 1-propanol, acetaldehyde, propanal, butanal, furfural, acetic acid, and ethyl acetate. The more volatile compounds are evaporated during baking, as mentioned before. Depending on the quality of the network, gas-retention capacity, and permeability, the aroma will be more or less retained by the bread. The different types of bread also have different aromas and intensities. (*See* **Browning**: Nonenzymatic; **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Development of Bread

The factors that influence the development of bread are as follows: the quantity and quality of gluten, the quantity of sugars (owing to their capacity to produce gas), and the quantity of yeast, salt, and other ingredients such as fat. Other technological factors include: the breadmaking process and duration of fermentation, temperature of baking, duration of baking, and characteristics of dough pieces.

During baking, there is an increase in dough volume owing to the following: (1) water in the aqueous phase in dough is vaporized by the action of heat; (2) carbon dioxide retained in the dough is dilated by the heat; and (3) the network becomes more elastic, owing to the change in thiol/disulfide bonds between adjacent protein chains, and favors a satisfactory oven spring.

Thus, the dough development is related to the following factors: the concentration of gas, the elasticity and resistance of the network, and the gas-retention capacity. If the dough has a high elasticity and a great capacity to retain gas, the bread will rise greatly, have a less specific weight, and have a uniform soft crumb, whereas, if the dough has little elasticity or little gas-retention capacity because of a short and rigid network, the bread will be small, with a nonhomogenous alveolus and agglomerate crumb.

Loss During Baking

During baking, dough loses weight mainly from evaporation of water (about 95%) and minimally from vaporization of ethanol, CO_2, volatile acids, and esters. These losses occur principally on the crust, which withstands higher temperatures than the crumb, which contains more moisture. A short baking time reduces the weight loss, but the resulting bread is of a poor quality because of insufficient browning and lower crumb elasticity. In addition, the amount of thermolabile vitamins, such as riboflavin (B_2) and thiamine (B_1), is smaller.

Defect of Baking

It is very important to control the temperature of the oven and the injection of steam. The main defects during baking are due to insufficient or excessive heat, and insufficient or excess steam. Insufficient heat affects the quality of the bread, giving an excess of volume, a rough crumb, thick, uncolored crust, and an excessive loss of weight. Excessive heat produces bread with little volume, a dark crust with bubbles, nonuniform crumb and an underbaked appearance. Insufficient steam leads to cavities between the crumb and crust. Excessive steam produces a crust that is too soft and has white bubbles.

In conclusion, the effects of baking are as follows: an increase in the volume of bread, the formation of crumb and crust, the decrease of thermolabile vitamins, and the development of flavor and color.

Sourdough Bread

B J B Wood, University of Strathclyde, Glasgow, UK

Background

Sourdough breads, although their consumption is lower than that of yeasted breads in developed countries, probably predate the latter products. This review examines the history, microbiology, and nutritional significance of sourdough breads. Outlines of some typical production processes are also provided, but the reader is referred to the sources cited in the Further Reading section for detailed accounts of sourdough bread manufacture.

Sourdoughs are so called because the bread is leavened with a mixture of yeast(s) and lactic acid bacteria. It should be appreciated that a conventional yeast leaven will always contain some lactic acid bacteria, and that there will be a contribution to the final flavor that is attributable to them, but this will be minor and certainly will not result in a significant acid taste in the final bread. In a true sourdough, however, the contribution of the lactic acid bacteria will always be detectable, at least to the experienced palate, and quite often, the acidity is sufficient to be noticeable to the normal consumer. The sourdough way of making bread is of great antiquity, and many experts would agree that it is almost certainly the oldest way of leavening doughs, as a sour leaven will arise naturally from organisms already present in the flour if a mixture of flour and water is left in a warm place for a few hours; if this is used to inoculate a fresh flour/water mixture (dough), which is then allowed to ferment and a portion of it is used to inoculate a third portion of dough, and so forth, there will be a gradual evolution of a compatible mixture of yeast and *Lactobacillus* species. This type of continuing re-inoculation has much in common with maintaining liquid inocula by the process sometimes referred to as 'backslopping.' From the first mixing of flour and water, the developed sour ferment can be used to leaven a batch of bread dough, but as the sour is developed through succeeding generations, its quality and the consistency with which it leavens bread dough will improve, and the resulting bread will be more uniform and predictable in its quality, other things, such as flour quality, being equal. In some traditions, the sour dough starter is thus maintained for a very long time, possibly centuries, whereas in other practices, the sour starter is begun again every so often.

Historical Background

Many people, especially in the USA, think first, or only, of the San Francisco area when sourdough breads are mentioned. These bakers trace their roots back to the days of the pioneers, when sourdough bread, pancakes, etc. were an essential part of life in the covered wagon trains. The same heritage is found in Alaska, where the pioneers and especially the gold-miners were called 'sourdoughs,' as any reader of Jack London's stories and Robert Service's poems will know. Indeed, the latter called one of his poem collections *Songs of a Sourdough*. Dried yeast was not available at that time, so sourdough was the only way to have bread and other biologically leavened foods on the trail or in remote encampments.

This way of making bread, pancakes, and other foods would not have seemed particularly strange in those days as many of the settlers would know, or have kinship with, Europeans with traditions of making this type of bread.

This type of baking is still very widespread in Germany, Scandinavia, Eastern Europe, etc., but, perhaps surprisingly, French breads also quite often use this type of leaven. Even in Scotland, there was a traditional way of making bread using a liquid leaven called a 'Parisian barm,' which was still practised in some areas until quite well into the twentieth century, and one commerical bakery was still using a combination of Parisian barm and a final leavening with pressed yeast until a few years ago.

Allied Products

Many foods with a relationship to sourdough breads are produced in various parts of the world. Surplus barm is used in making soups, e.g., Kvass is a sharp, refreshing acidic drink found in Russia and much of Eastern Europe and is traditionally made by toasting or rusking sourdough rye bread, crumbling it into water, then allowing a fermentation to take place, after which the golden-brown, sharp, slightly sparkling, rather nutty-tasting liquid is poured off and drunk. The brew is kept going by replenishing the mixture with fresh toast and water at intervals, but if a brew is to be started *de novo*, fermentation is assured by inoculating with a portion of sourdough.

The Italian festive cake called 'panettone' is properly made with a sourdough starter especially maintained for this purpose by regular re-inoculation into a basic panettone dough, and there are reputed to be a number of similar products in various parts of the world. There is also a link with products such as the Indian food called 'Idli,' although it is a little tenuous, as Idli is made from a mixture of black gram (a variety of mung bean) and rice, and the leavening action is due to gas produced by the heterofermentative lactic acid bacterium *Leuconostoc*. Another variation is found in the use of presoaking to prepare certain ingredients for use in specialist breads. In a particular case, a Scottish bakery was using whole and kibbled (i.e., coarsely ground, crushed into large pieces or bruised) grains in breads such as the Vogel formula loaf and Turkestan-style bread. The whole and kibbled grains and coarse bran were mixed with water then left in the bakery overnight to soak up all the water that they could. The next morning, this mixture was incorporated with the other ingredients to make the final dough, which was leavened with pressed yeast in the usual manner. The bakery had not appreciated that the overnight soaking in the warm environment of the bakery was having any particular effect. They assumed that the only purpose of it was that which they had originally intended, namely to insure that the materials in question had imbibed all the water that they could. However, the bakery workers had noticed that the vessels containing the materials had a sour aroma and a marked frothiness when uncovered in the morning. In fact, there was a vigorous growth of lactic acid bacteria and some wild yeasts in the mixture overnight, and the acidity carried through to the finished bread, where it made an appreciable contribution to the flavor of the product.

Effects of Sour Fermentation on the Bread

Several effects are observed in addition to the obvious effect of an acid note to the flavor. The dough proteins are particularly affected, with changes in elasticity and extensibility that may result in the dough becoming in effect stronger, thus improving the baking performance of weak flours, and it is thus clear why sourdough formulations are so often associated with rye breads, as rye flour is much weaker than the typical wheat flour. Rye flour also differs from wheat flour in that it possesses higher levels of α-amylase, so that if a rye-based dough is fermented at neutral pH, excessive breakdown of the starch is observed. At the lower pH associated with the sour dough process, the amylolytic activity is reduced to an acceptable level.

Sourdough fermentations result in an increased hydrolysis of phytate from the grain; two factors are probably at work here, the fact that these are rather slow fermentations, so allowing more time for the seeds' phytases to effect hydrolysis, plus the lower pH, which is optimal for phytase activity. There is evidence for both phytase and phosphatase activity in lactic acid bacteria isolated from such ferments (especially those from the 'pre-soaks' described in the previous section). However, the significance of the results or the contribution that such activities (if confirmed by more detailed work) may make to the finished bread has not yet been established. The dietary significance of phytase activity is that phytic acid is a powerful chelating agent for a number of nutritionally important metal ions, including calcium, copper, iron, and zinc. Therefore, reducing the level of phytic acid will aid the absorption of these nutrients by the bread's consumer, which may be particularly important to those on vegetarian and 'macrobiotic' diets, although some authorities suggest that even the supposedly over-fed US consumer may not be consuming enough of these nutrients and may even be nutritionally compromised for them. The six phosphate residues that are present in each molecule of phytic acid and the inositol molecule are also made available to the consumer of the bread only upon hydrolysis of the phytic acid.

The acids formed in the fermentation are principally lactic and acetic (ethanoic) acids, and it is believed that their presence may contribute to the storage life of the bread by acting as mild antimicrobials, particularly effective against molds, which are often the first agents of biodegradation of bread. There is also evidence that the acids are damaging to the spores of *Bacillus* species, bacteria often present in the ingredients used for breads, particularly the wholegrain and so-called 'organic' types of materials favored by some makers of sourdough breads, because of their association with particular lifestyles. There is also good evidence that the acidity and possibly other factors associated with sourdough fermentations increase the time between baking and the onset of evident staling of the loaf.

Sourdough Bread Processes

From the foregoing, it is clear that there are many variations on the theme of sourdough bread production, but in order to keep this discussion within reasonable bounds, it is convenient to present two basic types, bearing in mind that other approaches are not necessarily just variants on the processes described here, as many of them have a quite clear identity, e.g., the Scottish 'Parisian barm' process mentioned

above. However, the majority of the sourdough bread produced commercially can be legitimately regarded as variants on one or other of the two main types.

Rye Breads (Particularly in Germany)

The work of the Detmold (Germany) group of Spicher and colleagues over many years has provided a deep understanding of the sourdough breads of Germany. They report that several microbial species participate in the fermentations. From some sources, it seems to be the practice to restart the German sour ferments fairly frequently, and this probably helps to bring about the diversity of species. However, Spicher notes that 'The development of commercial sourdough starter cultures over several decades has led to a certain natural selection of organisms that predominate in the fermentation.' This observation is in agreement with the work of other investigators who have studied sourdoughs from various parts of the world. Spicher also reports that attempts to replace these natural associations of organisms with pure cultures, as has been done with success in the production of commercial pressed yeast for the baking industry, has not been possible. An opposite claim will be discussed later.

Among the processes in German practice according to Spicher are multistage, two-stage, and single-stage sourdoughs. The last require the addition of yeast for good leavening, whereas the two-stage and multistage processes develop a yeast flora sufficient to leaven the dough fully. The single-stage processes are classified into the Detmold, Berlin, and Manheim (salt-sour) methods. In the Detmold process, the amount of starter and the temperature used for the fermentation are such that the process takes about 15–24 h. The temperature is in the range of 20–28 °C, with the amount of starter (as a proportion of the sourdough) ranging from 2% at 27–28 °C to 30% at 20–23 °C. The sourdough is made from a mixture of 55.6% rye flour and 44.4% water. When acidification is complete, this sourdough is blended with a mixture of wheat and rye flours and water plus the necessary yeast. Spicher quotes a typical mixture as 49.5 kg of sourdough, 42.5 kg of rye flour, 30.0 kg of wheat flour, and 46.0 l of water, giving a final proportion of 70% rye flour to 30% wheat flour. In the Berlin process, the combination of a high temperature and a high addition of seed sour, plus a softer mixture, gives adequate acidification in only 3–4 h. Spicher quotes a typical mix for the souring stage of the Berlin process as 8.0 kg of seed sour, 40.0 kg of rye flour, and 36.0 l of water, giving a proportion of 52.6% flour to 47.4% water. The sourdough is mixed with 30.0 kg of rye flour, 30.0 kg of wheat flour and 32.0 l of water, again giving a final ratio of 7:3 for rye to wheat flour. In the salt-sour process, the fermentation to produce the sourdough is longer than in the preceding processes, about 48 h being typical, although the presence of the salt will permit times up to 80 h to be used without loss of quality. The mixture for the souring stage contains 5.0 kg of seed sour, 25.0 kg of rye flour, and 25.0 l of water, plus 500 g salt, and is fermented at an initial temperature of 30–35 °C, dropping to 15–20 °C during 48 h of fermentation. This dough is mixed with 45.0 kg of rye flour, 30.0 kg of wheat flour, and 43.0 l of water to give the final 7:3 ratio of rye to wheat flour. Because of the inhibitory effects of the salt, it is necessary to add 2.5–3.5% w/w of compressed yeast to the final dough mixture, as compared with the 1.0–1.5% used with the preceding processes.

In some other processes described by Spicher, and referred to above as multistage and two-stage, the sour is increased in volume by successive inoculation of larger mixes of rye flour and water, each stage used to inoculate the next. The processes seem to be rather more favorable to the growth of desirable types of wild yeast alongside the lactic acid bacteria (LAB), with the result that either less compressed yeast is added than in the single-stage processes or no added yeast at all is needed in some of the multistage processes.

In these multispecies fermentations, the major LAB, according to a number of authors, are *Lactobacillus plantarum* (homofermentative), *L. brevis*, and *L. fermentum* (both heterofermentative). From the hexose sugars available for fermentation, homofermentative bacteria produce lactic acid only, or to such an overwhelming extent that other fermentation products are negligible in practice. Heterofermenters produce a mixture of products, including lactic and acetic acids, ethanol, and carbon dioxide, the ratios of these products being influenced by various environmental factors. Other products exist of course, and some of these play a part in the flavors that are characteristic of lactic-fermented products. In addition, LAB can utilize various pentose sugars, with the production of equimolar amounts of lactic and acetic acids. However, it is the homo- or heterofermentative aspect of the fermentation that is important here. According to previous reports, the best-quality bread results when the three species of bacteria are all present. The heterofermenters are essential for development of the 'typical flavor of sour rye bread.' However, the use of the heterofermenters alone gives a bread whose crumb lacks elasticity, but inclusion of the homofermentative *L. plantarum* restores this desirable attribute. The latter organism on its own gives the desired crumb characteristics, but the bread lacks aroma. Thus, both types

of organisms are essential for production of the finest quality of bread.

Spicher and coworkers have reported that the yeasts found in sourdoughs used in the production of rye breads fall into four types: *Candida krusei, Saccharomyces cerevisiae, S. exiguus*, and *Pichia saitoi*. Again, the environmental conditions influence the distribution of yeast species in doughs. Interactions between the yeasts and LAB are complex, and they can stimulate, inhibit, or have no obvious influence, one upon another.

A previous study of a sourdough started spontaneously on Swedish rye meal obtained a rather different result, with some similarities to the flora of the wheat sourdoughs (to be discussed below) in that the fermentation came to be dominated by only one species of yeast, although in association with three principal LAB isolates. The yeast was identified as *Saccharomyces delbrueckii*. The identities of the LAB were less certain, except that of *Pediococcus pentosaceus*; the other two dominant isolates were assigned as *Lactobacillus* sp. I and sp. II (probably *L. alimentarius*).

Wheat Sourdough Breads

The most important study of these products is that done on the San Francisco process by a group of workers from the US Department of Agriculture's Western Regional Research Laboratories, including Kline, Sugihara, Miller, and McCready. They reported that the fermentation is dominated by just two microorganisms, *Lactobacillus sanfrancisco* and the yeast *Saccharomyces exiguus* (sometimes referred to as *Torulopsis holmii*), now reclassified as the new species *Candida milleri*. Thus, both of the dominant organisms are types first isolated from this fermentation, although both have since been reported from other bread fermentations and also from other types of fermentation.

The most striking aspect of these studies is that the workers have been able to offer an explanation for the remarkable stability of the fermentation, characterized by a constant ratio of yeast to LAB cells of 1:100. The yeast, unlike the usual compressed baker's yeast (*S. cerevisiae*), cannot utilize maltose, whereas the LAB can utilize only this sugar, so they live in harmony because they do not compete for food. Indeed, they appear to have a symbiosis, as the LAB utilizes maltose by the phosphorolytic route, thus discarding one glucose molecule for every maltose used; the yeast assimilates the glucose, and there is evidence to suggest that the yeast liberates compounds that are stimulatory, or even essential, for the growth of the LAB, which is known to be exceptionally fastidious in its nutritional requirements. Growth of the LAB has been shown to be strongly stimulated by a small peptide, which is present in freshly prepared yeast extract, and also to be somewhat stimulated by various minerals and vitamins present in the extract. The yeast also has the unusual property that it is exceptionally resistant to the antibiotic cycloheximide, which is used in media for enumerating LAB because of its ability to completely inhibit the growth of most yeasts. In collaborative studies of Polish bakeries with scientists at the Politechnika Lodzka and in an examination of a Polish-Jewish bakery in Glasgow, the presence of yeasts and LAB with characteristics similar to those described above has been demonstrated, and Magdalena Wlodarczyk has independently discovered the biochemical basis of the important symbiosis between the yeast and the LAB.

In the San Francisco process, the starter is routinely rebuilt every 8 h, although it can be stored in the refrigerator for several days without any evident deterioration. According to Sugihara, the rebuilding is done by mixing 100 parts of developed sponge with 100 parts of high-gluten wheat flour and 46–52 parts of water (all by weight). During incubation, the pH of this mixture, initially 4.4–4.5, decreases to a final value of 3.8–3.9. To make bread, 20 parts of this starter sponge are mixed with 100 parts of what in the USA is called regular patent wheat flour, 60 parts of water and two parts salt. From an initial pH of 5.2–5.3, the value drops during 7 h of proofing to a final value of 3.9, when it is ready for baking.

Pure Cultures in Sourdough Bread-making

Sugihara reports a French study in which pure cultures of a yeast (*Candida tropicalis*) and a LAB (*L. plantarum*) were inoculated into a mixture of one part of wheat flour and 10 parts of water plus nutrients, with equal numbers of each organism, then incubated at 30 °C for 17 h, when the count of each organism had increased 100-fold. This was then used as an inoculum for breadmaking. Polish work has demonstrated that separately cultured *C. milleri* and *L. sanfrancisco* can be mixed in the bakery and used for the production of a starter, which is reported to give results superior in flavor, general quality, and consistent production characteristics to those obtained with their conventional starters; this technology is now being applied, together with improved designs of equipment for developing the sour, in bakeries in Lodz. These results are in marked contrast with the claims reported earlier in this review that pure cultures were not satisfactory for production of sourdough breads; this difference may relate to the type of bread that is being produced.

The Danish company, Chr. Hansen's Laboratorium A/S, is now offering a selection of freeze-dried starter cultures under the brand name 'Florapan.' Florapan L-22 is *Lactobacillus delbrueckii*, a homofermentative strain reported to give a 'mild and pleasant flavor' to the bread in which it is used. L-73 is also homofermentative (*L. plantarum*) but is reported to give the bread a 'piquant, spicy flavour.' Finally, L-62, the heterofermentative *L. brevis*, gives a 'penetrating but rounded taste and a long shelf-life of the bread.' The bacteria are particularly recommended for whole-grain flours because of their requirements for vitamins and minerals. The company advises that a freshly inoculated dough be allowed to sour overnight before use, but that where a fully developed dough is added to a fresh dough at a ratio of up to 1:20, 8 h of development can be sufficient. The developed dough is then used at about 30–40% of the final mixture, which includes baker's yeast. Their literature makes no comments on the crumb texture of the breads produced with the different bacteria, although it should be noted that the German workers attached significance to this aspect, concluding that for the best combination of texture and flavor, it is necessary to use a mixture of homo- and heterofermentative bacteria. As far as can be determined, no biochemical or other reason has been advanced for the claimed texture differences, so there would seem to be some scope for some useful research here.

A combination of technical advances in our understanding of, and capacity to control, sourdough fermentations has made these processes more reliable on a commercial production scale. At the same time, an increased public interest in the more traditional and 'ethnic' types of foods has created an increasing demand for these breads. The development of small bakeries of the type often referred to as 'craft' or 'artisan' bakers, has contributed to this process. Further improvements in processes, products, and marketing strategies are possible and can further increase the market penetration of these bread types.

Dietary Importance

D A T Southgate, Norwich, Norfolk, UK

The History of Bread

Bread has played such a key role in the human diet that 'bread' is often taken as being synonymous with food as a whole, and in some dialects, it is used as a slang term for money, the means of obtaining food. Bread indeed has a very long history of use in the human diet.

The cultivation of cereals, especially wheat, appears to have started in the Middle East, and alongside the evidence for the cultivation of wheat, one finds evidence of loaves apparently produced with

yeast, and baked in ovens. Wheat is the primary cereal for producing bread, although in Northern Europe at the northern limit of cultivation for wheat, rye is widely used in breads, and wheat/rye mixtures are widely consumed. Earlier archeological evidence provides artefacts in the form of querns used for grinding cereal grains mainly barley, which was usually eaten as solid cakes.

Wheat as a cereal has the special compositional property that when ground grains are mixed with water and yeast, the fermentation of the starch produces a very attractive type of food. There are many references to leavened and unleavened breads in the Old Testament, and the Greeks and Romans both produced breads analogous to those consumed today. The cultivation of wheat provided an abundant source of food energy, together with a protein level and a protein with a balanced amino acid composition that made it a very nutritious food. In addition, the wheat grains could be stored from one harvest to the next and, if necessary, for longer periods to cover periods when crops failed. This led to wheaten bread becoming an important staple food. There is clear evidence of the importance of bread in the diet of both the Greeks and the Romans. The milling of wheat grains in querns and wind- or water-powered millstones exerts a shearing force on the grain separating a flake of the outer branny layers while progressively breaking the endosperm into smaller fragments and eventually flour. The bran and flour can be separated by sieving to produce a white flour, which, from earliest times, was used to produce a more prestigious food. Both the Greeks and the Romans argued about the merits of white versus wholemeal breads, a debate that continues to the present time.

In medieval times, wheaten bread was extremely important in the diet of the poorer classes, and a system of rigorous price control was developed to ensure that the peasants were kept supplied with ample bread. Severe penalties were also implemented to prevent the bread being adulterated with inferior foods such as pulses. In the UK, the price of bread has continued to be seen as extremely important by successive governments, as a means of keeping the people well fed and contented. To a certain extent, bread has become a 'token food' with regulations as to the size of loaves, the price of loaves, and permitted ingredients and additives. During both world wars, the extraction rate of bread flour was controlled at a high level to reduce shipping requirements, and in World War II, fortification with calcium and, later, iron and some vitamins was obligatory to maintain the nutritional value of the diet, with bread being used as a vehicle. Recently, proposals have been made to fortify bread with folic acid, to prevent neural-tube defects, and vitamin D, to ensure that Asian immigrants to the UK obtain this vitamin from their wholemeal chapatis.

Thus, since it first became part of the human diet, wheat and the breads made from it have provided an important staple food, and, despite the growth of affluence and the wider variety of foods available to most developed populations, it remains an important and nutritious food. Most current dietary advice regarding healthy eating advocates the consumption of a substantial amount of cereal foods in the diet, and this of course includes breads. The recognition of the role of dietary fiber in the diet has emphasized the importance of wholemeal and higher extraction breads, but most advice returns to the theme that all breads are good foods.

Nutritional Composition of Bread

Although much of the focus of this article will be on wheaten bread, some information on rye breads has also been included because these are also widely consumed, and in the UK, mixed grain breads have achieved some popularity. The focus on breads has been limited to those breads prepared by fermentation of the dough with yeast, although many communities consider many nonfermented rye products as breads.

Bread Production

Wheat and, to a lesser extent, rye and barley proteins contain gluten, which, as the dough is kneaded (or developed mechanically) forms a network within the dough that traps the carbon dioxide produced by fermentation of the carbohydrates in the flour by the yeast. This causes the dough to rise and leads to the development of the crumb texture when the dough is baked. The increased volume of the bread is an important factor in the sensory quality of bread and is possibly why breads have become established in the diet. Baking produces a crust that contains some starch granules that are not fully gelatinized and, in well-baked bread, can produce starch degradation products and even some carbon. These modified carbohydrates in the crust are important for the sensory characteristics of bread, but do not materially affect the nutritional value. Some salt is usually added to the dough to assist in the activation of the yeast, and other 'flour improvers' are added to facilitate the development of cross-linking in the gluten and so strengthen the network. Vitamin C is the only permitted improver in wholemeal bread in the UK, but the baking process effectively destroys any residual vitamin.

Composition of Wheaten Breads

The composition of some typical wheaten breads is given in Table 1 with a range taken from British, Italian, and Danish Food Composition tables to illustrate values from southern and northern Europe. It should be stressed that there is some variation in composition; the protein content, for example, depends very much on the selection of wheat mixture chosen by the bakers. The majority of home-grown wheats in the UK are soft, lower-protein wheats and need to be mixed with harder, high-protein wheats, typically from North America. Table 1 illustrates the difference that the inclusion of the bran makes, with the wholemeal breads typically containing two to three times as much dietary fiber (the values cited are for nonstarch polysaccharides). In most bread mixes, a small quantity of fat, usually as oil, is incorporated into the mix. In Denmark, there is a preference for softer crumbs, and the fat levels are higher. In the USA, milk powder may be included to produce similar softer crumbs. The levels of fat in Italian white bread are very low and probably represent an anomaly due to the choice of method for fat. Most of the carbohydrate is starch, with small amounts of free sugars and dextrins in the crust.

The water contents vary with the extent of staling, but the Italians seem to prefer a drier white bread. Table 2 lists the corresponding values for several inorganic constituents. The sodium contents are substantial, and bread is an important source of sodium in the diet. Recently, there have been moves within the bread producers to lower the levels as a public health measure. Salt plays an important role in bread flavor, in addition to activating the yeast, so reductions will have to be phased in.

The wholemeal breads have higher potassium, phosphorus, iron, and zinc levels, representing the higher concentrations of these elements in the outer layers of the grain. Incorporation of the germ in the bread also increases the levels over the values for white bread. The UK data for calcium and iron are higher than in other countries because of fortification of all flours except wholemeal.

Table 3 lists values for a number of vitamins. The concentration of most B vitamins is higher in the outer layers of the grain, so the values for the wholemeal breads are higher, except for folate in Danish breads. The thiamin and niacin values in the British breads represent the effects of fortification.

Rye Breads

Table 4 lists the compositions of several rye breads taken from the British and Danish food composition tables. This shows that rye breads fermented with yeast are very similar in overall composition to wheaten breads. The Danish appear to prefer a

Light	42.8	6.2	1.3	47.6	7.5	562	266	208	2.1	0.20	0.7	43	Denmark

slightly higher moisture content, which reflects the higher water-binding activity of the carbohydrates in rye. The rye breads tend to contain higher amounts of dietary fiber, and this has a higher proportion of soluble nonstarch polysaccharides than wheat. Rye grains have a different structure to wheat, and the bran is less easily separated from the endosperm, so the light rye bread is of a higher extraction than white wheaten breads.

The wider range of rye breads cited in the Danish tables is typical of northern Europe, where rye breads and rye/wheaten mixtures are widely consumed. Rye proteins contain gluten levels that are less effective in increasing the volume of the bread, and the inclusion of a proportion of wheat is widely practiced in Germany and Scandinavia.

Nutritional Significance of Bread in the Diet

This derives both from the quantitative nutritional contribution of breads in the diet and from the qualitative characteristics of the components of both wheat and rye grains.

Qualitative Aspects

Protein Breads are often seen as important in the provision of carbohydrates, and consequentially as a source of energy, and over the past 30 years as a source of dietary fiber. This limited view of breads as carbohydrate foods is misleading because their proteins are important nutritionally. White bread contains 8.4 g per 1002 kJ (235 kcal), so the protein: energy ratio is well above that considered nutritionally essential. Protein–energy malnutrition is virtually unknown amongst populations where wheat is the stable cereal. The amino acid compositions of both wheat and rye proteins are reasonably well balanced with the sulfur-amino acids being limiting, so a combination of bread and vegetables provides a very good combination. Baking results in a small reduction in the available lysine content but still retains the overall protein quality.

Carbohydrates The major carbohydrate in bread is starch, with relatively minor amounts of free sugars. Some degradation of the starch occurs in the crust during baking, producing soluble dextrins and some Maillard reaction products. The production of bread leads to the formation of some retrograded starch, which is physiologically resistant to digestion in the small intestine. The resistant starch is formed from the amylose portion of the starch that combines to form insoluble crystalline products. The proportion of 'resistant starch' increases with staling of the bread. The bulk of the starch, however, in breads, especially white bread, is rapidly digestible and is responsible for the high glycemic index of white bread.

The dietary fiber in wheat comes principally from two sources: the outer branny layers contain cellulose and noncellulosic polysaccharides. Wheat and rye bran noncellulosic polysaccharides are both rich in arabino-xylans, which are important in the water-binding properties of the flour. The bran layers are lignified and resistant to bacterial degradation in

the large intestine. The dietary fiber in wheat bran is one of the more effective sources of dietary fiber for increasing fecal bulk.

The endosperm contains smaller quantities of thin-walled cells, the walls of which are rich in cellulose and β-glucans.

Minerals and vitamins Wholewheat breads contain significant amounts of potassium, magnesium, phosphorus, and iron, together with important amounts of thiamin, niacin, and small amounts of folates. A substantial proportion of the phosphorus is present as phytic acid, and this has been shown to reduce the bioavailability of calcium and iron. At the start of World War II, there was nutritional concern that the availability of dairy products would be reduced and that any increase of the extraction rate to conserve the imported grain would result in reduced amounts of calcium being available in the diet. This led to the fortification of wheat flours with calcium carbonate. When the extraction rate of bread was increased to make a higher proportion of the imported wheat grain to be used for human consumption, this also increased the amounts of thiamin, niacin, and iron in the bread. When, in the early 1950s, the production of white bread was again permitted, it was decide that the nutritional composition of all flours, except wholemeal, should be maintained by fortification with iron, thamin, and niacin to maintain the levels in the higher extraction breads available during the war.

Consumption and Nutritional Contributions

Since classical times, bread, especially wheaten bread, has provided the staple source of energy and the other nutrients it contains. This was particularly true for the mass of the population in ancient Egypt and classical Greece and Rome. This reliance of the lower socio-economic groups on bread as the staple source of energy and nutrients continued through medieval times to the early years of the 20th century in Europe. In the UK, bread was seen as a special food, and successive governments saw controlling the price of bread as the key to keeping the 'masses' contented, just as it was in Roman times. Even amongst the poorer members of the community, however, there was a preference for white 'low-extraction' flours that were seen as purer and conferred some measure of status on the consumer. This continues, despite repeated advice from the medical and other health professionals that higher-extraction breads are better for health. Probably, such breads were less easily adulterated in earlier times with cheaper beans or barley flour.

The key to assessing the dietary importance lies in considering the amounts of bread consumed together with the composition of those breads. The UK National Food Survey provides a continuous record of food consumption over the last 47 years. In its earlier years, it measured only foods purchased to be consumed within the home, but more recently, because the consumption of meals outside the home has increased, the Survey has included estimates of them.

During World War II, bread was not rationed and thus provided a major source of energy. As mentioned previously, the extraction rate of bread-making flours was controlled to around 80–85%, resulting in a bread that was gray/brown for most of the 1940s. Consumption was then of the order of 1721 g per person per week (Table 5), but when the war ended, rationing was introduced, and consumption fell to around 1420 g.

Control on flour was abolished in 1956, and consumption switched very rapidly from the 'national loaf' at about 80–85% extraction to white at about 1200 g, illustrating very clearly the popular preference for white bread. Since that time, the overall consumption of breads has shown a steady decline, reflecting the improved economic status of the population and the increased availability of other foods. The National Food Survey data for the earlier years are, however, for foods purchased for the home, and with improving economic conditions, the consumption of meals outside the home increased in importance. In recent years, the growth in 'sandwich shops' providing bread-based meals for consumption at midday means that the consumption of bread *per se* may not have declined so extensively.

Table 6 lists some data for 1997 on the patterns of bread purchases within different income groups,

Table 5 Changes in total bread consumption in the UK (grams per person per week)

[a]Income groups are based on the total household income: Group A highest 10%; Group B next 40%; Group C next 40%; Group D lowest 10% of families with earner in family.

Table 7 Nutrient contributions of breads to UK intake in 1997 combined contributions of white, brown, and wholemeal) (per person per day)

Nutrient	*Contribution*	*Percentage of total intake*
Energy (kcal)	142	7.9
Protein (g)	11.0	17.0
Fat (g)	1.2	1.5
Sugars (g)	1.6	1.3
Starch (g)	27.6	21.1
Dietary fiber (nonstarch polysaccharides) (g)	1.8	14.5
Calcium (mg)	60	7.3
Iron (mg)	1.3	13.9
Sodium (mg)	345	13.4

showing the greater consumption of bread by the lower income groups and especially amongst those receiving the state old age pension. This group includes those with additional pensions from employment, and the group as a whole may have a net income above those in the lowest income group, D. It is interesting to note the dominant position of white bread in the lower income groups. Bread consumption amongst the large families in the lower income groups tends also to be higher, emphasizing that bread still provides an important stable food.

Importance as a Source of Nutrients

Table 7 shows the contribution of bread to the intakes of some nutrients (per person per day) and the percentage contribution to the total intakes. These show that bread makes a greater contribution to protein intakes than energy. The contribution to fat intakes is very minor, but it must be recognized that bread acts as a vehicle for introducing fat into the diet via spreads and sandwich fillings. The dietary fiber intake comes almost equally from white and wholemeal breads because of the relative proportions consumed. Despite fortification, bread is a minor source of calcium in the diet, although iron fortification means that bread is a significant iron source. The contribution of bread to sodium intake has been a cause of some nutritional concern and is currently being addressed by the bread industry.

Conclusions

Bread, especially wheaten bread, has played an important role in the human diet ever since wheat began to be cultivated in the Middle East. It remains an important stable source of nutrients and energy, and as a source of complex carbohydrates, a food whose consumption, especially the higher-extraction types, should be encouraged as part of a healthy diet.

Dough Fermentation

M Collado-Fernández, University of Burgos, Burgos, Spain

Background

Fermentation involves a complex system of reactions brought about by microorganisms that may be present simultaneously. There are different types of fermentation resulting from the action of yeast and other microorganisms such as lactic acid bacteria. The principal type of fermentation is the action of the yeast on fermentable sugars to produce carbon dioxide (CO_2), ethanol, and some aromatic compounds.

The organoleptic characteristics of bread, namely, the texture, flavor, and aroma, depend on the conditions of the dough fermentation.

Fermentation begins when the yeast is in contact with the dough and finishes some minutes after the dough has been placed into the oven. There are two phases in the fermentation: the bulk fermentation or first fermentation or first proof and the fermentation or final proof or proving. The bulk fermentation tends to be substituted by intensive kneading or by other methods.

During fermentation, there must be a balance between gas production and gas retention and the characteristic viscoelastics of dough. The dough undergoes several changes like weight loss, changes in carbohydrates, and phytates.

Yeast

Yeast is a living unicellular organism, has a length of 6–8 μm, and is round to oval in shape. One gram of yeast contains around 15×10^9 cells. The yeast cell has an external membrane called the cell wall. This has a selective permeability and has an important role in controlling (by osmotic processes) the movement of nutrients and other substances into the cell and the release of other substances such as CO_2 and ethanol. Bakers' yeast is *Saccharomyces cerevisiae*. Commercial production of yeast is based on growth, on an industrial scale, of a pure selected strain. The cell culture obtained is separated from the culture medium and prepared for processing. The yeast can be compressed (most common), granular, dried in the form of a pellet, instantaneous, encapsulated, frozen, or in the form of a 'cream.' These variations are related to the physical form of the yeast and, mainly, the yeast moisture content. In terms of the speed of yeast fermentation, there are two types, standard and rapid, related to the maltose adaptation. Rapid yeast is more active than standard yeast, and is adapted for use in accelerated breadmaking systems.

Yeast is a versatile organism that can act under aerobic and anaerobic conditions. Under aerobic conditions, yeast grows quickly, owing to the oxygenation of sugar, which produces new yeast, water, and the energy needed for its growth. Under anaerobic conditions, yeast transforms the sugar into carbon dioxide and ethanol by fermentation.

The speed with which yeast consumes sugars and produces CO_2 depends on factors such as: the yeast strain used, resistance to osmotic pressure, maltose adaptation, yeast concentration, flour fermentative capacity, temperature and pH of the dough, and presence of dough inhibitors.

Strain

The selection of yeast strain is a function of the fermentative properties of the dough, the breadmaking process, the high stability of its characteristics, and a good industrial yield.

Resistance to Osmotic Pressure

Some strains have a high tolerance to osmotic pressure, but others do not and consequently die. The increase in osmotic pressure in the cell wall is due to factors such as salt and sugar concentration, the invertase action of the yeast itself. The decrease in water in the formulation of the doughs that include high levels of fat and sugar, and especially problems presented by frozen dough sugar; during freezing, the free water decreases, and the osmotic pressure increases.

Maltose Adaptation

In order to maintain a good production of gas, yeast requires a plentiful and continuous supply of glucose as an energy source. The action of α- and β-amylases of flour in damaged starch gives maltose (starch damage results from modifications in the structure of starch during the milling process). This disaccharide is transported into the cell, in which it is broken down into two molecules of glucose. The metabolic changes to this new source of glucose from starch are only active when yeast detects the presence of maltose in the medium, and its functioning takes some time (lag phase). Consequently, the rate of gas production decreases until this mechanism is working fully, and then, gas production increases. The decrease in gas production is lower as soon as the maltose adaptation begins, which is different for rapid and standard yeast strains. The choice of one over another depends on the breadmaking process to be used.

Yeast concentration

When sugar is not added to dough, the limiting factor of gas production is the quantity of maltose available. The increase in yeast concentration at one temperature leads to an increase in the rate of gas production and greater sugar depletion.

Fermentative Capacity of Flour

The quantity of amylase in flour determines the degree of glucose production from starch, so long as there is enough damaged starch.

Temperature

Temperature has an important influence on yeast activity: at 4 °C, there is no activity, and fermentation

does not occur, at 10–15 °C, the yeast activity and fermentation are slow, at 20–40 °C, fermentation is very active, at 45 °C yeast activity slows down, and at 55 °C, the yeast dies. Thus, the best storage temperature for yeast is 4 °C (0–10 °C). Depending on the strain used, an increase of 1 °C in the dough gives an 8–12% increase in fermentation speed. Although, at 38 °C, there is more gas production, there is also lactic and butyric fermentation (which is undesirable).

pH

Yeast is very tolerant to fluctuations in environmental pH (2–8), but the optimum pH for yeast activity is between 4 and 6. Usually, the pH of dough is 5, although the pH may be lower when sourdough is used.

The undissociated forms of organic acids produced from parallel fermentation to alcoholic fermentation, that is, produced by lactic acid bacteria of flour and by contamination of yeast, are inhibitors of fermentative activity. They have greater effects at lower pHs, the critical zone being between 4 and 5, and these values correspond to the final fermentation.

Presence of Dough Inhibitors

The copper and chlorine present in water used in breadmaking processes can act as fermentation inhibitors. Organic acids, such as those used as preservatives (acetic and propionic acid) and others formed during fermentation, can also act as fermentation inhibitors.

Sources of Sugar used by Yeast

Yeast uses four different sources of sugar: (1) trehalose endogenous, (2) free sugar from flour, (3) sugars obtained by the action of enzymes in oligosaccharides and polysaccharides in the flour, or added as additives, and (4) added sugars such as sucrose. Fermentation begins with trehalose, then later with the free sugars and sugars added, and finally with maltose. The hydrolysis of sucrose to glucose and fructose is faster than the fermentation of glucose and fructose. The consumption of glucose is greater than that of fructose, and initially, the consumption of maltose is low, but when most of the other sugars have been consumed, the yeast ferments the maltose rapidly. This also depends on the capacity of yeast to adapt to maltose.

Carbohydrate Metabolism

Yeast ferments monosaccharides – glucose (mainly), fructose, and mannose, disaccharides – sucrose, maltose, and trehalose – and trisaccharides (rafinose).

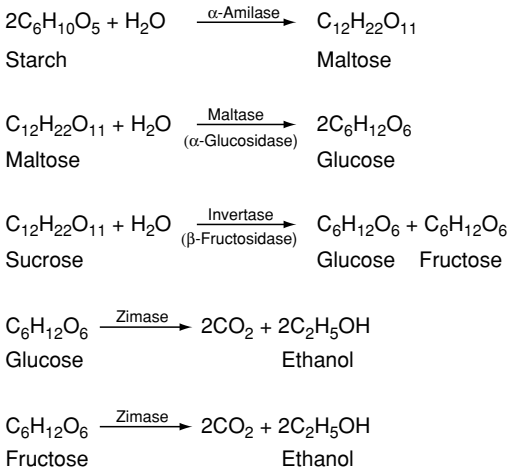

Figure 1 Carbohydrate transformation during dough fermentation.

Yeast does not consume lactose. The transformation of carbohydrates during dough fermentation is shown in Figure 1.

Yeast can transform carbohydrates in different ways: via the Embden–Meyerhof–Parnas pathway (EMP, glycolysis) and from hexose monophosphate (HMP). Under anaerobic conditions, the carbon dioxide formed is by the EMP pathway, and under aerobic conditions, the carbon dioxide may be formed by HMP from pyruvate (via the tricarboxylic acid (TCA) cycle or Krebs cycle). Under aerobic conditions, yeast grows rapidly and accumulates a small amount of carbon dioxide and ethanol, whereas under anaerobic conditions, yeast grows slowly and produces a large amount of carbon dioxide and ethanol.

The pyruvate formed in these ways is very important as a precursor to acids, alcohol, and other volatile compounds, which have an influence on the flavor and aroma of bread (Figure 2).

Production and Retention of Gas

The quality of gluten is related to gas retention, but also, the degree of gas retention depends on the rate of diffusion. During kneading, air is incorporated into the dough, and air bubbles are formed. These bubbles contain mainly nitrogen, because it has a low solubility in water, and oxygen is quickly used up by the yeast cells within the dough. Yeast cannot create new bubbles, as the pressure (P) in a bubble is related to the radius (r) of the bubble and the interfacial tension (γ) by the law of Laplace: $P = 2\gamma/r$. The creation of new bubbles is only possible by punching or remixing the dough, or by the use of surfactants that change the interfacial tension. The more bubbles are formed, the finer the grain is.

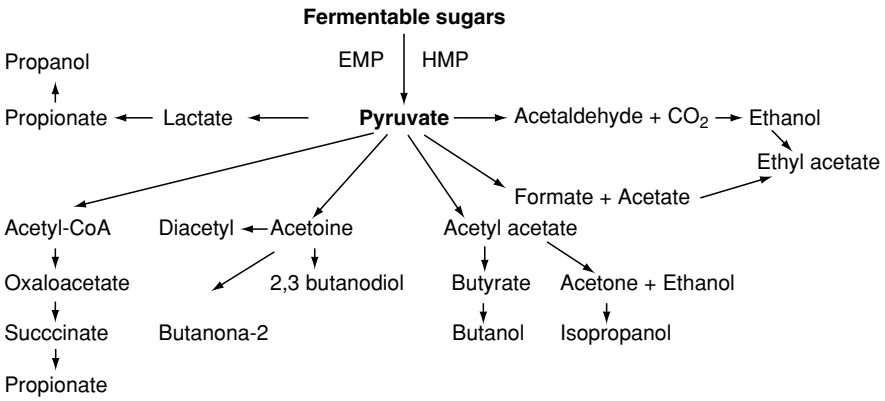

Figure 2 Some of the breakdown products from sugar metabolism.

During kneading, yeast is mixed into the dough, and fermentation starts. The major breakdown products are carbon dioxide and ethanol. Initially, carbon dioxide is produced in the aqueous phase, the pH decreases, and this phase becomes saturated with carbon dioxide. As the fermentation proceeds, carbon dioxide is retained in the air bubble, and nitrogen is displaced. Then, the dough is leavened, because the aqueous phase is saturated by CO_2 and the newly formed CO_2 is retained in preexisting bubbles. At this point, the quality of gluten is also very important to retain the gas, and thus, carbon dioxide is retained in the dough in two phases: contained within the gas cells and dissolved in the aqueous phase. At the pH of dough, most of the carbon dioxide is present as CO_2 and a small amount of this as CO_3^{2-}, HCO_3^-, or H_2CO_3.

Only 45% of the total gas produced is present at the end of fermentation. The loss of carbon dioxide is due to the different steps of breadmaking process, namely initial fermentation, punching, rounding, molding, and final fermentation.

The gas-retention capacity of the gluten decreases with time and is critical when the dough is placed into the oven. The high temperatures expand the retained gas and increase the volume of the dough, and so if the gluten has a good gas-retention capacity, it will yield bread with a good volume, otherwise the bread will be flat. The vaporization of ethanol and water present in the dough also contribute slightly to dough expansion.

Fermentation

There are two phases in fermentation: bulk fermentation, first fermentation, or first proof and the main fermentation, final proof, or proving. Bulk fermentation takes place from final kneading to the dividing of the dough. In this phase, the dough undergoes several physical modifications that allow it to be cut and molded. This phase tends to be substituted by intensive kneading or other methods. The final proof takes place from molding to baking, so this phase really is the fermentation.

The relative lengths of time of these phases depend on the physical properties of the dough, which depend on the kind of wheat used: when using soft flours that produce dough that is short and not very elastic, the fermentation time should be reduced.

During fermentation, the temperature and relative humidity need to be taken into account. The temperature used depends on the kind of bread and the breadmaking process (usually 28–30 °C), with lower temperatures requiring longer fermentation times (1–1.30 h or 2–4 h), but also depends on the yeast concentration used. If the temperature is lower, the dough will be very cold, the fermentation will be longer, and gas production will decrease. As the fermentation is longer, the concentration of sugar increases, and the texture of the bread will be of a lower quality and rough grained, and will have a colorful crust with shorter shelf-life. If the temperature is higher, the crumb will be rougher, and nonalcoholic fermentation may occur. If the relative humidity is < 75%, the skin of the dough will be very dry and will lose its elasticity.

During fermentation, the pH of dough changes, principally owing to the formation of lactic acid. Initially, dough has a pH of about 6.2, and during fermentation, the values are about 5.76 or 5.67. This acidic environment improves the formation of gluten, which is more extensible, and in bread, this slows down the growth of mold.

The pH of dough has a great influence on fermentation, because yeast needs an acid environment (pH 5.8–6.2), and also influences the properties of protein and the activity of enzymes.

During fermentation, dough increases the force (*W*, work (related to the curve of the alveogram)) and decreases the tenacity (*P*, pressure (related to the height of the curve of the alveogram)) so the relation *P*/*L* decreases (*L* being extensibility). The capacity of dough to withstand excessive mechanical work is called dough tolerance. Generally, doughs that ferment slowly are more tolerant.

Fermentation Types

Not all sugar is transformed by yeast. Lactic acid bacteria (usually present in dough, especially in sourdough) carry out fermentation, consuming sugar and producing CO_2 (Figure 3). The types of fermentation are: alcoholic fermentation, lactic fermentation, butyric fermentation, and acetic fermentation.

Alcoholic Fermentation

This is the principal type of fermentation. Yeast transforms fermentable sugars, mainly glucose, into carbon dioxide and ethanol. The optimum pH for alcoholic fermentation of dough is 5. If the pH is higher (> 6), the breakdown products of fermentation are glycerine and acetic acid as well as carbon dioxide and ethanol.

Lactic Fermentation

Lactic fermentation is achieved by the hydrolysis of lactose or glucose by lactic acid bacteria, giving lactic acid. Usually, yeast is contaminated with lactic acid bacteria. The optimum temperature for lactic fermentation is 35 °C, so this fermentation is slow at the temperature of yeast fermentation. The lactic acid acts in the dough, giving a more elastic gluten.

Butyric Fermentation

Different bacteria, such as *Clostridium butyricum*, may use the lactic acid to produce butyric acid. The temperature of this reaction is about 40 °C, so during dough fermentation, these bacteria cannot act. However, if the dough has a long fermentation time, it increases its temperature (more than 32 °C), and butyric fermentation may occur, affecting the aroma of bread. The pH of this reaction is 3.2–3.8.

Acetic Fermentation

Acetic fermentation is carried out by *Mycoderma aceti*, which transform the ethanol into acetic acid. The optimum reaction for *Mycoderma aceti* occurs under aerobic conditions. The contribution of acetic acid alone to the total acidity of the dough is 5%. The excess of acetic acid content gives short and rigid

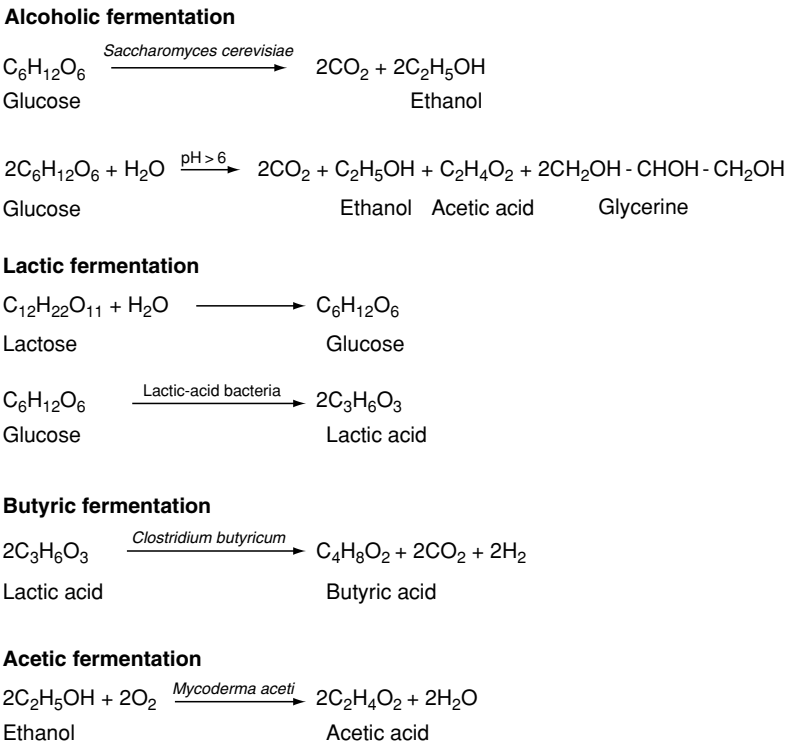

Figure 3 Types of fermentation during the breadmaking process.

gluten. Therefore, it is necessary to insure that the ratio of lactic acid to acetic acid formed is 3/1.

Controlled Fermentation

Controlled fermentation is one of the new techniques to apply cold, to stop, or to decrease the fermentation. The possibility of controlling and programming fermentation has the advantage in that it is possible to regulate bread production, avoid working at night, produce fresh bread any time, and utilize the advantages of long fermentation, i.e., a better shelf-life aroma, and flavor.

Raw Materials

The flour must be of good quality ($W = 160$–180; $P/L = 0.4$–0.6, falling number 300–350 s), because the dough must not ferment before the block phase, and flour needs less enzymatic activity than traditional fermentation. Standard yeast must be used, because the fermentation must not begin before the block phase. The yeast concentration is usually 2–3% (based on flour weight). Fresh sourdough is also added in the bread mixture.

Manufacturing

The kneading time required for dough development is 20% longer than the traditional breadmaking process, because the flour is stronger. Two to 3% less water in the formulation is recommended, to insure that the dough is not too soft, and the final temperature of the dough should be 22 °C to avoid premature fermentation. The dough is divided, rounded, and molded as soon as possible, and then pieces of the dough are placed into a controlled fermentation cabinet.

Proof Cabinets

The design of the proof cabinet has evolved with time. Traditional bakeries used wood cupboards with large boxes to ferment the dough, and some still use these. These proof cabinets present some problems, because they are affected by the temperature of the workroom, and the fermentation is not the same in all the pieces of the dough. Nowadays the proof cabinets are isolated and have automatic control of temperature and relative humidity. The ideal relative humidity should be the result of the addition of dough hydration and moisture from the flour (for example, if water added to the mixture is 55%, and the flour moisture is 14%, the ideal relative humidity will be 69%), so the dough will be neither rough nor sticky.

Types of Proof Cabinet

There are several different types of proof cabinet: the traditional fermentation cabinet, the controlled fermentation cabinet, and the block fermentation cabinet.

Traditional fermentation cabinet In this cabinet, only heat and humidity are used. The usual conditions are: temperature of 28–32 °C and relative humidity of 70–85%. If a high temperature (> 30 °C) is used, a high relative humidity (> 75%) is also required.

When the temperature is > 28 °C, during dough fermentation, lactic and butyric acid are formed, increasing in numbers with increasing temperature. Also, the enzymatic reactions in dough are more active at these temperatures, so the dough is softer, the bread volume increases considerably, and the bread is insipid and has a shorter shelf-life.

If the temperature is < 26 °C, there is less production of lactic and butyric acid during the fermentation, the fermentation time is longer, the enzymes are less active, and the bread volume is lower, but the bread has a good flavor.

The reduction in the amount of yeast and the increase in fermentation time lead to a bread with a firm crumb and thick crust.

Controlled fermentation cabinet This cabinet controls dough fermentation temperature allowing progressive heating. Previously, these cabinets did not canalize the air, and the dough was rough. Heating was rapid, and there was condensation on the dough surface, which gave a red and translucent crust. The result was bread with great variations in quality, color and volume. Nowadays, these cabinets have a regulating system, depending on the size and volume of the pieces, but there are four phases: block, refrigeration, heating, and fermentation.

Block In the first phase, the dough is cooled, and fermentation is stopped when the temperature in the dough reaches about 2 °C. Usually, temperatures of about −2 °C (0 to −14 °C) are used.

Refrigeration In this phase, the temperature of the dough is usually at 0–2 °C until fermentation begins.

Heating In this phase, there is a gradual increase in temperature to prevent the dough surface becoming rough. The dough temperature increases gradually until the fermentation temperature is reached.

Fermentation It is very important to regulate the temperature and relative humidity to ensure uniform fermentation of dough.

Block fermentation cabinet This cabinet has only two phases: block and refrigeration. The functions of these phases are the same as that of the controlled fermentation cabinet, but the dough temperature needs to be increased before fermentation. The dough is kept in this cabinet for some time before fermentation, and another cabinet is needed for fermentation.

Physical and Chemical Changes in Dough During Fermentation

The transformation of the dough into bread is very complex, because dough contains very reactive chemical compounds, enzymes, microbial flora, different ingredients, and additives (depending on the formulation). In addition, the formation of dough may have different processing conditions (depending on the breadmaking systems used). Therefore, bread shows great variations in organoleptic characteristics. Most of the chemical, biochemical, and microbiological modifications that take place, during fermentation depending on processing conditions, thus it may be possible to lead fermentation in some way by controlling the conditions.

Yeast's functions during fermentation are:

- to produce enough CO_2 and in time increase the dough and make the dough softer;
- to modify the physical properties of gluten, for the maturation of the dough;
- to decrease the pH of the dough, thus allowing lactic bacteria to grow;
- to produce certain chemical compounds that give bread its characteristic flavor; and
- to modify the bread volume and texture.

The functions of lactic acid bacteria during fermentation are:

- to produce acids that inhibit the development of undesirable microorganisms, producing the conditions for enzymatic processes.
- to produce catabolites that influence the dough rheology and the sensorial characteristics of bread.

During fermentation, the dough undergoes several changes, such as weight loss and changes in carbohydrates, phytates, lipids, nitrogen compounds, and flavor and aroma compounds.

Weight Loss

The decrease in dry matter content (fermentation loss) during fermentation observing can be estimated by the volume of carbon dioxide evolved. The major proportion of carbon dioxide produced during fermentation results from alcoholic fermentation, and other fermentations may contribute about 5%. During alcoholic fermentation, the consumption of 1 mol of glucose produces 2 mol of carbon dioxide, according to Gay Lussac's law, and 1 ml of carbon dioxide released corresponds to a decrease in dry matter content of 3.65 mg. Thus, fermentation loss is influenced by the breadmaking processes used, and the straight dough method has less fermentation loss than the sponge and dough process (3.2% versus 5.5%, based on flour weight). In the Chorleywood process, the yield of bread from flour is about 4% higher than in bread made by traditional methods. This difference is due to a substantial decrease in fermentation losses.

Changes in Carbohydrates, Phytates, and Lipids

The carbohydrate concentration decreases during fermentation. The most important change during the fermentation is the transformation of fermentable sugar into carbon dioxide and ethanol by yeast action.

Sugar metabolism by yeast has already been mentioned. Sugar metabolism may be changed by temperature conditions (fermentation being controlled). Increasing the sugar concentration increases gas production up to the limit of osmotic pressure at which yeast cannot survive. Decreasing the pH increases gas production.

Another path for sugar metabolism is by lactic acid bacteria. Heterofermentative lactic acid bacteria produce carbon dioxide, but this gas production is less than that from yeast (Figure 4). The principal function of lactic acid bacteria is to decrease the pH, and increase the aroma and flavor of bread.

The lactic acid/acetic acid relationship is very important, because it influences the aroma and flavor of bread. For rye bread, this relationship is closer than that of wheat bread, and the intensity of bread flavor is higher. The production of acids may be controlled

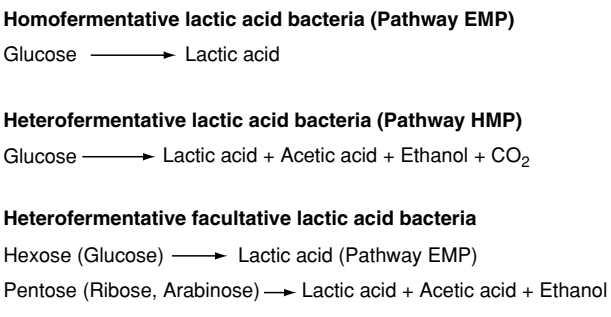

Figure 4 Metabolism of sugar by homofermentative and heterofermentative lactic acid bacteria.

by adding acid-producing microorganisms, such as heterofermentative facultative lactic acid bacteria, which produce acetic acid. The hydration of dough, temperature, and presence of yeast also have an influence on production of acids.

In terms of chemical changes in starch, as mentioned earlier, starch is a source of sugar for fermentation. α-Amylases hydrolyze damaged starch forming the substract for β-amylases action yielding the breakdown products dextrin and maltose.

In terms of nondigestible carbohydrates, the concentration of fiber increases during fermentation, and in long periods of fermentation, there is an increase in the amount of hemicelluloses.

Phytates are associated with the fiber content. Phytic acid in wheat and flour is present as phytine associated with calcium and magnesium. Phytine has a heterogeneous distribution in the kernel of wheat. There is a greater proportion of phytine in the germ and bran than in the endosperm. During fermentation, there is dephosphorylation of phytic acid by phytase, and the concentration of phytate decreases, decreasing the capacity to form a complex with minerals and protein.

Concerning lipids, polar lipids improve the structure of bread and increase the soft crumb. Nonpolar lipids deteriorate the structure of bread and decrease the bread volume.

Changes in Nitrogenous Compounds

The effects of fermentation on nitrogenous compounds are as follows: (1) there is a modification in the structure of gluten, thus making the dough more extensible and improving the gas retention; (2) there are changes in amino acids, peptides, and other soluble compounds, which are precursors of the flavor and aroma of bread, and a source of nutrients.

The protein network in dough is able to retain carbon dioxide in the air bubbles and is sufficiently elastic to expand without disrupting during the fermentation and when the gas volume increases during baking. This is possible because of the chemical changes in the bonds of gluten and other wheat proteins. The mechanical work during the dough mixing process breaks some of the hydrogen and disulfide bonds, linking adjacent protein chains, and the new bonds formed are in different positions. Expansion of the gas formed during fermentation produces new bond changes, thus improving the dough extensibility. When the dough matures, there is a balance between the consistency of the three-dimensional protein network, its extensibility, and its permeability.

Amino acids and peptides may be formed by proteolysis of the dough. Lactic acid bacteria have proteinases and peptidases, and the free amino acids and peptides may be metabolized by the yeast. During fermentation, the amino acids may lose an atom of carbon giving an aldehyde or two or more atoms of carbon, yielding inferior organic acids or hydrocarbons. The breakdown products of oxidation and reduction of aldehyde yield acid and alcohol, respectively. Alcohols and acids react to yield esters, and thus, there are a many compounds related to aroma and flavor (Figure 2).

The amino acids are precursors of aroma and flavor from the Maillard reaction, which takes place during baking. The overfermentation of dough depletes the amino acids and the color and flavor of bread decreases.

In conclusion, depending on the breadmaking process used, and if sourdough is added, the organoleptic characteristics of bread will be different, due to their influence on changes that take place in dough during fermentation.

BREADFRUIT

D Ragone, National Tropical Botanical Garden, Kalaheo, HI, USA

Introduction

Breadfruit has long been a staple food in the Pacific islands and is now widely distributed and used throughout the tropics, as is a related species known as breadnut. The discovery of breadfruit by westerners and subsequent distribution of breadfruit and breadnut in the 18th to 20th centuries are discussed. Two species of breadfruit (*Artocarpus altilis* and *A. mariannensis*) and breadnut (*A. camansi*) are described. The importance and use of breadfruit in various Pacific island groups and methods of preparation, including traditional techniques to preserve fruits, are summarized. Production and use of breadfruit and breadnut in the Caribbean includes information on local and export markets. Harvest and yields of both crops are discussed. Use and nutritional composition of breadfruit and breadnut for fresh consumption are provided, as is an overview of commercial processing and postharvest handling of breadfruit.

History and Distribution of Breadfruit and Breadnut

Breadfruit derives its name from the fact that the fruits, when baked or roasted, have a starchy, dense consistency similar to bread or root crops such as potatoes, yams, or sweet potatoes. Native to New Guinea and possibly also the Moluccas, breadfruit has been an important staple crop for more than 3000 years. Islanders spread it throughout the vast Pacific during their voyages of exploration and discovery. By the late 1500s, when western ships first ventured into the region, breadfruit had been established in every island group settled by indigenous islanders. The only exceptions were New Zealand, which was too cool for this subtropical plant, and certain small coral atolls in Micronesia and Polynesia, where it was too dry to grow the tree.

Breadfruit was a remarkable and delicious food for western sailors arriving on those distant shores. Voyages to the Pacific from Europe were arduous, months-long passages, and the quality of food served to the crew became more and more unpalatable as the voyage progressed. The main provision was generally weevil-infested hardtack (flour and water baked into a biscuit). The sailors were delighted with this new island food. Fresh-roasted in a fire, breadfruit has a satisfying, aromatic smell, much like bread as it comes out of the oven. Its moist, dense, doughy texture and subtle flavor round out its similarity to bread. The scientific name, *Artocarpus altilis*, is derived from the Greek, with *artos* meaning bread, *carpus* meaning fruit, and *altilis* originating from the word *utile*, meaning useful, and has memorialized it as the tree which produces fruits like bread.

As those voyagers returned home they spread the word about this wondrous new plant and its potential as a food crop for other tropical countries. The growing interest in breadfruit set the stage for one of the grandest sailing adventures of the 18th century – Captain William Bligh's ill-fated mission on *HMS Bounty* to introduce Tahitian breadfruit to the Caribbean – and the extraordinary tale of courage and sailing skill that saved the survivors of the mutiny. The hundreds of breadfruit plants aboard ship were less lucky; the mutineers tossed them all overboard and sailed back to Tahiti and then on to Pitcairn Island.

Lesser known is that in 1793 Captain Bligh successfully completed his mission by introducing more than 600 plants of several seedless Tahitian cultivars to the islands of St Vincent and Jamaica. Most of the breadfruit in the Caribbean today originated from those plants. During this period the British and French also distributed breadfruit to Mauritius, the Maldives, Indonesia, and Sri Lanka. In the 19th and early 20th century breadfruit was widely distributed throughout the tropical countries of the world: Central and South America, India, South-east Asia, northern Australia, Africa, and Madagascar. However, its popularity and use vary greatly by locale. Breadnut, *A. camansi*, a closely related species from

the Philippines – grown for its nutritious, high-protein seeds – was also introduced to other tropical areas where it is now widespread, especially in the Caribbean, parts of Central and South America, and coastal West Africa.

Description of Breadfruit and Breadnut

A member of the Moraceae or fig family, breadfruit is a stately and attractive evergreen tree reaching heights of 15–20 m or more. The tall, straight trunks may be as large as 2 m in diameter at the base. It has large glossy, dark-green, leathery leaves ranging from almost entire with only slight lobing to deeply pinnately lobed (Figure 1). The long-lived, multipurpose trees begin bearing in 3–5 years (Figure 2) and are productive for many decades. They provide nutritious food, timber, and medicine, as well as feed for animals. The trees require little attention and input of labor or materials and can be grown under a range of ecological conditions.

Fruits are usually globose (Figure 3) to oblong, ranging from 8 to 20 cm wide and up to 30 cm long and weigh from less than 0.5 kg to more than 5 kg, depending on the cultivar. Each fruit is composed of the fused perianths of up to 2000 flowers attached to the fruit axis or core. As the fruit develops this area grows vigorously and becomes fleshy at maturity, forming the edible portion of the fruit. The rind is attractively patterned with five- to seven-sided disks, each representing the surface of an individual flower. In the center of each disk is a distinctive scar formed by the withered remains of the stigmatic lobes. The fruit rind is light green, yellowish-green, or yellow when mature and often stained with dried latex exudations. The surface varies from smooth to slightly bumpy or spiny. The flesh is creamy white or pale yellow in color and may be seedless except for numerous minute, abortive seeds surrounding the fruit core. Seeded breadfruit contain from one to many normal seeds (Figure 4). Breadfruit is considered to be parthenocarpic and does not require pollination to develop normally.

A third species of breadfruit, *A. mariannensis*, grows wild in the islands of Palau, Guam, and the Mariana Islands and is cultivated throughout the islands of Micronesia. The leaves are generally smaller and glossier than those of *A. altilis* and

Figure 1 Typical fruit and leaf of seedles breadfruit.

Figure 2 Productive 4-year-old breadfruit tree.

Figure 3 Smooth-textured globose breadfruit.

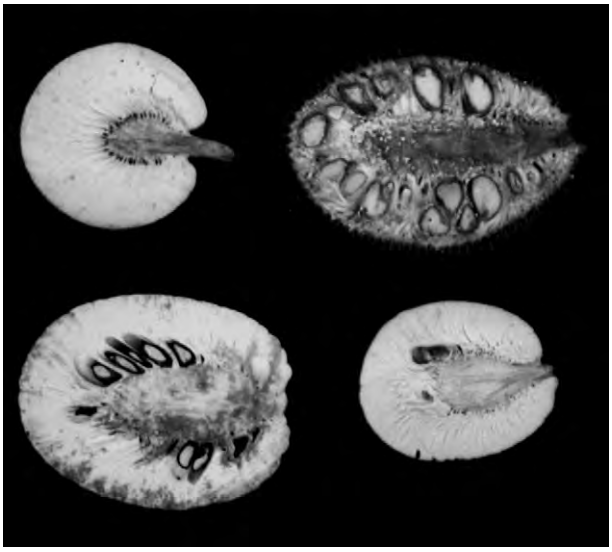

Figure 4 Variation in seed number of breadfruit and breadnut.

A. camansi. They are usually entire or have a few lobes, typically in the upper third of the leaf. The dark green cylindrical or asymmetrical fruits are generally smaller than breadfruit, with deep yellow-colored flesh when mature. Each fruit contains several to many seeds. Hybrids between *A. altilis* and *A. mariannensis* are common in Micronesia.

Production and Use

In the Pacific Islands

Breadfruit has long been an important staple crop in the Pacific Islands, and the islanders have selected and cultivated hundreds of cultivars. In Melanesia, seeded breadfruit grows wild in lowland areas of New Guinea, and the seeds are a valued food and an important component of the subsistence economy. Breadfruit is cultivated throughout the Solomon Islands and is a major subsistence food only in the easternmost islands. Breadfruit is equally important in Vanuatu, and it is still widely grown and used in certain areas of Fiji. Throughout Polynesia, breadfruit is an important staple food crop, especially in Samoa. Breadfruit remains the main staple food on atoll islands in Micronesia, and is the most important crop in season on the high volcanic islands where it is a primary component of traditional agroforestry systems.

While most breadfruit is produced for subsistence purposes, small quantities of fresh breadfruit are available for sale in village and town markets, especially in population centers where urban households must purchase traditional foods and rely heavily on imported foods. In Hawaii, fresh breadfruit is occasionally available in ethnic grocery stores and from local farmers' markets, but demand far exceeds supply. There is interest in establishing commercial breadfruit plantings to provide fresh fruits and chips for the local market and export. Although little breadfruit is currently exported from the Pacific islands, a large potential market for fresh fruits exists in the large communities of Pacific islanders living in Auckland, Honolulu, Los Angeles, and other urban areas of the USA and Canada.

Everywhere in the Pacific the starchy fruit is basically prepared and consumed in a similar fashion. It is typically cooked by roasting halved or whole in an open fire or earth oven, boiling, or occasionally is fried as chips. Because breadfruit, like all starch crops, is relatively bland, islanders have developed simple methods to enhance its flavor. Freshly grated and squeezed coconut cream is often added. A popular preparation is pudding made from mature or ripe cooked breadfruit that is grated or pounded, mixed with coconut cream, wrapped in leaves and baked. In many islands, these starchy puddings are the main form in which breadfruit is consumed. Puddings make a portable, tasty travel food that keeps for several days. Steamed or boiled breadfruit is also pounded until it becomes paste-like or doughy. It is preferred when at least 1 day old and can be kept for several days, when it begins to ferment and sour.

Traditional methods of preserving fruits Since breadfruit is a seasonal crop that produces much more than can be consumed fresh, Pacific islanders have developed many techniques to utilize large harvests and extend its availability. Preserved breadfruit also adds diversity to the daily diet. Drying is the simplest method for preserving breadfruit. Cooked breadfruit is halved or sliced into bite-sized pieces and dried over hot stones heated in a fire. Occasionally, thin slices are dried in the sun. Dried breadfruit is usually eaten without additional preparation, but it can be made into soup or ground into meal and mixed with water or coconut cream to make a porridge.

The most common method of preservation is the preparation of pit-preserved breadfruit. Pit storage is a semianaerobic fermentation process involving intense acidification which reduces fruit to a sour paste. Analysis of breadfruit fermented for 7 weeks showed that the starch was broken down first to maltose, then glucose, and eventually to lactic acid and carbon dioxide. Protein and carbohydrate levels remained relatively unchanged, while fat content and iron and calcium levels increased slightly (Table 1).

Fermented breadfruit is still made every season throughout Micronesia and to a limited extent elsewhere in the Pacific. Mature fruits are peeled, cored, and in the atolls, soaked in sea water for 12–48 h. They are then placed in a leaf-lined pit (Figure 5) and covered with leaves and a thick layer of soil or rocks. Fermented breadfruit can last for a year or more, and it is removed and eaten at various stages of fermentation depending upon need and taste preference. Fermented breadfruit is usually washed, then pounded or kneaded, and cooked before being eaten. Traditional storage practices are being modernized to fit contemporary lifestyles. Fermented breadfruit can be made in plastic tubs, coolers, or other containers that can be made relatively airtight. There are several advantages: it yields a cleaner, more uniform product, it is less labor-intensive, and smaller quantities can be made.

Table 1 Proximate composition of breadfruit and breadnut seeds per 100 g (dry weight) edible portion

	Breadnut seeds[a,c,d]	*Breadfruit seeds*[b]
Water (%)	56.0–66.2	47.7–61.9

In the Caribbean Islands

In the Caribbean breadnut and breadfruit are both widely grown, with seedless breadfruit more commonly cultivated and used. Since its introduction in the 1790s it gradually became an accepted food and an important component of the daily diet. In most cases, breadfruit is used to supplement other staple starchy foods in season and is the main source only in certain rural areas. It is a major source of food in Jamaica where more than 2 million trees were estimated to be growing in the 1970s. In the Windward Islands breadfruit is very popular for backyard planting in urban areas, and scattered trees are found island-wide. Breadfruit is prepared boiled, steamed, or roasted, and has lent itself to the creation of regional dishes such as 'oil down' – made with salt-cured meats, breadfruit, coconut milk, and dasheen leaves – which is popular in Trinidad, Tobago, and Grenada. In season, fresh breadfruit can be found in any local market, and a small quantity of processed breadfruit products such as frozen, dehydrated, and canned slices, flour, chips, and candied male flowers are also locally available. Breadnut is popular mainly in Trinidad, Tobago, and Guyana where immature and mature seeds are boiled and eaten as a snack.

The Caribbean is the major supplier of breadfruit to Europe, the USA, and Canada, providing more than 90% of the fruits for the UK market, with the rest coming from Mauritius. Jamaica is one of the largest exporters in the region. Most of the fruits are

Figure 5 Leaf-lined breadfruit fermentation pit in Micronesia.

harvested from backyard trees and small plantings, but there are efforts underway to establish orchards to support and expand the export market in the Caribbean.

In Other Tropical Areas

Breadfruit is more a subsistence crop than a commercial crop in most areas of the world, with the Pacific and Caribbean islands being the major production areas. In season, breadfruit and/or breadnuts supplement other staple foods for home consumption in Indonesia, the Philippines, and parts of West Africa, Central and South America, South-east Asia, India, and Sri Lanka. Some fruits may be available at local markets in these areas, especially Indonesia. Breadfruit has never been adopted as a major foodstuff in Africa, possibly because of failure to introduce ways of making the fruit into a food acceptable to local tastes. Recently, farmers in Queensland, Australia, have become interested in establishing breadfruit orchards for the export market.

Harvest and Yields

Breadfruits are harvested as needed and generally picked when mature, but not yet ripe. Breadnut seeds are harvested from ripe fruits and the seeds are separated from the soft pulp. Breadfruits are usually harvested with a sharp scythe or curved knife attached to the end of a long, sturdy pole (Figure 6) and are allowed to drop to the ground in most areas. Fruits that fall to the ground are damaged and soften sooner than those that are hand-picked. Most yield estimates are very general and a figure often cited is 700 fruits per tree per year, each averaging 1–4 kg. An average of 200 fruits per tree, each weighing from 1 to 2 kg, has been estimated for the Caribbean. Yields for the South Pacific are generally given as 50–150 fruits per tree per year, although a study in Pohnpei recorded from 212 to 615 fruits per tree depending on the cultivar. Hectare yield estimates range from 16 to 50 tons based on 100 trees ha^{-1}. Mature breadnut trees in the Philippines have been reported to produce 600–800 fruits per season. The average number of seeds per fruit is variable, ranging from 32 to 94 per fruit, each seed weighing an average of 7.7–10 g. Based on 100 trees ha^{-1}, each average 200 fruits per tree, an average yield of 11 MT ha^{-1} of fresh seeds has been estimated.

Figure 6 Using long-handled poles to harvest breadfruit from a 20-year-old tree.

Composition and Use

Seeds

The seeds of breadfruit and breadnut have a thin, dark-brown outer skin about 0.5 mm thick and an inner, fragile paper-like membrane which surrounds the fleshy white edible portion of the seed. Seeds are firm, close-textured, and have a sweet pleasant taste that is most often compared to chestnuts. The small, immature fruits of breadnut are sliced and cooked as vegetables, seeds and all. Seeds are harvested from ripe fruits and boiled or roasted with salt. Breadfruit seeds are usually cooked with the raw breadfruit or are boiled or roasted. They generally are smaller than breadnut seeds and sometimes have a slightly bitter flavor.

The nutritional composition of breadnut and breadfruit seeds is shown in Table 1. The seeds, especially breadnuts, are a good source of protein and are low in fat, compared to nuts such as almond, brazil nut, and macadamia nut. The fat extracted from the seed is a light yellow, viscous liquid at room temperature with a characteristic odor similar to that of peanuts. It has a chemical number and physical properties similar to those of olive oil. Seeds are a good source of minerals and contain more niacin than most other nuts. Four amino acids (methionine 3.17 g, leucine 2.6 g, isoleucine 2.41 g,

and serine 2.08 g) comprised 50% of 14 amino acids analyzed.

Fresh Fruits

Breadfruit is a versatile food that can be cooked and eaten at all stages of maturity, although it is most commonly consumed when mature but still firm, and is used as a starchy staple. The relatively bland fruit can form the basis for an array of dishes, and it takes on the flavor of other ingredients in the dish. Very small fruits, 2–6 cm or larger in diameter, can be boiled and have a flavor similar to that of artichoke hearts. These can be pickled or marinated. Mature and almost mature breadfruit can be boiled and substituted for potatoes in many recipes. Ripe fruits are very sweet and can be eaten raw or used to make pies, cakes, and other desserts. In the Philippines, candied breadfruit is made by boiling slices in coconut and sugar.

Breadfruit's carbohydrate content is as good as or better than that of other widely used major carbohydrate foods. Compared to other staple starch crops, it is a better source of protein than cassava and is comparable to sweet potato and banana. It is a relatively good source of iron, calcium, potassium, riboflavin, and niacin. A comparison of nutrient composition of fresh and fermented mature fruits, and breadfruit flour is shown in Table 2. The nutritional composition of breadfruit varies among cultivars and should aid in the selection of cultivars for different uses for fresh consumption and processed products.

Fruit quality and attributes Fruit texture is an important attribute that affects cooking and processing. Seedless and few-seeded breadfruit both exhibit a wide range of textures at the mature stage. Preferred fruits are generally those that are dense, smooth, and creamy when cooked. There are cultivars with mealy flesh, as well as ones with fibrous, stringy flesh, and spongy ones which are full of what appear to be fine threads of latex. The quality of cooked fruit also depends on the method of preparation: different cultivars provide different results when boiled, roasted, or baked. Some cultivars are suitable for roasting but become mushy and fall apart when boiled. The potential for wide-scale processing by freezing, canning, or production of flour will be enhanced by selection of suitable cultivars. The presence or absence of seeds will affect how fruits are handled and processed. Fruits with seeds are probably inappropriate for large-scale canning or chip-making operations but are excellent for home use because they are a good source of protein and make breadfruit a more complete food.

Table 2 Proximate composition of breadfruit per 100 g edible portion

	Fresh[a,b,d]	*Flour*[c,e]	*Fermented*[a]
Water (%)	63.8–74.3	2.5–19.0	67.3–71.2

Postharvest Handling

A major limitation on the greater utilization of breadfruit is the seasonal nature of the crop – the trees typically bear fruits for just several months of the year – and the highly perishable nature of the fruit. Small-scale commercial processing of breadfruit involves canning slices in brine in Jamaica for local and export markets. Breadfruit flour and chips have been made on a limited basis, and the flour has been evaluated as a substitute for enriched wheat flour and as a base for instant baby food. The starch has been extracted and may find use in industrial applications such as textile manufacture.

The keeping quality of breadfruit is limited by a rapid postharvest rate of respiration, with the fruits typically ripening and softening in just 1–3 days after harvest. Breadfruit's perishability restricts local marketing and limits its export potential since fruits ripen before they reach their destination. Shelf-life can be extended by several days by careful harvesting and precooling fruits with chipped ice in the field and during transport. Refrigeration markedly increases shelf-life for both untreated fruits and ones stored in sealed polyethylene bags. However, fruits show symptoms of chilling injury at temperatures below 12 °C. Satisfactory fruit quality is best maintained at 12–16 °C with a shelf-life of 10 days for unwrapped fruits and 14 days for packaged fruits. Controlled-atmosphere storage has good possibilities. Fruits kept

at 16 °C in atmospheric containers of 5% carbon dioxide and 5% oxygen remained firm for 25 days with some browning of the skin.

Cooked breadfruit can be frozen, and this storage method deserves greater attention as it may provide a simple, effective means to utilize this crop better. Small sections of fruit which have been boiled for 2–5 min compare most favorably in flavor, color, and texture of fresh cooked breadfruit and can be kept at −15 °C for 10 weeks or more. Sections of fruit that are frozen without first being boiled discolor on cooking after storage and have poor flavor.

Since breadfruit is generally preferred while mature and still firm, nutritional studies, development of commercial products, and research to extend shelf-life have focused on this stage. Ripe fruits generally go to waste or are used as animal food, and there has been little attention given to expanding the use of ripe fruits. A greater proportion of the breadfruit crop could be utilized and marketed if food products incorporating ripe breadfruit, such as baby foods, baked goods, and desserts, are developed. Breadfruit is a reliable, easy-to-grow, nutritious staple food which has the potential to be more widely grown and used in the world's tropical regions. This can best be accomplished by selecting cultivars that extend the fruiting season and developing better methods of postharvest handling and simple, economical means of processing the fruits.

BREAKFAST AND PERFORMANCE

C Ani and S Grantham-McGregor, University College London, London, UK

Introduction

Breakfast is the first main meal of the day. As the name suggests, it is a meal taken after a long period of overnight 'fasting.' Starting the day without breakfast has been likened to embarking on a long-distance drive with an empty fuel tank. In this article, we will discuss what constitutes an adequate breakfast, and review the evidence for the effect of breakfast on children's cognitive performance and school achievement. We will also explore some of the possible mechanisms underlying these effects. Although there is no precise standard of what an adequate breakfast should contain, it is generally recommended that it should provide between

20 and 25% of the recommended dietary allowance of energy and other nutrients. In western countries, the widespread fortification of breakfast products (e.g., cereals) with vitamins and minerals means that eating an adequate breakfast usually increases the chances of meeting daily micronutrient requirements. Many school-aged children miss breakfast or have inadequate breakfast. Children from poor or disorganized families are at high risk of missing breakfast, as are children of working mothers. In developing countries, children may have to walk long distances to school as well as do household or farming work before going to school and thus use a considerable amount of energy before arriving at school. Therefore eating breakfast is likely to be particularly important.

Studies from several western countries show that skipping breakfast is common among adolescent girls. For example, 30% of 14–15-year-old girls in a Swedish study skipped breakfast. This trend has been blamed on efforts by young girls to fit 'desirable' body images portrayed by the media. Although the obvious goal for skipping breakfast is to limit calorie intake, paradoxically, skipping breakfast may actually increase overall daily calorie intake by increasing the likelihood of eating more at lunch, or relieving hunger with higher-fat snacks.

An important question is, does missing breakfast affect children's ability to achieve in school? Several studies have shown that children who usually miss breakfast have poorer cognition and school achievement than children who eat breakfast. However, missing breakfast is often associated with poverty and disorganized families, which may independently affect children's function. Therefore the best evidence of the effect of eating breakfast comes from experimental studies in which children are given breakfast or asked to miss it. We will first review evidence for breakfast affecting children's cognition, including attention, memory, and problem-solving.

Breakfast and Cognitive Performance

The short-term effects of having or missing breakfast have been examined in several studies conducted in schools. In these, children who had breakfast were compared with those who did not have breakfast on tests of cognitive performance. The results were inconsistent. A possible explanation is that the studies had no control over the children's prior diet and activity and there were no baseline measures before treatment to compare with after-treatment measures. The most rigorous experiments have been done in a laboratory setting, where the effect of missing or receiving breakfast was examined in the same children in a crossover design. Children were given cognitive tests on the mornings when they received breakfast and when they did not, and their performance was compared. The studies achieved tight control over the children's prior diet and activity by admitting them overnight to the laboratory before the experiments. The rigor of the studies was improved by random assignment of children to receive breakfast or placebo on the first occasion. Two such studies in the USA found that the children's performance on cognitive tests improved when they received breakfast. In two other studies in Jamaica and Peru, undernourished children's cognition deteriorated when they missed breakfast whereas well-nourished children were not affected.

It appears that the quality of breakfast is also important. One study from Sweden using a crossover design found that children who received adequate breakfast (e.g., cereal, yogurt, sandwiches, and milk) performed better in tests of creativity and addition as well as physical exercise compared with those who ate inadequate breakfast (e.g., sweet rolls and sweet drink).

In a Jamaican study conducted in schools, children were given breakfast at school regardless of whether they had it at home. The study had a crossover design and all children were tested after 1–2 weeks of receiving breakfast and after not receiving breakfast. In spite of loss of control over previous diet and activity the findings were similar to the previous Jamaican study. The undernourished children showed benefits in their performance on cognitive tests on the mornings when they received breakfast.

In summary, the evidence from the best-controlled studies indicates that missing breakfast or having an inadequate breakfast affects children's cognitive performance especially if they are already undernourished.

How Can Breakfast Affect Cognitive Performance?

The cognitive effects of breakfast are likely to be mediated by several factors. The relief of hunger may play a role. Children who miss breakfast may suffer short-term hunger during midmorning school work. Hungry children may be easily distracted and undermotivated and thus not attend to learning tasks. Eating breakfast can relieve these adverse effects of hunger on children, thereby improving the children's ability to learn.

Second, the nutritional components of breakfast may have direct metabolic benefits on cognition. In particular, glucose or its precursors is thought to be important. Several studies in elderly subjects, young adults, and children have found that glucose drinks

improve memory and concentration. Reaction times and driving ability have also been improved with glucose drinks. In one study, memory in people who ate breakfast correlated with their levels of blood glucose. Another study showed that a glucose drink improved the memory of those who missed breakfast to the same level as those who had eaten breakfast. However, a glucose drink did not improve memory any further in those who had eaten breakfast. This finding suggests that beyond a certain threshold of blood glucose level, higher levels of intake confer no extra cognitive advantage. Interestingly, glucose did not improve all cognitive functions in subjects who missed breakfast and recall of a story was not improved with glucose. The findings suggest that, while glucose may explain some of the cognitive benefits of breakfast, it does not account for all of them.

In order for glucose to influence mental performance, there should be a biochemical mechanism linking it with mental function. Such a link is thought to exist through the role of glucose in the biosynthesis of acetylcholine, a neurotransmitter associated with memory. Acetylcholine is synthesized from choline and acetyl-coenzyme A (acetyl-CoA), and glucose is the major substrate for the synthesis of acetyl-CoA. It has been shown that increased glucose levels can enhance the synthesis of acetylcholine and that giving glucose can ameliorate falling levels of the neurotransmitter. Animal studies have also shown that giving glucose ameliorates the loss of memory produced by drugs that inhibit acetylcholine. While glucose plays a role in some of the short-term cognitive benefits of eating breakfast, other nutrients (e.g., protein, energy, iron, iodine, etc.) may contribute to mental performance in the medium to long term.

Millions of children in developing countries are underweight and short for their age (stunted). These children generally have poorer cognitive function than adequately nourished children. Several studies of children under 3 years have shown that nutritional supplementation improves concurrent mental development and in some cases long-term development. We are unaware of long-term supplementation studies beginning at an older age. Micronutrient deficiencies, including iron, iodine, and zinc, have also been implicated in causing poor cognition in school-aged children. So providing an adequate breakfast containing protein, energy, and micronutrients over a long period of time should improve undernourished children's nutritional status and thereby improve their cognitive development.

Breakfast and School Performance

School achievement depends on three main factors, including the children's innate cognitive ability and biological state, school characteristics such as the quality of teaching and availability of reading materials, and home factors such as parental educational level and their attitude to school. The amount of time children spend engaged on a task is a critical determinant of whether they learn the task. Time on task depends not only on the amount of time actual teaching occurs but also on the children's attendance and, when present, if they are actively engaged in a task or distracted. As shown in Figure 1, there are several ways breakfast (especially when provided in schools) could improve school performance. First, as discussed above, eating breakfast is likely to prevent midmorning hunger and improve children's cognitive ability. In addition, it may improve classroom behavior,

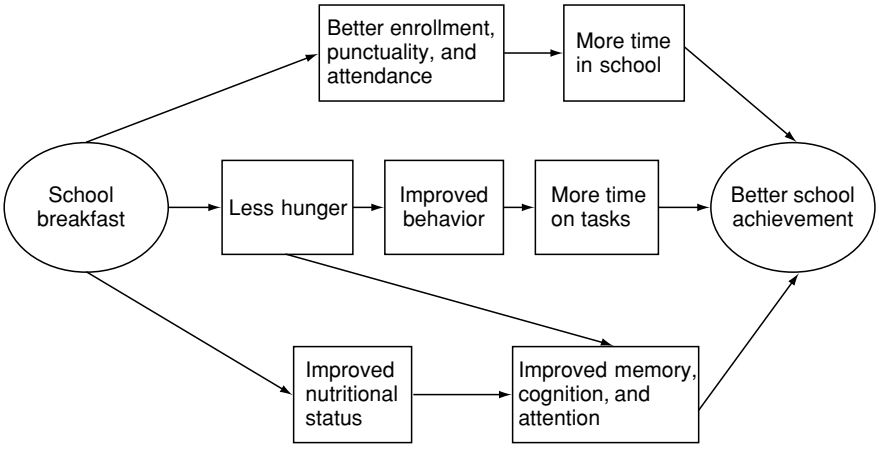

Figure 1 Mechanisms for the effects of breakfast on school performance. Adapted with permission from Ani C and Grantham-McGregor SM (1999) The effects of breakfast on educational performance, attendance and classroom behavior. In: Donovan N and Street C (eds) *Fit for School. How Breakfast Clubs Meet Health, Education and Childcare Needs*, pp. 14–22. London: New Policy Institute.

including reducing disruptive behavior and improving concentration. The opportunity to eat breakfast at school may also encourage children to attend school more frequently, particularly in situations where food is short at home. The children may also be more punctual if they want to eat breakfast before school begins. All these factors may increase the time the children spend actively engaged on learning tasks.

In addition, where undernutrition is prevalent, children who eat adequate breakfasts regularly are more likely to become well nourished and to perform better in school. We will now review studies examining the relationship between breakfast, classroom behavior, and school achievement.

Classroom Behavior

Although early studies reported improvements in children's classroom behavior when they were given breakfast, they were generally poorly designed, making interpretation difficult. The measurements were often subjective and depended on reports from teachers, who were aware of whether the children had been given breakfast. There are a few more recent and better-designed studies. These studies have shown when children received breakfast they were off-task and out of their seats less often, and participated more actively in teaching activities and showed better peer interaction. However, the situation is complicated and, in a Jamaican study, children's behavior in response to receiving a school breakfast varied according to the atmosphere and organization of the classroom. In well-organized classrooms their behavior improved with breakfast but in poorly organized, overcrowded classrooms their behavior actually deteriorated and they were out of their seats more often and less on-task.

One study showed that children who were provided with a glucose drink were more attentive and showed fewer signs of frustration when given a difficult task.

School Attendance

In the USA, it has been shown that students participating in the Department of Agriculture School Breakfast Program were more likely to attend and less likely to be late to school compared with nonparticipants. Other studies in poorer countries like Peru and Jamaica have also consistently found improved attendance among participants in school breakfast programs.

School Achievement

There are few well-designed evaluations of school breakfast programs; most have failed to have control groups or pretreatment measures. Low-income students who participated in a school breakfast program in the USA were found to perform better in tests of mathematics, reading, and language compared with nonparticipating students from similar backgrounds. In a randomized controlled trial in Jamaica, students given breakfast over two school terms performed better in arithmetic compared with those who received a low-calorie drink. Another study in Peru showed that the vocabulary of nutritionally at-risk students improved when given school breakfast for as little as a month, compared with similarly disadvantaged but nonparticipating children. However, the effects of breakfast on school achievement have not been studied more than one school year, so it is unknown whether the improvements continue.

Overall Conclusions

There is good evidence that missing breakfast detrimentally affects children's cognitive function, especially if they are undernourished. Glucose benefits cognition in children who have missed breakfast and there is some suggestion that the short-term effects of breakfast on cognition may be partly but not wholly explained by the metabolic effect of glucose. In undernourished populations, long-term benefits could be mediated by improvements in nutritional status.

There is also good evidence that if breakfast is provided at school in high-risk populations, the children's attendance and punctuality improve. There is some evidence that classroom behavior and school achievement also improve. However, there is a need for more rigorous studies in both developing and developed countries and the long-term benefits need to be evaluated. In view of the demonstrable benefits of breakfast to children's performance, policy-makers should consider implementing school breakfast programs in high-risk populations.

BROWNING

Contents

Nonenzymatic

Jennifer M Ames, University of Reading, Reading, UK

Introduction

The term 'nonenzymatic browning' refers to the chemical reactions that result in the formation of brown color when food is heated. In contrast to enzymatic browning, no enzymes are involved in nonenzymatic browning reactions. The most important nonenzymatic browning reaction is the Maillard reaction, which encompasses the cascade of reactions that occur when reducing sugars are heated with compounds possessing a free amino group (e.g., amino acids, amines, and proteins) and which result in thousands of reaction intermediates and products. The Maillard reaction is named after the French scientist, Louis Camille Maillard, who first investigated reducing sugar–amino acid interactions in 1912. Other nonenzymatic browning reactions include Maillard-type reactions between amino compounds and other compounds possessing a free carbonyl group, e.g., ascorbic acid and lipid oxidation products. A further type of nonenzymatic browning is caramelization, which occurs when sugars discolor in the absence of amino compounds. In all types of nonenzymatic browning mentioned, the chemistry involved is very similar. In this article (unless stated otherwise), the terms 'nonenzymatic browning' and the 'Maillard reaction' are used interchangeably and refer to reactions between reducing sugars and amino compounds.

As well as giving brown colors, the Maillard reaction results in various other outcomes in foods. These include development of flavor, increase in antioxidative capacity, loss of nutritional and functional properties, and formation of compounds with potential adverse effects on human health. Since the Maillard

reaction has so many important consequences for food quality, it is without doubt one of the most significant reactions that occur in food. Various factors affect the course of the Maillard reaction. These include the nature of the reactants, temperature, and time of heating, the pH and water activity (a_w) of the food and the presence of reaction inhibitors, e.g., sulfite. Due to the importance of the reaction, its control is important for food quality and kinetic approaches to modeling and control are showing considerable promise.

Chemistry

A summary of the chemical pathways comprising the Maillard reaction is given in Figure 1. The early stage of the reaction is well understood. It involves the condensation of the reducing sugar with the amino compound to give an *N*-substituted glycosylamine which rearranges to the 1-amino-1-deoxy-2-ketose, also known as the Amadori rearrangement product (ARP). The relative importance of the subsequent pathways largely depends on the pH of the food. At a pH below 5, the route involving 3-deoxyosone as the intermediate prevails but, if the pH is above 7, the pathways involving the 1- and 4-deoxyosones and the 1-amino-1,4-dideoxyosone are more important. Since most foods are in the pH range 4–6, the 3-deoxyosone route usually predominates. The 3-deoxyosone reacts with amino acids to give melanoidins (the final products of the Maillard reaction which are macromolecular and colored), Strecker aldehydes via the Strecker degradation (Figure 2) and pyrroles and furfurals and their derivatives. Enaminols, which are products of the Strecker degradation, subsequently condense to give pyrazines (Figure 2). The other deoxyosones are much less stable than the 3-deoxyosone. They are converted into reductones which may react with other intermediates to give melanoidins. In addition, these deoxyosones (as well as other Maillard intermediates, e.g., the *N*-substituted glycosylamine) readily fragment via retro-aldolization. The low-molecular-weight products that result are highly reactive and may participate

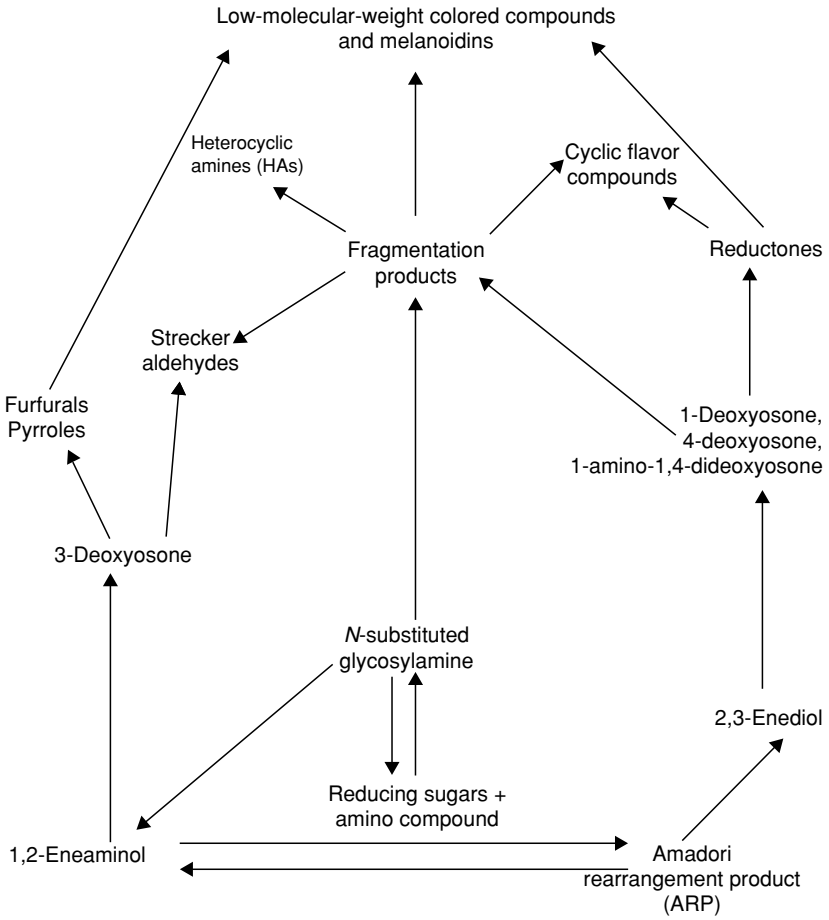

Figure 1 Outline of the chemical pathways of the Maillard reaction.

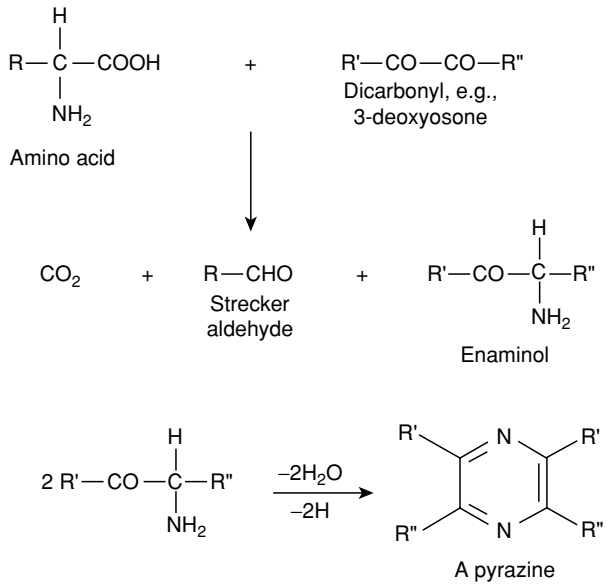

Figure 2 Strecker degradation and pyrazine formation.

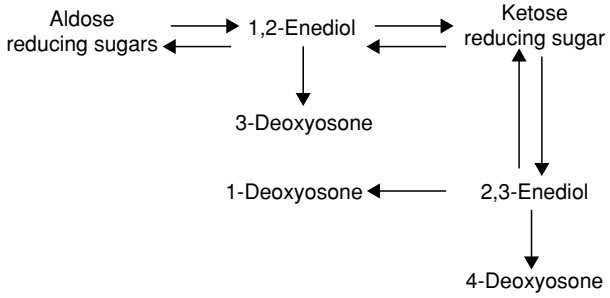

Figure 3 Degradation of reducing sugars at temperatures above 130 °C, or at pH values below 3 or above 8, and in the absence of amino compounds.

in the Strecker degradation, condensation reactions resulting in cyclic products, and reactions leading to melanoidins.

At temperatures above 130 °C or at pH values of below 3 or above 8, sugars degrade in the absence of amino acids to give key intermediates that also form in the Maillard reaction (Figure 1), as shown in Figure 3.

Flavor

Hundreds of flavor compounds formed by the Maillard reaction have been identified. The compounds concerned are largely those that contribute to aroma (i.e., they are volatile and are thus perceived by the nose), although a few components that possess specific tastes (and are therefore perceived by the tongue) have also been reported. Roasted coffee, cooked meat, bread, cookies, breakfast cereals, roasted nuts, and baked potatoes are among the foods that owe their particular flavor to the Maillard reaction. Also, the Maillard reaction is employed by the flavor industry for the production of process or reaction flavors. In addition to the development of desirable flavors, the Maillard reaction is responsible for off-flavors in certain foods, particularly in commodities in which the original fresh flavor of the product is desired. Thus, it can lead to cooked or stale flavors in processed orange juice or dried milk powder. (*See* **Flavor (Flavour) Compounds: Structures and Characteristics.**)

Table 1 Volatile compounds derived from the sugar, the amino acid, and sugar/amino acid interactions

Compounds derived from the sugar	*Compounds derived from sugar–amino acid interactions*	*Compounds derived from the amino acid*
Furans	Pyrroles	Sulfur compounds
Pyrones	Pyridines	Aldehydes
Cyclopentenes	Pyrazines	Thiazoles
Carbonyls	Oxazoles	Cyclic polysulfur compounds
Acids	Thiophenes	

The volatile Maillard flavor compounds may be divided into three groups: those formed from the sugar, those formed from the amino acid, and those requiring both the sugar and the amino acid for their formation (Table 1). Strictly speaking, it is only the compounds in the latter group that are formed by the Maillard reaction, i.e., reducing sugar–amino compound interactions. Members of a further category of aroma compounds are formed by reactions involving intermediates of both the Maillard reaction and lipid degradation. These components often possess fried odors and contribute fried aromas to foods such as potato chips. Much less is known about the products of the Maillard reaction that may contribute to taste. However, it has been established that some pyrrole derivatives contribute to the bitter taste of roasted coffee and malt. The structures of some specific compounds, together with their odor (or taste) threshold values and contributions to food flavor, are given in Table 2.

Color

The compounds formed early on in the Maillard reaction are colorless and absorb in the ultraviolet (UV) region of the electromagnetic spectrum. As the reaction progresses, absorption in the UV region intensifies and begins to tail into the visible region, resulting in the appearance of yellow, orange, and brown

Table 2 Properties of selected flavor compounds

Compound	*Odor threshold value ($\mu g\,kg^{-1}$)*	*Odor*
Butanedione (diacetyl) $CH_3COCOCH_3$	7	Buttery
3-(Methylthio)propanal (methional) $CH_3SCH_2CH_2CHO$	200	Cooked potatoes
2,5-Dimethyl-4-hydroxy-3(2*H*)furanone (furaneol) 	0.04	Caramel, burnt pineapple, strawberries
Methylpyrazine 	6×10^4	Nutty
2-Acetyl-1-pyrroline 	0.1	Freshly baked wheat bread crust
2-Acetyl-1,4,5,6-tetrahydropyridine 	1.6	Crackers
Trimethyloxazole H_3C 	5	Green, nutty, sweet
2-Acetylthiophene 	0.1	Onion-link, mustard-like
bis(2-Methyl-3-furyl) disulfide 	2×10^{-5}	Cooked meat
2-Actylthiazole 	10	Nutty, popcorn
3-Methyl-5-pentyl-1,2,4-trithiolane 		Fried chicken
	5–10 $\times$ 10[3][a]	Bitter

colors. The Maillard reaction is responsible for the desirable yellow or brown colors in foods, including bread crust, potato chips, popcorn, cookies, and other flour confectionery, but it can also lead to discoloration, e.g., in heated fruit juices and milk powder.

The colored Maillard reaction products may be divided into two groups, i.e., the low-molecular-weight compounds that possess up to about five linked rings, and the macromolecular melanoidins. Most work on colored Maillard reaction products has concerned the low-molecular-weight compounds isolated from model food systems. A selection of compounds isolated from aqueous sugar–amino acid systems, heated with or without additional furfural, is shown in Figure 4. Progress in the field of low-molecular-weight colored Maillard products has advanced rapidly over the last 5 years. Nevertheless, much remains to be done.

No homogeneous melanoidin has been isolated from a food or model food (sugar–amino acid) system to date and no structures for melanoidins isolated from food are available. Progress concerning the structures of high-molecular-weight melanoidin-like structures has been made by investigating the polymers produced on polymerization of first, 2-hydroxymethyl-*N*-methylpyrrole in trichloromethane and, second, *N*-methylpyrrole with 2-formyl-*N*-methylpyrrole (or furfural) in methanol. Figure 5 gives an example of the structures identified by $^{1}H/^{13}C$ nuclear magnetic resonance spectroscopy, fast atom bombardment–mass spectrometry and matrix-assisted desorption ionization–time of flight–mass spectrometry. Although the formation of such regular homopolymers in food systems is unlikely, it is reasonable to expect that the type of structure depicted in Figure 5 represents a domain of a food melanoidin.

It has been demonstrated that heating food proteins (casein) in the presence of glucose results in protein cross-linking and a parallel increase in color

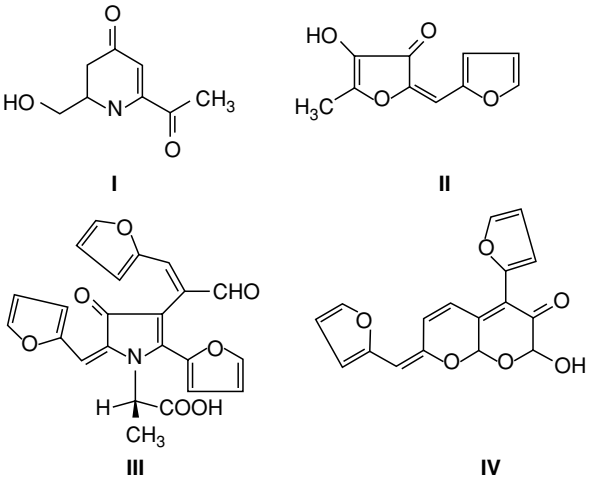

Figure 4 Selected low-molecular-weight colored compounds. **I**, from xylose and glycine; **II**, from xylose and glycine or xylose and lysine; **III** and **IV**, from xylose, alanine and furfural. (**I**: 2-Acetyl-6-(hydroxymethyl)-5,6-dihydro-4*H*-pyridinone; **II**: 2-furfurylidene-4-hydroxy-5-methyl-3(2*H*)-furanone; **III**: 4-[1-formyl-2-(2-furyl)ethenyl)]-5-(2-furyl)-2-[(2-furyl)methylidene]-2,3-dihydro-α-methyl-3-oxo-1*H*-pyrrole-1-acetic acid; **IV**: 4-(2-furyl)-7-[(2-furyl)-methylidene]-2-hydroxy-2*H*,7*H*,8a*H*-pyrano[2,3b]pyran-3-one.)

intensity of the reaction products. This color development is due to the incorporation of colored Maillard reaction products into the cross-linked protein. Therefore it is likely that, in foods, a portion of the brown color formed on heating is due to low-molecular-weight colored Maillard products binding to colorless protein backbones giving protein cross-linking and browning.

Antioxidant Activity

The Maillard reaction may influence the oxidative stability of foods because some Maillard reaction products are able to retard lipid oxidation. An increase in stability may be achieved by modifying the heat process applied, e.g., to milk, adding Maillard reaction precursors, e.g., to cookie dough, prior to heat treatment, or addition of Maillard reaction products to susceptible foods, e.g., margarine.

An increase in pH and the amino compound–sugar molar ratio enhances the formation of nondialyzable melanoidins and the inclusion of nitrogen in the Maillard reaction products. There is a positive correlation between all these factors and antioxidant activity. Nondialyzable melanoidins can scavenge hydroxyl radicals and other active oxygen species. Antioxidant activity increases with formation of melanoidins up to a maximum and then decreases with further heating and browning. Reducing activity and metal chelating ability are factors that may account for antioxidant activity. A strong candidate for such activity is the reductone group. However, enediol-like reductones and amino reductones (examples of the latter being those formed by the Amadori rearrangement) may act as antioxidants or prooxidants, depending on the reaction conditions, and the structures responsible for antioxidant activity remain uncertain. (*See* **Antioxidants**: Natural Antioxidants; Role of Antioxidant Nutrients in Defense Systems.)

Nutritional Effects

The Maillard reaction can result in serious loss of availability of essential amino acids, both in the free form and in peptide chains. Loss of the available amino acid occurs as soon as the ARP is formed. In most foods, lysine destruction is most significant, due to its ε-amino group. Ascorbic acid and also vitamins possessing a free amino group, e.g., thiamine, can participate in Maillard-type reactions leading to loss in activity of the vitamin concerned. Various Maillard reaction products may complex nutritionally important metals, e.g., copper, zinc, iron, thus making them unavailable. ARPs or more advanced reaction products fed orally to humans increase zinc excretion via urine. The effect is more marked in patients fed intravenously.

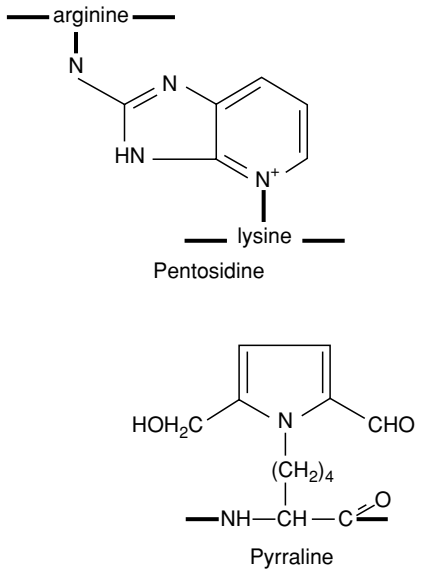

Figure 6 Structures of pyrraline and pentosidine. The peptide backbone is represented by a solid line.

The posttranslational modification of proteins and the development of protein cross-links as a consequence of the Maillard reaction reduce protein digestibility (as well as functionality). Pyrraline (identified in heated milks) and pentosidine (identified in roasted coffee) are examples of such modifications and their structures are shown in Figure 6. Reduction in protein digestibility may be due to decreased access by digestive enzymes to the modified protein or by the direct inhibition of the enzymes. The main effect is to block normal tryptic hydrolysis on the carboxyl side of lysine.

Mutagen Formation

More than 20 heterocyclic amines (HAs) that are products of the Maillard reaction have been identified at the p.p.b. level in cooked beef, pork, lamb, chicken, and fish muscle. Amino acids, sugars, and biochemicals present in muscle tissue, e.g., creatinine and creatine, are all required for their formation. The structures of a selection of HAs are shown in Figure 7. The amounts produced increase with temperature and time of cooking; temperatures encountered during, for example, grilling and frying favor their formation. Most HAs cause mutations in bacteria, mammalian cells and cancer in animals. They are the most potent mutagens examined by the Ames test and are able to produce frameshift mutations in

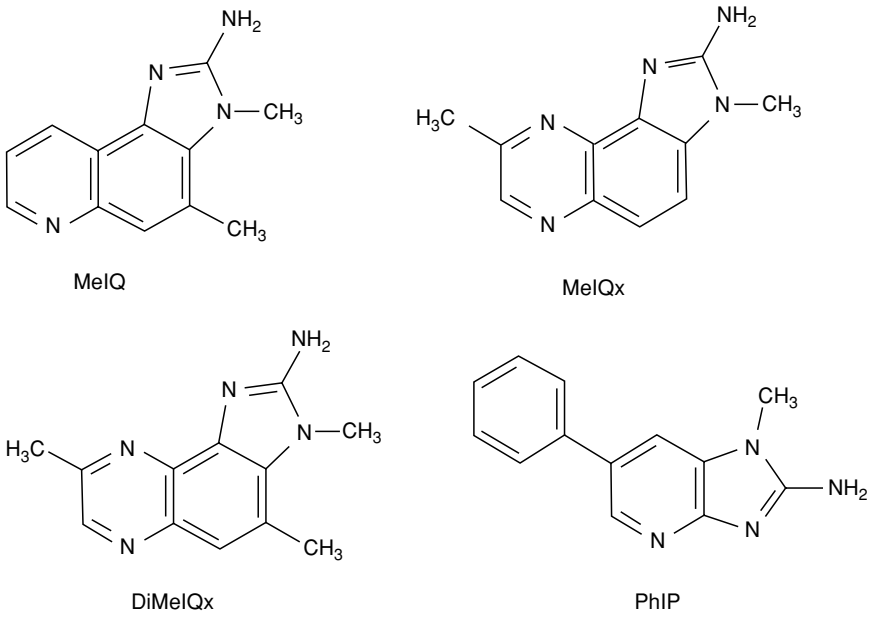

Figure 7 Structures of selected heterocyclic amines. MeIQ, 2-amino-3,4-dimethylimidazo[4,5-*f*]-quinoline; MeIQx, 2-amino-3, 8-dimethylimidazo[4,5-*f*]quinoxaline; DiMeIQx, 2-amino-3,4,8-trimethylimidazo[4,5-*f*]quinoxaline; PhIP, 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine.

Salmonella and base pair substitutions in hamster ovary cells. The risk to humans of consuming foods containing measurable amounts of HAs is difficult to estimate and requires epidemiological studies. Estimates based on animal cancer data and surveys of human food intake suggest that the average exposure to cooked food containing HAs gives a 10^{-4} risk of lifetime cancer. This average value is subject to substantial variation due to differences in diet, cooking methods, and genetic factors.

Although HAs are the mutagens formed during the Maillard reaction that have received most attention, other Maillard products are also reported to be mutagenic, including methylglyoxal and 5-hydroxymethylfurfural (HMF). (*See* **Mutagens**.)

Factors Affecting the Maillard Reaction

The extent and course of the Maillard reaction are affected by the profile of components in the food capable of acting as reaction precursors, temperature and time of heating, pH, and a_w. The reaction is also affected by metals, oxygen, and the presence of inhibitory agents, e.g., sulfite. When attempting to control the Maillard reaction, the aim may be to stop it or to steer it towards a particular outcome in terms of flavor or antioxidant activity. In any case, the reaction is difficult to stop once it has started.

The Maillard reaction may be minimized by removing one of the required reaction partners, i.e., the reducing sugars for protein-rich foods or the amino compounds for carbohydrate-rich foods. In jam-making, limiting the cooking time after addition of sucrose reduces its inversion to glucose and fructose in the acidic medium. An alternative to removing the reducing sugars or amino compounds is to process separately the carbohydrate and protein components of a food, e.g., cream-style soups.

Pentose sugars, e.g., ribose, react faster than hexose sugars, e.g., glucose and fructose, which in turn react faster than reducing sugars that are disaccharides, e.g., maltose and lactose. Amino acids also react at different rates. Of the free amino acids, when color formation is measured, lysine and glycine are among the fastest while cysteine is the slowest. In peptide chains, the amino acid residues with reactive side chains, e.g., lysine and arginine, react the fastest. The amino acid has a large effect on the flavor formed. Cysteine gives meaty notes, methionine results in a potato aroma, and cracker and bready odors are produced by proline.

The Maillard reaction increases with temperature. Q_{10} values range from 2 to 8 according to the system and parameter being measured. Therefore, if the aim is to stop the reaction, the temperature should be reduced to as low a level as possible. The profile of reaction products formed varies according to the temperature and time of heating and it is not possible to produce the profile obtained at a high temperature by heating at a lower temperature for a longer time. This

can be illustrated by comparing the aroma of meat resulting from boiling at 100 °C and from roasting at 200 °C. The two aromas are easily distinguished because different reaction pathways, and thus different aroma compounds, are favored by the different cooking methods.

The pH of the system plays a key role in determining the relative importance of the reaction pathways followed (see section on Chemistry, above). At pH values below about 5, the 3-deoxyosone route is favored while routes involving the other deoxyosones are favored above pH 7. In fact, there is no sharp cut-off point. All the pathways operate at all pH values of relevance to food, the ratio of products being influenced by the pH. Thus, pH is a parameter that can be manipulated to achieve the required profile of reaction products.

Since water is a product of the Maillard reaction, the reaction occurs less readily in high-a_w foods. In low-a_w foods, the reactants are less mobile and this also impedes the reaction. In practice, the Maillard reaction is favored by intermediate a_w values (0.5–0.8). When the aim is to prevent the Maillard reaction, a_w is of great concern during the drying or concentration of food. In such cases, the food must be taken through the intermediate a_w stage as quickly as possible, especially if heat is used. The formation of individual Maillard reaction products is favored by different a_w values and therefore a_w represents another means of optimizing the profile of reaction products formed.

Since the Maillard reaction is so difficult to stop once it has begun, the food industry may resort to the use of sulfite (normally a solution of sodium bisulfite or sodium metabisulfite) to control it. The sulfite combines with reducing sugars and Maillard intermediates possessing carbonyl and dicarbonyl groups to inhibit the reaction.

Kinetics and Modeling

The Maillard reaction is much more complex than most reactions that have been modeled by physical chemists. However, since the reaction is of such interest to the food industry, attempts have been made to describe it using kinetics and mathematical equations, in order to make valid predictions concerning color, flavor, and antioxidant activity for various food compositions processed and stored under different conditions. As a result, it is possible to predict accurately the color development (absorbance at a single wavelength of a model system) at a particular time. Rate constants have also been published for a limited selection of Maillard aroma compounds. However, since the Maillard reaction is qualitatively and quantitatively affected by many factors, the direct application of models may be of very limited use. There is a great need for further application of kinetics principles to the Maillard reaction so that various aspects of the reaction may be predicted and, ultimately, controlled in foods.

BROWNING

Toxicology of Nonenzymatic Browning

P A Finot, Nestec, Nestlé Research Centre, Lausanne, Switzerland

Introduction

Reactions between reducing sugars and free amino groups in foods, without any catalytic involvement of enzymes, lead to nonenzymatic browning (Maillard reaction) causing a reduction in nutritive value and certain physiological and/or toxicological effects. The browning reaction develops during both home cooking and industrial processing of foods. Whilst contributing to an improvement of the organoleptic properties of foods, through aroma development, browning is often an undesirable side-effect of obligatory heat treatments applied for microbiological (sterilization and drying) or nutritional (cooking) reasons and for convenience (storage). Since the Maillard reaction occurs so frequently and Maillard reaction products are present in practically all meals, an understanding of its biological implications is of importance.

Because of the multiplicity of the food systems, the complexity of the chemical reactions, and the large variety of heat treatments involved, any generalization on the biological outcome of nonenzymatic browning of foods is not easy. Nevertheless, a number of studies of model amino acid/protein and sugar reaction systems permits a classification of the biological outcome as: (1) nutritional; (2) physiological; and (3) toxic (including genotoxic) effects.

Nutritional Effects

The nutritional effects of the Maillard reaction in foods are due both to the chemical modification of essential nutrients which thereby become unavailable (direct effects) and to the presence of Maillard products which reduce the bioavailability and disturb the metabolism of other nutrients (indirect effect).

Since it proceeds through many chemical routes and produces a large number of chemical species, the Maillard reaction has been divided for clarity and convenience into two distinct stages, early and advanced, which are associated with different nutritional and physiological consequences (Figure 1).

The Early Maillard Reaction

This first stage involves the reaction between a free amino group and a reducing sugar to form, through the Amadori rearrangement, a stable deoxyketose addition compound, also called the Amadori compound. This is the obligatory step for the continuation of the reaction to the advanced stage.

At this Amadori stage, nutritional damage has already been done. No enzyme in animal tissues can split these complexes to regenerate the amino compounds, which are nutritionally unavailable. In the case of amino acids, rat growth and metabolic studies have shown that the Amadori compounds are biologically unavailable. Cecal and large intestinal microorganisms in experimental animals can liberate the complexed amino acids, but this occurs too late in the digestive/absorptive process for a significant *in vivo* utilization. The nutritional loss includes those free amino acids and peptides that have reactive α-amino groups, protein-bound lysine which has a reactive ε-amino group, and vitamins (thiamin, pyridoxine, and folic acid).

In a model system representative of the early stage, comprising milk powder stored at 60 °C or lower for several weeks, the most quantitatively important nutrient which is damaged is lysine. This is due to its high level in milk protein compared to the other amino compounds and of the high reactivity of its ε-amino group (Table 1). Milk is one of the most sensitive foods to this reaction because of its high content of the reducing sugar lactose in addition to lysine. The most important negative consequence of the early Maillard reaction is therefore the 'blockage' of lysine in milk-based products (infant formulae and weaning foods). Lysine is essential for growth and its requirement is high ($103\,mg\,kg^{-1}\,day^{-1}$ for babies as compared to $12\,mg\,kg^{-1}\,day^{-1}$ for adults). The high, recommended lysine level in baby formulae (minimum of 6.7 g per 100 g of protein, equal to the level in mother's milk) is reached using cows' milk which contains an excess of lysine of at least 20% compared to mother's milk.

Industrially treated milks contain a certain amount of such blocked lysine as its Amadori compound, the amount varying between 0 and 15% depending on the treatments applied (Table 2). Higher values are reached with the roller drying process, though this process is no longer used in the industrial-scale production of milk formulae.

Lysine bioavailability is also affected by the Maillard reaction in other heat-treated foods like bread, biscuits, and pastas, but the negative nutritional consequences

are much lower than for milk-based infant formulae as these cereal foods are poor sources of lysine.

Quantification of Lysine Damage

Many biological and chemical methods have been developed to quantify available and reactive lysine respectively. Available lysine (= reactive lysine × digestibility) may be evaluated after enzymic hydrolysis, by microbiological tests and, in animals, by growth tests. Reactive lysine may be measured as ε-*N*-dinitrophenyl-lysine after derivatization with fluorodinitrobenzene, as homoarginine after derivatization with *O*-methylisourea, and as lysine after reduction of the Amadori compound with sodium

Table 2 Lysine blockage in processed milk

borohydride. Reactive lysine can also be determined after conventional acid hydrolysis, by the furosine method. This method is based on the property of fructosyl-lysine to produce upon acid hydrolysis a new amino acid, i.e., furosine. The measurement of the furosine level allows quantification of the Amadori compound of lysine and calculation of the amount of reactive lysine.

The Advanced Maillard Reaction

This stage of the reaction starts with the degradation of the sugar moiety of the Amadori compound involving dehydration, scission, oxidation, and Strecker degradation, leading to the generation of new molecules (premelanoidins) contributing to aromas and flavors that vary in their characteristics according to the conditions employed. Some of these molecules are chemically more reactive than the initial sugar, e.g., α-dicarbonyls, reductones, and aldehydes. They react not only with free amino groups still present in the food, but also with a larger number of radical groups such as hydroxyl, amines, and other nitrogen-containing molecules, vitamins, and the side chains of amino acids.

Polymerization of premelanoidins leads to the formation of the high-molecular-weight melanoidins, the reactions involved being responsible for the developments of pigments.

During the advanced stage of the Maillard reaction, loss of lysine and of B-vitamins in foods is accelerated. Other amino acids become less bioavailable because they are either chemically modified or a decrease in the total food nitrogen digestibility occurs. Lysine lost as new unavailable addition product(s) can be calculated by difference as 'lysine in advanced Maillard compound(s)' (Table 2). These addition products do not regenerate lysine on acid hydrolysis and their chemical structures are still unknown.

Indirect Effects

Associated with the presence of Maillard reaction products, a good example of an indirect negative nutritional effect of nonenzymatic browning is the reduction in protein digestibility. This is due to the inability of proteases and peptidases to hydrolyze the peptide bonds now containing modified amino acids. Feeding such a protein results in an increase in the amount of fecal nitrogen and a decrease in the bioavailability of the chemically unmodified amino acids. Another indirect effect is a modification of the metabolism (intestinal absorption, utilization, and urinary excretion) of some minerals and trace elements (calcium, zinc, iron, and copper). The increase in the urinary excretion of zinc, iron, and copper in patients fed intravenously a sterilized aqueous solution of free amino acids and glucose, and the hyperzincuria observed in rats fed heated casein–glucose and casein–lactose mixtures, would be due to the chelating effect of Maillard reaction products. However, this increase in urinary zinc being a relatively minor route of excretion compared to fecal excretion, zinc retention, and zinc status is not reduced in rats.

Physiological Effects

Many physiological changes in tissues of animals have been attributed to feeding Maillard reaction products. It has not always been easy, however, to distinguish between the changes that are directly due to the reduced nutritive value of the reacted protein and those that are probably induced by the Maillard components of the test protein in the diet. Furthermore, in many of these studies which corresponded to model systems, the reaction products tested were incorporated in the diets at such high levels that interpretation of observation has remained difficult.

Reduced growth rate and increased relative weight of liver, kidney, and cecum have been noted in rats fed a severely reacted (brown) compared to an unreacted mixture of egg protein and glucose. Parallel increases in values for blood glucose and urea nitrogen, and serum transaminases and alkaline phosphatase were also observed with the reacted mixture. The lower growth rate, attributable to the reduced nutritive value of the reacted egg protein, may partly explain the above differences. Long-term rat feeding trials, designed to eliminate the influence of the nutritional factors through increased dietary protein level, improved protein quality, and a lower, more realistic level of incorporation of the reacted egg protein under test showed less dramatic effects. Nevertheless, an apparent effect of the reacted brown Maillard compound was evident in the depressed growth rate, enlarged liver, spleen, and cecum, lowered serum triglycerides, increased total iron, and histopathologically observed fatty changes in the liver.

Activities of intestinal mucosal dissacharidases (lactase, sucrase, and maltase) were also reduced in rats fed the reacted, brown egg protein, compared to those fed the unreacted material. Some improvement occurred on fortification of the diet with amino acids (apparently) destroyed during reaction, although a persistent decrease in the activity of these enzymes demonstrated a specific inhibitory effect of the Maillard compounds.

Diarrhea is often observed in animals fed high levels of severely browned Maillard products. This is likely to be a direct consequence of the increased amount of indigestible protein available for fermentation in the cecum, which is often found to be enlarged.

During the progress of the nonenzymatic browning reaction, additional glycosyl residues become fixed to specific milk proteins leading to an increase in their allergenicity. Using a skin reactivity test, a good correlation has been shown between the degree of browning and allergenic response of a modified bovine β-lactoglobulin. Whilst this may explain one of the mechanisms responsible for the enhancement of the allergenicity of a protein, it does not explain the 'how and why' of allergy to cows' milk protein.

Maillard reaction products of low molecular weight which are partially absorbed can affect the activity of detoxifying enzymes. Rats fed browned egg albumin exhibited increased hepatic benzo[*a*]-pyrene hydroxylase activity and decreased colonic aminopyrine *N*-demethylase activity compared to animals fed nonbrowned egg albumin. This suggests that Maillard reaction products may modify the metabolism of endogenous substrates, exogenous drugs, and other xenobiotics.

Dietary melanoidins appear to decrease plasma cholesterol in rats and to modify the composition of fecal, neutral steroids, suggesting that melanoidins influence the intestinal metabolism of cholesterol.

Maillard reaction products also interact with the microorganisms of the digestive tract. Thus they strongly inhibit the activity of glycosyl transferase of *Streptococcus mutans* which has an active role in the development of dental caries. This inhibition would hence reduce the adherence of this microorganism to the tooth surface. Also, in the gut, the microflora is able to regenerate the amino acids from their Amadori compound and oxidize the advanced Maillard reaction products.

Toxicity

Studies of the toxicity of Maillard reaction products, both *in vitro* and *in vivo*, are a recent development. This interest comes from the observation that Maillard reactions involving creatinine (a typical molecule of animal tissues) or protein pyrolysis represent a carcinogenic potential due to the formation of heterocyclic amines. In addition to these amines, there exist mutagenic products of the premelanoidin and melanoidin types resulting from heat-processed carbohydrate-rich foods such as bakery products, caramel, coffee, and other milk and meat products.

Mutagenic/Carcinogenic Heterocyclic Amines

Using the short-term Ames microbiological test, it has been possible to detect mutagenic activity in broiled fish and meat. A series of heterocyclic amines has been isolated from cooked foods and from protein and amino acid pyrolysates. Some of them, 2-amino-3-methylimidazo [4,5-*f*]quinoline (IQ), 2-amino-3,4-dimethylimidazo [4,5-*f*]quinoline (MeIQ), 2-amino-3-methylimidazo [4,5-*f*]quinoxaline (IQx), 2-amino-3,8-dimethyl-imidazo [4,5-*f*]quinoxaline (MeIQx), 2-amino-3,4,8-trimethylimidazo[4,5-*f*]quinoxaline (4,8-DiMeIQx), and 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP), possess an imidazole ring which is formed from creatinine. The remaining parts of the molecules (pyridines and pyrazines) are derived from Maillard reaction products formed by amino acids and sugars. Since creatinine is present only in animal protein sources, this class of substances is found only in these foods, albeit at low levels in the charred portions of broiled fish and the surface of grilled meat (PhIP 1 p.p.b; MeIQx 1 p.p.b.) and in beef extracts (IQ 70 p.p.b; MeIQx 8–90 p.p.b.).

The other heterocyclic amines detected in foods are pyrolysis products formed from tryptophan: 3-amino-1,4-dimethyl-5*H*-pyrido[4,5-*b*]indole (Trp-P-1), 3-amino-1,4-dimethyl-5*H*-pyrido[4,5-*b*]indole (Trp-P-2), from glutamic acid: 2-amino-6-methyldipyrido-[1,2-*a*: 3′,2′-*d*]imidazole (Glu-P-1), 2-aminodipyrido-[1,2-*a*: 3′,2′-*d*]imidazole (Glu-P-2), from phenylalanine: 2-amino-5-phenylpyridine (Phe-P-1), and from soya bean globulin: 2-amino-9*H*-pyrido[2,3-*b*]indole (AαC), 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole (MeAαC). The heterocyclic amines which are produced in very small amounts in foods have been found to be carcinogenic in rats and mice (Table 3). The major target organs are the small and large intestines, liver, lung, and blood vessels.

Mutagenicity of Melanoidin-Type Products

Heated mixtures of free amino acid or food proteins and sugars possess a weak mutagenic activity in the Ames test. This activity varies with the composition of the mixture and the conditions of the reaction. Generally, the mutagenic activity observed *in vitro* correlates quite well with the formation of brown

Table 3 Mutagenic and carcinogenic effects of heterocyclic amines

Compound	*Source*	*Mutagenicity*	*Carcinogenicity*			
		Revertants (μg) TA 98	*Species*	*Concentration (%)*	*Experimental period (weeks)*	*Target organs*
Products formed from creatinine						
IQ	Broiled sardines	433 000	Rats	0.03	72	Liver, intestine, skin

IQ, 2-amino-3-methylimidazo [4,5-*f*]quinoline; MeIQ, 2-amino-3,4-dimethylimidazo-[4,5-*f*]quindine; MeIQx, 2-amino-3,8-dimethyl-imidazo [4,5-*f*]quinoxaline; Trp-p-1, 3-amino-1,4, dimethyl-5*H*-pyrido [4,5-*b*] indole; Trp-P-2, 3-amino-1-methyl-5*H*-pyrido[4,5-*b*]indole; Glu-P-1, 2-amino-6-methyldipyrido-[1,2-*a*: 3′,2′-*d*]imidazole; Glu-P-2, 2-aminodipyrido-[1,2-*a*: 3′ 2′-*d*]imidazole.

pigments and with the presence of molecules with high antioxidant capacity.

The demonstration that carbonyl compounds can produce free radicals lends confirmation to the observation that the mutagenicity of the antioxidant fraction of the Maillard products is deactivated by catalases. This apparent contradiction suggests that, when applied at high concentration to *in vitro* tests, Maillard products can induce mutations due to an 'overpowering' of their prooxidant activity, a phenomenon already observed with other antioxidants, such as the antioxidant vitamins and phenolic compounds.

When considering model systems reflecting normal cooking conditions a relatively weak mutagenic activity was observed compared to that of heterocyclic amines. The typical mutagenic effects of this class of compounds reflect base pair, in contrast to frameshift mutations, as caused by heterocyclic amines. Furthermore, their mutagenic effect has been found to be effectively inactivated by the liver microsomal enzymes (S9 liver fraction), in contrast to heterocyclic amines which require S9 activation to mutagenic/carcinogenic species. (*See* **Mutagens**.)

Examples of heated foods with such a weak mutagenic activity that is metabolically deactivated *in vitro* are some commercial caramel preparations (ammonia and sulfite/ammonia processes), hydrolyzed plant proteins and roasted coffee. However, it has been confirmed in animal feeding studies that melanoidin-containing foods such as roasted coffee and roasted cocoa are neither mutagenic nor carcinogenic. Moreover, tested *in vivo* under well-controlled physiological conditions, Maillard reaction products with antioxidant activity are found to act as antimutagens and/or anticarcinogens.

Antioxidant and Antimutagenic Activity of Melanoidin-Type Products

Many Maillard reaction products exhibit antioxidant properties which are utilized with success in different types of food. Such reaction products include premelanoidins which are rich in carbonyl compounds as well as melanoidins. The observed antioxidant property depends on the conditions of the reaction and on the amino acids. Thus, reaction mixtures containing histidine have been found to have the highest antioxidant activity. The mechanism itself of the antioxidant

activity in food systems involves both the reducing capacity of the carbonyl compounds in the premelanoidins and melanoidins, and the property of the melanoidin brown pigments to chelate prooxidant metals, copper, and iron.

That Maillard reaction products possess antimutagenic and/or anticarcinogenic properties has been evidenced. Thus, such reaction products inhibit mutagenic activity of several foodborne heterocyclic amines and of aflatoxin B_1. Antimutagenic and possible anticarcinogenic activities have been attributed to melanoidins and α-dicarbonyl compounds generated either during the aminocarbonyl or caramelization reactions. The scavenging of active oxygen by melanoidins, demonstrated by means of electron spin resonance, can explain their antimutagenic effects. The involvement of antioxidant reactions in the antimutagenicity of heat-reaction products suggests that these compounds might have anticarcinogenic properties which include inhibition of nitrosamine formation, scavenging of active oxygen involved in cancer initiation and promotion, and also change in the chemical structure of carcinogens during the browning process.

Nitrosamines of Amadori Compounds

Amadori compounds have been shown to be nitrosated to mutagenic *N*-nitroso derivatives. This has led to the postulation that such compounds, if present in human food or if formed in the stomach, will constitute a health hazard. However, heated foods rich in Maillard reaction products with antioxidant properties can both inhibit nitrosamine formation and reduce nitrosamine-induced carcinogenicity. (*See* **Nitrosamines**.)

Introduction

The discoloration which occurs in plant material after cell disruption and results in the formation of brown or sometimes yellow, black, or pink pigments is mainly due to the process of enzymatic browning. Besides plant materials which are primarily concerned, enzymatic browning also affects some animal materials, e.g., melanosis (black spot) of shrimp.

Cell disruption can arise either from mechanical injury or temperature changes which lead to physiological disorders or even cell death (e.g., for deep-frozen products). This loss of cell integrity results in the decompartmentation of phenolic substrates and enzymes and then, in the presence of molecular oxygen, the oxidative production of colored pigments.

Brown pigmentation following this enzymatic reaction, and subsequent nonenzymatic reactions, is generally considered to be detrimental to food quality from both the organoleptic and nutritional points of view. The prevention of enzymatic browning has always been a challenge to food scientists owing to the loss of quality that it causes in many food products, e.g., fruits and vegetables during either storage or processing. It is only in a few exceptional cases that the enzymatic browning is desirable (prunes, dates, tea, tobacco, etc.).

With a better knowledge of the mechanism of browning reactions, it will be possible to propose processes which avoid or at least minimize this discoloration and which can be adapted to each particular product. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments).

Nomenclature

Two kinds of enzymes are able to act upon diphenols in the presence of molecular oxygen according to the reaction scheme shown in **Figure 1**. Both have the trivial name polyphenol oxidases, but they are somewhat different in nature. The first class of enzymes, catechol oxidases (1,2-benzenediol: oxygen

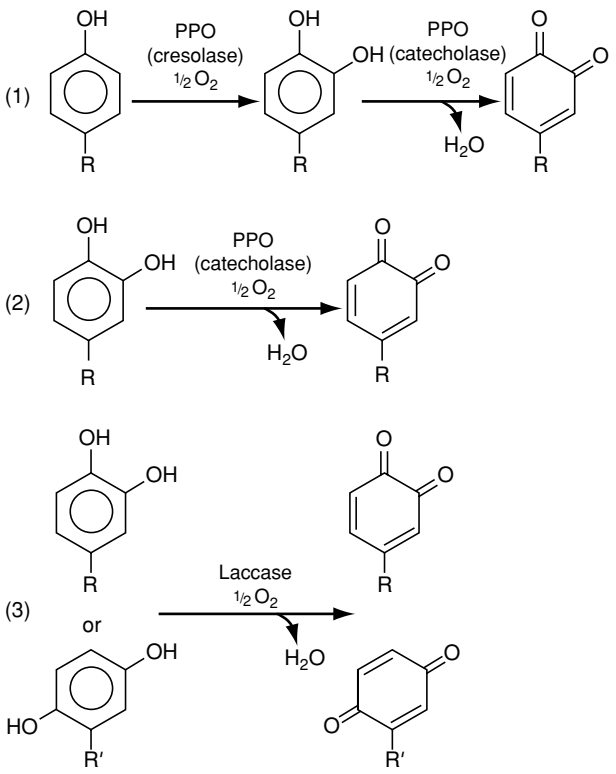

Figure 1 Reactions catalyzed by polyphenol oxidases. Reproduced from Browning: Enzymatic-Biochemical Aspects. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

oxidoreductase, EC1.10.3.1), catalyze two distinct reactions (reactions (1) and (2) of Figure 1), namely hydroxylation of monophenols into *o*-diphenols (cresolase activity) and oxidation of *o*-diphenols into *o*-quinones (catecholase activity). Both reactions consume oxygen and the overall stoichiometry is 1 mol of oxygen for 1 mol of monophenol, giving 1 mol of *o*-quinone and 1 mol of water. The second class, laccases (benzenediol: oxygen oxidoreductase, EC1.10.3.2), oxidize *o*-diphenols as well as *p*-diphenols, forming their corresponding quinones (reaction (3) of Figure 1). The stoichiometry is one atom of oxygen for 1 mol of diphenol giving 1 mol of quinone and 1 mol of water. The unique ability to oxidize *p*-diphenols can be used to distinguish the laccase activity from that of the first class of polyphenol oxidases. In all cases, the quinones formed are very reactive and, depending on the nature and the concentration of the reactive species in the medium, they can enter in numerous secondary enzymatic and nonenzymatic reactions which will be described later.

The nomenclature of these enzymes is somewhat confusing since, besides the two designated as EC1.10.3.1 and EC1.10.3.2, a third one, EC1.14.18.1 (monophenol, L-DOPA: oxygen oxidoreductase), exists. It is referred to as monophenol monooxygenase (tyrosinase) and corresponds to the same enzymes as EC1.10.3.1 but which always catalyze the hydroxylation of monophenols. For the sake of simplicity, we will use the general terms of polyphenol oxidase (PPO) for the first class (EC1.10.3.1) and laccase for the second class (EC1.10.3.2). (*See* **Enzymes:** Functions and Characteristics.)

Enzymatic Browning Factors

The different factors of enzymatic browning are examined, including some minor ones which may occasionally play an important role, e.g., peroxidases.

Enzymes

Polyphenol oxidases (EC1.10.3.1) PPOs are copper oxidoreductases exhibiting both cresolase and catecholase activities. However, many enzymatic preparations have a very low cresolase activity or none at all. It is difficult to insure that the latter activity was originally absent in the plant or has not either been extracted or has been destroyed during extraction owing to its lability. Cresolase activity is often lost during purification. Thus, in a preparation, the ratio of catecholase to cresolase activity (when the latter is present) can vary from 1 to 40.

PPO is present in a wide variety of plants. In a particular plant, PPO activity varies from one organ to another and varies inside an organ, depending on the tissue considered. PPOs have been found in different cell fractions, in organelles (chloroplasts and, more precisely, in thylakoids, mitochondria, peroxisomes) where the enzymes are tightly bound to membranes and in the soluble fraction of the cell. The degree of binding to membranes varies with the tissue and its ontogenic state. Thus, the overall PPO activity is higher and mostly present in bound forms in young green fruits, whereas it generally decreases and the proportion of soluble forms increases in ripe fruits.

Extraction of the PPO activity from plant sources is complicated by the presence of endogenous phenolic substrates which are oxidized and then interact with proteins. Besides destroying activity, this may induce 'new' enzymatic forms corresponding to artifacts. As a consequence, this oxidation has to be prevented by adding a reducing agent (e.g., ascorbic acid or a thiol) and/or a phenol-complexing compound (e.g., polyamide, polyvinylpolypyrrolidone (PVPP), or polyethylene glycol) to the extracting solution. Solubilization after preparation of an acetone powder is a frequently used procedure. Detergents (Triton

X100 or X114) are also used, but probably induce modifications of the enzyme structure and properties. Most of the purification procedures are based on fractional precipitation by ammonium sulfate followed by one or several chromatographic steps. Until the mid-1980s, the molecular mass of PPOs was believed to be around 40–45 kDa. However, PPOs from a number of plant species have now been characterized with molecular masses ranging from 20 to 180 kDa. This disparate estimation of molecular mass, traducing the heterogeneity and multiplicity of forms of the enzyme, can partly be attributed to artifacts of protein isolation and electrophoresis, as exposed above. Moreover, they can correspond to small multigene families for PPO. In fact, PPO genes characterized from different leaf and fruit plant species (including faba bean, apple, tomato, potato, spinach, Virginian pokeweed, and grape berry) are present in the plant genome as gene families. To date, cDNAs for PPOs cloned from these various plants have been found to encode mature peptides of 56–67 kDa with 8–12 kDa putative transit peptides. The nuclear encoded-plastid protein is thus translocated as a precursor with this transit peptide that can direct its transport into the thylakoid membrane or lumen. The copper content of various plant PPOs has not yet been well established, but their deduced amino acid sequences from the cloned PPOs genes have revealed two highly conserved copper-binding domains, showing significant homology with that of closely related bacterial, fungal, or mammalian tyrosinases.

Most of the PPOs studied show an optimum activity between pH 4 and 7. However, there are often discrepancies in the published values for PPOs from the same source. In addition, several reports indicate differences in pH optimum depending on cultivars and maturity. These differences have been attributed to variations in the proportions of isoenzymes which have distinct pH optima. Moreover, pH optima were found to vary with the phenolic substrate used for several enzymatic preparations. The effect of temperature on PPO activity has been less investigated than that of pH. The optimum temperature ranges from 15 to 40 °C, depending on the same factors as pH.

Laccases (EC1.10.3.2) The laccases catalyze the oxidation of *o*- and *p*-diphenols into their corresponding quinones according to reaction (3) in **Figure 1**. They occur much less frequently in the plant kingdom than PPOs. Their presence has been mainly reported in many fungi and in species of the genus *Rhus* (e.g., the Japanese lacquer tree). They are almost absent from fruits and vegetables, with the exception of certain peach cultivars and apricots. Nevertheless, the distinction between PPO and laccase activities is not always clear-cut since the presence of endogenous phenols can induce the coupled oxidation of *p*-diphenols and therefore leads to a false conclusion on the presence of a laccase type of activity. Selective inhibitors can be used to ascertain the type of activity. Thus, cinnamic acid, salicylhydroxamic acid, 4-hexylresorcinol, phenylhydrazine, and carbon monoxide inhibit PPO activity more specifically, whereas cetyl trimethyl ammonium bromide, a cationic detergent, is more specific for laccases.

Most fungi laccases are glycoproteins with a basic subunit consisting of a single polypeptide chain of 50–70 kDa containing a considerable amount of carbohydrate (10–45%) and four atoms of copper. The effect of pH on laccase activity is similar to that observed for PPO activity, i.e., an optimum pH which ranges between 4 and 7.5 and depends on the substrate being used.

Peroxidases (EC1.11.1.7) The peroxidases are enzymes whose primary function is to oxidize hydrogen donors at the expense of peroxides. They are highly specific for hydrogen peroxide, but they accept a wide range of hydrogen donors, including polyphenols. The overall reactions catalyzed are shown in eqns (1) and (2).

$$AH_2 + H_2O_2 \rightarrow A + 2H_2O \qquad (1)$$

$$2AH + H_2O_2 \rightarrow AA + 2H_2O \qquad (2)$$

Peroxidases are glycoproteins with a hematin compound as cofactor. Their molecular weights range between 30 and 55 kDa. Depending on the enzyme source, the isoenzyme considered, and the hydrogen donor substrate, the optimum activity is between pH 4 and 7. In many, but not all cases, the peroxidase isoenzymes are activated by calcium ions. The higher thermostability of some isoenzymes is well known, and the residual peroxidase activity after blanching is often used as an index of thermal treatment.

Although peroxidases are widely distributed, especially in plants, they generally appear to be little involved in enzymatic browning of fruits and vegetables following a mechanical stress. The explanation could be that the peroxidase activity is limited by the internal level of hydrogen peroxide. However, their involvement in slow processes such as internal browning during cold storage of fruits is possible.

Nevertheless, the direct involvement of peroxidase in browning still needs confirmation, just as does that of laccase which may not be present in some fruits and vegetables. Therefore, the following sections will be mainly devoted to PPO activity.

Substrates

Susceptibility to browning varies widely from one plant to another. This variation is linked to both quantitative and qualitative aspects of their phenolic content. Thus, browning after bruising of fruit cultivars with similar amounts of total phenolics can be either more or less intense. Among the wide variety of phenolic compounds found in fruits and vegetables, only a small number serves as direct substrates for PPO. Caffeic acid derivatives and monomeric flavan-3-ols (mainly (+)-(gallo)catechin and (−)-(gallo)epicatechin) often appear to be the best substrates. Other quantitatively important classes of phenols, namely anthocyanins, flavonols, and condensed forms of flavan-3-ols (tannins), are weakly if not directly oxidized by PPO. The same holds for other less important classes of phenols (flavones, flavanones, flavononols, chalcones, and dihydrochalcones). This restricted activity is probably related to the presence of a sugar moiety in many of these molecules which could cause steric hindrance since the aglycone forms are often good substrates of PPO. Nevertheless, phenolic compounds which are not direct substrates can actively participate in browning through coupled oxidation reactions. Thus, in model systems, it has been shown that the degradation of anthocyanins, procyanidins, and flavonols by PPO is greatly accelerated in the presence of caffeic acid derivatives or catechins. The *o*-quinones enzymatically formed from either of the latter compounds are able to promote cooxidation reactions leading to both the degradation of the former compounds and the regeneration of good substrates for the enzymatic reaction. This degradation and the phenolic copolymerization resulting from nonenzymatic coupled oxidations (reactions (2) and (3) of Figure 2) lead to products which may be intensely brown.

Many studies have been devoted to the specificity of PPO towards phenolic substrates. Usually, the apparent Michaelis constant (K_m) is higher than 1 mmol l^{-1}, indicating a relatively low affinity. However, for a particular substrate, the K_m values can vary widely depending on the PPO source, and the same holds for the relative rate of oxidation among different

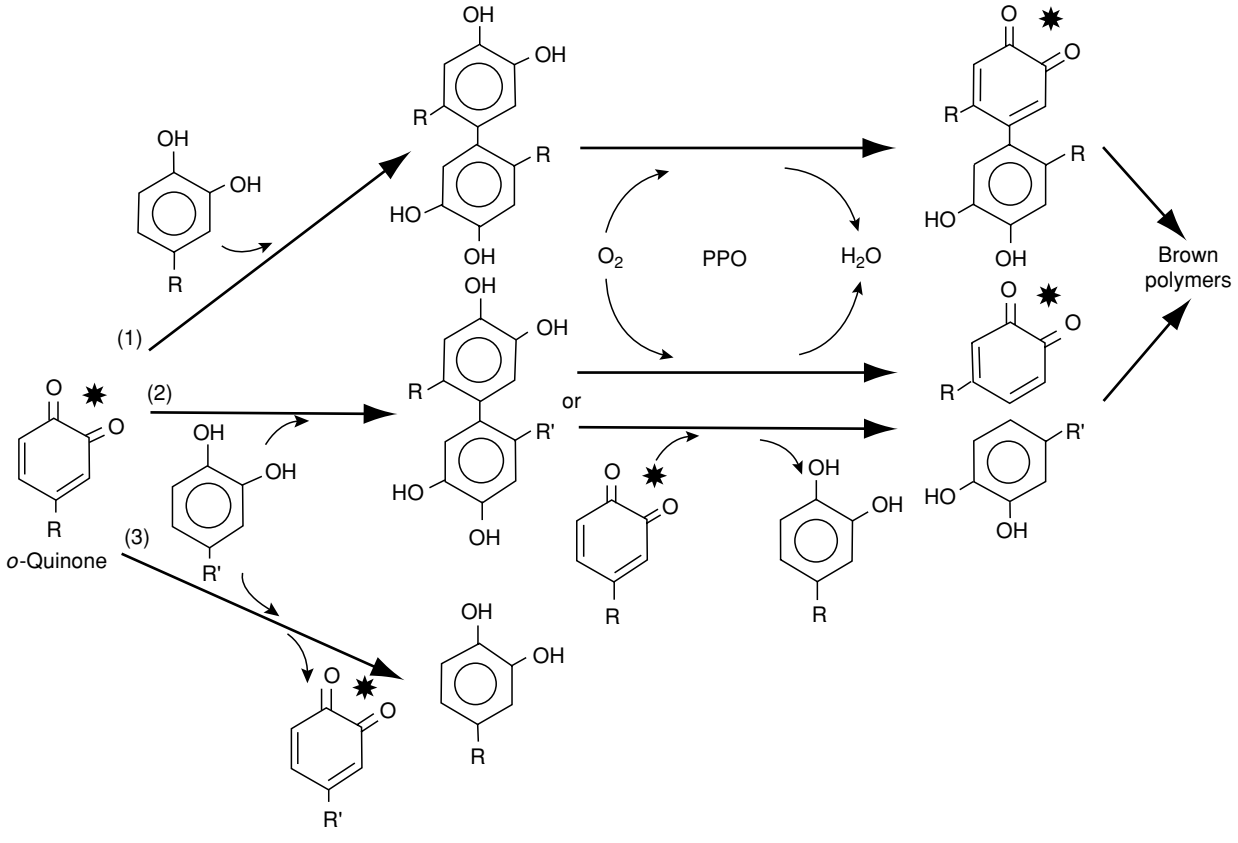

Figure 2 Reactions of *o*-quinones with phenolic compounds. (All reactions are nonenzymatic except those with polyphenol oxidases (PPOs). Reactions (2) and (3) are able to regenerate the original phenol.) Products with differing color intensities are indicated by asterisks. phenolics (Table 1). It is often suggested that the preferred substrate is the most abundant phenolic, although this is not always true.

By contrast, few studies have concerned oxygen, the other substrate. Steady-state kinetics carried out on PPO indicate that it probably follows an ordered Bi-Bi mechanism in which the oxygen binds first. The reported values for equilibrium constant (K_{mapp} O_2) are in the range 0.1–0.5 mmol l^{-1}, corresponding to a rather low affinity for the oxygen (compared to, for example, cytochrome oxidase: 0.5–1 μmol l^{-1}). (*See* **Oxidation of Food Components; Phenolic Compounds; Tannins and Polyphenols.**)

Reaction Products

The primary products of enzymatic oxidation are *o*-quinones. These molecules have different spectral properties and their color depends on the pH and the phenol from which they originate. Some of the molar extinction coefficients at maximum wavelengths are given in Table 2, and show a wide range of variation.

The colors are different from their precursors, since after oxidation catechin is bright yellow, chlorogenic acid is dull orange-yellow, whereas DOPA is pink. Moreover, the *o*-quinones are reactive compounds, as illustrated in Figures 2 and 3. Consider Figure 2 for the reactions with phenolic compounds. *o*-Quinones can react with another phenol molecule, resulting in a dimer of the original phenol (reaction (1) of Figure 2). This dimer, having an *o*-diphenolic structure, can be subject to reoxidation either enzymatically or by another *o*-quinone and gives larger oligomers with different color intensities. The *o*-quinones can also react with a different phenol molecule, either leading to a copolymer (reaction (2) of Figure 2) or regenerating the original phenol and giving a different *o*-quinone (reaction (3): coupled oxidation of Figure 2). In Figure 3, corresponding to reactions with nonphenolic compounds, another coupled oxidation reaction is observed with ascorbic acid (reaction (1) of Figure 3), since the phenol is regenerated with the simultaneous formation of dehydroascorbic acid.

Table 2 Molar extinction coefficients of quinones from different *o*-diphenolic substrates of polyphenol oxidases

Substrate	*Wavelength (nm)*	*Extinction coefficient*
Pyrocatechol[a]	390	1417
3,4-Dihydroxyphenylacetic acid[a]	390	1311
4-t-Butylcatechol[a]	400	1150
4-Methylcatechol[a]	400	1400
L-DOPA[a]	480	3388
Hydrocaffeic acid[a]	412	1124
Chlorogenic acid[b]	420	2000
(+)-Catechin[b]	380	1200

Adapted from:
[a]Waite JH (1976) Calculating extinction coefficients for enzymically produced *o*-quinones. *Analytical Biochemistry* 75: 211–218.
[b]Rouet-Mayer MA, Ralambosoa J, Philippon J (1990) Roles of *o*-quinones and their polymers in the enzymic browning of apples. *Phytochemistry* 29: 435–440.

With sulfites colorless addition compounds are formed, together with regenerated diphenol (reaction (2) of Figure 3). The *o*-quinones can form additional compounds with thiol groups by nucleophilic substitution (reactions (3) and (4) of Figure 3). Cysteine, either free or bound in small peptides (e.g., glutathione) or in large proteins, generates colorless compounds. However, due to their *o*-diphenolic structures, these compounds can be either oxidized by laccase or react with excess *o*-quinones (by a coupled oxidation mechanism) and form intensely colored products. The same kind of addition reactions occur with amino groups (primary or secondary amines), although a little less readily ((reactions (5–7) of Figure 3). Furthermore, substitutions with other thiol or amino groups of proteins may occur, leading to intra- and intermolecular cross-links. Lastly, water slowly adds to the *o*-quinones to form triphenols which are readily oxidized by excess *o*-quinone (by a coupled reaction mechanism), leading to the *p*-quinones (reaction (8) of Figure 3). (*See* **Amines; Ascorbic Acid**: Properties and Determination.)

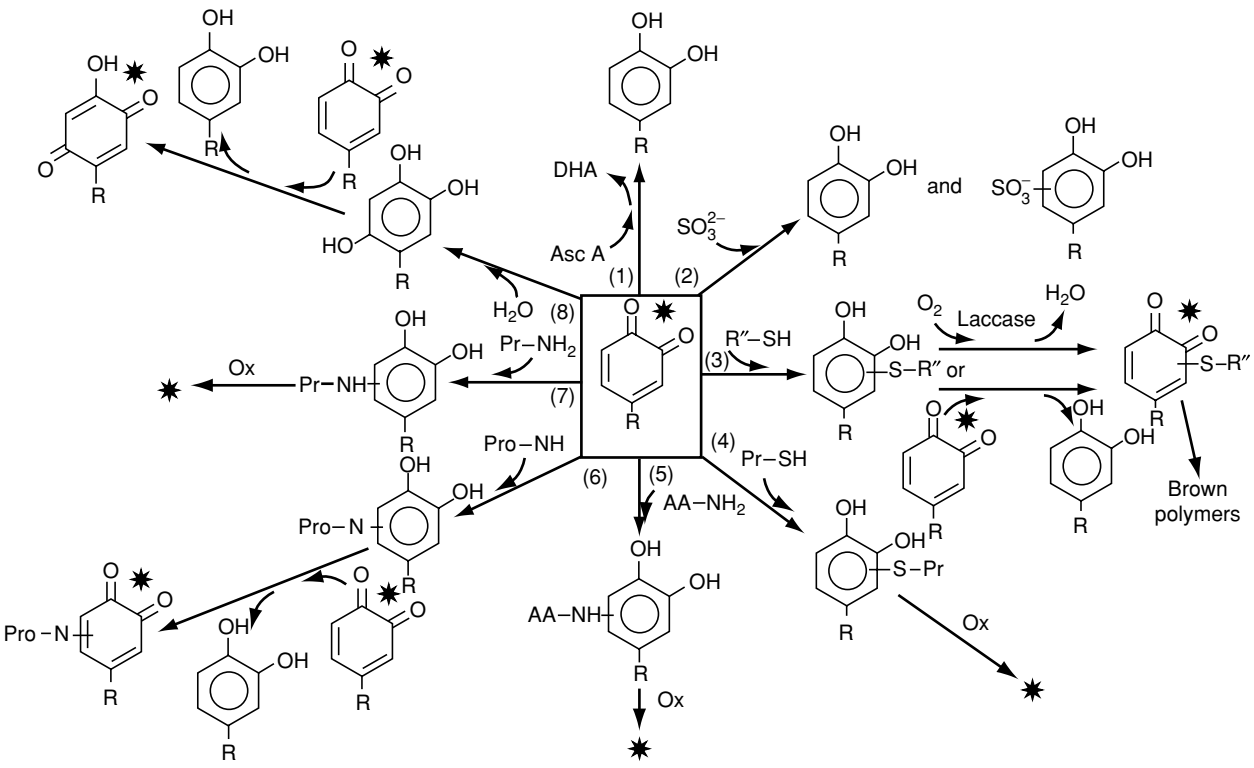

Figure 3 Reactions of *o*-quinones with nonphenolic compounds. (All reactions are nonenzymatic except those with laccase. Reactions (1), (2), (3), (6), and (8) are able to regenerate the original phenol.) Products with differing color intensities are indicated by asterisks. Ox, further oxidation reactions by oxygen or *o*-quinone; Pr-SH and Pr-NH_2, proteins; Pro-NH, proline; AA-NH_2, amino acids; Asc A, ascorbic acid; DHA, dehydroascorbic acid; R″SH, small thiol compounds (e.g., cysteine and glutathione). Reproduced from Browning: Enzymatic-Biochemical Aspects. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The reactivity (or in other words, stability) of the *o*-quinones in these different cases is very variable. It depends strongly on the substituted nature of the parent phenol, and on the medium (composition, pH, temperature, etc.). Thus, in the same conditions, the *o*-quinones derived from 4-methylcatechol are more stable than those from chlorogenic acid which, in turn, are more stable than those from catechins. Obviously, the presence of reactive molecules, with amino or thiol groups, in the medium can greatly affect the stability of the *o*-quinones. Moreover, the reactivity with reducing compounds, namely those entering in coupled oxidation reactions, is under the control of the redox potentials of the systems involved. Thus, the *o*-quinones of chlorogenic acid are able to cooxidize catechins into *o*-quinones of catechin and regenerate chlorogenic acid, whereas the reverse is not true.

Inhibition of Enzymatic Browning

Enzymatic browning is often an undesirable reaction and its prevention is a major concern for food scientists. Therefore, a large part of the many studies devoted to enzymatic browning concern its control. This section gives only the physicochemical basis for the control of the reaction. The more applied view of the problem in food technology will be described in the next article. The different ways of browning control can be divided into three classes, depending on whether they affect enzymes, substrates, or reaction products. However, some inhibitors are able to act simultaneously on more than one of these factors.

Action on Enzymes

First, heat treatment is often employed, and usually short exposure to temperatures between 70 and 90 °C is sufficient to inactivate PPOs. High-pressure treatments have also been proposed for the denaturation of PPO. Very high pressures (400–500 MPa) are needed to inactivate the enzyme at 25 °C. However, PPO appears to be more vulnerable to high-pressure CO_2 treatment (close to 6 MPa) or to a combined treatment of heat and ultrasonic waves under moderate pressure (manothermosonication). Since the optimum pH of most PPOs lies between pH 4 and 7 (see earlier) on

the one hand, and the phenols are more readily oxidized when the pH increases on the other, acidification below pH 4 is often proposed, although PPOs are still active in some cases (grape, apple, etc.).

Besides these general treatments, more specific chemical inhibitors are known. PPOs having copper as a prosthetic group are inhibited by many metal-chelating agents such as cyanide, azide, diethyldithiocarbamate, and ethylxanthate, although inhibition depends on the source of the PPO. Inhibition by halide ions observed in numerous cases is pH-dependent, increasing when the pH decreases; it may be caused by the formation of a complex between the halide ion and copper which is enhanced by low pH values. Due to their structural resemblance to phenolic substrates, aromatic carboxylic compounds are usually found to be competitive inhibitors. As has been shown for apple PPOs, the inhibitory properties are highly dependent on structure (Table 3). Thus, for a particular substituent, inhibition decreases in the order cinnamic, benzoic, phenylpropionic, and phenylacetic acid. In each series, inhibition is slightly enhanced by *p*-hydroxy substitution and greatly reduced by *o*-methoxy substitution. Moreover, the presence of a benzene nucleus is not an absolute requirement for the inhibitory effect since sorbic acid, an aliphatic carboxylic acid with two conjugated double bonds, is almost as effective as benzoic acid. In all cases, inhibition increases as pH decreases and it was shown that the un-ionized form of the carboxylic group is mainly responsible for inhibition.

More recently, substituted resorcinols have been recognized as PPO inhibitors. Although resorcinol is a poor PPO inhibitor, the 4-substituted resorcinols exhibit the highest inhibition properties. Among them, the 4-hexylresorcinol has been proposed as a valuable sulfite alternative for use in the food industry in order to prevent enzymatic browning. It has been shown that 4-hexylresorcinol inhibits PPO in a non-classical mechanism involving the rapid formation of an enzyme–inhibitor complex which undergoes a slow reversible reaction (slow-binding competitive inhibitor).

Action on Substrates

Inhibition of enzymatic browning can also be obtained by removal of one of the two substrates (oxygen and phenolic compounds) from the reaction medium. Complete oxygen removal is the most satisfactory way to control the phenolic oxidation catalyzed by PPOs. However, although this method may be applied to dead tissues, either by creating a physical barrier to oxygen diffusion or by vacuum infiltration (a more detailed description on this subject will be given in the next chapter), it is inapplicable to living tissues due to the risk of metabolism deviations caused by anaerobic conditions. Concerning the phenolic substrates, two methods are available. The first one is the physical elimination by ultrafiltration or by specific adsorbents. In the latter case, the most widely used, polyvinylpyrrolidone (PVP) and its insoluble form (PVPP), are very effective in controlling enzymatic browning. Thus, PVP has also been shown to be a competitive inhibitor of PPOs. Other complexing agents of phenols can be used, such as polyethylene glycol or polyamide. In the same way, borate acts by complexing the *o*-dihydroxy groups of phenolic substrates. Lastly, the inhibitory properties of β-cyclodextrins, observed in apple juice browning, are related to their abilities to form inclusion complexes with PPO substrates. A similar mechanism of browning inhibition could be ascribed to some polysaccharides such as carragenan, amylose sulfate, xylan, and chitosan.

The second way of removing phenolic compounds is by their modification. This can be performed by two kinds of enzymes. The first modification is methylation of the *o*-diphenolic substrates of PPOs by an *O*-methyltransferase (e.g., caffeic acid is converted to ferulic acid). Unfortunately, this elegant

Table 3 Inhibition constants of sodium halides and some carboxylic acids for apple polyphenol oxidases at pH 4.5. All are competitive inhibitors, with the exception of sodium chloride, which is noncompetitive

Inhibitor	K_i *(inhibition constant)* $(mmol\,l^{-1})$	*Inhibitor*	K_i $(mmol\,l^{-1})$
Sodium iodide	117	Sodium bromide	106
Sodium chloride	20	Sodium fluoride	0.07
Benzoic acid	0.64	*p*-Hydroxybenzoic acid	0.57
Vanillic acid	10	Syringic acid	34.5
Cinnamic acid	0.092	*p*-Coumaric acid	0.04
Ferulic acid	0.29	Sinapic acid	15
Phenylacetic acid	13	Phenylpropionic acid	1.4
p-Hydroxyphenylpropionic acid	1.1	Sorbic acid	0.51

Adapted from Janovitz-Klapp A, Richard F, Goupy P, Nicolas J (1990) Inhibition studies on apple polyphenol oxidase. *Journal of Agricultural and Food Chemistry* 38: 926–931.

process is impeded by the high cost of the enzyme (*S*-adenosylmethionine: catechol *O*-methyltransferase) and one of its substrate (*S*-adenosylmethionine). The second modification is oxidative ring opening by protocatechuate 3,4-dioxygenase. However, in addition to its cost, this enzyme has poor catalytic activities on caffeic acid and its derivatives.

Action on Reaction Products

Acting on reaction products is the third way of controlling enzymatic browning. *o*-Quinones are very reactive primary products (Figures 2 and 3) and, using chemical means, they can either be reduced back to *o*-diphenols or trapped as colorless addition compounds. However, secondary products resulting mainly from the oxidative polymerization of *o*-quinones often give highly colored compounds which become less reactive as the browning reaction proceeds. Therefore, almost all the compounds listed in the section on reaction products which act on *o*-quinones, and more especially ascorbic acid and its derivatives, thiol compounds and sulfite derivatives, can be used for the control of enzymatic browning. However, their effectiveness in preventing browning is greatly reduced if their use is delayed until after the reaction has started.

Besides chemical means, brown pigments can be removed more or less completely by physical treatments such as ultrafiltration or use of resins in order to trap polymers of *o*-quinones. This can be an efficient method for the clarification of liquids such as fruit juices and wine.

Lastly, several studies have been devoted to the isolation of 'natural' inhibitors of enzymatic browning. Thus, low-molecular-weight compounds exhibiting inhibitory properties have been detected in cultures of *Penicillium expansum* and *Dactylium dendroides*. Inhibitors have also been found in anise oil, cumin, and several medicinal plants. Similarly, it has been shown that Maillard reaction products and honey extracts contain substances which are able to inhibit the PPO activity. Nevertheless, in most cases, these inhibitory compounds have been only partially characterized and their exact mechanism of inhibition is not fully understood. (*See* **Antioxidants:** Natural Antioxidants; Synthetic Antioxidants.)

In recent years, considerable progress has been made in understanding PPOs and polyphenols of fruits and vegetables. However, many studies were restricted to model systems with an enzyme acting on one phenolic substrate only. There is a great need for studies on enzymatic action on mixtures of phenols on the one hand, and on nonenzymatic reactions that follow *o*-quinone formation on the other. This research would give valuable information on how phenols affect both the enzymatic activity and the kind of brown pigments formed, and it would help to give a better understanding of the relation between the extent of browning and the phenolic composition of fruits and vegetables.

Background

Enzymatic browning affects numerous plant organs and seafoods which are rich in oxidizable phenols such as fruits, vegetables, aromatic plants, fungi, and shrimps. It occurs during various procedures used in the food industry: deep-freezing, dehydrofreezing, freeze-drying, hot-air drying, etc. In practice, there are three approaches to prevention of this browning: varietal selection, physical methods, and chemical inhibitors.

The various methods currently used or likely to be used in the future for prevention of browning are reviewed in this article. Deep-frozen fruits and vegetables are considered in detail, since enzymatic browning is most difficult to resolve in these products. Also, the preventive methods used during industrial drying and freeze-drying, and even canning and bottling, are in fact very similar.

A brief review is then given of the methods of measurement of browning and of the questions raised by objective assessment.

Practical Methods of Preventing Browning

Choice of Raw Material

Some plant tissues, such as fruits or vegetables, are less sensitive to browning than others. Most berries – raspberry, blackcurrant, redcurrant, bilberry – are virtually unaffected. Other species, however, quickly brown on freezing and thawing unless previously subjected to antioxidant treatment. They are generally rich in total phenols and poor in ascorbic acid in cases of fruits with pips (apple, pear, quince), and stone fruits (apricots, peaches, plums).

The phenol content of fruits and vegetables varies naturally according to the degree of ripeness, the soil and climate, but also depends substantially on intraspecific genetic characteristics. The Sunbeam peach variety, for instance, which does not brown, contains 20 times less total phenols than the Elberta variety, which is sensitive to browning. This plainly illustrates the value of the development by genetic selection of new, low-phenol varieties. (*See* **Ascorbic Acid**: Properties and Determination; **Phenolic Compounds**.)

Physical Methods of Prevention

Mechanical Factors

Browning is enhanced by wounding of plant tissue, notably during industrial processing. Upkeep of machine blades is important to insure that fruits and vegetables are cut cleanly.

Effect of Temperature

Cold A marked slowing in enzymatic browning is induced by a reduction in temperature. None the less, color change is still rapid at 0 °C. This means that the most sensitive products are frozen by methods allowing the crystallization temperature of water to be reached as rapidly as possible. This is the case with mushrooms, for which cryogenic techniques are obligatory when they are frozen without prior antioxidant treatment. The same is true for peeled slices of white peach which brown during freezing if the cooling exceeds 10 min.

Once frozen, color change is practically blocked at the temperature of commercial storage (−18 °C). When the temperature rises, browning starts again, and will be more marked if the cellular structures of the plant organ have been severely damaged by freezing, chemical peeling, and slicing.

Heat Heat treatment, or blanching, without doubt constitutes the simplest and most direct method

of enzyme inactivation. It consists of brief immersion (from 1 to 6 min depending on size) of the product in water, boiling syrup, or steam close to 100 °C.

Catechol oxidases are inhibited above approximately 70 °C. Their heat stability is closely pH-dependent; it is maximal at about pH 6 and decreases very rapidly below and above this value.

In the deep-freezing of foodstuffs, blanching is principally applied to vegetables that are eaten cooked (potatoes, salsify, asparagus, etc.), but it is also selected to stabilize frozen fruit purées, particularly of apricots. Blanching is little used with whole or sliced frozen fruits that are eaten raw, since it results in loss of firmness and in flavor changes which are unacceptable to the consumer. This is why blanching is only used for fruit with tissue sufficiently impermeable to oxygen, to escape deep browning. Examples are apricot and peach, for which the brief surface treatment scarcely alters the organoleptic qualities. When blanching of pears and, particularly, apples (20–25% lacunae) is incomplete, marked deep browning occurs on thawing.

Other Physical Methods for Prevention

Electrodialysis, ultrafiltration Electrodialysis, based on dissociation of the water molecule using a bipolar membrane, is applicable for the control of enzymatic browning in food liquids. This technique, applied to cloudy juice extracted from MacIntosh apples, results in the reduction of juice pH to 2 with a complete inhibition of polyphenol oxidase (PPO). After readjustment at pH 3.5 (the initial juice pH), the electrodialysis treatment leads to an improvement in the juice color during storage, a large decrease in mineral concentration, and a slight loss in malic acid without noticeable change in the composition of sugars. The latter modifications result in a less acidic and somewhat milder apple juice.

Ultrafiltration can be used as a clarification process in fruit juice processing. Use of polyethersulfone/polyvinylpyrrolidone membranes permits reduction of the amounts of polyphenols in apple juice, leading to a large improvement of the stability of color and clarity during storage.

High-pressure, ultrasonic waves High-pressure processing appeared in the last decade as an alternative to heat treatments for inactivation of microorganisms and food-quality enzymes (including PPO). However, at room temperature, complete inactivation of PPO requires pressures higher than 400–500 MPa which are not industrially relevant for the moment. Therefore, several processes using high pressures in combination with other treatments, such as acidification, moderate heat treatment, CO_2, and ultrasonic waves, have been proposed to inhibit enzymatic browning in fruits, vegetables, and crustaceans.

Protection from Oxygen

When plant organs cannot be blanched, protection from air constitutes another way of preventing browning. Prevention fails, however, as soon as the anoxic conditions no longer hold, and color changes are even accelerated by the destruction of cell structures caused by freezing and thawing.

In the food industry, products are protected from oxygen using a variety of methods, either singly or combined.

Airtight packages These are indispensable for preventing the browning of sensitive fruits with active oxidase systems. In hermetically sealed metal cans, pitted cherries in syrup do not brown, even at −7 °C, whereas spoilage occurs very rapidly if the container is not airtight. The differences between airtight and nonairtight packages increase as the temperature rises. Browning is also a function of the degree of can filling, and hence the quantity of residual air in the headspace.

Partial vacuum A partial vacuum of 380 mmHg is enough to block the browning of frozen peaches in syrup stored at −7 °C. However, stronger vacuums should be avoided since, on thawing, raw fruit will have an unpleasant spongy consistency, and fruit packaged in syrup will tend to acquire an unwanted translucent appearance. (*See* **Chilled Storage**: Packaging Under Vacuum.)

Oxygen-poor atmospheres Browning can also be avoided by keeping the foodstuff in oxygen-poor atmospheres. This can be achieved chemically, or by use of an inert gas. The chemical approach involves the enzymatic oxidation of the sugar present in the medium (enzymatic deoxygenation), thus leading to the consumption of oxygen trapped within an airtight package. The sugar combines with oxygen under the effect of added glucose oxidase, giving gluconic acid. This process has been shown to be effective in laboratory tests with peaches, but to our knowledge has not undergone industrial development.

The use of carbon dioxide or pure nitrogen atmospheres also effectively protects frozen fruits against enzymatic browning. Nitrogen, furthermore, affords better protection of the original flavor and aroma.

Minimally processed products (i.e., ready-to-use, cut fruits and vegetables) are very susceptible to enzymatic browning since they are wounded, living

tissues. In this case, complete removal of oxygen is inapplicable due to the risk of metabolic deviations caused by anaerobic conditions. According to the type of plant material, the packaging film has to be chosen by taking into consideration both the film-selective permeability towards oxygen, carbon dioxide and water on the one hand, and the plant respiratory metabolism on the other, in order to obtain the optimum atmosphere composition allowing an increased shelf-life upon storage at refrigerated temperatures.

Sugaring of fruits In this process, fruit is immersed in a covering liquid, either of a chosen concentration of sugar syrup, or of the fruit's own juice drawn out by contact with dry sugar.

Sugar (generally sucrose) has several effects. It increases the osmotic pressure of the surrounding liquid, which contributes to the reduction in size of ice crystals on freezing, thereby protecting cellular structures. It also increases the viscosity of the medium, thus slowing the rate of enzymatic spoilage reactions. It may also have a slight inhibitory effect on the enzymes of browning when the syrup concentration exceeds 20% (w/w). (*See* **Sucrose**: Properties and Determination.)

Sugar is also a well-known and valued enhancer of taste and aroma. However, it does result in some dilution of aroma when used in the form of syrup. This defect is attenuated when sugar is added to fruit in the dry form, but severe changes in consistency result, thus harming the fruit's appearance. In addition, the exuded juice collects in the bottom of the package and only effectively protects part of the package contents.

In commercial practice, sugaring is only used with frozen fruits intended for the manufacture of juice, syrup, liqueur, or purée; the concentrations used range from 1:9 to, more commonly, 1:4 (dry sugar: fruit).

Frozen fruits intended for direct consumption are frequently packaged under a covering syrup. The syrup concentrations are about 30–40°Brix for cherries, pears, and plums, 40–50°Brix for bananas, apples, and nectarines, and 40–60°Brix for strawberries, apricots, and peaches. None the less, syrup alone inadequately protects the most sensitive fruits, and an antioxidant is therefore incorporated. The most used antioxidant is ascorbic acid, and its derivatives, although other substances such as citric acid are employed, notably in the case of peeled, frozen bananas. The covering liquid comprises either a syrup of pure sucrose, or a mixture of sucrose and maize glucose. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

Chemical Methods of Prevention

Numerous chemical compounds inhibit enzymatic browning. Of these, few combine effectiveness with recognized innocuousness, unaltered product flavor, and reasonable cost. The use of most of these compounds is banned by legislation.

In the case of plant foodstuffs, the legislation of most countries only permits ascorbic acid and its derivatives, sodium chloride and, within stricter limits, citric acid and sulfur dioxide (as well as its derivatives, sodium sulfite and sodium metabisulfite). Recently, the GRAS (generally recognized as safe) status has been attributed to the 4-hexylresorcinol for use in the prevention of shrimp melanosis (black spot). (*See* **Legislation**: Additives.)

Ascorbic Acid

Ascorbic acid, which, with its first oxidation product dehydroascorbic acid, constitutes vitamin C, reduces *o*-quinones progressively as they are formed. Catechol oxidase, which indirectly controls the oxidation of ascorbic acid, is virtually unaffected during the reaction, so that browning begins as soon as the reductant has been consumed. (*See* **Ascorbic Acid**: Properties and Determination.)

In practice, concentrations of 0.1–0.3% prove adequate when, as is often the case, the external conditions are unfavorable to browning, i.e., low temperature, acidic and poorly oxygenated medium.

Ascorbic acid is effective above all when thoroughly mixed in liquid or paste products (apple juice, purée). It is also used at concentrations of 0.2–0.25% in syrups covering frozen fruit to enhance the protective effect against enzymatic browning.

One of the drawbacks of ascorbic acid (apart from its relatively high cost) is that it is readily oxidized and rapidly disappears from the medium. To counter this rapid disappearance various derivatives have been proposed as substitutes, such as ascorbic acid-2-phosphate (AAP), or ascorbic acid-triphosphate (AATP). These compounds are not reducing agents, and therefore remain stable in the presence of oxygen, but they do hydrolyze progressively, releasing ascorbic acid under the action of the phosphatases present in the plant tissue. Such compounds are not, however, effective if the medium is too acid (e.g., apple juice, pH 3.7), since the activity of phosphatases is then too low. They are effective, though, in solutions of soaked, sliced apples (0.8%) in cold storage.

Ascorbyl palmitate is a fat-soluble substance which over a long period is more effective than ascorbic acid in fruit juice when used at a concentration of 200 p.p.m. Its poor aqueous solubility, however, makes it ineffective in soaking solutions.

Sodium Chloride

Salt is frequently used in the food industry to slow microbial growth (bacteria, fungi), but is inadequately protective at low concentrations and imparts an unwanted salty flavor at high concentrations. At a pH below 5.5, however, salt is a good inhibitor of enzymatic browning, hence the value of using it in conjunction with citric acid for neutral plant products, such as cultivated mushrooms. (*See* **Preservation of Food**.)

Sodium chloride is sometimes used at low concentrations (1–2%) to afford temporary protection from surface browning of sliced, peeled apples intended for freezing, or to be sold as ready-to-use fresh foods. The soaking time is short, usually less than 1 min.

Used in combination with ascorbic acid, sodium chloride prolongs the duration of action of the acid.

Citric Acid

Oxidative enzyme activity is very pH-dependent (*See* previous article **Browning**: Toxicology of Nonenzymatic Browning). Highly acidic (pH < 2.5) or basic (pH > 10) media which result in protein denaturation destroy its activity. Although alkalization of the medium in which fruits are immersed is undesirable (spontaneous browning following nonenzymatic oxidation of *o*-diphenols), acidification can prove advantageous in certain circumstances. Apart from acetic acid used in vinegar production, citric acid is virtually the only substance authorized for this use. It is sometimes used in deep-freezing and in fruit conserves in syrup; thus, it is used to neutralize the rinsing water of halved, chemically peeled peaches, and at the same time to protect the fruit temporarily against enzymatic browning. The dose used is about 1% of the volume of water. (*See* **Acids**: Natural Acids and Acidulants; **Enzymes**: Functions and Characteristics.)

Sulfur Dioxide and its Derivatives

Sulfur dioxide, which is an antiseptic widely used in foodstuffs, is by far the most effective of currently authorized chemical inhibitors of browning. It even acts at very low concentrations and is inexpensive. It can also be used with certain fruits to eliminate unwanted red pigmentation, as in the case of Bigarreau Napoléon cherries, used in confectionery, which must first be decolorized using sulfite to insure that the pigment does not turn brown during heat treatment.

As an inhibitor of browning, sulfur dioxide has three actions: formation of colorless addition products with (colored) *o*-quinones; reduction of *o*-quinones to their original *o*-diphenols (colorless); denaturation of catechol oxidase (*See* **Browning**: Toxicology of Nonenzymatic Browning). Sulfur dioxide also reacts with many other chemical constituents of plant tissues (notably ketones and aldehydes). The strength of the chemical bonds formed varies with the pH and the type of molecule involved. It would appear that such products are the cause of the abnormal flavors which sometimes develop when sulfur dioxide is used at too high a concentration and is not subsequently eliminated.

Sulfur dioxide can be used in the form of a gas or in aqueous solution as sodium sulfite or disulfite. As a disulfite, it acts less rapidly, but is more easily controlled and results in a few flavor changes.

Of deep-frozen products, apples and apricots are most suited to sulfur dioxide treatment. Fruit slices or halved fruits are soaked for 3–4 min in solutions containing 0.4–0.5% sulfur dioxide.

High doses are sometimes authorized and used to stabilize fruit pulp intended for the making of jams of standard quality (antiseptic action) and to clear fruits before drying (notably apricots). In this case, however, these semiprocessed products will lose most of the treatment compound during subsequent operations. Nevertheless, the tendency of national and international regulations is progressively to restrict the use of sulfur dioxide, or even to ban it altogether, since it has been shown on occasion to be implicated in severe disorders in asthmatics.

4-Hexylresorcinol

4-Hexylresorcinol is probably the most promising among the recently identified browning inhibitors. This compound has obtained the GRAS status for use in the prevention of shrimp melanosis. In this case, a low concentration of 4-hexylresorcinol, up to 25-fold lower than sulfites, is required to obtain a comparable browning inhibition. Moreover, several studies have shown that this compound used either alone or in combination with ascorbic acid could adequately replace sulfites in different plant foodstuffs such as apple slices, potatoes, avocadoes, or apple and grape juices.

Assays for Evaluation of Browning

Accurate methods are required for the measurement of browning in tissue slices and extracts. This need is obvious when different cultivars are to be compared for susceptibility to browning or for evaluation of experimental treatments designed to control enzymatic browning.

Basically, two kinds of techniques are available. The first uses absorbance measurements, usually in the 400-nm region, on solutions after extraction and purification of the brown pigments. The second uses

tristimulus reflectance colorimetry and can be applied directly to cut surfaces or fruit purée. Although both methods are easy and rapid, they do have serious disadvantages. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Absorbance measurements evaluate only the soluble pigments. It is well known that, as the reaction proceeds, polymerization occurs (*See* preceding article **Browning**: Toxicology of Nonenzymatic Browning) and the solubility of a large part of the brown pigments decreases. The insoluble entities are eliminated during the filtration and centrifugation steps in the purification process. Moreover, according to the kind of pigments, which in turn depend on the original phenols and on their relative proportions, the wavelength of maximum absorbance ranges between 360 and 500 nm in the visible region. Therefore, absorbance measurements at a single wavelength are poorly correlated with the visual evaluation of browning.

Most of the data obtained in tristimulus reflectance colorimetry are now given as L (lightness), a (greenness or redness), and b (blueness or yellowness) values, or a combination of these factors. However, the values obtained are highly dependent on the method of measurement and on the state of the surface of the examined object. Thus, during browning, variations in tristimulus data are the result of both chemical and physical changes, the relative importance of the two processes being difficult to assess. Most authors use the decrease in lightness δL (i.e., the difference in L values before and after browning) to evaluate the extent of browning. Some authors have proposed a more sophisticated parameter, the color difference (before and after browning) δE, which can be calculated as:

$$\delta E = \sqrt{[(\delta L)^2 + (\delta a)^2 + (\delta b)^2]}$$

This value gives the distance in color space between two colors but not the direction in which they differ. Moreover, neither δL nor δE gives an idea of the resulting perceived color.

In intervarietal comparisons, numerous authors have tried to correlate the extent of browning, measured by one of the above methods with the phenolic content and/or the PPO activity (Table 1). Clearly, there is no clear-cut relationship between browning and any of these chemical parameters for all fruits. Thus, depending on the fruit species, a correlation can be obtained with both the parameters, one of them, or neither. There are two potential explanations for these difficulties. First, methods for evaluation of browning are only approximate and improved specificity is required. Second, the chemical parameters, and especially, the total phenolic content, are probably not sufficient to explain the extent of browning. In the preceding article **Browning**: Toxicology of Nonenzymatic Browning, it has been stressed that PPO has a wide specificity towards phenolic compounds, which are enzyme substrates to varying degrees. Moreover, the pigments resulting from these phenolics vary widely in color intensity and hue. Therefore, the relative balance among the different classes of phenols as well as the total phenol content are probably fundamental in explaining the degree of browning. Studies carried out both on apple cultivars and on model solutions of phenolic compounds oxidized under standardized conditions by purified apple PPO illustrate these remarks. Thus, the browning susceptibility of apple cultivars can be adequately determined by the simultaneous measurements of soluble (absorbance at 400 nm) and insoluble (lightness) brown pigments. Soluble pigments are correlated to the amount of hydroxycinnamic (mainly chlorogenic acid) esters degraded, whereas insoluble pigments are correlated to the flavan-3-ols ((−)-epicatechin and procyanidin B_2) degraded. Similarly, in model solutions containing both chlorogenic acid and (−)epicatechin oxidized by a constant amount of purified apple PPO, the tristimulus color values and the absorbance values at 400 nm are strongly correlated to the initial and degraded amounts of chlorogenic acid and (−)-epicatechin

Table 1 Relations between the extent of browning, phenolic content, and polyphenol oxidase (PPO) activity in different fruit species[a]

		Correlation with[b]		
Species	*Number of cultivars*	*Phenolics*	*PPO*	*Method used*[c]
Apple	7	0	0	S (A = 440 nm)
	3	+	0	S (A = 440 nm)
	4	0	+	S (A = 440 nm)
	6–8	+		R (tristimulus)

HD, hydroxycinnamic acid derivatives; FO, flavonols; FA, flavanols; DC, dihydrochalcones.
Adapted from Goupy P, Amiot MJ, Richard-Forget F, Duprat F, Aubert S and Nicolas J (1995) Enzymatic browning of model solutions and apple phenolic extracts by apple polyphenoxidase. *Journal of Food Science* 60: 497–501, 505.

(Table 2). Multilinear regression analysis indicates that both phenolics play a role in the darkening (decrease in *L*) and yellowness (increase in *b*). Chlorogenic acid contributes to redness (increase in *a*) whereas (−)-epicatechin is almost without effect. The same kind of experiments carried out on phenolic compounds extracted from nine different apple cultivars shows that the browning extent of the phenolic solutions after oxidation by purified apple PPO is strongly correlated to the initial and degraded amounts of hydroxycinnamic derivatives and flavan-3-ols (Table 3). However, besides these two classes, the flavonols and the dihydrochalcones appear to have a significant influence on the color development (mainly on the *b* value). Lastly, additional factors (other than phenols) may also be influential: some are chemical, such as the acidity and the concentration of reductants (e.g., as ascorbic acid), while others are physical, such as texture. The relative importance of each of these factors probably varies greatly from one species to another.

In conclusion, enzymatic browning can be controlled by physical treatments, which are not applicable in all circumstances, and by the use of chemical compounds. Very few of the latter are presently available to prevent enzymatic browning in foodstuffs, and none is ideal.

Ascorbic acid is a good inhibitor of browning, but cannot always be used and is, moreover, relatively expensive. Citric acid and sodium chloride have only a limited usefulness and are valuable principally as a complement to another treatment. Only sulfur dioxide is effective and inexpensive, but it has undesirable side-effects and research is therefore necessary to find a suitable substitute. For certain food products such as shrimp, 4-hexylresorcinol could be this substitute.

Existing techniques for the measurement of browning provide useful information on differences in color and color intensity. However, these techniques give a very imperfect assessment of the degree of browning as noted by an observer. The main reason is that human ocular acuity in perception of a difference in hue or color decreases sharply as the color of the object darkens or tends towards saturation. Much more work will be necessary to establish for each product a strict correlation between instrumental measurements and consumer perception.

BUCKWHEAT

G Mazza and B D Oomah, Pacific Agri-Food Research Centre, Summerland, Canada

Buckwheat

Buckwheat is a crop commonly grown for its black or gray triangular seeds. It can also be grown as a green manure crop, a companion crop, a cover crop, a source of buckwheat honey, and as a pharmaceutical plant yielding rutin. Buckwheat belongs to the Polygonaceae family and is not a true cereal. Like cereals such as wheat, corn, and rice, which belong to the grass family, however, the grain of buckwheat is a dry fruit.

Buckwheat is believed to have originated in central and northeastern Asia and was probably cultivated in China during the fifth and sixth centuries. It was introduced into Europe through Turkey and Russia during the fourteenth and fifteenth centuries and into North America in the seventeenth century. World production of buckwheat peaked in the early nineteenth century, and has declined since then. During the past 5 years (1995–1999) it has averaged about 2.7 million tonnes, with China and the former Soviet Union accounting for 58 and 34% of the global production, respectively. Other major producing countries are Brazil, Poland, the USA, Japan, Canada, France, Bhutan, Republic of Korea, and South Africa.

Types and Cultivars

Although the genus *Fagopyrum* contains at least 15 species of buckwheat, only two are utilized as food or feed, and wild buckwheat (*F. cymosum*), mainly found as tetraploid, is used on a sporadic basis as a green vegetable or as cattle forage. There are three major species of buckwheat: common buckwheat, *F. esculentum*, tartary buckwheat, *F. tataricum*, and perennial buckwheat, *F. cymosum*. Common buckwheat is also known as *F. saggitatum*, and a form of tartary buckwheat may be called *F. kashmirianum*. It is generally believed, however, that perennial buckwheat, particularly the diploid type, is the ancestral form of both tartary and common buckwheat.

Tartary buckwheat is cultivated in the Himalaya region of India and China, in eastern Canada, and occasionally in mountain areas of the eastern United States. It has some frost tolerance and is therefore

grown at higher altitudes where risk of frost damage is greater. The seeds and products made from them are greenish in color and somewhat bitter in taste. It is used primarily as feed or as a mixture of wheat and buckwheat flour, and often used as a source of rutin.

Common buckwheat is by far the most economically important species of buckwheat, accounting for over 90% of the world production. Many types, strains, and cultivars of common buckwheat exist. There are late and early maturing types, Japanese and European types, summer and fall types. Within a given type, there may be strains or varieties with tall or short plants, gray or black seeds, white or pink flowers. In general, however, common buckwheat varieties from different parts of the world may be divided into two major groups. The first group includes tall, vigorous, late maturing, photoperiod sensitive varieties found in Japan, Korea, southern China, Nepal, and India. The second group is rather insensitive to photoperiod, small and early maturing. All of the varieties in Europe and northern China belong to this type.

Prior to 1950, producers of buckwheat planted unnamed strains of buckwheat harvested from their own fields or obtained from their neighbors or local stores. Named varieties developed through plant breeding were first released in the 1950s. Tokyo, the oldest of the named cultivars introduced into North America, was licensed by the Agriculture Canada Research Station, Ottawa, in 1955. Other cultivars licensed for production in Canada are: Tempest, Mancan, and Manor, all developed at the Agriculture Canada Research Station, Morden, Manitoba since 1965. Mancan, which has large, dark brown seeds, thick stems and large leaves, is the Canadian cultivar preferred in the Japanese market because of its large seed, desirable flavor and color, and high yield of groats in the milling process. Recently, these older cultivars have been supplemented by newer cultivars such as AC Manisoba, Koban, and Koto. These new cultivars produce larger seeds and have an increased seed yield.

Cultivars licensed in the USA are Pennquad, released by the Pennsylvania Agricultural Experimental Station and the USDA in 1968, and Giant American, a Japanese-type cultivar apparently selected by a Minnesota farmer.

Cultivars developed in the former USSR since the 1950s include: Victoria, Galleya, Eneida, Podolyaka, Diadema, Aelita, and Aestoria. Representative cultivars from other areas of the world include: Pulawska, Emka, and Hruszowska from Poland: Bednja 4n from Yugoslavia; and Botan-Soba, Shinano No. 1, Kyushu-Akisoba Shinshu, and Miyazaki Oosoba from Japan.

Plant and Seed Morphology

Buckwheat plant is a broad-leaved, erect, herbaceous plant that grows to a height of 0.70–1.5 m. It has a main stem and several branches, and can reach full maturity in less than 90 days. The stem is usually grooved, succulent, and hollow except for the nodes. Before maturity, the stems and branches are green to red in color, and after maturity, they become brown. The plant has a shallow taproot from which branched, lateral roots arise. Its root system is less extensive than that of the cereals and constitutes only 3–4% of the dry weight of the total plant.

Buckwheat has an indeterminate flowering habit. The flowers of common buckwheat are perfect but incomplete. They have no petals, but the calyx is composed of five petal-like sepals that are usually white, but may also be pink or red. The flowers are arranged in dense clusters at the ends of branches or on short pedicels arising from the axils of the leaves. Common buckwheat has plants bearing one of two types of flowers. The pin-type flower has long styles, or female parts, and short stamens, or male parts, and the thrum-type has long styles and short pistils. The pistil consists of a one-celled superior ovary and a three-part style with knoblike stigmas and is surrounded by eight stamens. Nectar-secreting glands are located at the base of the ovary. The plants of common buckwheat are generally self-infertile, as self-fertilization is prevented by self-incompatibility. Seed production is usually dependent on cross-pollination between the pin and thrum flowers. Honey bees and leaf-cutter bees are effective pollinators. They increase seed set and seed yield.

The buckwheat kernel is a triangular, dry fruit (achene), 4–9 mm in length, consisting of a hull or pericarp, spermoderm, endosperm, and embryo. Large seeds tend to be concave-sided, and small seeds are usually convex-sided. The hull may be glossy, gray, brown, or black, and it may be solid or mottled. It may be either smooth or rough with lateral furrows. The hulls represent 17–26% (in tartary buckwheat 30–35%) of the kernel weight. Diploid varieties usually have less hull than tetraploids.

Structure of Kernel

Scanning electron microscopy of the buckwheat kernel has revealed that the hull, spermoderm, endosperm, and embryo are each composed of several layers. For the hull, these are in order from the outside toward the inside: epicarp, fiber layers, parenchyma cells, and endocarp. The spermoderm is composed of the outer epiderm, the spongy parenchyma, and the

inner epiderm. The endosperm is composed of an aleurone layer, 10–15 μm thick, and subaleurone endosperm containing starch granules surrounded by proteinaceous matrix. The embryo, with its two cotyledons, extends through the starchy endosperm. The terminal parts of cotyledons are often parallel under the kernel surface.

Composition

Proximate composition and selected mineral profiles of Mancan, Manor, and Tokyo buckwheat groats are shown in Table 1.

Carbohydrates

Starch is quantitatively the major component of buckwheat seed, and concentration varies with the method of extraction and between cultivars. In whole grain of common buckwheat, the starch content ranges from 59 to 70% of the dry matter. The chemical composition of starch isolated from buckwheat grains differs from the composition of cereal starches. The amylose content in buckwheat granules varies from 15 to 52%, and its degree of polymerization varies from 12 to 45 glucose units. Buckwheat starch granules are irregular, 4–11 μm in size, with noticeable flat areas due to compact packing in the endosperm. The starch has a water binding capacity of 79–104%, a blue value of 0.35, a swelling power and solubility at 60 °C of 2.35 and 0.5%, respectively, an amylograph viscosity at 92 °C of 640 Brabender Units (BU), an enzyme susceptibility (percentage of solubilized starch) of 2.63%, and an initial and final gelatinization temperature of 61.5 and 76.0 °C, respectively.

Buckwheat grains also contain 0.65–0.76% reducing sugars, 0.79–1.16% oligosaccharides, and 0.1–0.2% nonstarchy polysaccharides. Among the low-molecular-weight sugars, the major component is sucrose. There is a small amount of arabinose, xylose, glucose, and probably the disaccharide melibiose. (*See* **Sucrose**: Properties and Determination.)

Proteins

The protein content in buckwheat varies from 7 to 21%, depending on the variety and environmental factors during growth. Most currently grown cultivars yield seeds with 11–15% protein. The major protein fractions are globulins, which represent almost half of all proteins. The globulins consist of a major 13S legumin-like and a minor 8S vicilin-like fractions. The 13S fraction consists of eight subunits with molecular weights between 43 000 and 68 000. The 8S fraction consists mainly of 57 000 polypeptides with a few subunits in the 26 000–36 000 range. The albumin represents about 25% of the total seed proteins and consists mainly of a low-molecular-mass single-chain polypeptide of 8–16 kDa. Glutelin represents only 4% of the total seed protein. Prolamin has been fractioned into at least two peaks by gel filtration of Sephacryl S-200 and into three major and several minor components by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE). (*See* **Protein**: Chemistry.)

Buckwheat proteins are particularly rich in lysine. They contain less glutamic acid and proline, and more

arginine, aspartic acid, and tryptophan, than cereal proteins. Due to the high lysine content, buckwheat proteins have a higher biological value (BV) than the cereal proteins such as those of wheat, barley, rye, and corn. The digestibility of buckwheat protein, however, is rather low, and this is probably due to the high fiber content (17.8%) in buckwheat, which may be desirable in some parts of the world. Buckwheat fiber is free of phytic acid and is partially soluble. (*See* **Dietary Fiber**: Properties and Sources.)

Lipids

Whole buckwheat seeds contain 1.5–3.7% total lipids. The highest concentration is in the embryo and the lowest in the hull, each containing 7–14% and 0.4–0.9%, respectively. Groats or dehulled seeds of Mancan, Tokyo, and Manor buckwheat contain 2.1–2.6% total lipids (Table 1), of which 81–85% are neutral lipids, 8–11% phospholipids, and 3–5% glycolipids. The major fatty acids of buckwheat lipids are palmitic (16:0), oleic (18:1), linoleic (18:2), stearic (18:0), linolenic (18:3), arachidic (20:0), behenic (22:0), and lignoceric (24:0). Of these, the 16 and 18 carbon acids are commonly found in all cereals. The long chain acids, arachidic, behenic, and lignoceric, which represent, on average, 8% of the total acids in buckwheat, are only minor components or are not present in cereals. (*See* **Phospholipids**: Properties and Occurrence.)

Phenolic Compounds

The content of phenolics in hulls and groats of common buckwheat is 0.73 and 0.79%, and that of tartary buckwheat is 1.87 and 1.52%, respectively. Common buckwheat grown in Canada contains 1.2–1.6% of total phenolics with 70–79% of the phenolic acids being etherified. The total flavonoid concentration in common buckwheat seed and hulls varies with cultivar and location, and ranges from 19 to 387 and from 74 to 1314 mg per 100 g, respectively. Six flavonoids, rutin, orientin, vitexin, quercetin, isovitexin, and isoorientin, have been isolated and identified in buckwheat. Rutin and isovitexin are the only flavonoid components of buckwheat seed, while the hulls contain all six compounds. Rutin (quercetin 3-rutinoside), a well-known flavonol diglucoside used as a drug for treatment of vascular disorders caused by abnormally fragile or permeable capillaries, occurs in leaves, stems, flowers, and fruit of buckwheat. On average, about 300, 1000, and 46 000 p.p.m. of rutin are found in leaves, stems, and flowers, respectively, of common buckwheats. Other reported flavonols are quercitin (quercetin 3-rhamnoside) and hyperin (quercetin 3-galactoside). At least three red pigments have been found in hypocotyls of buckwheat seedlings. One of these is cyanidin; the other two are presumed to be glycosides of cyanidin. The phenolic acids of buckwheat seed are the hydroxybenzoic acids, syringic, *p*-hydroxylbenzoic, vanillic, and *p*-coumaric acids. Also in seed are soluble oligomeric condensed tannins, which, along with the phenolic acids, provide astringency and affect the color and nutritive value of buckwheat products. (*See* **Phenolic Compounds**.)

Biological Effects

Common buckwheat and its components are regarded as functional foods in Japan because of its rutin content. Rutin is known to increase the elasticity of blood vessels and therefore prevent hardening of the arteries. According to Chinese medicine, the leaf and stem of tartary buckwheat have a therapeutic function in treating ulcer, hemostasis, and hypertension, may improve vision and hearing, and acts as an adaptogen. In Nepal, consumption of tartary buckwheat is reported to aid in stomach disorders. Consumption of buckwheat has been associated with prevention and treatment of hypercholesterolemia. This effect of common buckwheat is due to its protein, which has a stronger hypocholesterolemic activity than that of soy protein isolate and behaves similar to dietary fiber. Intake of buckwheat protein extract retards mammary carcinogenesis in rats by lowering serum estradiol and reduces body fat because of its low digestibility. Bioactive peptides from buckwheat pollen have an immunostimulatory effect on lymphocytes and may therefore act as an immunomodulator in increasing immunity and curing cancer.

Buckwheat flour has been proposed to have physiological activity in the treatment of hyperlipemia, hyperglycemia, diabetes, and cardiovascular disease. A decrease in blood sugar level has been observed clinically in 75 diabetic patients treated with tartary buckwheat biscuits. Buckwheat bran is known to contain fagopyritols, a group of phytochemicals acting as an insulin mediator, that may have an important pharmacological use in the treatment of noninsulin-dependent diabetes mellitus (NIDDM). Rutin from buckwheat prevents the oxidation of ascorbic acid and protects the endothelium when given with vitamin C. Hence, the combination of fagopyritols and rutin can have a significant effect on the prevention of diabetes.

Buckwheat herb tea standardized to a total flavonoid content of 5% has been reported to prevent edema in patients with chronic venous insufficiency (CVI). This positive pharmacological effect is thought to be due to the capillary action of rutin resulting in

venous microcirculation. Leaves and flowers of buckwheat have been dehydrated and packaged with other essential oils for protection of the vascular system as a result of the rutin content. Tartary buckwheat has been reported to treat periodontitis and gum bleeding because of the high contents of quercetin and rutin. Green flour obtained by milling dried flowering buckwheat plants is already used in Japan as a natural food colorant for pasta, ice cream, and other food products as a source of dietary rutin.

Grading, Handling, and Storage

Grading

In most countries, buckwheat grain is priced according to its physical condition in terms of size, soundness, and general appearance. In Canada, buckwheat is marketed according to grades established under the Canada Grain Act. The grades are No. 1, No. 2, and No. 3 Canada, and Sample. The grade determinants are minimum test weight, degree of soundness, and maximum limits of foreign material (Table 2). Grades No. 1 and 2 Canada must be free from objectionable odors; No. 3 Canada may have a ground or grassy odor but should not be musty or sour. Test weight, seed size and foreign material are determined on a dockage-free sample. Seed size is determined with a No. 8 slotted sieve (3.18×19.05 mm) and is added to, and becomes part of, the grade name, e.g., buckwheat, No. 1 Canada large. Foreign material refers to cereal grains (wheat, rye, barley, oats, and triticale), weed seeds, and other grains that are not readily removable by mechanical cleaners and may include peas, beans, corn, and other domestic or wild weeds. Samples containing in excess of 5% are graded buckwheat, sample Canada (size) account admixture. Damaged seeds include frosted, moldy, distinctly green, or otherwise unsound and dehulled seeds.

In the USA, buckwheat is not marketed under official grades established by the USDA. However, some states (e.g., Minnesota) have Official Grain Standards that specify the use of Grades 1, 2, 3, and Sample. The grade determinants are similar to those of the Canadian grading system. The Russian standards for food buckwheat are: moisture ≤ 14.5, extraneous matter $\leq 3\%$ (including 0.2% mineral admixture of which 0.1% may be stones), pernicious admixtures $\leq 0.2\%$, spoiled grain $\leq 0.5\%$. The Japanese Buckwheat Millers Association prefers buckwheat, which has large and uniform seeds with black hulls and greenish groats.

Handling

The method of handling varies among production areas. In most cases, however, losses and quality changes of the grain occur at various postharvest stages. During harvest, shattering and losses due to germination, animals such as birds and rodents, and infection by molds occur in all countries. Threshing is done with combines or by beating the dried plants against stones or wooden bars, or by trampling the plants under bullock feet, carts, or tractor wheels. Transportation of grain from the field to market results in losses and quality deterioration. Losses during transportation are mainly due to spillage. However, exposure of the grain to rain or frost during transit leads to subsequent spoilage due to infection by microorganisms. (*See* **Cereals**: Handling of Grain for Storage.)

Storage

Like other grain crops, buckwheat is stored to ensure an even supply through time, to preserve the surplus grain for sale to deficit areas, and to be used as seed in the next planting season. Storage of the seeds may be at the farm, trader, market, government, retail, or consumer levels. Storage containers range from sacks to straw huts to bulk storage bins. In developing countries, traditional storage structures include: granaries of gunny, cotton, or jute bags, or structures manufactured from reed, bamboo, or wood and plastered with mud and cowdung. In North America, storage structures include metal, concrete, or wooden bins at the farm level, elevators and annex at

Table 2 Primary-grade determinants of buckwheat (Canada)

Grade	*Minimum seed density (kg hl^{-1})*	*Degree of soundness*	*Maximum limits of foreign material (%)*

No. 2	55	Reasonably well matured, cool, and sweet	3.0	0.05	0.05	2.5	3.0
No. 3	No minimum	May have a ground or grassy odor, but should not be musty or sour	3.0	0.25	0.25	5.0	5.0

[a]Number of kernel size stones in 500 g.

centralized receiving, storage and shipping points, and concrete silos at grain terminals. Bagged buckwheat is highly susceptible to attack by insects and rodents. Bulk storage in bins, elevators, and silos is recommended. (*See* **Cereals**: Bulk Storage of Grain.)

A moisture content of 16% of less is required for safe storage of buckwheat. If the seed requires drying, the maximum temperature of the drying air should not exceed 43 °C (Table 3). This temperature limit applies to seed for both seeding and processing. During storage at ambient temperature and relative humidity, the color of the aleurone layer changes from a desirable light green to the undesirable reddish brown. This undesirable quality change can be reduced by storing the seed at a lower temperature and at a relative humidity below 45%. Seeds can also be stored under controlled atmospheres (97% N_2, 1.5% O_2, and 1.5% CO_2). However, concentration of the major volatiles decreases, while the content of odor-active volatiles such as hexyl acetate and 1-hexanol increases in seeds stored under controlled atmosphere for 60 weeks. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

Primary Processing

Primary processing of buckwheat includes cleaning, dehulling, and milling. The aim of seed cleaning is to remove other plant parts, soil, stones, weed seeds, chaff, dust, seeds of other crops, metallic particles, and small and immature buckwheat seeds. The extent and sophistication of the cleaning equipment depend largely on the size of the operation and the requirements for the finished product(s). Milling of buckwheat seed can be carried out virtually by any equipment capable of milling cereal grains. Hammer mills, stone mills, pin mills, disk mills, and roller mills have been used to mill buckwheat. Of these, stone mills and roller mills are probably the most extensively used today.

The milling process may be of two types. In the first and most common type, the whole seeds are first dehulled and then milled. In the second type, the seeds are milled and then screened to remove the hulls. When dehulling and milling are separate operations, the seeds are segregated according to size and may be steamed and dried prior to dehulling. Dehulling is carried out by impact or abrasion against emery stones or steel, followed by air or screen separation of groats and hulls. A widely used buckwheat dehuller is built on the principle of the stone-milling with emery stones set to crack the hull without breaking the groat. The effectiveness of this type of dehuller depends on the clearance between the seed cracking surfaces, and for any seed size, there is an optimum setting. The ease of dehulling and percentage recovery of undamaged groats depends on variety and moisture content. From the dehuller, the groats are separated over sieves of different mesh for sizing into whole groats and two or more sizes of broken groats. Flour is produced by passing the groats through stone and/or roller grinders. (*See* **Flour**: Roller Milling Operations.)

When buckwheat seed is to be processed only into flour, and production of groats is not a requirement,

Table 3 Amino acid composition of buckwheat protein and its fractions

Amino acid	*Whole buckwheat*[a]	*Buckwheat groats*[a]	*Light flour*[a]	*Salt-soluble proteins*[b]	*Albumins*[b]

[b]Data from Radovic RV, Maksimovic RV, Brkljacic MJ *et al*. (1999) 2S albumin from buckwheat (*Fagopyrum esculentum* Moench) seeds. *Journal of Agriculture and Food Science* 47: 1467–1470, with permission.

the seeds are ground on break rolls or stone mills and then screened to separate the coarse flour from the hulls. The coarse flour is further reduced by a series of size reduction rolls, each grinding operation followed by sifting to fractionate the mixture of particles according to size. The flour yield ranges from 50 to 75%, depending on the size, shape, and condition of the seeds and efficiency of the dehulling and milling operations.

End Products

Buckwheat has multiple uses. It is used to make alcoholic drinks, the liquor prepared from tartary buckwheat being ascribed medicinal qualities. In China, it is used in the production of vinegar. Common buckwheat is also used as a source of nectar for honey production in many countries. Buckwheat is useful as a green manure crop for renovation of low-productivity land. The plant has been used as a smother crop as it germinates rapidly and produces a dense canopy that controls broad-leaved weeds. It also acts as a feed and cover crop for wildlife including deer, wild turkeys, and other birds.

Buckwheat flour is generally dark in color due to the presence of hull fragments. In North America, it is used primarily for making buckwheat pancakes, and is commonly marketed in the form of prepared mixes. These mixes generally contain buckwheat flour mixed with wheat, corn, rice, oat or soybean flours, and a leavening agent. Buckwheat is also used with vegetables and spices in kasha and soup mixes, and with wheat, corn, or rice in ready-to-eat breakfast products, porridge, bread, and pasta products.

In Japan, buckwheat flour is used primarily for making *soba* or *sobakiri* (buckwheat noodles) and *Teuchi Soba* (hand-made buckwheat noodles). These products are prepared at *soba* shops or at home from a mixture of buckwheat and wheat flours. The wheat flour is used because of its binding properties and availability. *Soba* is made by hand or mechanically. In both methods, buckwheat and wheat flours are mixed with each other and then with water to form a stiff dough that is kneaded and rolled into a thin sheet (1.4 mm) with a rolling pin or passed between sheeting rolls and cut into long strips. The product may be cooked immediately, sold fresh, or dried. (*See* **Wheat**: The Crop.)

In Europe, most buckwheat is milled into groats, which are used in porridge, cabbage rolls, or meat products (especially hamburger), or consumed with fresh or sour milk. Buckwheat groats with cottage cheese, sugar, peppermint, and eggs is used as stuffing in a variety of dumplings. Buckwheat flour is used with wheat or rye flour and yeast to make fried specialty products such as bread, biscuits, and other confectioneries. An extruded, ready-to-eat corn–buckwheat breakfast product of high nutritional value is being produced and marketed in western Europe. This product contains over 14% protein and 8% soluble fiber. Similar products have also been developed in Poland and the former USSR.

In most countries, the quality of buckwheat end products is controlled by law. According to Canadian Government Specifications, buckwheat flour must have $\leq 1.5\%$ ash and $\geq 1.1\%$ protein nitrogen on a 14% moisture basis, and contain $\leq 12\%$ moisture when delivered. Class B Pancake Mix should contain more than 40% and less than 50% buckwheat flour with admixtures of 50% wheat, corn, rice, or soybean flour.

Introduction

The world population of buffaloes has been estimated to be over 140 million heads. It can be seen from **Table 1** that about 97% of these are found in Asia and the Pacific regions. India has 75 million, China 21 million, Pakistan 14 million, and Thailand 6 million, which makes up most of the animals. About 98% of these animals are raised by small farmers owning not more than 5 acres of land and not more than five buffaloes.

Buffaloes (*Bubalius bubalis*) originated from the Indo-Gangetic plains, thrived in Asia, and have been a symbol of life, religion, and endurance. Buffaloes are classified into two classes: swamp buffaloes and water buffaloes. Buffalo raising mainly supports crop farming, especially rice cultivation. It is suggested that water buffaloes were in the service of humans as early as 2500–2100 BC.

The awareness of the potential of water buffaloes for meat has increased in recent years throughout the world due to its high content of lean meat. Buffalo meat is 25% higher in protein than beef and 50% lower in cholesterol. Most buffalo meat is derived from old animals slaughtered at the end of their productive life. As a result, much of the buffalo meat sold is of poor quality, but when buffaloes are properly reared and fed, their meat is tender and palatable.

Average cattle carcass weight in developing countries was much lower than that in developed countries and is not increasing rapidly. Therefore, despite a large increase in the number of animals slaughtered between 1974–76, 1980–82 and 1995–96, the contribution of developing countries to world beef supplies

Table 1 World distribution of buffaloes with slaughter rate and meat production in some Asian countries

Country	*Population (1000 heads)*	*Slaughtered (1000 heads)*	*Slaughter rate as a % of the population*	*Annual meat production (1000 tonnes)*
World	129 283	7461	5.8	1006

has not increased proportionally. In view of the immense cattle resources of developing countries – some 65.2% of the world's total – a priority development objective in the tropics, where most developing countries are located, must be to increase productivity per head of cattle. Developing countries contributed some 27.8% of world beef and veal production in 1974–76, rising to 33.3% in 1982 and 39% in 1996.

Buffalo Nutrition

Buffaloes are mostly located in countries where land, cultivated forage crops, and pastures are limited. They are mainly raised on crop residues, sometimes supplemented with green fodder or byproducts, available from the processing of cereal grains, oil seeds, fruit, and vegetables. Buffaloes are known to be good converters of poor-quality roughage into milk and meat. They are reported to have a 5% higher digestibility of crude fiber than high-yielding cows and a 4–5% higher efficiency of utilization of metabolic energy for milk production. Buffaloes can gain as much as 1 kg in weight per day in good-quality roughage and concentrates. They digest feed more efficiently than cattle, particularly when feeds are fibrous and high in lignin and cellulose.

Carcass Dressing

The best and most hygienic way to dress a carcass is with the carcass hanging from some kind of hoist. Whether or not the carcass is hung, the nature of the dressing technique and the way that the carcass is cut will depend upon local custom and, of course, upon variations in marketing techniques which may differ even within a community. One may find different categories of butchers, working with different facilities and often situated adjacent to each other, preparing different cuts of meat to suit a particular market.

In major meat-producing countries the whole side of meat is dressed and cut, but in many tropical countries this is not practical. The hot carcass is cut into several recognizable pieces that facilitate transport which may be on a man's head, on a cart, or even in the boot of a taxi. Although such methods expose the carcass cuts to contamination, they do at least insure rapid distribution of fresh meat. Most consumers in the tropics still demand fresh and not chilled or frozen meat.

Hide should be carefully removed, using proper knives to avoid damage to this valuable byproduct. The carcass should be washed after dressing. The stomach and intestine should be cleaned out and washed, and the contents and washings disposed of separately, as is the blood. Stomach and gut casings may be processed in the tripery.

General Examination of the Carcass

This should be done in a methodical manner, whatever the status of the slaughter house or abattoir facilities. The criteria laid down, for example in the UK, regarding methods and stipulations of meat inspection can also apply to meat inspection in a tropical environment. Every carcass should be examined for the following.

State of Nutrition

Physiological leanness resulting from lack of feed and water must be differentiated, as far as possible, from pathological leanness due to disease. In trade cattle in the tropics this may be difficult since, in many cases, cattle on long treks are not only deprived of food, but exposed to tick-borne diseases. In a temperate climate the percentage of water within the meat of normal buffalo is not above 76.5% and the percentage of protein is about 22% or a ratio of less than 4:1. In extremely emaciated animals the ratio may be 80% water and 19% muscle, or greater than 4:1. Emaciated meat has no place in the export market.

Bruising, Hemorrhage, and Discoloration

This condition is undesirable in any carcass, whether it is due to some localized condition, or more generalized conditions, such as helminthiasis, trypanosomiasis, and tick-borne diseases. Edema reduces carcass quality and storage stability of the meat.

Efficiency of Bleeding

This is pertinent to any community since it affects both keeping quality and flavor of meat. Most consumers in the tropics do not eat meat that is improperly bled and because of this local butchers are often highly suspicious of stunning and new slaughter methods. They insist on casting the animal and cutting the jugular vessels or cutting off the head, pithing, or some other slaughter technique that insures good bleeding-out.

Swelling and Deformities

This receives much less attention under slaughter conditions in the rural tropics, where meat is more of a luxury for special occasions, than in the larger abattoirs adjacent to urban communities.

Age and Sex

These factors are also not considered in most tropical countries unless quality meat is required for elite households or special occasions.

Abnormal Odors

These do not arouse particular attention in the cattle and buffalo meat market unless, for example, there is some specific odor encountered, as in putrefying meat or in the sweet-smelling meat of rinderpest-infected animals.

Buffalo Meat Quality

Buffalo carcass has rounder ribs, a higher proportion of muscle, and a lower proportion of bone and fat than beef. Buffalo meat is higher in protein content than the meat of other species. The amino acid composition, especially of critical amino acids of skeletal muscles, is higher than that of the ox. Buffalo beef has more isoleucine, leucine, lysine, phenylalanine, tyrosine, threonine, valine, and histidine but less tryptophan, cystine, and methionine than beef. Except for cystine, the daily allowance recommended by the Food and Agriculture Organization can easily be met by carabeef as the principal source of protein. About 100 g of carabeef lean meat per head per day is enough to meet all the amino acids (except cystine) required for the body. Buffalo meat has about 44% more lysine than egg protein. Buffalo meat and beef are in many ways quite similar, e.g., muscle pH (5.4), shrinkage on chilling (2%), moisture (76.6%), protein (19%), and ash (1%). Buffalo fat, however, is always white and buffalo meat is darker in color than beef because of more pigmentation and less intramuscular fat (2–3%), which leads to 'marbling,' compared with beef (3–4% intramuscular fat). Some of the data regarding carcass components of buffaloes slaughtered at different body weights is given in Table 2.

Detailed Inspection of the Carcass

After a general examination the carcass is subjected to a more detailed examination. The following is a summary of procedures applicable in a tropical environment.

Table 2 Effect of body weight on carcass components of buffaloes

Slaughter body wt (kg)	*Carcass wt (kg)*	*Dressing (%)*	*Meat (%)*	*Fat (%)*	*Bone (%)*
480	277	59.7	66	17	14
446	239	53.6	69	13.1	17.9
356	193	62.8	66.7	12.9	19.7
300	151	51	70	6	19
260	141	55.5	67	12	18
258	139	53.9	67.5	12.7	19.8
161	83	51.4	66.8	9.7	23.5

Reproduced from Mudgal VD and Sharma DD (1993) Buffalo meat. In: *Encyclopaedia of Food Science, Technology and Nutrition*, vol. 1, pp. 521–529. London: Academic Press, with permission.

The Head

1. The tongue should be loosened but not detached and the surface and deep structures inspected.
2. The gums and root of the mouth should be inspected.
3. The lymph glands around the pharynx and large salivary gland behind the angle of the jaw are examined. Lymph glands act as filters of disease agents and, if swollen, hemorrhagic, or abscessed, indicate disease in the tissues that they drain.
4. The cheek muscles should be free from oozing serum and should not be of yellow or greenish color.
5. The eyes should be examined for microbial defects.

Abdominal Cavity

Stomach, intestines, and spleen The outer, and when necessary, the inner surfaces of the stomach and intestines, the surface and substance of the spleen, and the surfaces of the omentum or loose covering over the stomach should be examined. The lymph glands related to these organs are also examined.

Liver The surface and substance of the liver should be examined and the bile ducts incised to check for the presence of the liver fluke. The thick end of buffalo livers should be incised and examined in detail.

Kidneys The renal, lymph glands and adrenal glands should be examined and, when necessary, the kidneys should be exposed and incised.

Uterus and Ovaries The substance of the uterus, its inner and outer surface should be examined.

Chest Cavity

The pluck should be examined before the organs are separated from each other. Lungs should be examined by observation and palpitation and, unless obviously diseased, they should be incised at the base. The heart covering should be opened and the heart examined and, if necessary, incised.

Udder

This should be incised and examined by observation and palpation and the associated supermammary lymph glands should be examined in detail.

Testicles and Penis

The outer surface and substance of the testicles and penis should be examined. The superficial inguinal lymph glands or those situated under the skin in the groin area should be examined in detail.

Feet

The feet should be examined, especially for lesions suggesting foot-and-mouth disease.

Buffalo Meat Products

Buffalo meat is used as a food item in a similar way to other meats such as beef (e.g., grilled, fried, etc.). In South Asia meat curry is also prepared. Buffalo meat has very good emulsification and binding properties and is ideal for sausage making. Buffalo meat has all the properties needed to prepare direct meat products such as pastarma and gabrovi in Bulgaria, and biltong in Nepal and Brazil. The common Asian uses of buffalo meat are kebabs, koftas and tikkis, bheja, curries, corned meat, and sausages.

Preservation of Buffalo Meat

Although fresh meat has the highest nutritional value and is preferred by most consumers, it is frequently preserved and stored for future consumption. The four most widely used preservation methods are drying (including smoking), curing, canning, and refrigeration. In many cases, combinations of these, for example, drying and salting, are used together to produce the desired results.

Drying

Air drying of meat dates back to early human history and, although commercial techniques for the preparation of dehydrated meat are available, these are generally very costly to operate. Air drying is a comparatively simple process, provided it is done in hot, dry weather. Physiological emaciation of cattle, commonly found in starved animals, does not interfere with the final dried product, although the yield from such carcasses may be low. One of the best known dried meat products is biltong. Although simple and cheap to prepare, preslaughter care of animals is essential for the production of biltong that has good keeping qualities. The procedures for biltong production are as follows:

1. The carcass meat is cut into long strips of equal thickness, cutting the fibers lengthwise. The best dried meat is obtained by physically tearing rather than cutting the muscles so that groups of fibers can be dried as a unit.
2. Strips of meat are then salted either by rubbing the salt by hand just before hanging or strips are left covered with salt overnight. Spices and peppers may be added, according to local taste, also saltpeter, which is a mild preservative which also imparts a good red color to the meat.
3. The strips of meat are then hung in the sun on galvanized wire in such a fashion that they should not touch one another, to allow free circulation of air.
4. After about 12 h drying the strips should be removed, straightened, and turned round for the other side to be properly dried. The time taken for good drying will depend upon the weather.
5. Where dried meat is to be kept for periods longer than 4–6 weeks, it may be necessary to smoke it or to add surface insecticide in low concentrations, if this is allowed by local ordinances. Such dried meat is best stored in polythene bags.

The advantages of dried meat are due to its high content of protein, its good keeping qualities if protected from moisture and attacks of insects such as beetles, and its retention of minerals and vitamins after processing. The disadvantages are that exposure to air and light can bring about rancidity of the fat. Exposure to moisture will also lead to decomposition and/or moldiness. Dried meat can be eaten dry, or raw, or it can be treated as fresh meat, after soaking in water.

Salting and Drying

Salted meat, known as charqui, is first cured in salt and then dried, and differs from biltong in that it contains more moisture. When processed, it resembles dried salted fish in appearance. Pieces of fresh meat for initial curing should be 1.5–2.5 kg in weight and about 2.25 cm thick. These are first hung for a period of about 1 h to cool, after which they are then allowed to drain off on slats. Final curing consists of placing the pieces of meat in a series of layers with about 2.25 cm salt between them, to make up a series of meat/salt layers some 1.25 m high. The pile of layers is then covered with planks and heavy stones to press the pile. The next day the layers in the pile are reversed in position, and this reversal of layer position continues for 5 days, after which the meat is ready for drying. This is done by pressing the meat between planks, or by passing it through a sort of wooden mangle. In hot, dry climates, sun drying on bamboo slats or on chicken wire in the early morning and evening is sufficient. The meat should not be allowed to overheat, otherwise the fat will melt. This type of dried, salted meat has good keeping quality. Before eating it should be soaked in water, which is then poured away in order to get rid of excess salt.

Dehydration

Dehydrated meat is prepared using special equipment to control temperature and humidity, as well as being carried out under a vacuum. The process is generally not suited to the developing stages of beef and buffalo meat industries. The chief advantages of dehydrated meat are its light weight, ease of storage and packing, and the reliability and excellence of the water-reconstituted product. Two major processes of preparation are the vacuum contact plate process and the Platt or Zimmerman process. In the Zimmerman process fresh meat is immersed in heated oil under vacuum; the oil acts as a medium for the transfer of heat to the meat. There are certain technical difficulties in removing all the oil from the meat by centrifugation, but this method is cheaper than the vacuum contact plate process.

Heat Sterilization (Canning)

The principle of this process is that the produce is sealed in a container after applying heat to kill microorganisms which may cause spoilage of the product. The process is not dissimilar to that of home bottling of fruit. The basic principles involve heating the food product sufficiently to kill the microorganisms, followed by sealing in a vacuum. The length of heating time will depend on several factors, including the type of microorganisms to be destroyed, the moisture content and acidity of the product, the amount of protection offered by fats or oils, and the quantity of other substances, such as salt, that may be present. Meat for this process must be properly prepared before canning and, if necessary, precooked. Oxygen and air are driven off to provide the vacuum, either by closing the can under vacuum, or by passing the can through an exhaust box, where the air and oxygen are driven off by heat and the can is sealed before cooking.

Smoking

This is one of the oldest methods of preserving meat, the simplest method being to hang slices above an open fire. It imparts good keeping qualities and, provided the right woods are used, a pleasant flavor. Smoked meat does not easily go bad and it is also resistant to flies and beetles. Its longer keeping properties can be improved by a combination of curing and smoking. Smoked meat is often prepared for export in developed countries. For these and to dampen down the smoke, an alternative method is to use a large oil or petrol drum, the bottom of which is removed and the top made into a lid. A fire pit is dug near the drum and the smoke from the pit is directed through a covered trench into the base of the drum, in which the meat is hung. The smoke escapes through the top, where the lid can be adjusted to control its rate of flow. Meat for smoking must not come from fevered or emaciated animals. Such meat remains wet and flabby and does not smoke well.

Meat may be smoked raw or after being cured or previously cooked. It should be cut along the muscle fibers into flat slices to allow good smoke penetration. Large pieces of meat need higher temperatures and a longer period of smoking. Where salt-cured meat is used for smoking, the brine should be washed off the surface of the meat with clean water, otherwise the salt will form a crust on the surface of the meat during smoking.

Refrigeration

Preservation of meat by this method was first used on a commercial basis in northern Europe, using natural ice shipped from the Arctic. Mechanical refrigerators came into use during the latter part of the nineteenth century in order to ship meat from the Argentine, Australia, and New Zealand to Europe. There are now rapid developments in refrigerator transport of meat carcasses from production areas to internal consumer markets and for export in some tropical countries. There are three major temperature ranges at which buffalo meat is processed by cooling. These are: the initial cooling range (0 to $-5\,^{\circ}C$), the chilling range (-3–$10\,^{\circ}C$), and the freezing range (-10 to $-18\,^{\circ}C$).

Curing and Pickling

There are several methods and substances used for preserving by curing. Some of these are used for curing pork and other meats, but only those relevant to beef and buffalo meat will be briefly mentioned here. Curing is not the same as preserving meat by the use of antiseptics. Curing agents such as salt, sugar, or vinegar are harmless for the consumer, and while they do not kill microorganisms they prevent their multiplication. At the same time, they may also impart special flavors or even improve the flavor of some products. Antiseptics and certain other chemical preservatives may kill microorganisms, but if improperly used may be harmful to the consumer, so there is strict legal control over their use. The following ingredients are used for curing and preservation: salt and sugar used in high concentration and also jointly with other curing ingredients, Bengal saltpeter or potassium nitrate, Chile salt peter or sodium nitrate, vinegar, and various spices. Although spices are mainly used to impart flavor, they also have some inhibitory action in high concentrations on microorganisms. Cures may be used dry, when the dry ingredient is rubbed

into the surface of the meat, or in solution as in pickling and brining, or as a mixture.

Utilization of Waste from Buffalo Meat Industry

The waste (excluding meat, bone, fat, and hide) amounts to 25% of the live weight. The list of various wastes obtained from the buffalo meat industry and their uses is given in Table 3.

Microbiological Quality of Meat

Contamination of buffalo meat may occur through the water used in the abattoir and meat-processing plant, equipment used for processing, and personnel handling the product. The microflora consists of bacilli, micrococci, streptococci, and staphylococci, *Escherichia coli* and other coliforms, pseudomonads, salmonellae, clostridia, yeasts, and fungi. The type of microflora depends upon the initial source of contamination of the carcass and additional contamination during subsequent handling of the meat. The standard plate counts of meat processed in plants are reported to be around 10^5 cfu g^{-1}. The lower number of organisms in buffalo meat processed in modern slaughterhouses could be attributed to the better hygienic measures employed during processing.

Table 3 Important biochemicals and pharmaceuticals obtained from the buffalo meat industry

Byproducts	*Biochemicals /pharmaceuticals*
Blood	Plasma, serum, albumin, hematinics, blood-meal
Fibrin	Peptone, fibrin foam, fibrin powder, bioplasm
Pancreas	Insulin, glucagons, pancreatin, trypsin, and chymotrypsin
Lungs and intestinal mucosa	Heparin
Liver	Liver extract
Thyroid	Thyroxine
Pituitary	
Anterior	Follicle-stimulating hormone (FSH), adrenocorticotropic hormone (ACTH), prolactin
Posterior	Oxytocin, vasopressin
Adrenals	Epinephrine (adrenaline)
Testis	Hyaluronidase
Gallbladder	Bile, bile salts
Heart	Cardiolipins, cytochrome C
Spinal cord, brain	Cholesterol, lecithin
Bones	Gelatin, bone morphogenetic protein (BMP)
Hooves	Neats foot oil

Undesirable microbial contamination is possible at any stage if proper procedures are not followed. Certain strains of *E. coli* can cause gastrointestinal disease in humans, either by enterotoxin production or by penetrating the intestinal epithelium. *Staphylococcus aureus* has also been reported in dressed meat. *S. aureus* has been reported to be widely distributed in market meats.

It has been confirmed that the hygienic processing of meat improves the bacteriological quality of meat and reduces the incidence of food-poisoning organisms. The concept and basis of meat hygiene and inspection relate to the fundamental principle that the meat reaching the market is sufficiently well examined before and after slaughter, as well as during the process of cutting, dispatching and retailing, to insure, as far as possible, freedom from diseases which can be transmitted to humans. In developed countries optimum precautions can be taken at all stages, during ante- and postmortem inspection and transportation and processing stages of the carcass and byproducts. In developing countries the rigid criteria of inspection accepted in the developed world cannot be applied to local marketing, although much can be and is being done by local authorities to protect the consumer and abattoir workers from exposure to infection. The following describes some of the diseases carried in buffalo meat.

Bovine Tuberculosis

There is increasing evidence that bovine tuberculosis, which is also transmissible to humans, is becoming more prevalent in the tropics. This may be due to an increase in the incidence of the disease, or may be an indication of improved detection. Since infection is by ingestion of infected meat or milk, adequate inspection of the carcass, with particular reference to the lymph glands, is essential. This is a bacterial disease of both animals and humans and causes gastrointestinal infections as well as lung infections. Meat-borne infections can occur from contamination of meat by tuberculosis-infected human carriers such as butchers and handlers and by contact with meat derived from infected animals during the abattoir routine. Careful antemortem and postmortem inspection combined with good slaughter hygiene are essential to reduce the danger of widespread contamination.

Salmonellosis

Salmonella bacteria affect a wide range of domestic and wild animals, as well as humans. They cause mainly enteric infections and in the tropics human gastrointestinal infections caused by salmonellae are common. Meat-borne infections can frequently occur, not only by contact with meat derived from

infected animals, but also from meat which has been contaminated by human carriers of salmonellae during slaughter procedures. Contamination of meat from infected animals during slaughter is a considerable problem and careful ante- and postmortem inspection combined with a satisfactory standard of slaughter hygiene are essential to reduce the danger of widespread contamination and subsequent dissemination of the bacteria.

Anthrax

This is a highly infectious bacterial disease of animals, quite commonly encountered in tropical countries. Humans can acquire the disease from infected carcasses or byproducts by handling, inhaling contaminated air, or eating infected meat. Anthrax can often be detected by proper antemortem inspection, but the disease can be overlooked. Even an experienced inspector may have difficulty under certain conditions in differentiating anthrax from other septicemic diseases. For these occasions minimal laboratory facilities for early on-the-spot provisional diagnosis are essential.

Once an infected anthrax carcass has been removed unnoticed from the abattoir the disease can spread rapidly. The anthrax bacillus forms resistant bacterial spores which can remain viable in the soil and elsewhere for very long periods. Care should be taken to remove a suspected carcass from the abattoir floor. To avoid further contamination the premises should be disinfected with a 2% caustic soda solution. Carcasses infected with anthrax should be destroyed completely, if possible by burning. If buried, the pit should be sufficiently deep to prevent the carcass being dug up by dogs or other predators. Lime sprinkled on the carcass before burial also helps reduce the danger of the disease spreading.

Cysticercosis

This condition is prevalent in cattle in many tropical areas and is a particular health hazard to humans because infected cattle and buffalo muscles contain the cysts, which are an intermediate or developmental stage of *Taenia saginata*, one of the large human tapeworms. Cattle and buffalo grazing on pastures contaminated with human feces containing these tapeworm eggs can become infected. The muscular tissue of the cattle and buffalo then become infected with the tapeworm cysts and if humans eat improperly cooked beef they become infected and the cycle of development can recur.

Meat inspectors usually cut into the cheek muscles and heart muscles to check for the presence of cysts. In Zebu-type cattle the hump is also a further useful site for muscle incisions.

Hydatidosis

The importance of this disease lies in both its human health and economic aspects. The dog is the most important link in the biological cycle of this tapeworm and for this reason control should be directed at proper treatment of dogs with anthelmintics, keeping them out of slaughter premises, and the proper disposal of the viscera of all slaughter animals. The hydatid cysts are intermediate developmental stages of dog tapeworms. These cysts can develop not only in large and small ruminants and swine, but also in humans, where they may even locate themselves in the brain. From the human infection standpoint, the hydatid cysts in the viscera of sheep and swine are the most dangerous as far as potential infection of scavenging dogs is concerned, because cysts in these animals are much more fertile than those found in cattle and buffalo.

Introduction

Buffalo plays a pivotal role in the agricultural economy of many Asian, European, African, and Latin

American countries. Among farm livestock buffalo is being increasingly recognized as an animal for milk, meat, and draft. Despite its significant contribution as a multipurpose animal, this species has received little of the care and attention which it rightly deserves. A major bottleneck in the enhancement in production potential of buffaloes has been inadequate research and paucity of information. It is often falsely presumed that the scientific information generated on cattle can be extrapolated to buffaloes.

Milk Production

In terms of the percentage of world milk production from buffaloes, India ranks first (65%), followed by Pakistan (22%), China (5%), Egypt (4%), and Nepal (2%). Various compositional and functional properties render buffalo milk (BM) eminently suitable for the manufacture of dairy products such as ultra heat-treated (UHT) cream, dried icecream mixes, dairy whiteners, edible casein, and caseinates. However, from a technological point of view, BM is often considered not an ideal fluid for the manufacture of several types of cheeses, milk powders, evaporated and condensed milk, and infant formulae. Due to several biochemical differences between BM and cows' milk (CM), conventional processing technologies are often unsuitable and cannot be applied directly for processing BM.

Emerging research and development trends in BM processing suggest that there is ample scope for tailoring the technology, particularly in the developing world where buffaloes enjoy a preeminent position in milk production. Several region-specific traditional milk products owe their unique characteristics to BM. The suitability of buffalo as a milk producer is now distinctly gaining importance throughout the world.

Comparative Appraisal of Gross Composition of Buffalo and Cows' Milk

BM is reputed for its richness and creaminess. The compositions of BM and CM are compared in Table 1; BM has a higher content of fat, lactose, casein, whey proteins, and minerals than CM. All of the casein in BM is present in the micellar form while in CM only 90–95% of the casein is in the micellar state and the rest is present in serum phase. The proportion of bovine casein which is micellar depends on the temperature range and the gravitational force used to sediment casein micelles. The size of the casein micelles is bigger (110–170 nm) in BM compared to CM (range 50–500 nm, mean 120–150 nm). The voluminosity of the casein micelles in BM is 2.68–3.72 ml g^{-1} compared to 4.18 ml g^{-1} for CM casein. Similarly, the solvation (hydration of casein micelles) of BM is lower (2.60–2.90 g water g^{-1} casein compared to 3.48 g water g^{-1} of casein from CM). The opacity of BM casein micelles is three times higher than CM casein. BM casein micelles contain higher levels of calcium and magnesium but lower levels of sialic acid and hexose. The lactoferrin content of BM is 32 mg 10 ml^{-1} compared to 15 mg 100 ml^{-1} of CM. No genetic polymorphism is exhibited either by the caseins or whey proteins in BM.

Table 1 Concentration of major constituents in buffalo and cows' milk

Constituents	*Concentration (%)*	
	Buffalo milk	*Cows' milk*
Water	83.18	85.5
Total solids (TS)	16.82	13.5
Solids not fat (SNF)	10.01	9.11
Fat	6.71	4.39
Proteins	4.52	3.3
Lactose	4.45	4.44
Total ash	0.80	0.73
Calcium	0.18	0.12
Magnesium	0.02	0.01
Sodium	0.05	0.05
Potassium	0.11	0.15
Phosphorus	0.10	0.10
Citrate	0.18	0.18
Chloride	0.07	0.1
Ca/P ratio	1.8	1.2

Adapted from Sindhu J (1999) Physico-chemical profiles of cow and buffalo milk in relation to milk processing. In: *Advances in Processing and Preservation of Milk: A Compendium of Short Term Course Notes*, pp. 97–103. Karnal, India: National Dairy Research Institute.

Milk Lipids

BM fat contains higher proportions of high melting triglycerides (9–12%) than CM (5–6%) and as a result it is more solid. Similarly, the proportion of butyric acid-containing triglycerides is higher (50%) in BM than in CM (37%). As a consequence of the higher proportion of butyric acid-containing triglycerides, the emulsifying capacity of BM fat is superior to CM fat. Fat globules are bigger (4.15–4.6 μm) in BM than in CM (3.36–4.15 μm). These are rendered chargeless at much higher pH (4.5–4.6) in BM compared to CM (pH 4.3). BM fat contains less (0.22%) free fatty acids than CM (0.33%). The concentration of unsaponifiable matter (392–398 mg 100 ml^{-1}) is also lower in BM than in CM (414–450 mg 100 ml^{-1}). Similarly, the phospholipid content of BM is also less (21 mg 100 ml^{-1} compared to 37.37 mg 100 ml^{-1}. The total and free cholesterol content is 275 mg and 210 mg, respectively, per

100 g of BM ghee, which is much less than corresponding values of 330 mg, and 280 mg $100\,g^{-1}$ in CM ghee. On the other hand, the esterified cholesterol of BM is much higher (64 mg $100\,g^{-1}$) CM than (48 mg $100\,g^{-1}$).

Milk Salts

The concentration of calcium and magnesium is about 1.5 times higher in BM than in CM. On the other hand the concentration of sodium, potassium, and chloride is lower than in CM. The content of colloidal calcium and magnesium (160 and 9 mg, respectively $100\,ml^{-1}$) in BM is much higher than in CM (80 and 3 mg, respectively, $100\,ml^{-1}$). Only about 20% of calcium and 55% of magnesium in BM is present in a dissolved state compared to 33% and 75% respectively in CM. The Ca/P ratio is much higher in BM (1.8) than in CM (1.2).

Vitamins

BM is a rich source of most water-soluble and fat-soluble vitamins. The average concentrations of vitamins in milk of buffalo, Indian, and western cow are summarized in Table 2; vitamin A content is higher in BM ($340\,IU\,kg^{-1}$) than in CM ($230\,IU\,kg^{-1}$). However, due to the absence of carotenoids and the high fat content in BM, its total vitamin A potency per unit weight of fat is less than CM. Similarly, the tocopherol (vitamin E) content of BM is slightly higher ($334\,ng\,kg^{-1}$ milk) than $312\,ng\,kg^{-1}$ CM. However, due to the higher fat content in BM, its fat is poor in tocopherol ($26\,ng\,g^{-1}$ fat compared to $35\,ng\,g^{-1}$ fat in CM).

Pigments in Buffalo Milk

Biliverdin IX alpha, a latent blue-green pigment, occurs in fresh BM. This pigment is absent from CM and is considered to be an important characteristic of BM. The average concentration of biliverdin in skim milk of Murrah and Surati buffaloes is 51.8 and 65 μg $100\,ml^{-1}$, respectively. The concentration of this pigment in BM varies significantly at different stages of lactation and lactation number. Biliverdin was primarily associated with α-, β-, and κ-caseins and the proteose-peptone fraction of BM. Biliverdin is converted to bilirubin on storage and souring of BM. This pigment binds to BM lipids and imparts the characteristic greenish-yellow appearance to BM fat and butter prepared by the traditional fermentation process.

Other Constituents

BM is rich in taurine ($6\,mol\,l^{-1}$), compared to 4.0 mol l^{-1} in CM. In contrast, the concentration of urea in BM, 17–22 mg $100\,ml^{-1}$ is much lower than the level in CM (37–40 mg $100\,ml^{-1}$). The levels of lipase and alkaline phosphatase are lower in BM than in CM. However, free amino acids are present at a higher concentration (0.44%) in BM than in CM (0.15%).

Differences in Physicochemical Properties of Cow and Buffalo Milk

Precise and indepth information on the physicochemical and functional attributes of milk is an essential prerequisite for automated industrial processing. Most of the prevalent processing technologies apparently originated in the western world, where CM and milk products predominate. Therefore, processing strategies were essentially based on knowledge of the chemistry and functionality of CM. Species-related differences in milk composition have become the subject of topical interest, as processing of milk from species other than cow is being adopted by the dairy industry in several countries. With the emergance of buffaloes as a predominant milk species, particularly in countries of Asia, Africa, and Latin America, coupled with rapid dairy development,

Table 2 Average concentration of some vitamins in milk of Buffalo, Indian, and western cow

Vitamins	*Concentration in milk*		
	Buffalo (Bubalus bubalis)	*Zebu* (Bos indicus)	*Western cow* (Bos taurus)
Vitamin A ($IU\,ml^{-1}$)	340	230	136–157
Thiamin ($\mu g\,ml^{-1}$)	0.2–0.5	0.2	0.2–0.8
Riboflavin ($\mu g\,ml^{-1}$)	1.59	2.33	1.7
Pyridoxine ($\mu g\,ml^{-1}$)	3.25	2.6–3.0	
Ascorbic acid (mg $100\,g^{-1}$)	6.72	1.94	1.65–2.75
Tocopherol ($\mu g\,g^{-1}$)	334.2	312.2

Table 3 Physicochemical properties of buffalo and cows' milk

Properties	*Buffalo milk*	*Cows' milk*
Specific gravity (20 °C)	1.03	1.03
Viscosity (in cP at 20 °C)	2.25	1.45
Curd tension (in g)	32.85	28.54
Surface tension (dyn cm^{-1} at 20 °C)	45.5	42.5
Freezing point (°C)	−0.55	−0.53
pH (at 20 °C)	6.7	6.6
Acidity as % lactic acid	0.16	0.15
Redox potential (volts)	0.31	0.26
Electrical conductance (m ohm)	43.22–6.77	4.0–5.50
Thermal conductance (kcal h^{-1} m °C at 37 °C)	0.57	0.46
Heat capacity (cal g^{-1} °C at 30 °C)	0.83	0.93–0.95
Heat-stability (in min at 130 °C)	32.28	32.0

Adapted from Sindhu JS (1999) Physico-chemical properties of cow and buffalo milk in relation to milk processing. In: *Advances in Processing and Preservation of Milk: A Compendium of Short Term Course Notes*, pp. 97–103. Karnal, India: National Dairy Research Institute.

efforts have been made to develop and adopt appropriate technologies for BM processing. It becomes essential to understand the unique physicochemical and functional properties of BM to overcome the various challenges encountered during its processing. BM has higher specific gravity, viscosity, curd tension, pH, oxidation reduction potential (E_h), thermal conductivity, and thermal expansion than CM but its heat capacity and rennet stability are lower than CM. In the fluid state, BM is as stable as CM to various physicochemical factors. In contrast, the heat-stability of concentrated milk product is significantly lower than BM. Owing to differences in physical properties, milk from the two species behave differently when processed for manufacturing of the products. A comparison of the physicochemical properties of BM and CM is given in Table 3.

Comparison Between the Quality of Dairy Products from Cows' and Buffalo Milk

Edible Casein and Caseinates

Due to the higher content of casein in the form of larger micelles and the presence of all of the casein in the micellar state, it is easier to manufacture edible casein and caseinates from BM. The yield of these products is also higher from BM due to lower losses in the whey because of greater size and low hydration of the micelles.

Coffee and Tea Whiteners

Due to higher protein, fat, and calcium content in BM, the yield of whitener from BM is higher. The product is superior due to higher whitening capacity when made from BM. The larger size and greater opacity of casein micelles from BM may be responsible for a better-quality product. The higher emulsifying capacity of BM fat may also be responsible for the better dispersion of whitener used in coffee or tea.

Icecream

Buffalo milk is considered as a better source of fat for icecream due to higher emulsifying capacity. Further, BM ingredients produce better body and texture in icecream.

Infant and Health Foods

Better absorption of fat due to higher emulsifying capacity, better absorption of calcium due to higher concentration of calcium, magnesium, lactoferrin, free amino acids, esterified cholesterol and taurine and lower concentration of sodium, potassium, chloride, urea, and free and total cholesterol in BM compared to CM is beneficial for human nutrition. These attributes make BM superior to CM as an ingredient for infant and health foods provided its curd tension is reduced to improve digestibility.

Certain Varieties of Cheese

Certain varieties of cheese, like Mozzarella and white pickled Domiati cheese, are superior in quality when made from BM. The manufacture of Domiati cheese is easier from BM as it is easier to handle the curd to as it is firmer and the yield is higher.

Yogurt

Buffalo milk is better suited for the manufacture of yogurt as its manufacture is easier and there is no need for prior concentration or the addition of dried milk due to higher total solids in fat.

Problems Associated with Buffalo Milk Cheese

Cheddar cheese is manufactured mainly from CM in major cheese-producing countries. However, in India the major share of milk production is from buffaloes. The adaptation of well-known technology for the production of various products from BM posed many problems, primarily because of its qualitative and quantitative differences. CM, in general, is considered to be the most suitable raw material for cheese. The main problems encountered in the manufacture of hard-type cheese from BM have been faster renneting, lower retention of moisture, slower lipolysis and proteolysis, and poor flavor, body, and texture development. BM cheese is criticized for its higher fat content and hard, rubbery, and dry body and texture.

The defects in BM Cheddar cheese are mainly attributed to the physicochemical and compositional characteristics of milk. The high buffering capacity of BM due to its higher calcium phosphate and casein content is the cause of a slower development of acidity. Faster renneting time may be attributed to its higher colloidal content (about 160 mg $100\,ml^{-1}$ compared to only 8 mg $100\,ml^{-1}$ in CM). The lower retention of moisture in the curd may be the result of low solvation (hydration) of its calcium compared to CM casein. Hard, rubbery, and dry body may be due to the high curd tension which, in turn, is the result of higher content of casein with bigger size of the micelle, high content of calcium and magnesium, more so in the colloidal state, large proportion of solid fat with bigger size of globules, and low voluminosity and solvation of casein micelles compared to the same in CM. The slower rate of proteolysis and lipolysis is the cause of the higher curd tension of BM.

Technology for Manufacture of Buffalo Milk Cheese

In view of the above-mentioned problems associated with the manufacture of BM cheese, research was initiated in the area of cheese in the early 1960s at the National Dairy Research Institute, Karnal, India. Since a major share of milk production is from buffaloes and BM is known to be unsuitable for cheese production, attention was given to this raw material. Cheddar cheese, the most common variety made in India, does not develop proper flavor, body, and texture when it is made from BM. The main problem is the faster rate of syneresis which results in lower moisture content in finished cheese. This in turn adversely affects the three most important biochemical reactions, i.e., glycolysis, proteolysis, and lipolysis, which constitute the major activities in cheese flavor development. In order to overcome this problem, attempts should be made to develop a manufacturing technique which would insure greater retention of moisture and accelerated rate of glycolysis, proteolysis, and lipolysis. A presalting method has been developed which envisages the addition of 1% salt to the cheese milk. This method resulted in the best product. However, addition of salt to the milk makes the whey unsuitable for use in food products.

BULIMIA NERVOSA

D S Goldbloom and P E Garfinkel, Centre for Addiction and Mental Health, Toronto, Ontario, Canada

Definition

The symptom of bulimia refers specifically to binge eating, i.e., the consumption of a large amount of food in a discrete period of time with a sense of loss of control. As an isolated symptom, bulimia may occur in a number of normative and pathological states. Isolated episodes of pleasurable binge eating among adolescents and young adults are relatively common. Pathological binge eating may occur in medical conditions such as Prader–Willi syndrome or idiopathic Parkinson's disease.

The term bulimia nervosa (BN), however, refers to a distinct psychiatric disorder of eating behavior which includes but is not limited to episodes of binge eating. It is also characterized by distinct psychological preoccupations regarding fears of becoming fat and self-esteem yoked to body weight that parallel concerns in its companion disorder anorexia nervosa (AN). Accompanying the episodes of binge eating, and fueled by the fears of obesity, are feelings of loss of personal control and efforts to counteract the effects of ingested calories through a variety of purgative techniques.

Unlike the long-recognized AN, BN was formally characterized as an autonomous disorder as recently as 1979; the formal diagnostic criteria for BN as described by the American Psychiatric Association in 1994 are:

A. recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   1. eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat in a similar time and under similar circumstances
   2. a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)

B. recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise

C. the binge eating and inappropriate compensatory behaviors occur, on average, at least twice a week for 3 months

D. self-evaluation is unduly influenced by body shape and weight

E. the disturbance does not occur exclusively during episodes of anorexia nervosa.

There are two subtypes:

1. Purging type: during the current episode of BN, the person has regularly engaged in episodes of self-induced vomiting or the misuse of laxatives, diuretics, or enemas.
2. Nonpurging type: during the current episode of BN, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

Prevalence

BN is largely but not exclusively a disorder of females, typically between the ages of 16 and 40. The existence of a frequency criterion for binge eating has on the one hand reduced estimates of the prevalence of this disorder since its initial description; on the other hand, evidence exists that this frequency criterion is highly arbitrary and does not capture the full spectrum of the disorder. Approximately 1% of western adolescent and young adult females meet diagnostic criteria for BN.

Etiology and Groups at Risk

The etiology of BN is unknown; physiological, psychological, and cultural cues have been invoked in its pathogenesis and risk factors in these three domains have been identified. The commonest acute precipitant of binge eating *per se* is food restriction, whether experimental or self-imposed, as in dieting or AN. This may result from adaptive physiological signals in the hypothalamus to ingest calories. At the same time, the cognitive consequences of having eaten when trying to abstain from food may provoke a transient relaxation of rules about food that results in a binge-eating episode. Finally, the abundant and frequently instant availability of food in western society may facilitate impulses to binge eat.

At the level of the individual, risk factors include dieting behavior and weight preoccupation,

particularly in the context of AN; up to 50% of AN patients also exhibit bulimic behaviors. Premorbid obesity is a risk factor in the sense that these individuals are likely to be dieting and experiencing the prominent negative social attitudes to obesity. Impulsivity – as manifested by substance abuse, recurrent self-harm behavior, intense and unstable interpersonal relationships, and an inability to tolerate mood states such as depression and boredom – may be an independent risk factor. This cluster of symptoms is often labeled borderline personality disorder.

At the familial level, psychiatric disorders such as depression, substance abuse, eating disorders, and antisocial behavior are overrepresented compared to control populations. It has been argued that BN may represent the cultural shaping of an underlying familial vulnerability to psychiatric disturbance. As with AN, families of individuals with BN may place undue emphasis on the importance of thinness.

At the level of society, the emergence of BN as an autonomous disorder in the latter third of the 20th century parallels the increased emphasis on thinness, dieting, and dieting disguised as thinness, as well as the mushrooming of technology that allows more widespread promulgation of social values. Many women with BN have 'failed' to achieve the weight loss requisite for a diagnosis of AN but share a set of beliefs and values commonly seen in AN. For others, BN represents only one expression of impulsive dyscontrol.

Psychopathology

A morbid fear of fatness and a self-appraisal based largely on body weight and shape are the overriding psychological preoccupations characteristic of BN. Psychometric assessment of eating and related attitudes parallels the findings obtained in AN. It is important to recognize that in BN the act of binge eating seldom occurs in response to normative hunger. The extent to which it represents a physiological response to food deprivation usually reflects intensive dietary restriction for the purpose of weight loss. However, the subjective perception of binge eating falls typically into two categories: counterregulation and distraction. Counterregulation refers to the phenomenon whereby individuals who pursue dietary restraint find they have violated their self-imposed limits; their response is one of resignation to loss of control which then triggers binge eating. In the case of BN, this permission to binge eat is facilitated and perpetuated by the availability of purging behaviors. Distraction refers to the role of binge eating in escaping from or quelling unpleasant or intolerable psychological states, such as depression, anger, boredom, or conflict; indeed, some individuals describe their eating binges as automatic states where they dissociate, losing touch with all feelings. Street drug and alcohol misuse as well as nonlethal self-injurious behavior may serve a similar function.

Clinical Features

As with AN, the commonest precipitant of BN is dieting behavior. However, BN may occur without the emaciation characteristic of AN. This may be especially true where women have been premorbidly overweight. Women with BN who have never had AN still experience up to a 30% fluctuation in adult body weight, compared to the 10% fluctuation among women without an eating disorder. Food that is usually avoided or assigned a negative moral value inevitably becomes food consumed during eating binges where dietary restraint is abandoned.

BN is typically a secretive behavior. Eating binges often occur in the evening after a day of caloric restriction and/or psychological stressors. Individuals may consume between 3000 and 6000 calories in an hour or less, and they describe their eating as rapid, often without savoring the taste, and with a sense of loss of control and inability to stop. Macronutrient analysis of binge food indicates a high quantity of carbohydrate, although perceived high-carbohydrate foods often have a significant fat content as well. A loss of the normal sense of satiety is evident from both subjective ratings and objective measures of the quantity of food consumed. Ironically, the aftermath of a binge-eating episode is often heightened dysphoria, weight concern and self-loathing, which then precipitate purging behavior.

The commonest form of purgation is self-induced vomiting, with individuals using a finger, toothbrush, or pen to stimulate an oropharyngeal vomiting reflex. The commonly available emetic, ipecac, has also been used for this purpose with catastrophic results: ipecac contains emetine, which is directly toxic to cardiac muscle. Other methods of counteracting the effects of ingested calories include laxative, diuretic, and diet pill abuse. These lead to a variety of physiological and psychological complications, including low serum and intracellular potassium levels from losses through vomiting and diuresis; this may precipitate cardiac arrhythmias. An associated state of metabolic alkalosis results from chloride losses through vomiting. Alternating diarrhea and constipation may result from laxative abuse. Diet pills are typically amfetamine-like psychostimulants that not only suppress hunger but also produce anxiety, insomnia, irritability, and dependence. Less obvious forms of purgation include

intensive exercise for the primary purpose of weight loss and severe dietary restriction after binges; this latter feature serves to perpetuate the disorder.

There are few physical characteristics of BN that facilitate its diagnosis. However, two potential signs of the disorder are hypertrophy of the parotid salivary glands (likely secondary to overstimulation) and calluses or erosions on the dorsum of the hand (caused by friction against the incisor teeth while inducing vomiting). The acid content of the vomitus has an erosive effect on dental enamel and may promote gum recession, leading at times to an initial diagnosis of BN by dentists. Feelings of depression and anxiety are common in BN; indeed, these women and their families are at higher than normal lifetime risk for the development of autonomous mood and anxiety disorders. However, when these symptoms coexist with BN, it is often difficult to separate them from other sequelae of the eating disorder.

Because BN is a disorder that generates secrecy, isolation, and shame, affected individuals may wait months or even years prior to seeking treatment. This contributes to the chronicity of the disorder.

Diagnosis

The diagnostic criteria of the American Psychiatric Association listed above reflect the confluence of behavioral and psychological features characteristic of BN. Earlier definitions of this disorder were less restrictive and included a wider range of eating disturbance without regard to binge-eating frequency or weight and shape concerns. This led to epidemiological overdiagnosis without regard to clinical severity. However, problems remain with respect to the definition of a binge-eating episode. For some individuals, the sense of loss of control associated with eating 'forbidden' foods such as two biscuits or a piece of cake may constitute a qualitative or subjective binge, whereas there is consensus that eating more than is normal under the circumstances constitutes a quantitative or objective binge. The accuracy of self-reported binge-eating quantities hampers research in BN.

The diagnosis of BN must be considered in the absence of disclosure by the individual where sequelae such as unexplained low potassium are evident. BN may also contribute to disruption of normal menstrual function among women of a statistically normal body weight.

Treatment

The treatment of BN includes but is not limited to the reestablishment of normal eating behavior, whether through education, psychotherapy, or drug therapy. Unlike AN, individuals with BN are often eager to overcome their eating disturbance, although this is accompanied by a morbid fear of weight gain.

Treatment begins with a careful history which includes longitudinal weight history, including weight prior to the onset of dieting and desired weight; the discrepancy may reflect a conflict between culture and biology. The acute precipitants of binge-eating states are identified and the nonbinge meals are quantified. Methods of purgation and their potentially lethal complications are elicited. The associations between psychological states, eating behaviors, and weight and shape concerns may be facilitated by self-report diaries where individuals with BN discover these connections. Unlike AN, weight gain may not be a goal but weight stabilization may occur as a result of cessation of dieting and bulimic behaviors; typically, these individuals experience significant weight fluctuations.

An educational approach may include readings on cultural bias and body weight, the effect of dietary chaos and deprivation on physiological and psychological states as well as eating behavior, and the biological regulation of body weight. Indeed, research demonstrates that guided reading may be an effective first step in the treatment of individuals with BN. Individual psychotherapy may explore the origins and extent of dysfunctional attitudes related to eating, weight, and shape, as well as more global underlying disturbances related to self-esteem and self-appraisal; this approach, entitled cognitive behavioral therapy, is the most validated treatment for BN and is usually administered over 8–20 sessions. Often a specific meal plan may be prescribed, not to promote weight gain but to avoid long intervals of deprivation that may precipitate binge eating. Learning to tolerate feelings and impulses through understanding, or through learning more adaptive coping strategies, may also be useful. Interestingly, research evidence also supports the efficacy of another short-term intervention called interpersonal therapy, which focuses on current relationships and does not include direct examination of eating behavior.

The use of a wide range of antidepressant drugs has been studied since 1983. The early evidence confirmed that tricyclic antidepressants, monoamine oxidase inhibitor antidepressants, and selective serotonin reuptake inhibitor antidepressants exert an antibulimic effect which is independent of their effect on mood. The most extensively studied and validated such antidepressant is fluoxetine, which is licenced for the treatment of BN in many countries. Their mechanism of action in BN is unclear but may relate to effects on neurotransmitters involved in

hypothalamic regulation of appetitive behavior. Extensive abnormalities of serotonin and norepinephrine (noradrenaline) have been documented in BN. More recent studies which have compared and combined antidepressants and individual cognitive behavioral therapy have suggested that while both are effective alone, the combination confers no particular advantage and there is greater compliance and duration of effect with psychotherapy. To date, no predictor variables exist which will help determine which of these disparate treatments will be most effective for an affected individual.

Hospitalization is rarely necessary for individuals with BN. However, when the disorder is accompanied by suicidal tendencies, serious electrolyte compromise, or coexistent diabetes mellitus, hospitalization may assist in crisis resolution or metabolic stabilization.

Prognosis

The long-term prognosis of BN is relatively less well known than for AN because of the recency of both description of the disorder and the development of effective interventions. It is known that individuals with BN are vulnerable to mood, anxiety, and substance misuse disorders, as well as a general impairment in social adjustment. Some follow-up studies of 5 years indicate that two-thirds of the treated sample recovered from BN; low self-esteem at the onset of treatment and persistent vomiting at the end of treatment have been identified as poor prognostic factors. In contrast to AN, the mortality rate of BN is very low (0.3%) in outcome research.

BURNS PATIENTS – NUTRITIONAL MANAGEMENT

J A Marlett, University of Wisconsin-Madison, Madison, WI, USA

Background

Successful nutritional therapy for the person with a thermal injury is among the most challenging and diverse tasks for the nutritionist. Appropriate therapy is determined by the extent and body location of the burn, the presence of related conditions such as inhalation or electrical injuries, and the age and previous health status of the patient. Some epithelial elements remain after second or partial thickness burns, making regeneration of the skin possible in most cases. No epithelial components remain after third-degree or full-thickness burns, and skin grafting or other coverings are needed for wound closure. While partial thickness burns can cause nutrition-related problems, nutritional therapy is an essential component of the treatment of full thickness burns. The focus of this chapter is the nutritional care of patients with 20% or more full thickness burns or more than 25% partial thickness burns who require special nutritional attention. Pediatric and geriatric patients may tolerate less extensive burn, whereas a healthy young adult may tolerate more without special nutrition intervention.

With a severe thermal injury comes hypermetabolism and a catabolic response. Levels of immune and inflammatory mediators and hormones are elevated. Provision of adequate nutrition is critical for adequate treatment, but determining adequate intake is difficult, because the hypermetabolic response includes negative nitrogen balance and inappropriate insulin responses. Fluid status and pathological state are dynamic in the burn patient, which causes continuous fluctuation in nutrient needs. Further, surgery to excise and close wounds, and dressing changes temporarily change energy needs.

The severity of a thermal injury is usually defined by the extent of body surface area (BSA) burned. Although specialized burn units have diagrams that allow accurate calculation of BSA, the 'rule of nines' is a convenient method of estimating the total surface affected. Each upper extremity and the head is considered to be 9% of body surface; each lower extremity, the anterior trunk and the posterior trunk is 18% of body surface. The remaining 1% is assigned to the perineum.

Energy Needs and Sources

Traditionally, the energy needs of the burn patient are estimated using a formula that includes the preinjury weight, basal energy expenditure, and the percentage BSA burned (Table 1). These formulas may overestimate energy needs, and it is now recommended that the individual energy needs of both children and adults be estimated using indirect calorimetry. Respiratory gases are used in an indirect calorimetry formula to determine daily energy needs as kcal per day ($\times 4.18$ for kJ per day) $= 1.05-1.2 \times [3.78$ (oxygen consumed, $l\,min^{-1}) + 1.16$(carbon dioxide produced, $l\,min^{-1}) - 2.98$(urea nitrogen excretion, g per h)]. Complete urine collection is needed for 12–24 h to determine urea nitrogen.

Most clinicians now recommend that protein intake comprise 20% of energy intake; this level also is suitable for the pediatric patient, provided that indices of nitrogen status (e.g., blood urea nitrogen, nitrogen balance, fluid status) are monitored. The most common proportion of fat used for the burn patient is 25–30% of energy, although a lower fat intake has been shown to reduce infectious morbidity, including pneumonia, and duration of hospitalization. If a low-fat diet is used, linoleic acid should provide 4% or more of the kilocalories to prevent essential fatty acid deficiency. Excess fat intake can lead to hypderlipidemia and an immunosuppressive response. The remainder of kilocalories, 50–65% of the total, is carbohydrate.

Micronutrient Needs

Electrolyte requirements are addressed as part of fluid resuscitation and maintenance. Needs for other minerals by the burn patient have not been well defined, and, with the exception of zinc, it is generally thought that body stores, dietary intakes, and the amounts included in a standard multivitamin are sufficient to meet needs during the recovery phase. A daily zinc supplement as 220 mg per day of zinc sulfate (100 mg per day for patients 3 years or younger) is recommended, on the assumption that it will promote healing of burn wounds, as has been shown for other types of wounds. Vitamin intakes provided by the diet are usually supplemented with a standard daily multivitamin. Ascorbic acid is further supplemented at 500 mg (250 mg) twice daily, as is vitamin A at 10 000 IU per day (5000).

Table 1 Equations for prediction of energy needs of burn patients (kcal/24 h)[a]

For adults:

Curreri (Curreri PW, Richmond P, Marvin J, and Baxter CR (1974) *Journal of the American Dietetic Association* 65: 415)

(25 kcal × preburn weight, kg) + (40 kcal × %BSA)

Long (Long C (1979) *Journal of Trauma* 19: 904–906)

Male: 66.5 + (13.7 × weight, kg) + (5 × height, cm) − (6.8 × age, years) × activity factor × injury factor

Female: 665 + (9.6 × weight, kg) + (1.8 × height, cm) − (4.7 × age, years) × activity factor × injury factor

where the activity factor is 1.2 confined to bed and 1.3 out of bed, and the thermal injury factor is 2.1

Toronto (Allard JP, Pichard C, and Hoskino E (1990) *Journal of Parenteral and Enteral Nutrition* 14: 115–118)

−4343 + (10.5 × %BSA) + (0.23 × previous day's kilocalorie intake) + (0.84 × basal energy expenditure) + (114 × previous day's average body temperature) − (4.5 × days postburn)

where basal energy expenditure is determined using the Long equations without the activity and injury factors

Ireton-Jones (Ireton-Jones C, Turner WW, Liepa GU, and Baxter CR (1992) *Journal of Burn Care and Rehabilitation* 13: 330–333)

629 − (11 × age, years) + (25 × weight, kg) − (609 × obesity)

where the presence of obesity is 1, and the absence is 0.

For children:

Mayes (Mayes T, Gottschlich MM, Khoury J, and Warden GD (1996) *Journal of the American Dietetic Association* 96: 24–29)

0–3 years: 108 + (68 × weight, kg) + (3.9 × %BSA)

5–10 years: 818 + (37.4 × weight, kg) + (9.3 × %BSA)

[a]%BSA is the percentage of body surface area burned. Multiply the result of a formula by 4.18 to convert to kilojoules.

Meeting Nutrient Needs

Enteral formulas, which are nutritionally complete liquid diets administered through a tube placed in the gastrointestinal tract, are employed in most instances, as the burn patient cannot usually voluntarily ingest sufficient food to maintain an adequate energy intake. Burn patients have been successfully treated with the end of the tube placed either in the stomach or in the upper part of the small intestine. It is difficult to provide adequate energy with a low-fat enteral diet, because the volumes required are so great. Nutrition by a parenteral or intravenous route may be indicated in special circumstances, for example if the gastrointestinal tract cannot be used. Occasionally, parenteral nutrition may be used in combination with enteral, when use of the latter is not providing adequate nutrition. Parenteral nutrition, however, is not the standard more of nutrition for the burn patient, as it is more costly than, and has not been shown to be superior to, other routes.

Oral intake is the first choice, but it should be used only when the patient can consume sufficient food at meals and in between meal snacks to achieve an adequate energy intake. Nutrient-dense snacks and liquid supplements help to achieve an adequate intake. Occasionally, *ad libitum* oral intake is combined with enteral formula administered overnight to provide adequate nutrition.

Since early introduction of nutrition improves patient response to treatment, nutrient intake is initiated within the first 24–72 h after injury, as soon as fluid and hemodynamic status are stabilized. Early feeding is also important, as it has been shown to help maintain the integrity and motility of the gastrointestinal tract.

Preexisting conditions
Cardiovascular disease
Hypertension
Obesity
Diabetes mellitus

Nutritionally Relevant Complications

Complications that affect nutrition therapy of the burn patient can be divided into three classes: (1) those related to the thermal injury; (2) preexisting metabolic conditions; and (3) those related to the method of feeding, e.g., enteral or parenteral nutrition (Table 2). Electric shock can have substantial neuromuscular effects; the ability to ingest food orally or gastrointestinal motility may be hampered (Table 2). Inhalation injury usually means that the patient will be placed on a ventilator. A very high carbohydrate intake, such as would occur if a low-fat diet were used, can exacerbate ventilator dependency, and the overall macronutrient distribution of energy needs to be evaluated in this context. Oral and esophageal damage also can occur with prolonged exposure to smoke and toxic fumes and would counterindicate oral ingestion of food. A stress ulcer in the stomach, known as Curling's ulcer, which frequently occurs in the burn patient, is now prevented by prophylatic antiacid therapy. The potential for a gastric ulcer and the poor gastric emptying that

also may occur in the patient with thermal injury are reasons why enteral (vs. oral) nutrition is used; the stomach may be bypassed, and the feeding tube is placed in the upper part of the small intestine.

The skin is the primary barrier for the body against the external environment. When it is lost, as in the severely burned patient, body tissues become exposed to the environment, which contains a variety of bacteria and viruses. Current therapy includes a variety of techniques and medications to prevent and treat infection in the burn patient. None the less, a burn patient frequently has cutaneous infections that may pass into the blood, causing septicemia. The fever that accompanies an infection increases energy needs, and septicemia also produces a hypermetabolic state. Metabolic rate is estimated to increase about 10% for each 1 °C increase in body temperature. Nutrient requirements need to be reevaluated in the burn patient when an infection ensues.

A thermally injured patient may have one or more preexisting diseases that affect the overall diet pattern (Table 2). Consideration should be given to lowering dietary fat if the patient has significant cardiovascular disease, and sodium if chronic severe hypertension is present. Obesity complicates the determination of adequate energy intakes, as well as wound closure and healing in the burn patient. During the hypermetabolic phase, protein becomes a primary substrate for energy; there is little value in providing a hypocaloric diet during this phase, as the obese patient will metabolize body protein if adequate amounts are not provided. When normal metabolic pathways resume, consideration can be given to a modest (10–25%) reduction in estimated energy needs when the burn patient is obese. Careful and continual coordination of insulin availability, blood glucose concentrations, and food intake is needed in the burn patient who also has type 1 diabetes mellitus, the form of the disease in which the body does not produce insulin. Similar monitoring is also needed for the person with type 2 diabetes, in whom insulin response to food intake is not normal, but monitoring is less frequent. Extra care also is needed if the patient with diabetes is given a very high (more than 55–60% of kilocalories) carbohydrate diet.

Many of the problems associated with tube feedings can be avoided by the experienced clinician. If the infusion rate is too fast and administration of the feeding too frequent, there can be potential problems, particularly for burn patients, for the simple reason that they have to be given more in order to meet their nutrient needs. Gastrointestinal stress that usually occurs in the burn patient is manifest as a poor emptying of the stomach; thus, 'residuals,' or the amount of feeding remaining 2 h after its administration, need to be determined frequently if the feeding tube is placed in the stomach. It is also important to keep the head of the patient elevated (at least a 30° angle) to prevent aspiration, which is the movement of gastric contents toward the mouth and subsequent entrance into the trachea and ultimately the lungs.

Since the feeding tube may be in place for a long period of time, smaller-diameter tubes are used, because they are less irritating. These smaller-bore tubes, however, cause mechanical problems, because they become more easily clogged. Clogged tubes are prevented by a rigorous maintenance protocol and by not administering ground, solid medications through the tube.

Gastrointestinal complications of tube feedings include nausea and vomiting, diarrhea, constipation, and abdominal cramping or pain, all of which also can be caused by the injury and by medications unrelated to nutrient intake. Many of the gastrointestinal problems can be prevented by maintaining constant administration of the feeding with a pump. Nausea, vomiting, and abdominal cramping may be a result of retention of food in the stomach; if this does not resolve spontaneously within a couple of days, the tube can be repositioned so that food is delivered to the gastrointestinal tract beyond the stomach. Diarrhea can be caused by gastrointestinal dysfunction, too rapid a rate of administration, and bacterial infection in the gut.

Metabolic Modulators

Several new therapies have been proposed to counteract the catabolism and hypermetabolism that accompany a burn injury. However, many of the studies to evaluate these new therapies have been very limited in scope or conducted using animal models or critically ill patients who were not burned. This is an active area of research, but data available at this time do not support the use of most of these therapies. Growth hormone administration does not appear to benefit the burn patient. Very high doses of insulin appear to reduce protein losses, but such doses have not been well accepted by burn centers, as they require frequent blood glucose monitoring. Arginine and glutamine are viewed as conditionally essential amino acids, that is they are indispensible in situations of severe metabolic stress when body synthesis may be inadequate. No convincing evidence exists that they are of benefit specifically in the burn patient, although they are included in some protocols, on the basis that they may help and are unlikely to hamper recovery.

The use of a particular group of enteral feedings, called immune-enhancing therapies, for the burn

patient is clearly controversial, with the results of studies indicating a beneficial effect, no effect, or possibly a detrimental effect on the burn patient. These formulas contain various amounts of dietary nucleotides, arginine, glutamine, carnitine, taurine, and/or ω-3 fatty acids. These formulas are three two four times more costly than standard enteral formulas, and few of these ingredients have been evaluated for their independent effects.

Metabolic complications of enteral feedings include hyperglycemia, hypertonic dehydration, hypernatremia, hyperkalemia, hypokalemia, and hypophosphatemia. Hyperglycemia can be caused by sepsis or severe infection and the hypermetabolism that accompanies a thermal injury. Hyperkalemia may signal compromised cardiac output or renal function. Generally, these metabolic complications are very rarely caused by the enteral feeding in the burn patient, because intake is so closely monitored.

BUTTER

Contents

The Product and its Manufacture

E Richards, Bridgend, UK
A M Fearon, The Queen's University of Belfast, Belfast, UK

Background

Butter has long been recognized as a valuable food. Its method of manufacture has changed little over the years except in respect of the equipment used. The traditional craft methods have given way to large-scale sophisticated continuous production, but both can still be found.

In the process of buttermaking, cream is subjected to severe agitation or 'churning.' This causes physical damage to the milk fat globules and results in phase inversion from the oil-in-water emulsion of cream to the water-in-oil emulsion of butter. Butter is composed of a continuous fat phase and a dispersed phase comprising water and globular fat. (*See* **Colloids and Emulsions**.)

Butter is permitted to contain certain other ingredients. These include salt (sodium chloride), coloring agents such as carotenes and annatto, acidity regulators, and starter cultures for the manufacture of lactic or ripened butter.

Production of premium quality butter requires attention to the quality of the raw material, process hygiene, and efficiency. The equipment used in creameries today makes a product of more uniform flavor and texture than the older craft methods and from a better-quality raw material.

Economic forces are emphasizing the need to maximize efficiency and flexibility in processing and production methods. Butter manufacturers have had to reexamine their product properties and investigate technological and other means to enhance these in the eyes of consumers. (*See* **Butter**: Properties and Analysis.)

Types of Butter

Sweet cream:

- salted with a salt content normally about 2%, but can vary from 1.5 to 3%;
- unsalted.

Lactic:

- slightly salted with a salt content of approximately 1%;
- unsalted.

Whey:
Sometimes called 'farmhouse butter.' This is found in localized areas and is manufactured from whey cream – a by-product of cheesemaking. The salt content is about 2%. (*See* **Whey and Whey Powders**: Production and Uses.)

Raw Materials

The quality and handling of the raw material are of paramount importance in achieving a premium-quality end product.

Cream

The essential elements are:

- clean milk;
- efficient separation to a specific fat content;
- efficient pasteurization (heat treatment) and cooling;
- good temperature control during storage;
- care in the physical handling of the cream.

(*See* **Cream**: Types of Cream.)

Raw milk for butter manufacture must contain less than 100 000 microorganisms per milliliter. In fact, milk with a much lower microbiological content (less than 20 000 organisms per milliliter) is now commonly obtained from UK herds. The quality schemes in operation within the UK insure good milk quality, and this is reflected in dairy product standards. (*See* **Milk**: Processing of Liquid Milk.)

Milk is separated into cream and skimmed milk by means of a centrifugal separator. At all stages in the handling of the milk and in the preparation of the cream, care is taken to avoid damage to the fat globule membrane (FGM) by excessive pumping or turbulence. The FGM is composed primarily of protein

and phospholipid and stabilizes the fat phase in milk while also protecting the fat from oxidation and enzyme attack. Separators are designed to cause as little damage as possible, while achieving a high degree of efficiency.

The optimum fat percentage of the cream, to obtain the maximum churning efficiency, needs to be adjusted according to the method and equipment used to make the butter. Traditional methods advise a fat content of 30–35%, whereas modern continuous buttermakers normally operate at 40–44% butterfat for sweet cream and 38–40% butterfat for an acid or cultured cream.

Cold separation (<10 °C) has the advantage that milk may be processed on arrival at the factory. Although the separation is less efficient, free fat levels are low, and the cream has a higher phospholipid content. This improves its whipping properties.

Heat treatment of the cream can be achieved on a small scale by heating in a vat to a temperature of not less than 63 °C and holding the cream at that temperature for at least 30 min. This 'holder method' is slow and inefficient, as heating and cooling are carried out in the same vessel. It is only suitable for small quantities of cream.

For larger-scale production, cream is treated in a continuous high-temperature, short-time (HTST) plate heat exchanger to a minimum of 72 °C for at least 15 s. At higher processing temperatures, there is a danger of oxidative rancidity promoted by migration of copper from the serum to the fat globules. For this reason, it is recommended that cream used for buttermaking be processed at a maximum of 77 °C for 15 s. However, in practice, flash heating to 85 °C is often used to produce a desirable slightly nutty or caramelized flavour. (*See* **Pasteurization**: Principles.)

Feed and weed taints concentrate in the fat phase of milk, and these may be removed by vacreation, a form of heat treatment under vacuum. The heated cream is held in contact with steam under reduced pressure, then separated to allow volatile taints to be drawn off. This is a combined heating and flavor-stripping treatment. Evaporative cooling to approximately 60 °C may also be used to adjust the fat content of the cream. The final cooling of the cream takes place in a plate heat exchanger. A milder, flavor-stripping method using vacuum treatment after an HTST process may also be used.

The cream used for buttermaking must be cooled and stored at a low temperature to encourage crystallization of the fat. This period, usually a minimum of 8 h, is often called 'ageing' the cream. The latent heat released will increase the temperature of the cream to 7–8 °C from the initial cooled temperature of 5 °C. Aging is essential to achieve a low fat loss into the buttermilk and produce butter of the desired texture. (*See* **Butter**: Properties and Analysis.)

Both the rate of cooling and the temperature of holding are important in determining the size of the fat crystals and the proportion of solid-to-liquid fat achieved within the final butter. Large silo tanks for storage are preferable to a series of small cream tanks. There is improved homogeneity, allowing the buttermaking equipment to operate with a more consistent product for a longer period.

Cream temperature treatments ('Alnarping') may be applied to improve butter spreadability and produce a consistent butter despite seasonal variation in milk fat composition. However, these have had limited success. A more effective means has been through altering the cow's diet to increase the proportion of unsaturated fatty acids in milk fat. This reduces butter firmness at low temperatures. Incorporating vegetable oils into cream and applying margarine process technology have been very successful developments, but the resultant products may not be identified as 'butter'. (*See* **Butter**: Properties and Analysis.)

Water

Water, wherever used, must be of the highest possible microbiological quality.

Lactic Cultures

A soured or ripened cream is traditionally required to produce lactic butter. Although it is possible to allow milk or cream to sour naturally, it is neither advisable nor practical. A culture of lactic microorganisms – *Lactococcus lactis* subsp. *cremoris* (formerly *Streptococcus cremoris*), *Lactococcus lactis* ssp. *lactis* (formerly *Streptococcus lactis*), *Lactococcus lactis* biovar. *diacetylactis* (formerly *Streptococcus diacetylactis*) – may be added to the cream to produce the desired acidity, flavor, and aroma. The primary aroma producers are *L. lactis* biovar. *diacetylactis* and *Leuconostoc mesenteroides* ssp. *cremoris*. (*See* **Lactic Acid Bacteria**.)

Salt

Salt adds flavor and also acts as a preservative in sweet cream butter. For short-term storage, bulk butter is stored at temperatures of −18 °C whether it has added salt or not. Intervention (EC-subsidized) butter – for long-term storage – is unsalted and is stored at −25 °C.

Only pure, finely milled, vacuum-dried salt (of at least BSI 998 (1969) or equivalent standard) should be used for butter.

Manufacturing Processes

Churn Method

Batch process A batch-type butter churn may vary in capacity from a few liters up to maximum of about 45 000 l. These churns were originally made of wood (Figure 1) but latterly of stainless steel (Figure 2).

After cleaning and disinfection, the churn must be specially prepared to prevent the butter from sticking to the surface. With wood, this is achieved by scalding with boiling water and immediately cooling with chilled water. This treatment leaves a film of water on the surface of the wood and prevents the butter from adhering to it. All wooden equipment must be kept wet until used.

The surface of stainless steel equipment also requires special physical preparation. The detergents used in the cleaning of such equipment must contain silicates to maintain the special 'nonstick' surface. (*See* **Cleaning Procedures in the Factory**: Types of Detergent; Types of Disinfectant.)

Batch butter churns may be barrel- or cone-shaped with fixed or rotating internal 'workers.' As the churn is rotated, the combined actions of rotating and beating cause the cream emulsion to break, forming the butter grains (fat phase) and buttermilk (aqueous phase).

During the first few turns, gases, e.g., carbon dioxide from heterofermentative fermentation, may be liberated from the cream. In order to maintain an even pressure within the churn, it is necessary to release these gases. This is done by depressing a small valve in the lid of the churn.

Each churn has an indicator glass – a small window through which it is possible to see what is happening inside the churn. When hand churning, the cream feels heavier as it begins to thicken. This takes about 15–20 min from the beginning of churning. The cream emulsion breaks and small grains of butter form. These are clearly seen on the indicator glass. The actual size of the butter grains varies according to the type and size of the churn. It is essential not to allow them to grow and form lumps, which will cause an uneven distribution of buttermilk.

For hand churning, the grains should be kept small, approximately 3 mm in diameter – traditionally stated as the size of wheat grains.

Chilled water at approximately 5 °C is added to harden and control the size of these grains, as well as removing the traces of buttermilk. Washing reduces the yield, and is not necessary if the cream is of good quality and all the necessary hygienic precautions have been observed in the preparation of the butter churn.

Salt may be added dry or in the form of brine as a final wash. The addition of brine (10% solution) to butter grains has been used to reduce the need for chilled water. This can be important during warm weather when there is a lack of chilled water. It will

Figure 1 Wooden butter churn (nineteenth century). From National Museums and Galleries of Northern Ireland, Ulster Folk & Transport Museum, with permission.

also prevent streakiness due to uneven mixing of the salt. For dry salting, the calculated quantity is sprinkled on to the butter grains to give approximately 2% in the final product.

The butter grains are 'worked' to expel excess moisture, create an even, fine distribution of water droplets and produce a close textured, evenly colored product. This may be carried out using the workers inside the churn or externally on a small scale, by using Scotch hands. These are made of grooved wood (or plastic) and are also used to shape and print attractive designs on the finished packs (Figure 3).

During the period of working, drainage, and addition of dry salt, samples are tested to determine the salt and moisture contents. The operator determines the 'end point' of working when the moisture content is between 15.5 and 16% and by visual assessment of the butter. At this stage, the butter is removed from the churn in readiness for packing.

The moisture content of butter must not exceed the legal maximum of 16%. Manufacturers attempt to be as near to that limit as possible to ensure the maximum yield.

Cultured butters Traditionally, cream is inoculated with specific cultures of bacteria. The reduction in pH and development of flavors produce a lactic-flavored end product. This is regarded by some as a more desirable product, i.e., a fuller-flavored butter. (*See* **Starter Cultures**.)

This method of making butter requires starter culture facilities with the necessary laboratory controls, and additional equipment such as cream-ripening tanks as well as cooling and aging facilities. There must also be a well-controlled program of temperature controls and pH monitoring.

Figure 3 Using Scotch hands to work butter. From National Museums and Galleries of Northern Ireland, Ulster Folk & Transport Museum (L882/10), with permission.

The cream is inoculated with approximately 1% of culture and incubated at 20–27 °C to achieve a final pH of 5.3–4.7, depending on the preferred lactic flavor. The cream is then cooled to stop the fermentation and to attain the desired fat crystallization.

The method of manufacture on a batch basis is no different from that employed for sweet cream. The disadvantage of this traditional system is that the buttermilk has a lactic content that causes problems in its disposal. The behavior of the starter culture is not always consistent, and this can result in end-product variations.

Because of the problems and expense of culturing cream and the disposal of 'lactic' buttermilk, several methods have been developed to make lactic or cultured butter from sweet cream.

The NIZO method developed in the mid-1970s consisted of churning sweet cream and adding a special mix containing cultured whey concentrate and bacterial culture while working the butter grains. This gave the major advantage of being able to manufacture from sweet cream, thus producing sweet cream buttermilk, which has a far greater commercial value than cultured cream buttermilk.

The indirect biological culturing system, as described, for example, by Pasilac – Danish Turnkey Dairies Ltd, involves the addition of two types of prepared starter culture to the churn at the working stage. The combination of aroma-producing bacteria and the acidity of the culture mix result in the final pH and flavor of the butter conforming to that of traditional cultured butter.

The addition of a starter distillate provides an alternative method of flavoring butter without the need for culturing equipment, while acidity is increased by addition of lactic acid.

Continuous Buttermaking

Continuous buttermaking equipment began to be widely used in the 1960s. The success of this equipment was such that, within a decade, most of the batch churns used in commercial butter manufacture had been superseded.

Continuous buttermaking equipment gives an advantage over the batch process in terms of hygiene, uniform product quality, and process efficiency.

Cream processing is an integral part of the whole buttermaking system. The preparation of the cream is similar to that for traditional manufacture. From the storage tanks, it is pumped into the first stage of the buttermaker at a constant speed and temperature.

The capacity of continuous buttermakers varies from small units of $12\,kg\,h^{-1}$ to more than $10\,000\,kg\,h^{-1}$ (Figure 4).

Although design features vary, the basic principles remain the same. A continuous buttermaker consists of: (1) the churning section; (2) the separating section and (3) the working section(s) (Figure 5).

Churning section A multibladed beater operating at high speeds (approximately 1000 rpm) within a cylindrical chamber introduces air into the cream and damages the fat globules. The distance between the cylinder wall and the beater blades is only 2–3 mm. In just a few seconds, the cream emulsion is broken, and the initial agglomeration of fat globules takes place. A mixture of small butter grains and buttermilk is then transported from this beating chamber into the next unit, the separating chamber.

Separating chamber This consists of a rotating drum where the final churning takes place and in which there is a perforated filter – a separation drum – to separate the buttermilk from the butter granules. The drum rotates slowly so that as the buttermilk is drained away, the butter grains are gradually clumped together.

Cooling may be achieved by circulating chilled water in the walls of either churning chamber. In some machines, the first buttermilk is cooled and recirculated. It is in this particular section that the grains of butter are allowed to grow to the required size.

The speed of the beaters, the temperature of churning, and the butterfat content of the cream will all vary slightly. An experienced butter manufacturer will adjust these parameters according to the season, equipment, texture, and consistency of the resultant butter. A firmer milk fat and, therefore, firmer butter are obtained in winter than in summer. In addition, the temperature of the cream has to be maintained at a lower temperature, e.g., 5–7 °C, in summer, whereas it could be at 10 °C in winter.

There is an observation window for the operators – similar to the sight glass of traditional equipment. The control panels may also have display screens, allowing operators to observe the processes inside the machine.

Working sections Augers transport the butter along the working sections and through aperture plates. The process kneads or works the butter, expelling more buttermilk and influencing the final body and texture of the finished product. The moisture droplets must be fine and evenly dispersed.

During this process of working, salt (if required) is added in the form of a 50% saturated slurry. Water may be added to adjust the final moisture content, and in the case of lactic butters, the mix of flavor distillates or concentrated bacterial cultures is added at this stage. The second part of the working section operates at a much higher speed to ensure that the culture or salt is correctly distributed.

The working sections are cooled with chilled water. The link between the first and second working sections operates under vacuum. This provides controlled deaeration of the butter, thus giving the end product a very close texture and improving the shelf-life. The body and texture of butter worked under vacuum are quite different from the open structure of traditionally worked butter.

To allow for the stoppages that must occur during normal production, a 'balance tank' is maintained between the buttermaker and packing equipment to buffer flow variation (Figure 6). This butter 'trolley,' as it is known, is constructed of stainless steel and performs the essential task of maintaining the flow of

Figure 6 Butter buffer tank. From APV Unit Systems, Denmark, with permission.

butter both from the buttermaker and to the packing equipment.

Packing

Wholesale The butter is packed in bulk or retail packs directly from the churn or from the trolley of a continuous buttermaker. Bulk butter is normally packed in 25-kg quantities in cardboard cartons. These can be lined with parchment paper, but colored polythene, enabling the inner wrapper to be readily seen, is the preferred lining material.

The simplest form of bulk butter packer is the 'Vane'-type packer – this is simply a hopper into which the butter is fed, either manually or pumped from the buttermaker trolley. The butter is extruded by a screw-conveyor through a suitably sized nozzle into the lined carton. When the carton is full, the flow of butter is stopped, and the butter is 'cut' with a heated wire. The full carton is then removed and checked for weight, which is adjusted manually. The liner is closed, ensuring there is no exposed product, and the carton is sealed, coded, and palletized. The normal quantity is 50 cases of 25-kg butter per pallet.

For large-scale production, automatic packers are normally an integral part of continuous buttermaking installations (Figure 7). The cardboard cartons are loaded flat, and the inner wrap is polythene from a reel. The machine forms the carton, lines it, and presents it for filling. Once full, the weight is checked,

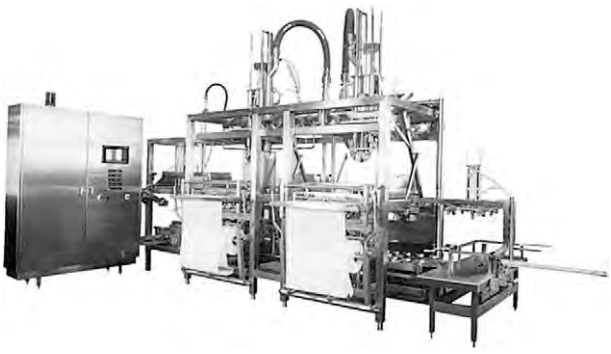

Figure 7 Butter packing line. From APV Unit Systems, Denmark, with permission.

and if necessary, additions are made via an 'injection unit,' which adds the required quantity of butter below the original surface.

On achieving the correct weight (25 kg), the liner is folded over the top surface, and the carton is closed, sealed, and coded. This minimal exposure to possible contamination has contributed greatly to the extension of the keeping quality of butter. Automatic palletization is also a feature of some installations.

Retail Butter is required to be sold in metric quantities. Most retail packs are in 250- or 500-g weights. The shape of the packs vary from a brick of differing dimensions to rolls, and packs may be foil- or parchment-wrapped. Attractively designed plastic tubs holding 250 or 500 g are also available.

For retail packing, the butter is formed in an appropriately shaped chamber on a rotating drum. This formed portion (roll or brick) is pushed out of the chamber into the waiting coded wrapper (parchment or foil), which is then folded. The portions are checkweighed before passing onwards to an automatic case packer and palletizer. The butter at this stage is still very soft in consistency, and any mishandling is likely to deform the portion.

Catering butter portions are packed in foil or plastic tubs with foil lids. The machines developed to pack this size of butter portion must operate at maximum efficiency. The quality of the butter, in terms of body and texture, is of secondary importance. The butter is extruded into the partly folded foil held within a shaped chamber, and the folding is then completed. Alternatively, the butter is discharged into a plastic tub before sealing.

Larger catering packs, e.g., 2-kg plastic tubs, are filled by extrusion before the lid is applied.

Reworked butter For marketing or distribution reasons, it may be necessary to rework bulk butter.

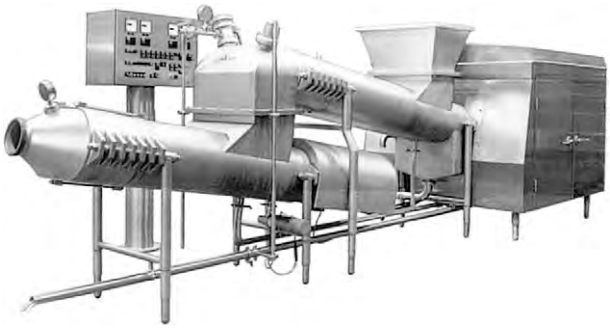

Figure 8 (see color plate 13) Butter reworking system. From APV Unit Systems, Denmark, with permission.

This butter, in 25-kg blocks that have been stored at either −18 or −25 °C, can be either attemperated, i.e., brought to a temperature suitable for packing, before working, or handled frozen.

Attemperation traditionally involves placing bulk butter in a store at 5–8 °C for a period to attain that temperature. The use of microwave tunnel heaters has reduced the space and time necessary, and is a more efficient way of attemperation. Blocks of butter may be brought up to blending temperature within hours, then blended and standardized on a batch or continuous basis to the required salt and moisture contents for packing.

An alternative process employs a butter reworking system that first chops the frozen butter blocks into strips. The spaghetti-like strips of butter leave the chopping unit at a temperature of 0–2 °C. They are then transferred into the blender where they are worked several times and vacuum-treated before repackaging in retail units (Figure 8).

Product Evaluation

Notwithstanding the aesthetic requirements of packaging and any legal requirements, the most important quality parameters of butter are its taste and keeping quality.

The modern continuous machines and their associated equipment are normally cleaned in place (CIP). Close collaboration between the design engineers, operators, and quality controllers is necessary to ensure effective cleaning. (*See* **Plant Design:** Basic Principles; Designing for Hygienic Operation; Process Control and Automation.)

Attention to detail, monitoring the critical aspects of the process, whether it be batch or continuous, is essential. It is, however, normal to sample the finished product to confirm that the desired microbiological, chemical, and organoleptic qualities have been achieved.

Microbiological

Microbiological guidelines for the acceptance of bulk butter into intervention storage are described by the Intervention Board for Agricultural Produce. For butter to be acceptable, it must have:

Total viable count: < 1000 organisms per gram (maximum 5000);
Coliforms: absent in 1 g;
Yeasts and molds: less than $10\,g^{-1}$.

Chemical

Butter composition and protection of use of the designated term 'butter' are described by the EC Council Regulations No. 1898/87 and No. 2991/94, respectively. Butter must contain not less than 80% milk fat but not exceeding 90%; a maximum water content of 16% and a maximum dry nonfat milk material (milk solids not fat) of 2% are permitted. Substances necessary for the manufacture of butter may be added, but such substances may not be used to replace in whole or part any milk constituent. Regulations for butter composition in other major butter-producing countries, New Zealand (Regulation 111. Butter, Food Regulations 1984) and USA (US Code of Federal Regulations Title 7, Volume 3, 7CFR58.345 and Title 21, Section 321a), are similar to the EC regulations. However, the New Zealand regulations also permit the fat phase used to prepare butter to be standardized for consistency by the removal or addition of physically fractionated fractions, provided that the fatty acid profile of the butter falls within the typical range. Such a product must then be identified as 'standardized butter'. The Australian New Zealand Food Standards Code may be found at www.anzfa.gov.au/foodstandardscode/.

Constant monitoring of the moisture and salt levels – where appropriate – is carried out during processing. On-line devices are available that link the machine controls to the moisture and salt determinations. These are necessary to match the manufacturing speeds now possible where traditional chemical analysis is too slow. However, these automated techniques still require calibration against standard laboratory methods.

Organoleptic Grading

The grading of butter involves much more than the tasting of the product. Grading normally takes place no less than 48 h after manufacture – a period necessary to allow the butter to 'cool' and 'settle.' Scoring standards and identification of defects are described for butter for intervention storage in the Official Journal of the European Community (1995) No.

L46/27. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods; Practical Considerations.)

The butter must first be stored or 'tempered' at 10 °C for 24 h prior to examination. A sample (plug) of bulk or tub butter is taken using a borer. For other retail portions, the brick or roll is cut half way down, and the lower half is broken apart.

The qualities measured are:

1. Flavor and aroma. These are judged by the smell and taste. A portion of the butter should be tasted but not swallowed. (*See* **Sensory Evaluation**: Aroma; Taste.)
2. Consistency. A very good butter should have a close body and waxy texture and should be well spreadable. The appearance of the butter will provide the experienced butter grader with much information. A portion of the plug is broken off to enable the texture to be examined, and a section is cut to observe the cut surface. Scoring reflects the desirability of the compact 'plastic' nature of butter produced by modern technology. The more open and grainier consistency of traditional butter may be viewed as a defect or alternatively considered in the 'specialties' category. (*See* **Sensory Evaluation**: Texture.)
3. Appearance and finish. Evenness of color and absence of free moisture, giving a 'clean, dry' butter, are the requirements for good-quality butter. Traditionally made butter had a very open texture, and free moisture was a frequent fault. With the advent of the vacuum section in continuous buttermakers, this particular characteristic or fault is now rarely seen. (*See* **Sensory Evaluation**: Appearance.)

Each of these attributes is given a score, dependent on the perceived relative importance of the characteristic. Scoring for acceptance for intervention storage is shown in Table 1. The United States Department of Agriculture (USDA) defines detailed criteria for butter grading based on flavor, body, color, and salt characteristics (USDA Standards for Butter, 58.2621–27, 1989).

Defects

Defects that arise in the finished product can normally be attributed to problems arising from two main areas: (1) the quality of the original milk or cream and its handling; (2) manufacturing defects; or a combination of both.

Taints and poor microbiological quality will give rise to off-flavors. A reduced shelf-life and physical defects can be caused by poor hygiene, temperature abuse, the use of inappropriate pumps, and over-agitation.

Utilizing cream received from other sources can give rise to numerous problems unless the receiving plant can be absolutely sure of the conditions under which it was produced and handled.

Operating faults, such as an imbalance between the speed of the first section of the buttermaker and too slow a cream flow, will cause the grains to be too large. Consequently, the buttermilk will not drain away cleanly, and the result will be a streaky, weak-bodied butter with free moisture.

Underchurning, with too high a cream flow and too slow a churn speed, results in small grains and incomplete separation of the fat and aqueous phases. This gives a butter with a very high moisture content and a pale color.

Overworking due to, for example, too much product in the working section, excessive conveyor speed, or apertures being too restricted, will give a weak-bodied, lifeless, and sticky butter, difficult to handle and likely to lose points at grading.

An open-textured butter with uneven salt and moisture distribution may be caused by too slow an auger speed, inadequate vacuum or too little product in the working section, or insufficient restriction at the adjustable apertures.

A mottled butter with excess moisture or excess salt can be the result of an inaccurate salt:water ratio in the slurry, or an improperly mixed slurry.

Packed butters held under chilled conditions have a finite life. Defects can develop from exposure to light, and taints are easily absorbed if butter is stored near strong flavors or smells. Foil-wrapped or sealed retail packs stored under the recommended chilled conditions should retain their premium quality for 2 months, whereas parchment-wrapped butters will develop surface faults after some 4–6 weeks.

Properties and Analysis

A M Fearon, The Queen's University of Belfast, Belfast, UK

Introduction

In the manufacture of traditional creamery butter, cream is churned to bring about a phase inversion and then worked to give a product having a continuous fat phase and a disperse phase containing water and globular fat. The properties of butter are determined both by its chemical composition and by the physical treatments applied throughout its manufacture. This article reviews the physical properties and chemical composition of butter, what factors affect these properties, and how they may be determined.

Physical Changes During Churning

The first stage of the physical transformation of cream into butter by churning occurs during the aging or tempering of the cream prior to churning. During this period, milk fat crystallizes and the fat globule membrane is weakened. The churning process is based on the incorporation of air into cream to create a foam and is achieved by vigorous agitation. Fat globule membranes, already weakened by cold aging, are further damaged by the mechanical stresses applied, and liquid fat escapes. This brings about collapse of the foam and clumping of the fat globules to produce butter granules which are then worked together to form butter. Some globular fat is present in the final product, but the amount will depend on the prechurning tempering treatment and the severity of the working conditions before and after processing.

Butter Microstructure

The microstructure of traditional creamery butter and the influence of processing factors thereon have been studied using freeze-fracture techniques in association with electron microscopy. These have shown how cream tempering conditions can influence the crystallization pattern of milk fat within the globules and hence their process stability and, ultimately, product firmness. The cold–warm–cold cream tempering procedure, which was developed to improve the spreadability of winter butter, results in globules with a thick surface shell of solid fat and crystal aggregates of varying shape and size in the liquid fat in the interior. This type of cream globule can withstand mechanical stress during churning and consequently gives a softer butter with a higher proportion of globular fat than that obtained from a low-temperature cream treatment. Electron microscopy studies have also shown how intensive mechanical working of butter during processing destroys fat globules, resulting in a highly homogeneous structure with a more crystalline interglobular phase and consequently a firmer texture. A recent development in butter manufacture has been the application of scraped surface technology, developed by the margarine industry, to produce a more spreadable product.

Chemical Changes During Churning

Butter is basically a concentration of milk fat along with some water and milk solids-not-fat (MSNF). The composition of the fat in butter reflects that of the original milk fat, although there is some loss of phospholipids, sterols, and free fatty acids, particularly volatile fatty acids, into the buttermilk during separation and churning. Greater change occurs in the physical state of milk fat during churning than in the chemical nature of its constituents. However, the combination of agitation of the milk during milking with extended holding of the milk on the farm and at the factory before pasteurization lead also to an increase in concentration of free fatty acids and consequently lipolyzed flavor in the product. The increase in lipolysis is probably due to increased accessibility of the fat to lipolytic enzymes because of damage to or loss of the protective milk fat globule membrane. Lipolyzed flavor may increase in stored butter due to the preferential release of short-chain fatty acids by enzymes with a high specificity

for these acids (secreted by psychrotrophic bacteria). In sweet cream butter (as opposed to lactic or ripened butter), in particular unsalted butter, the primary cause of flavor impairment is lipolytic rancidity. Thus, good manufacturing practice, at both the farm and the factory, is necessary to prevent a high level of free fatty acids in the final product.

Chemical and Physical Properties of Butter

Chemical Composition and Analysis

The composition of butter is described in the food regulations of most countries. Typically, butter contains 80–84% milk fat, 15.3–15.9% water, about 1% milk solids other than fat (casein, lactose, and minerals) and 0.03–1.8% salt. Milk fat is the only fat permitted in butter, although in some countries lower-melting milk fat fractions may be added during manufacture to produce a softer product which complies with the definition of 'butter.' A maximum water content (16%) is usually stated as it is important for the good keeping properties of the product. Butter may be salted or unsalted, but may not contain any added antioxidants. In some countries, natural coloring agents, such as annatto, turmeric, carotene, or curcumin are permitted. Neutralizing salts and lactic acid cultures are allowed for the manufacture of ripened or lactic butters.

Analytical methods for butter are included in the inventory prepared by the International Dairy Federation (IDF), the Association of Official Analytical Chemists (AOAC) and the International Standards Organization (ISO) on methods of analysis for milk and milk products. Apart from standard methods of analysis of butter components (moisture, fat, solids-not-fat, and salt), other analytical methods are cataloged, including methods to characterize milk fat, to determine the presence of a foreign fat, and to detect rancidity in butter.

Not surprisingly, many of the analyses for butter are concerned with the composition and properties of its fat. Some classical chemical constants for milk fat are summarized in Table 1.

Milk fat contains a comparatively high proportion of water-soluble volatile fatty acids, in particular butyric acid. The presence of these is the basis of both traditional (Reichert–Meissl, Kirschner) and modern (chromatography) tests to detect the presence of adulterating fat. Iodine value (a measure of unsaturation) is a useful identifier of summer or winter butter but it has commercial value too. Butter-makers in mainland Europe and Ireland apply the appropriate cream-tempering treatment, the Alnarp process, to produce harder or softer butter on the basis of cream iodine value.

Table 1 Chemical constants for milk fat

Chemical constant	*Value*
Saponification value (SV) SV = mg KOH needed to saponify 1 g fat	220–240
Iodine value (IV) IV = g iodine reacted with 100 g fat	26–42
Reichert – Meissl number (RMN) RMN = cm^3 of 0.1 mol l^{-1} alkali needed to neutralize the water-soluble volatile fatty acids distilled from 5 g saponified fat	20–35
Polenske number (PN) PN = cm^3 of 0.1 mol l^{-1} alkali needed to neutralize the water-insoluble volatile fatty acids distilled from 5 g saponified fat	1.0–3.3
Kirschner number (KN) KN = cm^3 of 0.1 mol l^{-1} alkali needed to neutralize the water-soluble volatile fatty acids distilled from 5 g saponified fat and which form soluble silver salts	18–30

Although more than 450 fatty acids have been identified in milk fat, only about 12 of these (Table 2) play a significant role in determining its physical, chemical, and nutritional properties. For detailed information on the composition of milk fat it is necessary to use chromatographic techniques. The fatty acid profile of milk fat is obtained by first preparing the more volatile fatty acid methyl esters and then separating these by gas–liquid chromatography (GLC) using a capillary column and a flame ionization detector. A triacylglycerol fingerprint of the fat may also be obtained using capillary column GLC, with resolution on the basis of carbon number and degree of unsaturation. Rapidly developing high-performance liquid chromatography (HPLC) techniques have found application for the resolution

of milk triacylglycerols whilst a combination of techniques, e.g., silver ion chromatography and reversed-phase HPLC, and new methods combining gas chromatography–mass spectrometry (GC-MS) can provide more detailed information on the molecular structure of milk fat.

Factors influencing chemical composition The fatty acids in milk fat originate from two main sources: those acids synthesized *de novo* in the mammary gland, C_4–C_{14} and a proportion of C_{16} acids, and those arising directly from the diet and taken up by the mammary gland from the circulating blood, i.e., the remainder of C_{16} and the longer-chain C_{18} acids. The principal factors which influence the relative contributions of fatty acids from these two sources are stage of lactation (shorter-chain acids) and composition of diet (longer-chain acids). Summer grazing of fresh pasture leads to a softer milk fat with a decrease in $C_{16:0}$ and an increase in $C_{18:0}$ and $C_{18:1}$ acids, whilst the reverse occurs during winter feeding of concentrates and silage.

Supplementation of the cows' diet with fats or oils to increase energy input, especially in early lactation, can also affect fatty acid composition. Generally, such a diet will tend to increase the yields of fatty acids $C_{18:0}$ and $C_{18:1}$ while decreasing the levels of the shorter- and medium-chain acids, C_6–C_{16}. If the supplemented fat is presented in a protected form, it can pass through the rumen without being subjected to ruminal hydrolysis or biohydrogenation and the composition of the resulting milk fat will reflect that of the supplement. Protected fats also allow rumen metabolic activity to proceed unimpaired by the adverse effect of large amounts of fat. The technology to produce protected fats has developed considerably since the early 1970s and is currently in use in Australia to produce butter with higher proportions of $C_{18:1}$, $C_{18:2}$ and $C_{18:3}$ fatty acids and lower proportions of the saturated C_{14} and C_{16} fatty acids. This butter has greatly improved spreadability whilst changes in the proportions of saturated-to-unsaturated fatty acids and the presence of *n*-3 fatty acids enhance the contribution of milk fat to human nutrition. Previous problems of rapid oxidation of milk fat arising from the high content of polyunsaturated fatty acids have been avoided by including additional vitamin E in the cows' diet. This additional natural antioxidant is transferred into the milk.

An alternative approach to feeding protected fats has been based on exploiting the $C_{18:0}$ to $C_{18:1}$ conversion which occurs during milk fat biosynthesis by the action of desaturase enzymes in the cows' intestine and mammary gland. The cows' diet must supply a high proportion of C_{18} fatty acids (e.g., from oilseed cereals) in order to optimize the desaturating activity of the bovine tissue. The resulting milk fat has an increased level of $C_{18:1}$ (oleic) acid and a reduced level of $C_{16:0}$ (palmitic) acid. Monounsaturated acids are less susceptible to oxidative reactions than polyunsaturated acids and the increased content of oleic acid in butter greatly enhances its spreadability at low temperatures.

Physical Properties

Physical constants Values for physical constants of milk fat are presented in Table 3. The refractive index for milk fat at 40 °C was once a valuable indication of its purity, but nowadays many fats used in the margarine industry will give a similar figure. The specific gravity of milk fat may be measured at different temperatures, although the difference in specific gravity between milk fat and other fats is greatest at around 40 °C.

Milk fat melts and solidifies over a temperature range so, rather than having a melting or solidification point, it has a melting and solidification interval (Table 3). Ideally, these ranges should coincide, but the dependence of the solidification interval on the rate of cooling and the influence of previous thermal history on the melting interval, as well as the dissolution rather than melting of fat crystals during heating, means that they rarely do so. Further information on the melting behavior of milk fat may be obtained using differential scanning calorimetry. This analysis is based on the thermal transitions that occur in a substance during heating and cooling.

The solid fat content in milk fat over a range of temperatures may be measured by nuclear magnetic resonance (NMR). This technique operates on the principle that protons placed in a strong magnetic field can, under certain circumstances, absorb energy from electromagnetic waves. This absorption, termed NMR, depends on the physical state of the protons and allows determination of the solid fat content (% SFC). The method was previously applied to butter only for research purposes but is now a regular quality control test for the dairy spreads, the physical

Table 3 Physical constants of milk fat

Physical constant	*Value*
Refractive index (40 °C)	1.4524–1.4561
Specific gravity (37.8 °C)	0.910–0.913
Melting interval	28–33 °C
Solidification interval	24–19 °C

properties of which at refrigerator temperatures are an important selling point.

Rheology Butter may be described as a plastic fat and depicted for rheological purposes by the Bingham model which describes ideal plastic behavior. In rheological terms, a plastic material flows when a stress greater than a limiting value (yield value) acts on it. However, aspects of butter behavior, such as work softening and thixotropic hardening, can only be explained by viscoelastic theories. Various instrumental techniques to measure butter firmness were evaluated by the IDF, which recommended the cone penetrometer as easy, quick, and cheap to use and with acceptable reproducibility. The IDF method relates penetration depth (p) to apparent yield stress (AYS) by the equation $AYS = gW/\pi p^2 \tan^2(\frac{1}{2}\alpha)$, where W is the cone mass, g the acceleration due to gravity and α the cone angle. For more detailed information on the textual characteristics of butter, a two-bite compression test using the Instron Universal Testing Equipment can be carried out. This provides a texture profile from which such properties as fracturability, hardness, cohesiveness, and springiness can be measured. German butter manufacturers favor the sectility test which measures the force at a set rate needed to cut through a portion of tempered butter with a wire of certain diameter and length.

Factors that influence butter consistency A number of factors, not all within the control of the manufacturer, influence butter consistency. The proportion of solid fat in butter is highly correlated with product firmness and is strongly influenced by the cows' diet. Feeding is responsible for the difference in firmness between summer and winter butters and can be directly related to the change in fatty acid composition of the milk fat, which is due largely to the changeover from summer grazing to winter silage and concentrates.

The number and size of fat crystals also affect consistency and are usually determined by crystallization temperature and rate during aging of the cream. Slow or stepwise cooling promotes the formation of fewer, larger crystals and a lower SFC which favor a softer fat. Cream aging is not required when butter is produced by scraped surface technology. The manufacturing process creates very many small (β') crystals in a firm, homogeneous product. Firmness is greatly reduced by mechanical working and, as fat crystallization is completed during production, postmanufacture hardening, common in traditional creamery butter due to crystal growth, is avoided.

Plastic fats like butter have a three-dimensional crystal network held together by reversible weak van der Waals attractive bonds and irreversible stronger bonds formed where crystals have grown together postmanufacture. During mechanical working of butter, such as the microfixing of bulk butter prior to retail packaging, the hardness of butter is reduced (work softening); and although the butter becomes harder again over several weeks it will not reach its original value. Work softening may be explained by the breaking of the bonds in the crystal network, while the reformation of reversible bonds into a new network structure is responsible for the gradual increase in hardness. This property of work softening has been exploited by butter manufacturers to produce an easier-spreading butter. Recovery of hardness during storage is slower at low temperatures but is accelerated by temperature fluctuations, hence such a product requires careful control during marketing.

Nutritional properties of butter Butter, along with other fat-containing dairy products, contributes just under 25% of dietary lipid in the UK and concern has been focused on the relationship of dietary lipid to coronary heart disease (CHD) and atherosclerosis. Two inversely related cholesterol-containing blood lipid fractions, low-density lipoprotein (LDL) and high-density lipoprotein (HDL), have an important influence on these diseases. High concentrations of plasma LDL generally indicate an increased risk of CHD with dietary saturated fats tending to increase LDL concentrations and polyunsaturated fats tending to reduce them. Milk fat, although containing about 30% oleic acid ($C_{18:1}$), is defined as a saturated fat, probably because of the low levels of polyunsaturated fatty acids present. Butter itself has been shown to cause elevated LDL levels and this has been linked not only to its content of saturated fatty acids but also to their esterified configuration. However, there is now evidence that *cis* monounsaturated fatty acids, far from occupying a neutral position in the diet and CHD, actually lower LDL concentrations whilst maintaining beneficial HDL levels. Consequently, the new 'monobutters' containing elevated levels of monounsaturated fatty acids (mostly oleic acid) will be attractive to consumers not only for improved spreadability but also for health reasons.

Interest has been shown recently in a branched-chain unsaturated fatty acid which is normally found in relatively small quantities in milk fat, conjugated linoleic acid (CLA). CLA, or its major isomer found in milk, *cis*-9, *trans*-11-octadecadienoic acid, has shown significant anticarcinogenic activity, antiatherogenic activity and other beneficial biological activity in studies with human cells and animals. CLA can arise directly in milk fat from biohydrogenation of dietary linoleic (18:2) acid in the cows' rumen.

Its major route into milk fat however, is via the desaturation of *trans* vaccenic acid, *trans*-11 18:1, (TVA), which is formed during the biohydrogenation of both linoleic and linolenic (18:3) acid. On reaching the cows' mammary gland, TVA is desaturated to CLA by the Δ^{-9} stearoyl Co-A desaturase enzyme. There are a number of research programs directed at increasing this and other functional fatty acids in milk fat by modifying the cows' diet.

Government recommendations for a healthy diet have included a reduction in total fat intake, particularly saturated fat. However, the balance of nutrients, fat types, and ratio of *n*-6:*n*-3 fatty acids must also be considered. Milk fat is an important source of fat-soluble vitamins, especially vitamin A, and provides small but useful amounts of vitamin D to diets of children, pregnant and lactating women, whose requirements are particularly high.

Dietary lipids, of the correct balance, are essential for our health but, in general, food will be eaten only if it is palatable. Milk fat contributes not only a pleasant flavor and aroma, but also an attractive texture and mouth feel.

Additives and contaminants Certain additives such as salt, natural coloring agents, lactic cultures, and neutralizing salts may be permitted in butter but these vary from country to country. However, butter may also contain very low concentrations of other components, called contaminants. Although contaminants are primarily synthetic chemicals, they also include microbial toxins, endogenous plant toxicants, heavy metals, and radionuclides. A comprehensive review of milk contaminants in Europe has been published by the IDF.

Chemicals such as the organocholorine-type pesticides and polychlorinated biphenyls have been scrutinized as they are lipophilic and tend to accumulate in the fat. However, levels of these chemicals detected in butter are below limits set in most countries and there is legislation in place governing their use. Organophosphates and carbamates are also widely used as pesticides but, as they are not lipophilic and are readily broken down by the cow, they give less cause for concern.

The risk of contamination of milk by such substances as detergents, disinfectants, and plasticizers (from packing materials and pipelines) may be minimized by good production practice both on the farm and at the factory. Antibiotics in milk can have a detrimental effect on the manufacture of cultured products and their use on farms is governed by legislation. Strict control of feed manufacture should avoid mold growth and the possibility of mycotoxin production and contamination of the milk.

There is little heavy metal contamination of butter through the feed, the cow acting as an effective filter. However, some contamination with copper and iron from dairy equipment can occur during and after milking; these metals act as prooxidants and the manufacturing treatments which are applied to butter make its component fat phase particularly susceptible.

There is little cause for concern over radionuclide levels in milk. Nevertheless, following the Chernobyl reactor incident in May 1986 and the associated increase in radioactive fallout over Europe, especially Scandinavia, monitoring of agricultural produce still-takes place. The isotopes concerned were iodine-131, cesium-134, and cesium-137. Although iodine-131 has a short half-life of 8 days, iodine accumulates in the thyroid gland and high concentrations can be reached. Milk was found to contain all three radioactive isotopes of concern but butter had very low levels, with the isotopes being distributed in the serum rather than the fat phase.

Dairy Spreads

Traditional table spread products such as butter must compete with the plethora of blended dairy spreads on the market. These blends have improved spreadability over butter, are more competitively priced, and appeal to the health lobby owing to their increased levels of unsaturated fatty acids and, in some instances, lower fat contents.

The simplest type of dairy spread may be obtained by blending cream or butter with a liquid vegetable oil such as soya bean oil. The mixture of cream and vegetable oil may be churned in a batch or continuous butter-maker, but if oil is added to butter itself, high shear rates are required to insure good mixing. Increasing the level of oil to improve spreadability at low temperatures results in oiling-off and loss of body at higher temperatures. This can be avoided by mimicking margarine manufacturers and including a proportion of saturated (hydrogenated) fat to maintain body and aid emulsion stability. Typically, such a product would contain a vegetable oil such as soya bean oil, a partially hydrogenated oil and cream, and may be manufactured in a continuous butter-maker or, more commonly, by using scraped-surface technology. The fat content of these two types of dairy spreads is usually in the region of 70–80%.

The third type of dairy spread available is the low-fat product. In low-fat spreads the aqueous phase makes up about 52–75% of the product compared with a maximum of 16% in butter. The fat phase is composed of vegetable oils, hydrogenated vegetable oils and possibly milk fat, with sodium caseinate or a

buttermilk protein concentrate added for both flavor and water-binding/emulsification purposes. The early low-fat products contained milk fat as the principal fat but both financial and consistency considerations have led to the development of products having no or very low levels of milk fat and depending on the milk protein for flavor. One particular problem arises with these products due to the use of milk protein. As the fat content is reduced, the water-in-oil emulsion becomes less stable and milk protein, when added to such products with fat levels around 40%, tends to promote a phase inversion to an oil-in-water emulsion. This problem may be overcome by increasing the milk protein level (and increasing the cost), modifying their properties by heat treatment and by carefully selecting the emulsifier and stabilizer levels needed to maintain a stable emulsion. This type of product, which most closely resembles margarine, is manufactured using margarine technology in a scraped-surface cooler to bring about crystallization, mainly in the β' form. During manufacture, it is critical for the keeping properties of the product that good moisture distribution with large numbers of discrete moisture droplets and an absence of channeling is achieved. All three types of dairy spreads, as with the new spreadable butters, require packaging in tubs, as the traditional foil laminate or parchment wrapping provides inadequate support. Because of increased levels of unsaturated fats and an increased aqueous phase (which results in a larger size of moisture droplet), these products should be stored at a low temperature to preserve chemical and microbiological quality.

CADMIUM

Contents

Properties and Determination

G Zurera Cosano and M A Amaro López, University of Córdoba, Córdoba, Spain

Background

Cadmium is a natural element in the earth's crust (atomic number = 48, atomic weight = 112.411, electronic configuration (K_r) $4d^{10}$ $5s^2$, and oxidation states 2). Cadmium metal is generally described as bluish or silver white in color, and as being relatively soft, ductile, and malleable, but this form is not common in the environment. It is usually found as a mineral combined with other elements such as oxygen (cadmium oxide), chlorine (cadmium chlorine), or sulfur (cadmium sulfate, cadmium sulfite). These compounds are all stable solids that do not evaporate, although cadmium oxide is often found as part of small particles present in air.

Most cadmium used is obtained as a byproduct from the smelting of zinc, lead, or copper ores, probably owing to its chemical similarity. Cadmium has a number of important industrial applications, but it is used mostly in metal plating (electroplating, alloys, and solders), pigments, plastics (stabilizers for polyvinyl chloride), batteries, photovoltaic cells, etc. Most uses of cadmium are 'dissip–ative,' the products using it are widely distributed in the environmental and hard to recycle.

Cadmium is fairly widely distributed and is found in shales and igneous rocks, coals, sandstone, limestone, lake and oceanic sediments, and soil. Cadmium has been listed as a pollutant of concern due to its persistence in the environment, potential to bioaccumulate, and toxicity to humans and the environment. Though cadmium has come into widespread use only fairly recently, it is quite likely that for many centuries this highly toxic metal has caused incidents of food poisoning. After mercury and lead, cadmium can probably be considered next in importance as an environmental pollutant.

Sources of Cadmium Exposure

Sources of exposure are many and include:

- Breathing contaminated work-place air (battery manufacturing, metal soldering or welding, smelting and plating operations, lithography, and engraving).
- Exposition of dust and fumes from the mining and refining of metals and contaminated air from the burning of fossil fuels (such as coal or oil) or the incineration of municipal waste materials.
- Eating foods containing cadmium; there are low levels in all foods (highest in shellfish, liver, and kidney), and drinking contaminated water.

- Inhalation of cadmium in cigarette smoke (most people who smoke have about twice as much cadmium in their bodies as do nonsmokers).
- Application of phosphate fertilizers or sewage sludge which increases cadmium levels in crops.

The primary source of cadmium exposure is food, since food materials tend to take up and retain cadmium (for example, plants from the soil, fish from water).

Occurrence in Foods

In order to understand the biological effects of cadmium in foods, it is necessary to have some idea of the distribution and occurrence of cadmium in air, water, and soil. Cadmium enters the air from mining, industry, and burning coal and household wastes and cadmium particles in air can travel long distances before falling to the ground or water. It enters water and soil from waste disposal and spills or leaks at hazardous waste sites; it binds strongly to soil particles, and some cadmium dissolves in water.

Furthermore, it is essential to try to determine how cadmium normally moves from one sector to another and to explore the way in which human activities may influence these processes. The importance of atmospheric cadmium in relation to its potential effects on humans lies not so much in its direct inhalation as in its possible contribution to soil, water, and vegetation through either dry or wet deposition and, ultimately, to food. In this respect, the solubility, pH, and chemical nature of the deposited fraction may be essential factors for controlling concentrations in food.

Cadmium in Air

Cadmium is universally present in the atmosphere in amounts varying from $1\,ng\,m^{-3}$ or less in rural or uncontaminated areas to 10–$50\,ng\,m^{-3}$ in congested urban areas. There is no definite relation of cadmium levels to the size of cities; some small but highly industrialized cities have levels which are greater than those of some very large metropolitan areas. The principal sources of cadmium in the atmosphere are thought to have resulted from emissions from smelters, reprocessing of various cadmium-containing metals, burning of plastics, or power generation from coal.

In areas around cadmium-emitting factories, cadmium concentrations in air are several hundred times greater than those in noncontaminated areas. The compounds of cadmium which exist in the atmosphere are not known with any certainty but it can be assumed that they are nonvolatile and that they are present in the particulate phase. Some of the probable forms are the oxide, sulfide, sulfate, chlorides, and other more complex ions or compounds.

Cadmium in Water

The cadmium content of water is extremely low. The occurrence in drinking water has of course been of special interest since this directly affects human intake. Cadmium levels in water, in the absence of contamination, are seldom above $1\,\mu g\,l^{-1}$. Contamination may occur as a result of the use of galvanized pipes and cisterns. Cadmium-containing solders in water heaters and other fittings can be another cause. Pollution of water due to the use of cadmium-rich sewage sludge for agricultural purposes has been reported on a number of occasions. The mean concentration of cadmium in rainwater is $0.001\,\mu g\,ml^{-1}$ in clean areas and $0.0037\,\mu g\,ml^{-1}$ in contaminated areas. The US Environmental Protection Agency estimates that consumption of the reference dose (RfD) of $0.0005\,mg\,kg^{-1}\,day^{-1}$ for cadmium in drinking water would likely not result in the occurrence of chronic noncancer effects.

Cadmium in Soils

Agricultural soils receive inputs of cadmium from soil supplements, such as phosphate fertilizers and sewage sludge, and from atmospheric deposition. Although the significance of sewage sludge as a source of cadmium contamination of soil is well established, European soil inventory studies indicate that, on a national basis, phosphate fertilizer and atmospheric inputs are the greatest sources of cadmium addition to soils. Levels in soils vary widely from about $0.06\,mg\,kg^{-1}$ in virgin soil to 10–$20\,mg\,kg^{-1}$ in the vicinity of some smelters.

Cadmium in Plants

Some species of plants have an ability to concentrate cadmium at levels that are sometimes much greater than those in the immediate environment. The ratio of cadmium concentration in plants to that in the corresponding soil has been reported to be as high as 10:1. The average cadmium content of terrestrial plants is about $0.6\,mg\,kg^{-1}$, although there is obviously a very wide variation even in uncontaminated areas. The range of values in species growing in clean areas is of the order of 0.01–$10\,mg\,kg^{-1}$ or more, but most plants contain below $1\,mg\,kg^{-1}$. However, some root crops such as carrots and parsnip, and some leafy crops such as spinach and lettuce, tend to contain more cadmium than other plant foods. This is also true of cereals and certain mushrooms, and this indicates that plants tend to take up cadmium from the soil, unlike lead. Variation in species is very great even

in plants growing in the same area, and there is also variation in different parts of the same plant. There seems to be good evidence that plants generally show increased tissue cadmium levels in response to an increase in the environment from normal sources or from soil, water, or air contamination.

Plants primarily absorb cadmium from the soil through their roots. This absorption is influenced by, among other factors, particularly the pH of the soil and the organic matter content. The cadmium concentration in plants is inversely related to the amount of organic matter in the soil. A large amount of organic matter in the soil limits the availability of cadmium to plants. Organic soils form the strongest metal complexes and hence retain the metal more firmly. An increased accumulation of cadmium by plants fertilized with superphosphate which contains cadmium as an impurity has been reported. With aerial application, it has been shown that the leaves of plants are an important entry point for cadmium.

Contamination of Food During Processing

The processing of vegetables prior to packaging can modify the content of cadmium. Washing and blanching decrease cadmium to varying degrees. These decreases are probably caused by cadmium being leached during washing and blanching and by thermal processing where cadmium is extracted into the water of brine.

Cadmium contamination occurs as a result of its use in plate-manufacturing equipment. Cadmium is readily soluble in weak acid solutions, so its use in food-processing plants should be confined to parts which do not come directly into contact with food. Another source of cadmium contamination is the utilization of ceramic and enameled utensils. Some glazed pottery, especially of the craft and homemade kind, is capable of releasing toxic amounts of cadmium and other metals into food.

Enameled kitchenware can also be a source of cadmium contamination of food, especially those which have bright colors, indicating the possible use of cadmium pigments. Another domestic source of cadmium contamination is the decoration and printing applied to glass tumblers and other containers. Furthermore, the spices, condiments, coloring, and preservatives which are added to foodstuffs may contain cadmium and be a vehicle of contamination. (*See* **Food Poisoning**: Classification.)

Cadmium Level in Foods

As cadmium is ubiquitous in the environment, all food is exposed to and contains cadmium. Except where there has been pollution, cadmium is normally found at a fairly low concentration in foodstuffs that generally contain less than $50\,ng\,g^{-1}$.

The Codex Committee of Food Additives and Contaminants (Joint Food and Agriculture Organization (FAO)/World Health Organization (WHO) Food Standards Programme) indicates that the dietary intake of cadmium fluctuates between 10 and 50 μg $person^{-1}\,day^{-1}$ for noncontaminated areas. The major sources of cadmium dietary intake are cereals, green leafy vegetables, potatoes, liver, and kidney (80% of total cadmium intake). Most fish contains little cadmium, with the average being less than $200\,ng\,g^{-1}$. Shellfish from unpolluted waters rarely have an average cadmium concentration greater than $1000\,ng\,g^{-1}$. A wide range of concentrations has been reported by different workers (Table 1).

Analysis of Foods for Cadmium

For cadmium analysis, an important aspect is the avoidance of airborne particulate contamination. The low level of cadmium in foods and the ubiquitous presence of significant levels of this element in some reagents, containers, and air make it necessary for the analyst to evaluate and eliminate all potential sources of contamination at each stage of the analysis.

Sample Preparation

Prior to the destruction of the organic matter, the sample should be subjected to drying and grinding in order to remove water from the product without reducing its dry-matter content. Normally, the moisture is removed and the analytical result expressed on a dry-weight basis. However, for nutritional purposes, it is common practice to express the concentration on a fresh-weight basis (i.e., wet-weight basis).

The drying procedure recommended by the Association of Official Analytical Chemists (AOAC) is vacuum oven drying at 100 mmHg pressure and at a temperature of 70 °C. The primary objective of grinding a sample is to homogenize it and, at the same time, reduce it to a suitable physical consistency so that it can be easily measured or weighed. A number of grinding procedures can be employed, but in any case reducing the sample to a finer particle size is desirable if the subsample chosen for analysis is to be less than 1.0 g. With all grinding procedures, contamination and segregation are potential sources of error.

Organic Matter Destruction

The traditional methods to solubilize biological and food samples are wet ashing with suitable oxidizing agents and dry ashing. Wet ash digestions are characterized by short ashing times (normally 3–4 h) and are

Table 1 Cadmium levels (ng g^{-1}) in individual food categories

Food category	*Cd level*	*Food category*	*Cd level*
Milk and dairy products

performed by adding acid or an acid mixture to the test portion and boiling until digestion is complete.

Numerous wet oxidation procedures have been proposed but they all fit basically into three categories of digestion mixtures: (1) HNO_3 and H_2SO_2, (2) HCl, H_2SO_2, and H_2O_2 and (3) mixtures containing $HClO_4$. Wet digestion is frequently criticized because elemental loss by volatilization can occur if the temperature of the digestion vessel is greater than 250 °C. A variety of procedures have been developed using different types of digestion apparatus to retain volatile elements. 'Hot-block' digesters have been used for improved temperature control and their reflux capabilities and 'PTFE (polytetrafluoroethylene) bomb' digesters have been used because digestion can take place in a sealed vessel, thereby retaining volatile elements.

The latest papers tend to suggest that the method of wet digestion in a microwave oven is perhaps the most interesting development in sample preparation

techniques. Current systems incorporate many features to improve digestion time, element recoveries, contamination, and safety. Improved recoveries can be achieved with systems operating under power-regulated control of pressure because these systems allow digestion to be completed without venting volatile elements. Sealed digestion vessels also reduce acid consumption and, in combination with Teflon construction, reduce contamination problems.

The advantages of microwave digestion with respect to the dry-ashing sample preparation method (at 550 °C) are rapid dissolution, complete digestion, sample integrity, minimal reagent use, lower reagent blank, simultaneous multiple sample digestion, possible automation, and contamination-free digested samples.

For the determination of cadmium in brine shrimp, four different digestion procedures were compared (dry ashing, wet ashing on a hot-block, high-pressure bomb digestion and microwave-oven digestion) and the conclusion was that microwave digestion (in polyethylene autosampler cups) was an excellent technique for the rapid digestion of submiligram amounts of biological materials.

Dry ash digestions use a long, slow ashing step, usually performed overnight in a muffle furnace, accomplished by high-temperature oxidation. The critical requirements are: (1) the nature of the ashing vessel; (2) position in the muffle furnace; (3) ashing temperature; and (4) time. Silica is probably one of the best materials for the ashing vessel, although glass beakers and well-glazed porcelain crucibles are also suitable. A critical initial requirement is to keep the temperature sufficiently low to prevent flaming or burning.

The ashing process is completed by the addition of a small quantity of inorganic acid to the residue and evaporation on a hot plate. The residue is redissolved in acid and the solution is brought to volume with distilled or deionized water. Element loss during the ashing process is greater for dry ash procedures than for wet ash procedures and 'ashing aids' are often employed to prevent loss of the more volatile elements. The addition of 1:1 dilute sulfuric acid to food materials prior to dry ashing eliminates losses of cadmium, although losses due to volatilization are possible as well as lack of recovery due to the formation of insoluble silicates.

Both techniques, wet oxidation and dry ashing, give reasonably comparable results and, in may instances, it is the analyst who makes the difference whichever technique is employed. However, wet digestion is recommended, using sulfuric acid and hydrogen peroxide: dry ashing can result in low recoveries since cadmium is volatile at temperatures over 500 °C, temperatures of below 450 °C being more appropriate. Furthermore, the digestion procedure selected needs to be tested for appropriate quality assurance and quality control guidelines that include the use of contamination control, digestion blanks, spiked test portions, replicate analyses, an appropriate reference material, and recovery calculations.

Analytical Techniques

Analysts nowadays have a number of techniques to choose from when making an elementary assay. The choice to be made depends on a number of factors, such as accuracy, precision, detection limit, sensitivity, the user's experience, performance with standard samples, and safety considerations. However, it may be the more practical considerations of instrument availability, cost, and sample form and quantity that become the governing factors rather than the choice being based on the above criteria. The analyst's skill, past experience, or lack of experience may dictate the selection of the analytical technique chosen. Personal preference may equally be a significant factor in this decision. (*See* **Analysis of Food; Heavy Metal Toxicology.**)

Spectrometric techniques are most commonly used and include flame atomic absorption spectrometry (FAAS), graphite furnace, or electrothermal atomization atomic absorption spectrometry (ETAAS) and inductively coupled plasma-atomic emission spectrometry (ICP-AES). (*See* **Spectroscopy**: Atomic Emission and Absorption.)

The general trend for solid sample introduction is slurry atomization. The slurries are prepared by grinding the sample with 3-mm diameter ZrO_2 beads in a laboratory shaker or mixing by ultrasonic agitation with dilute HNO_3. For determination of cadmium in protein foodstuffs and vegetables by ETAAS, the samples were stabilized with a thixotropic agent (Viscalex HV-30); to aid ashing O_2 was added during the ashing phase of the furnace program and matrix modifiers ($NH_4H_2PO_4$ and Pt) were included. The size of the food sample particles determined the stability of the slurry and also influenced the extent of matrix and chemical interferences. With respect to the direct insertion of solid samples into a graphite furnace, the use of a novel graphite tube described as a 'ring chamber tube' is reported; this obtains good accuracy for National Bureau Standards (NBS) and Standards Reference Materials (SRMs).

The main area of research in liquid sample introduction is based on flow injection systems to improve the analytical sensitivity. Preconcentration procedures are described, such as the use of microcolumn packed with a chelating resin. The compounds used most commonly as ligands are dithiocarbamates such as ammonium pyrrolidine dithiocarbamate (APDC),

diphenyl thiocarbazone (dithiozone), and others. They vary in their selectivity and are usually very dependent on the pH at which extraction is carried out. The organic solvent used most is methyl isobutyl ketone (MIBK).

The gaseous sample introduction is of a particular interest in the food industry, for technological and toxicological reasons, to determinate Sn, Se, As, and Hg in food samples by hydride generation AAS. For analysis of cadmium in food, the hydride generation is not used extensively.

Developments in methodology for atomic absorption spectrometry Atomic absorption spectrometry has been the most popular method for metal determination in general and the most widely used technique for analyses of trace elements in foods. The popularity of this method arises from its analytical specificity, good detection limits, excellent precision, and relatively low cost. The atomic absorption spectrophotometer consists of a light source (wavelength for Cd = 228.8 nm), an atomization source, and a dispersion/detection device. Three types of atomizers are commonly used: flame, graphite-furnace and chemical vaporization.

With regard to FAAS, the air–acetylene gas mixture is the most commonly used, producing a flame of about 2400 °C, but it is not totally interference-free. There are various ways to improve FAAS sensitivity for determination of cadmium in foods, such as the use of slotted quartz tubes, atom-trapping techniques (water-cooled and slotted-tube atom traps), where atoms are trapped (condensed) on to a cool silica tube which is situated in an air-C_2H_2 flame and flow injection systems with incorporation of minipreconcentration columns.

Graphite furnace or ETAAS has been used for the measurement of selected elements, including cadmium, when FAAS detection limits were insufficient. Perhaps the main development has been the introduction of graphite probe atomization to ETAAS.

The main problems with FAAS and ETAAS analysis are matrix and spectral interferences. Deuterium arc and Zeeman-effect background corrections have been applied to reduce spectral interference in cadmium analysis. While deuterium arc background corrections are generally inadequate, Zeeman-effect background correction appears to be satisfactory for routine analysis. Various 'matrix modifiers' (organic and inorganic reagents) have been used to reduce matrix effects, such as molybdenum, lanthanum, and ammonium dihydrogen phosphate. Solvent extraction of cadmium complexes is another approach taken to minimize matrix effects.

Developments in Multielement Analysis

Inductively coupled plasma (ICP) excitation has revolutionized the field of emission spectroscopy, providing the analyst with a powerful multielement technique with good sensitivity for cadmium at 214.440 or 226.502 nm. Food and food products can be prepared for ICP analysis by either wet oxidation or dry ashing and samples with a wide range of elemental concentrations can usually be handled without the need to dilute or concentrate, since the ICP has a fairly large dynamic range. The current qualities of ICP – high speed, low detection limits (less than 0.01 mg kg^{-1} for cadmium), and excellent instrument stability – make this technology attractive for a wide range of analytical applications.

ICP-AES is used preferentially due to the possibility of handling a wide range of samples with minimum interference and of quantifying many of the metals, reducing analysis time, and providing a more sensitive determination of refractory elements. The potential of inductively coupled plasma mass spectrometry (ICP-MS) is affected by polyatomic interferences for some mineral elements that can be overcome by different sample introduction methods (hydride generation, flow injection, slurry nebulization) or separating procedures with chelating resins.

X-Ray Fluorescence (XRF) and Neutron Activation Analysis (NAA)

X-ray fluorescence (XRF) and neutron activation analysis (NAA) are the two main methods for noninvasive *in vivo* determination of heavy-metal concentrations in humans. Various XRF techniques have been developed for the measurement of cadmium, mercury, and lead, primarily in occupationally exposed persons to evaluate whether these cadmium concentrations could reveal previous occupational cadmium exposure in humans. Today, the technique can also be used for measuring kidney cadmium levels in the general population.

Both techniques are being used in foods for the analysis of trace elements. In XRF, a powdered sample is bombarded with X-rays and the Kα line of the element is measured using one of several different detectors depending on the wavelength of the emitted radiation. This technique is somewhat limited in scope as to detected elements and their concentration range. By XRF spectrometry is able to determine Cd in food with a detection limit of 2.5 $\mu g\ g^{-1}$.

In NAA, the sample is bombarded with elementary particles to light atomic nuclei to generate radioactive nuclides. The properties and intensity of the resulting radioactivity permit the identification and quantitative determination of the elements present in the

bombarded sample. The main advantages of neutron activation are the excellent accuracy at microgram and picogram ranges, matrix effects are minimal, and the sample can be either liquid or solid in form. For determination of Cd, the characteristics pertaining to neutron activation are nuclear reaction with ^{114}Cd (n, γ) ^{45}Cd, the half-life of the product is 54 h, and sensitivity (g) 10^{-8}.

Electrochemical Methods

The electrochemical methods are polarographic, both direct and alternating current, and anodic or cathodic stripping voltametry and polarography. Both techniques rely on the fact that different metals require the application of different electrical potentials before they are deposited from solution on to the cathode. The polarographic methods are suitable for dilute solutions with sensitivities of 10^{-6} to 10^{-9} mol l^{-1}.

Anodic or cathodic stripping voltametry is even more sensitive than usual polarography. After the cadmium ions have been preconcentrated from the solution and amalgamated into a stationary hanging mercury drop electrode, the process is reversed by using a more negative potential than the reduction potential of cadmium. Cadmium is oxidized and stripped anodically, using a slowly increasing positive potential. The measured current recorded during the stripping step is a direct linear function of the bulk concentration of cadmium. The detection limit for cadmium determined by anodic stripping voltammetry was 1×10^{-9} mol l^{-1}.

AOAC International indicates a multielementary method including the determination of cadmium in foods (AOAC Official Method 986, 15, 1996) adopted as a Codex Alternative Approved Method (type III) for anodic stripping voltammetry of cadmium, lead, and zinc in all foods, and another anodic stripping voltammetry method for the determination of Cd and Pb in foods (AOAC Official Method 982, 23, 1996), which is not applicable to fats and oils.

Speciation Studies

The role of atomic spectrometric techniques in chemical speciation is well documented using separation techniques prior to cadmium detection. The type of fractionation technique and its coupling to atomic spectrometers can only produce meaningful results when particular attention is paid to the methods used for sample collection, pretreatment, and storage to avoid the changes that can occur. The principal applications in this field have been the use of ICP-MS or ICP-AES as a multielement detector for high-performance liquid chromatography (HPLC) for the analysis of cadmium bound to metallothionein. Other applications are ETAAS coupled with HPLC for the determination of inorganic species. (*See* **Chromatography**: High-performance Liquid Chromatography.)

All methods must be validated by the laboratory prior to routine sample analysis by quality assurance/quality recommended procedures to avoid variability in reporting elemental contents in foods and improve the quality and reliability of published analytical results and data quality indicators. (*See* **Quality Assurance and Quality Control**.)

Toxicology

M Nordberg, Karolinska Institutet, Stockholm, Sweden

Introduction

Cadmium toxicology has been extensively reviewed during the last decades. Focus on food sciences and nutrition has been directed to dietary food intakes of cadmium in the population. Toxicity of metals depends on the bioavailability, species, source, and route of exposure. Nutritional factors such as protein, calcium, zinc intake and iron status have an impact on the toxicity of cadmium. Acidification of lakes and soils influences the mobility of cadmium. In the population, different groups and subjects, e.g. with a low iron status (mainly women) have been identified as being more susceptible to cadmium exposure. It is thus important to identify vulnerable groups when setting recommendations for daily intake of cadmium.

Importance

Cadmium is considered an important world-wide pollutant. In the environment, humans are exposed to cadmium via food and drinking water. Cadmium bromide and iodide is used in photography and photoengraving, and cadmium sulfide (cadmium yellow) is used in high-quality paints, glazes, inks, and artists' pigments. Cadmium is present in the air as a result of incineration of household wastes and emission from industry, and mining. Cadmium particles can be transported in the air over long distances, and thus the ground and water can be contaminated far away from the emission source. Cadmium remains at levels depending on pH, bound to other compounds, in the soil and water. The body burden of cadmium is higher in smokers than in nonsmokers, because tobacco often contains cadmium. The mechanism for toxicity of cadmium involves metallothionein (MT), which also can be used as a biomarker in environmental exposure to cadmium and in biological monitoring.

Excessive exposure to cadmium gives rise to several human diseases, with itai-itai disease being the most severe. Cadmium has been shown to cause damage to the reproductive organs and to induce carcinogenesis in laboratory animals in organs such as the prostate and testes. Long-term human exposures have given rise to lung cancer in industrial workers. Cadmium was classified in 1993 as a human carcinogen (Group 1) by the International Agency for Research on Cancer (IARC), based on experience in experimental animals and in welding environments, where inhaled cadmium could cause lung cancer. Some uncertainty exists in this assessment, based on recent data. Because of the toxicological properties of cadmium, legislation implying considerable restrictions in its use has been passed in some countries. Industrial exposures as well as exposures in the general environment have to be kept below recommended exposure limits in order to avoid adverse health effects.

Discovered in 1917, cadmium is a soft, silver–white, tasteless, and odorless metal. It is a group IIB element in the periodic table with an atomic number of 48 and an atomic mass of 112.411. It appears together with zinc, but is softer, and is used, to some extent, in a similar way to zinc. Cadmium is found as an impurity of zinc carbonate, which, upon heating, changes color due to cadmium impurities. Several natural isotopes of cadmium exist. The melting and boiling temperatures are 320.9 and 765 °C, respectively.

Cadmium occurs in the earth's crust with an average distribution of 0.1 mg kg^{-1} and occurs naturally, associated with zinc, in the geosystem. It is found in sulfide ores, and many of the inorganic compounds, e.g., chloride and sulfate, are soluble in water. Cadmium oxides and sulfides are regarded as almost insoluble species of cadmium. Knowledge of cadmium's solubility in biological media is limited.

Occurrence

The frequent use of fertilizer explains the increased cadmium concentrations in the most heavily polluted areas. Cadmium occurs naturally, is widely dispersed in the environment, and is produced as a byproduct in the production of other metals. Human exposure occurs as a result of inhalation of cadmium-containing dust in industry and consumption of cadmium-containing food in the general population. Owing to its natural occurrence in the geo-environment, some farming products, including tobacco, may be high in cadmium. The concentration of cadmium can be 1–2 μg per cigarette.

Cadmium is present in food as a natural component. Foodstuff contains cadmium, with the highest concentrations being found in liver, kidney, cadmium-contaminated rice, and shellfish.

The Swedish National Board of Food Safety has calculated the contribution of cadmium from foodstuff to give a daily intake of 12 μg per day. This assumption is based on the concentrations of cadmium in foodstuff: meat, fish, and fruit 1–5; cereals, potatoes, root fruits 10–50; bran 150 and kidney and liver 100–400 μg kg^{-1}.

Metabolism and Kinetics

Absorption

Uptake of cadmium via inhalation is 5–35%, depending on the aerodynamic properties, solubility, and particle size. Higher uptake values are related to aerosols with a small particle size, e.g., cadmium in tobacco smoke. Uptake via the gastrointestinal tract in humans is estimated to be 4.6–7%. For humans with low iron stores, absorption values of up to 20% can be seen. Nutritional factors and dose influence the proportion that is absorbed. Conditions increasing the uptake of cadmium via the gastrointestinal tract include low intake of calcium, iron, zinc, and copper. A high intake of fiber can result in a lower level of intestinal absorption of cadmium.

Excretion/elimination

Excretion of cadmium via urine or feces largely depends on the route of exposure. Urinary excretion of cadmium has been demonstrated in a number of experimental studies in laboratory animals to represent about 0.01–0.02% of the total body burden

upon long-term exposure. In many mammalian species, urinary excretion increases slowly upon exposure to cadmium, and after renal damage has occurred, excretion of cadmium increases. For humans, it has been estimated that approximately 0.01% of the body burden is excreted in urine. Urinary excretion, like the body burden of cadmium, is age-dependent. If tubular proteinuria occurs, cadmium excretion increases. A high level of cadmium excretion without proteinuria may occur in short-term, high-level exposure. Cadmium is excreted in urine bound to MT.

Since it is not possible to distinguish net gastrointestinal excretion from unabsorbed cadmium in feces, it is very difficult to study net fecal excretion of cadmium. In oral cadmium exposure, approximately 95% of fecal cadmium represents unabsorbed cadmium. Fecal cadmium can be used as an indicator of oral intake. Studies of injected cadmium in experimental animals show that, initially, fecal excretion is greater than urinary excretion, calculated on a percentage basis. This is probably due to contribution from the bile. Data on fecal excretion of cadmium in humans are almost nonexistent.

Biological Half-life

The biological half-life of cadmium in the kidneys is estimated to be around 20 years in humans. Such a long biological half-life explains why cadmium accumulates constantly up to approximately 50 years of age in humans. Cadmium accumulating in the kidneys is probably largely bound to MT that is synthesized *de novo*. This process may be responsible for the long biological half-life of cadmium in the kidneys and its accumulation in long-term exposure.

Toxicokinetics

Cadmium accumulates in the body with age and has an extremely long biological half-life. Because of its long biological half-life of around 20 years, long-term toxicity is of particular interest. Also, short-term toxicity can be of interest. The kinetics of cadmium is related to chemical species of cadmium. Cadmium in the form of inorganic cadmium ions has a different metabolic pathway in the body compared with cadmium as metallothionein. For all types of damage caused upon cadmium exposure, MT is involved.

Toxicokinetic aspects including the mechanism for transport of cadmium to the kidneys by MT have been extensively studied in mammals and have provided evidence indicating that MT is important for transport of cadmium to the kidneys and that intracellular MT protects renal tubule cells from toxic insult by cadmium. The ratio of MT bound cadmium and nonMT bound cadmium is highly important.

After a single exposure, cadmium in blood plasma is mainly bound to albumin and other larger proteins immediately after uptake from the gastrointestinal tract or the lungs. There is time dependence, with a larger proportion of plasma cadmium being bound to low-molecular-weight plasma proteins (probably MT) at longer time intervals after a single administration. Cadmium bound to albumin is taken up in liver. In liver cells, cadmium–MT complex is dissociated, cadmium not bound to MT induces *de novo* synthesis of MT in liver cells, and the proportion of liver-cadmium bound to MT increases. In long-term exposure, there is a slow release of cadmium-MT from the liver to the blood. As mentioned before, after a single administration of cadmium, plasma-cadmium is mainly bound to albumin, and this form of cadmium is not taken up by the kidneys to any great extent. However, for cadmium injected into plasma as MT, the opposite is found, which means that a major part is taken up in the kidneys. In the tubular cells of the kidneys, the cadmium–MT complex is transported into the lysosomes, where MT is catabolized. The rate of influx of cadmium–MT into the renal tubular cell and the rate of *de novo* synthesis of MT in these cells regulates the pool of intracellular 'free' cadmium ions that can interact with cellular membrane targets in the tubules. When cadmium–MT influx into the lysosomes is limited, MT synthesis may be sufficient to produce enough MT to bind the limited amounts of cadmium. The 'free' cadmium pool is small, and no membrane damage occurs. Calcium transport in the cell is normal. When cadmium–MT influx into the lysosomal compartment is high, and *de novo* synthesis of MT is deficient, the 'free' cadmium pool is sufficiently large to interact with membrane targets to block calcium transport routes. This results in impaired uptake and transport of calcium through the cell with subsequent cell damage and increased excretion of calcium and proteins in urine. Cadmium–MT injection has frequently been used as a model to study several features of nephrotoxicity seen in long-term exposure to cadmium.

There has been some controversy over the role of cadmium–MT as a sequestering agent in the course of cadmium-induced renal tubular toxicity, and also the sensitive site in the cell has not been identified.

A role of metallothionein in transport of cadmium and nephrotoxicity, in modulating cadmium hepatotoxicity was advanced in the 1970s and has gained further support over the years. Cadmium bound to albumin is taken up in the liver. By transplanting cadmium-containing livers to noncadmium-exposed animals, i.e., animals with almost no tissue concentration of cadmium, a gradual uptake of cadmium in

the kidneys was demonstrated. These results support the transport model of cadmium in the body.

Iron deficiency increased levels of MT-1 in bone marrow of rats with hemolytic anemia, whereas the unchanged concentrations in liver and with a reduced renal concentration of MT indicate that MT-1 in blood reflects erythropoietic activity. This might explain how iron deficiency increases the absorption of cadmium. Cadmium is also recognized as a potent inducer of MT synthesis. Heavy exposure to cadmium gives rise to hemolytic anemia with increased urinary excretion, supporting the involvement of MT.

Health Problems Upon Cadmium Exposure

Cadmium has health effects upon both acute and long-term exposure.

Acute Toxicity

Cases of acute toxicity have been described in the past from ingestion of cadmium-contaminated food or drink. The symptoms of acute toxicity are nausea, vomiting, and abdominal pain. Acute toxicity after ingestion of drinks with more than 15 mg per liter of cadmium occurred in children after exposure to cadmium via a soft-drink machine. High cadmium concentrations can occur if acid food comes into contact with cadmium-plated utensils. A fatal case has been described after oral intake of a high dose of cadmium–iodine.

Chronic Toxicity

Human disease has occurred in some special situations, such as itai-itai disease in Japan, and renal dysfunction and increased occurrence of bone effects in Belgium and in China as a result of long-term effects related to cadmium pollution of the general environment.

Long-term exposure to cadmium via air, food, or water increases the cadmium concentration in the kidneys and gives rise to kidney disease. Other adverse effects that may be caused by cadmium exposure are lung damage, bone effects, liver dysfunction, and reproductive toxicity.

Chronic cadmium poisoning occurs as a result of long-term intake of food with increased cadmium concentrations or long-term inhalation of airborne cadmium in industry. Inhalation of cadmium affects the lungs. The most prominent adverse health effects upon long-term exposure to cadmium, regardless of exposure route, are renal tubular dysfunction and glomerular disturbance.

One of the most extreme forms of disease related to cadmium exposure by the oral route is itai-itai disease, described in Japan in the 1960s. Itai-itai disease is characterized by osteomalacia, osteoporosis, renal tubular dysfunction, malabsorption, and anemia. The bone effects are prominent features in humans suffering from itai-itai disease. The characteristics are multiple fractures and deformities of the spine and the long bones, and so far, these have been described only in Japan. Patients would suffer a considerable reduction in body height due to deformities of the spine, resulting from multiple compression fractures. In the long bones, characteristic pathologic fractures with osteoid formation (Milkmans pseudofractures) occurred, which is a typical finding in osteomalacia. Other characteristics included increased excretion of cadmium in urine and kidney damage with proteinuria. Itai-itai disease was a form of renal osteomalacia. The cadmium contamination of rice was due to cadmium contamination from a smelter that discharged material into the Jinzu River, which was used for irrigation of rice fields. Postmenopausal women were affected almost exclusively. The low calcium content of Japanese food may have been a contributing factor, like the tradition of dress to screen away from the sunshine, which gave the women only a low contribution of vitamin D, synthesized by the action of UV-light on the skin.

Epidemiological studies starting in the 1980s from Belgium, e.g., Cadmibel and PheeCad, concerning adverse health effects in humans in Belgium in the general environment reported an increased incidence of health effects occurring at much lower tissue concentrations of cadmium than were previously considered to be related to adverse effects by cadmium. It is interesting to investigate whether bone mineral disorders due to oral intake of cadmium can be related to the estrogen receptor, since it is known that itai-itai disease occurred almost exclusively in postmenopausal women. It has been reported that polymorphism for the estrogen receptor alpha is related to a reduction of bone mineral density in postmenopausal women in Japan. The genetic distribution of the receptor was, however, the same in itai-itai disease subjects. Nothing has been reported for the estrogen beta-receptor.

Epidemiological evidence indicates that diabetics might have an increased susceptibility to develop renal dysfunction upon cadmium exposure.

Kidney

Cadmium is a toxic metal with an extremely long biological half time, 15–20 years in humans. Upon exposure, adverse health effects may occur primarily as renal tubular dysfunction. Thus, the kidney is regarded as a critical organ independent of the exposure route. Cadmium is classified as a human

carcinogen based on the occurrence of lung cancer after inhalation.

After uptake cadmium in the blood is initially taken up by the liver and subsequently slowly redistributed to the kidneys because of its binding to the low-molecular-weight protein, MT. Cadmium bound to this protein in blood accumulates selectively in the kidneys. In long-time exposures, cadmium gradually accumulates, particularly in the kidneys but also in other tissues. When the concentration in the kidney cortex reaches 50 mg kg^{-1} or higher, damage to renal tubular cells may occur in the most sensitive persons, and the kidneys have a decreased ability to reabsorb proteins with increased concentrations of low-molecular-weight proteins and calcium in urine. As a result of long-term calcium losses and other metabolic changes related to the renal damage, osteoporosis, and, in severe cases, osteomalacia, occur (itai-itai disease; see Chronic Toxicity).

Cadmium-induced renal dysfunction influences cellular calcium metabolism. Cadmium accumulates in the kidneys, probably largely bound to MT that is synthesized *de novo*. This process may be responsible for the long biological half-life of cadmium in the kidneys and its accumulation after long-term exposure. The biological half-life of cadmium in the kidney is estimated to be around 20 years in humans. This explains why cadmium accumulates constantly up to approximately 50 years of age in humans. Renal toxicity develops when the total tissue concentration of cadmium in the renal cortex reaches levels between 50 and 300 $\mu g\, g^{-1}$. Renal tubular dysfunction occurs in various individuals at different total concentrations of cadmium in the kidney, depending on the variation among individuals in the ability to synthesize MT and other protective components.

Liver

Liver toxicity caused by cadmium can be modified by MT. Cadmium bound to albumin is taken up in the liver. Upon catabolism of MT, unbound cadmium is free to cause toxicity to liver cells. This happens after high cadmium exposure when MT levels are not high enough to handle all nonbound cadmium ions, e.g., the 'free' cadmium ions, Genetic polymorphism can influence the toxicity of cadmium, which is supported by studies in laboratory knock-out animals. The role of MT in cadmium-induced hepatotoxicity and nephrotoxicity, as well as in zinc-induced protection showed that MT-null mice were more sensitive to i.p. $CdCl_2$ hepatotoxicity. Zinc pretreatment by subcutaneous injection increased hepatic MT 80-fold in control mice, but not in MT-null mice, and prevented $CdCl_2$ hepatotoxicity in control mice only.

Endocrine Effects

Cadmium does not pass the blood–brain barrier, except when exposure is via nasal mucosa. Low-level cadmium exposure of lactating rats caused alterations in brain serotonin levels in the offspring.

Epidemiological evidence indicates an increased susceptibility in diabetics to developing cadmium-induced renal dysfunction, which might be related to changes in MT expression in diabetics.

Experimental studies on cadmium–MT nephrotoxicity show an increase in genetically diabetic as compared with normal Chinese hamsters. The Chinese hamster develops a subnormal pancreatic insulin release, insulin resistance in the liver, and sometimes hyperinsulinemia. These animals develop diabetic nephropathy with glomerular and increased effects of the glomerulus. The exact mechanisms behind cadmium-induced renal damage in diabetics need to be elucidated by further studies.

Physiological Conditions and Pregnancy

Pregnant rats have a faster decrease in hepatic cadmium levels and a faster increase in kidney cadmium levels compared with nonpregnant rats. Pregnant rats also have higher plasma cadmium levels and MT levels compared with nonpregnant rats. It is known from that that placental necrosis, fetal death and a condition in the dam similar to 'toxemia of pregnancy' develops after injection of cadmium in the late stages of pregnancy, including congenital malformations. Changes in brain development and related changes in brain enzymes have been reported in pups from rats treated orally with cadmium during pregnancy and lactation. Cadmium does not pass the placental barrier. This may have several explanations, including a sequestering role of MT. MT increases in the placenta of smoking pregnant women. The fetus is likely to be protected from cadmium exposure because the MT concentration increases in placental tissue. Human fetal liver contains MT rich in copper. There is a tendency in non-/ex-smokers towards increasing cadmium-blood levels during pregnancy, reaching a maximum at delivery, whereas an opposite tendency has been shown for smokers. The increase in nonsmokers may be related to the mobilization of cadmium from the liver to the blood during pregnancy.

Biological Monitoring

Biological monitoring of cadmium can be performed by measurements of cadmium in blood and urine. Cadmium in blood indicates ongoing or recent exposure to cadmium, and cadmium in urine reflects body burden. However, after external exposure to cadmium

has stopped, blood cadmium also reflects the body burden as the cadmium stored in the liver is released into the bloodstream. A metabolic model for cadmium can be used to estimate closeness to renal failure. Concentrations in urine and blood related to the risk of adverse effects are presented in the section on Risk Assessment below. Placental samples, if taken correctly, constitute a useful material for monitoring cadmium exposure in the human population. However, it is important to be aware that differences in cadmium within parts of the human placenta exist. Placental cadmium concentrations were four and six times higher than maternal and umbilical cord blood cadmium, respectively, Calcium, protein, and magnesia are excreted in urine after exposure to cadmium.

Cadmium analyses in biological samples should be handled carefully. The risk of contamination during sampling is largely due to contamination from smokers and if the persons handling the samples are smokers. Lack of knowledge of the smoking habits of the subject such as whether they are a present smoker, a previous smoker, or a person who has never smoked, is an another pitfall in interpreting concentration results in the sample. The long biological half-life of cadmium can influence the results up to 10 years after cessation of smoking. It is important to take into account smoking habits when drawing conclusions about the status of cadmium exposure and risk of development of adverse health effects due to cadmium exposure present or past. MT can be used as a bioindicator in monitoring both exposure and effects related to metal exposure. Humans with a low iron status and diabetics have been found to be more sensitive to cadmium exposure.

Risk Assessment

Risk assessment serves as a basis of preventive action for avoidance of adverse health effects in populations exposed to chemicals. Whether an agent causes reversible or irreversible effects is of importance in determining whether an effect is to be classified as a critical effect. It is important to define which characteristics and which cut-off level are chosen. The critical effect of cadmium exposure both in the general and work environment is renal tubular dysfunction. Renal damage occurs at a much lower cadmium concentration than previously estimated. Evaluations of recent studies in the general population concluded that an average level of cadmium in urine of 2.5 μg per gram of creatinine is related to a few percent excess prevalence of renal tubular dysfunction. A kidney cadmium concentration of 50 μg per gram of cortex wet weight, is reached after decades of a daily cadmium intake of 50 μg and results in excretion of cadmium in urine of 2.5 μg per gram of creatinine. This constitutes a higher risk of tubular damage than indicated by earlier estimates. These risk estimates are made for a population group in total. Estimates of risks for the development of renal tubular dysfunction have to be made for certain identified groups with increased risk, such as subjects with low iron stores and smokers. It has been suggested that a small percentage (1–5%) of such groups may develop renal tubular dysfunction with a lifelong daily intake of as little as 15 μg.

Oral intake of cadmium in high single dose via food or drink gives rise to vomiting, abdominal pain, and diarrhea in humans. Drinks of 16 mg of cadmium per liter and higher, corresponding to a dose of 3 mg and higher can result in the aforementioned symptoms. Long-term exposure via food in the form of rice with concentrations of around 1 mg kg^{-1}, which corresponds to an intake of 600 μg of cadmium per day, causes signs of malabsorption and some less pronounced symptoms. A weekly intake of 7 μg per kilogram of body weight corresponds to a daily intake of 70 μg or 1 μg per kilogram of body weight, which is equal to the provisional tolerable weekly intake (PTWI) for cadmium set at 500 μg. Lower lifelong exposures via food or drinks cause renal dysfunction in humans. This will likely reduce the present PTWI considerably.

After intake of 43 μg per kilogram of body weight as a single oral dose, early symptoms from the gastrointestinal tract in humans can be seen. This dose is set as an estimated lowest-observed-adverse-effect level (LOAEL) for a single dose of cadmium. Calculations based on LOAEL and a safety factor of 3–10 give a tolerable single dose between 0.3 and 1 mg (4–14 μg per kilogram of body weight). Long-term exposure, e.g. from months to a few years of daily intakes of 200 μg of cadmium (3 μg per kilogram of body weight), might be tolerated with the lack of symptoms from the gastrointestinal tract.

These doses for humans have not, at present, been connected with convincing evidence to cause reproductive or developmental effects. Because of this, a daily intake above 1 μg per kilogram of body weight should not be acceptable because of sensitive subpopulations such as children and pregnant or lactating women and humans low in iron status.

The PTWI is set to allow a certain variation of intake during a week provided that the weekly intake is not exceeded. Exposures above PTWI have to be compensated for by intakes below the PTWI for some time in order to avoid effects of the cumulative dose by long-term effects, e.g., renal dysfunction. Dietary intake of cadmium has been estimated to be 12–50 μg per day on average in various countries. The FAO/WHO has set a

PTWI of cadmium to 400–500 μg for adult persons, which corresponds to approximately 1 μg per kilogram of body weight for each day of the week.

A drinking-water guideline value of $5\,\mu g\,l^{-1}$ has been set by the WHO, which the US Environmental Protection Agency allows in drinking water. The Environmental Protection Agency regulates the cadmium concentration in lakes, rivers, waste sites, and cropland. The US Food and Drug Administration has a cadmium limit in food colors of $15\,mg\,kg^{-1}$. Sweden lacks threshold limit values for cadmium in food and is actively encouraging international organizations to set recommendations for the concentration of cadmium in food. A national recommendation restricts the intake of mammalian liver and kidney to one to two per week, or no consumption at all, depending on the age of the animal.

CAFFEINE

J Watson, Southampton General Hospital, Southampton, UK

Background

Caffeine is a purine-based chemical that is widely consumed throughout the world. In this article, consumption of caffeine and its subsequent metabolism are considered in detail. This is followed by a detailed description of the important physiological and psychological effects of this stimulant. The phenomenon of caffeine withdrawal is described because it is so commonly experienced and has important implications on caffeine consumption on a worldwide level. Finally, the therapeutic uses of this substance are considered.

Caffeine is a chemical substance that has been isolated from approximately 60 plants. In its pure form, it is a bitter-tasting, white, odorless, crystalline powder. Its botanical function is thought to be both an antifungal and insecticidal agent.

Caffeine was first isolated in 1820, by Runge and van Giese. It was included in the medical vocabulary in 1823, but it was not until 1875 that its structural formula was described by Medicus. Caffeine has a purine base, and its chemical name is 1,3,7-trimethylxanthine (**Figure 1**).

Caffeine is one of the most widely consumed substances in the world and, in moderate doses, is generally considered to have the effect of a mild stimulant, which is helpful in relieving minor fatigue and boredom, with a small risk of harmful effects. In view of

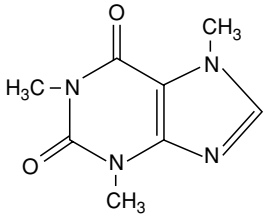

Figure 1 Chemical structure of caffeine: $C_8H_{10}N_4O_2$. Molecular weight: 194.19.

its ubiquitous use and popularity, an enormous investment has been made to examine health issues associated with its regular use.

Caffeine Consumption

There are various vehicles for caffeine consumption: some are internationally recognized, such as tea and coffee, but others are only locally consumed, e.g., maté in South America and miang in Thailand. Worldwide, the average caffeine consumption is estimated at 50 mg per day.

The properties of caffeine have been known since preliterate times, when its use was confined to specific areas – those where coffee plants grew wild (e.g., Ethiopia), until the time of European colonization, in the seventeenth century. At this time, caffeine-containing products were cultivated and subsequently became widely distributed. The combined physiological and psychological impact of caffeine depends on the pattern and degree of exposure to the drug. Thus, there has been extensive investigation into the caffeine content of widely consumed beverages and their consumption.

Caffeine Content of Beverages and Food

There is a marked variation in the estimates of caffeine content in different beverages. This arises from differences in:

- methods of preparation, e.g., methods of brewing tea and coffee;
- product source, e.g., black or green tea;
- reference volumes; and
- analytical methods.

Table 1 lists standard values that are widely quoted with respect to caffeine content.

Caffeine Consumption Studies

It is estimated that at least 80% of the adult population in the majority of countries worldwide consume caffeine on a regular (daily) basis. Variation exists in the nature of the caffeine vehicle. In the UK, 81% of adults drink tea, whereas in France, 81% drink coffee. In the USA, it is estimated that only 52.1% drink coffee, but more soft-drink beverages are consumed than in other countries.

Data for estimating a population's caffeine intake have been available from prospective and retrospective studies. In general, the former has gained more credence, and it has been shown repeatedly that there is a good correlation between reported caffeine intake and subsequent appropriate measurement of caffeine or caffeine metabolite levels. Table 2 shows the estimated mean intake of caffeine in several countries.

Table 1 Caffeine content of beverages and foodstuffs

Drink	*Caffeine content*
Coffee	
Ground roast	85 mg per 150 ml
Instant	60 mg per 150 ml
Decaffeinated	3 mg per 150 ml
Tea	
Leaf or bag	30 mg per 150 ml
Instant	20 mg per 150 ml
Cola	18 mg per 180 ml
Caffeine-free cola	0
Cocoa (hot chocolate)	4 mg per 150 ml
Chocolate milk	4 mg per 150 ml
Chocolate candy	5–20 mg per 100 g

Table 2 Estimated average daily consumption in certain countries

Country	*Mean intake (mg kg^{-1})*
USA	4
UK	3
Denmark	7

Pharmacokinetics of Caffeine

Absorption

Caffeine absorption from the gastrointestinal tract is rapid. About 90% of the caffeine in a cup of coffee is cleared from the stomach in 20 min, although the stomach is also able to absorb this substance. A wide variation in the time to reach peak plasma concentrations has been reported in humans (i.e., 15–120 min). However, absorption may be slowed by the presence of food in the intestine or when large amounts of the drug are ingested. On an empty stomach, the time taken is around 40 min, with 99% absorbed after 45 min.

Distribution

Once absorbed, caffeine, because of its hydrophobic properties, can pass through all biological membranes, including the blood–brain barrier. Salivary caffeine concentrations have been shown to correlate closely with plasma concentrations, reaching up to 85% of plasma levels.

After oral ingestion of 5–8 mg kg^{-1} in humans, the peak plasma caffeine concentration equals 8–10 mg l^{-1}. From this, it can be estimated that ingestion of a single cup of coffee, which provides a dose of 0.4–2.5 mg kg^{-1}, would give a peak concentration of 0.25–2.0 mg l^{-1}. In normal adults, the plasma half-life is between 3 and 7 h. Whereas there is little or no difference with increasing adult age, premature and full-term neonates show a markedly increased plasma

half-life, owing to the lower activity of cytochrome P450 and the relative immaturity of some elimination pathways. This state continues for up to 12 months but is then essentially stable throughout life.

Although the clearance rate is overall similar for men and women, it is related to the menstrual cycle, being slower in the luteal phase (6.85 h luteal vs. 5.54 h follicular). In the third trimester of pregnancy there is a significant prolongation of the plasma half-life (up to 15 h). In adult males who smoke, the caffeine half-life is decreased by up to 50% compared with nonsmokers.

Caffeine Metabolism

Caffeine is metabolized by the cytochrome P450 enzyme system. The major process is demethylation at the C3 position to produce paraxanthine, which accounts for up to 80% of caffeine metabolism. The other 24 excretory products include theophylline (1,3-dimethylxanthine), theobromine (3,7-dimethylxanthine), and both uric acid and uracil derivatives. Many of the metabolic steps may be saturable in humans, as the elimination half-time for caffeine and some of its metabolites is dose-dependent. Less than 2% of the ingested dose of caffeine is recoverable from the urine unchanged.

Mechanism of Caffeine Action

Caffeine exerts a variety of pharmacological actions at diverse sites, both central and peripheral. Whilst several processes have been investigated as being responsible for these effects, the mechanism must be activated by caffeine consumption within normal human amounts. This effectively rules out some hypotheses (Table 3).

Thus, the general consensus now is that the only known mechanism that is significantly affected by the relevant doses of caffeine (i.e., able to achieve an extracellular concentration of 10–50 μM) is binding to adenosine receptors and competitive antagonism of adenosine. Although the effects of caffeine on behavior have been well documented, understanding of its cellular mechanisms of action remains incomplete.

Adenosine receptors are widely distributed throughout the body, which befits the mechanism of caffeine action because of the substance's wide range of effects. For example, adenosine causes bronchoconstriction and negative inotropic effects on the heart, and inhibits gastric secretions, lipolysis, and renin release, all of which are the opposite of the effects of caffeine. Centrally mediated effects of adenosine are also the reverse of caffeine.

Four distinct adenosine receptors have been identified and cloned: A_1, A_{2A}, A_{2B}, and A_3. In humans, A_1 and A_{2A} have been shown to be important, as the other two are only stimulated with toxic concentrations of caffeine. Whereas caffeine is equally active at adenosine A_1 and A_{2A} receptors, it has been shown recently that the stimulatory central action of caffeine is mainly mediated through an inhibition of transmission of adenosine A_{2A} receptors.

Physiological Effects of Caffeine – General

The effects of caffeine are legion. Table 4 summarizes the effects of caffeine on the body, with the following sections describing the physiological effects on the functions of the cardiovascular, central nervous, and neuroendocrine (including adrenomedullary) systems. Psychological effects are considered separately.

Physiological Effects of Caffeine on the Cardiovascular System

The effects on caffeine on the cardiovascular system have been extensively researched in both experimental and epidemiological studies. It has generated much interest because of the debate regarding the

Table 3 Mechanisms of caffeine action

Potential mechanism of caffeine action	*Reference*	*Relative caffeine concentration required for effective activation (1 = a cup of coffee)*

Table 4 Summary of the physiological effects of caffeine on the body

	Effect of caffeine
Gastrointestinal system	Increases gastric acid secretion in susceptible individuals, not related to gastric ulcers
	Hepatic dysfunction increases caffeine half-life
	Digestive absorption of alcohol is increased when caffeine is consumed beforehand
Respiratory system	Relaxes bronchial smooth muscle
	Increases CNS sensitivity to carbon dioxide
Renal system	Stimulates renin release
	Diuresis resulting from increased glomerular filtration rate and decreased tubular reabsorption
Adipose tissue	Stimulates lipolysis
Bone tissue	In large amounts, coffee can contribute to a negative calcium balance in those with a low calcium intake

involvement of caffeine in cardiovascular disease. Experimental studies have investigated the effects of controlled caffeine exposure, whereas epidemiological studies have addressed the relationship of caffeine to cardiovascular disease.

Caffeine and Blood Pressure

The major cardiovascular effect of caffeine is peripheral vasoconstriction, resulting in elevated blood pressure, which is not accompanied by an increase in cardiac output. Acute tolerance to the pressor response does occur in regular consumers but is reinstated by a brief period of abstinence, as demonstrated by the referenced studies. This may be as short as 3 h. Other evidence has demonstrated that a second cup of coffee induces a pressor effect, albeit diminished. Finally, ambulatory blood pressure measurements on days of caffeine intake compared with placebo days are higher in usual caffeine consumers. Both systolic and diastolic blood pressures have been reported as being more significantly affected by an acute caffeine challenge.

In addition, caffeine increases cardiovascular responses to stress. This includes the pressor response to mental or physical stress, as well as other responses, e.g., cardiac output and forearm blood flow. As caffeine has pressor effects, it has been recommended as a treatment for orthostatic and postprandial hypotension.

Caffeine and Heart Rate

The effect of caffeine on heart rate is less well defined. Consumption within normal limits has been reported as being associated with a decrease, an increase or no change in heart rate. Whilst caution is advised with regard to tachyarrhythmias induced by caffeine, this is associated with excessive doses or underlying cardiac disease. Interestingly, it is widely believed that caffeine is associated with palpitations, tachycardia, and arrhythmias, by physicians.

Physiological Effects of Caffeine on the Central Nervous System

The physiological effects on the central nervous system are manifold. These include the effects of caffeine on cerebral blood flow, cerebral metabolism, and electrophysiological activity. The psychological effects will be considered separately.

Cerebral Blood Flow

Caffeine causes cerebro-vasoconstriction 30 min after ingestion, via antagonism of the vasodilatory properties of endogenous adenosine. This effect was first demonstrated over 60 years ago. A dose of 250 mg of caffeine causes a decrease in cerebral blood flow of 15–18% as measured by the Xenon inhalation technique. The effects of caffeine on cerebral blood flow have been demonstrated to last for 90 min and are independent of mood and arterial partial pressure of carbon dioxide.

Cerebral Metabolism

Following caffeine administration, the stimulant effects on the central nervous system (CNS) are associated with changes in local rates of cerebral energy metabolism. In rat studies, a caffeine dose of $10\,mg\,kg^{-1}$ causes increases in the motor and limbic systems, as well as the thalamus (specific nuclei only), substantia nigra, ventral tegmental areas, locus ceruleus, and raphe nuclei. These changes in glucose utilization correlate with changes in locomotor activity in rats and other behavioral modifications. The multiple areas of the brain that are affected by caffeine mean that, although the primary action of caffeine is to block adenosine (a neuromodulator), other neurotransmitters such as dopamine, norepinephrine, serotonin, acetyl choline, and glutamate are involved.

Neuroelectrophysiology

Caffeine is a cerebral stimulant, and thus its effects can be measured on an electroencephalograph. The

most consistent results from a number of studies is that moderate doses of caffeine effect the decrease in spectral power in the lower alpha and theta ranges. In addition, P300 amplitude increases with confidence, attention, arousal level, and reward. Such changes have been demonstrated with caffeine consumption.

Physiological Effects of Caffeine on the Neuroendocrine Function

The effects of caffeine in humans on the endocrine system appear to be confined to the endocrine response to stress, especially production of catecholamines and cortisol, although other hormones may be important too, e.g., growth hormone. Plasma concentrations and urinary excretion of epinephrine and norepinephrine are increased by caffeine consumption. Although the methods of augmentation have not been described in detail, it has been suggested that caffeine-stimulated release of adrenomedullary catecholamines is mediated by peripheral sympathetic nerves. Thus caffeine antagonism of adensoine receptors may result in increased sympathetic stimulation of the adrenal gland, leading to increased thyroxine hydroxylase activity and thus catecholamine synthesis. Like increased adrenaline production, norepinephrine synthesis is controlled centrally by sympathetic outflow.

Cortisol production is similarly augmented by caffeine and stress. This is thought to be mediated by an increase in adrenocorticotrophin. This action could also be partly due to caffeine's action on prostaglandins. The effects of caffeine on growth hormone and prolactin are less well defined.

Psychological Effects of Caffeine Consumption

Having previously discussed the effects of caffeine at a receptor and neuronal level, this section discusses the effects of caffeine on psychological responses. A large number of functions are affected, which would be beyond the range of this review, and so three specific functions are considered.

Behavior

Caffeine is erratically self-administered in animal models of drug self-administration. In humans, both self-administration and choice procedures have shown that caffeine acts as a reinforcer. In choice studies, subjects typically first sample caffeine or placebo and later have the opportunity to choose to self-administer one. Caffeine is chosen in preference to placebo in subjects with or without a prior history of caffeine consumption and is especially marked in those with a history of drug abuse. To date, the mechanism of action of caffeine on behavior in humans has not been extensively investigated. It is likely that an interaction between adenosine and dopamine receptors is important.

Performance

Owing to the enormous consumption of caffeine worldwide, there has been a vast amount of work on the performance effects of caffeine. It is far from clear how the benefits and drawbacks of its consumption balance out. In this section, the evidence for the psychostimulant effects of caffeine on performance is considered, as these are widely held to be the main benefits of caffeine use.

Numerous placebo-controlled studies have been published. Although the results are varied, with some studies showing no effect of caffeine, taken as a whole, they confirm a psychostimulant action of caffeine.

Whilst a wide spectrum of cognitive tests have been investigated in the above studies, usually, prior abstinence of caffeine was required at least overnight. This limits the relevance to caffeine consumption in everyday life. The problem with caffeine deprivation prior to testing, especially for a short period, means that symptoms of caffeine withdrawal can be invoked. Thus, it is not possible to describe the net effects of caffeine with these studies, especially as caffeine withdrawal has also been shown to decrease performance in both humans and animals. However, evidence in this area is inconclusive. A caffeine challenge of only 70 mg with 1.5 h of caffeine deprivation has been shown to improve simple reaction time.

Another standpoint in this discussion is founded on the demonstration of improved psychomotor performance in noncaffeine-deprived individuals. A large (9003 subjects) correlational study showed that there was a relationship between habitual caffeine consumption and performance (reaction time – simple and choice, verbal memory, and visuospatial reasoning), even when all variables were controlled for.

Mood

The effects of caffeine on mood have been studied extensively, and the results of these studies have been more consistent than in other areas of caffeine research. Caffeine in lower doses (up to 250 mg) has positive effects on mood in both caffeine-deprived and caffeine-tolerant studies. From these and many other studies, the benefits of acute caffeine ingestion on mood include an increase in energetic, confident, and alert feelings, as well as motivation to work, concentrate, or socialize.

Caffeine Withdrawal

The phenomenon of the caffeine withdrawal syndrome is well substantiated and characterized in detail. Table 5 lists the symptoms identified to occur in the caffeine-withdrawn state.

It is noteworthy that the prevalence of headache in the general population is 27%, yet only 6% coffee drinkers and 6% tea drinkers associate headache with omission of caffeine intake.

The time course for these symptoms to develop is short. Overnight abstinence is part of the usual pattern of caffeine consumption, and it is usual for withdrawal symptoms to develop. The symptoms increase for 24–48 h and then begin to improve. Usually, they have subsided by day 7. A high daily intake of caffeine can lead to a prolongation of the symptoms for up to 10 days or more. This may be explained by the fact that the rate of caffeine metabolism may vary by 13-fold throughout the population. It has been shown that caffeine consumption is directly related to the symptoms of caffeine withdrawal. A dose of 100 mg of caffeine per day is sufficient for caffeine withdrawal symptoms to occur. Three days of caffeine consumption is required before withdrawal symptoms occur.

Much work has been published on the subjective effects of caffeine withdrawal, but less work has considered performance. Although psychomotor impairment is not associated with up to 18 h of caffeine deprivation, impairments have been reported in a variety of tasks after 24 h.

The above summarizes the parameters whereby caffeine withdrawal occurs in an otherwise healthy population. It can be so disruptive to life that in 1994, the American Psychiatric Society included it in the DSM IV, although only as a 'proposed,' rather than an official, category.

Table 5 Symptoms of caffeine withdrawal

Increased	*Decreased*
Irritability	Well-being
Blurred vision	Desire to talk/socialize
Drowsiness/sleepiness	Urge to do work-related tasks
Yawning	Energy/active
Lethargy/fatigue/tiredness/ sluggishness	Contentment
Thick head	Flu-like feelings
Headache	
Self-confidence	
Heavy feeling in arms and legs	
Hot or cold spells	

Therapeutic Uses

A number of clinical uses have been suggested for caffeine. However, the only widespread therapeutic use at present is stimulating apneic premature infants. Initially, theophylline was identified to increase the respiratory rate, but caffeine had succeeded this because of its wider therapeutic index. Following a loading dose of caffeine, plasma caffeine levels are maintained carefully between 10 and 20 mg l^{-1}.

Other applications for caffeine include treatment of asthma and chronic obstructive pulmonary disease, because of its bronchodilatatory effects. In addition, it has been used to extend the duration of seizure, induced by electroconvulsive therapy. Uses in hypotension and allergic rhinitis have also been described. Caffeine may also aid the recognition of hypoglycemia induced by treatment of diabetes mellitus. Finally, caffeine is available in over-the-counter medicines for simple analgesia, cold remedies, and stimulatory preparations.

CAKES

Contents

Nature of Cakes

S P Cauvain, Campden and Chorleywood Food Research Association, Chipping Campden, UK

Definition

The definition of cake will vary slightly in different parts of the world but essentially the term refers to products which are characterized by formulations based on (wheat) flour, sugar and (whole) eggs and other liquids (milk), to which fat or oil may be added. The level of added liquids is such that a low-viscosity batter is formed rather than a dough. A key difference between cake and bread is that the former is most commonly baked in a mold, pan, or tin in order to contain the batter and to form a product of a given shape. Minimal processing of the batter is required before baking.

There is no significant gluten formation in cake batters and, indeed, cake-making technology exploits positive steps to prevent gluten formation. Modern cakes are produced by forming a complex emulsion and foam – the batter – which is processed by being heat-set. As a broad generalization, modern cake batters can be considered as fat, or oil, in water emulsion systems. The aqueous phase contains the dissolved sugar and suspended flour particles. In many batter systems air bubbles are incorporated by entrainment in the solid fat and they are held there rather than the aqueous phase. However, as the batter warms during baking, the air bubbles transfer from the fat to the aqueous-phase foam and expand. Later in the baking process the foam sets to yield the cake structure.

The key structure-forming component of cakes is the starch contributed by wheat flour and the modification of its gelatinization characteristics through the addition of sugars and high levels of liquids (egg, milk, water).

Cakes are characterized by being relatively high-density products, typically 0.4–0.7 ml g^{-3}, with a tender-eating, friable crumb, and sweet taste. Their final moisture contents typically lie in the region of 18–28%, lower than that of bread but higher than that of pastries, biscuits, and cookies. The organoleptic and mold-free shelf-life of cake products varies according to their formulations.

A Brief History of Cake Making

Representations of products described as 'cakes' are known from the twelfth century BC in Egypt. To what extent the products depicted equate to our modern view of cake is uncertain. Baking molds appear to have been used, since many of the products take the form of animals of the time. For example, a fried product resembling a snake is described. The first likely use of sweet substances in cooking/baking appears to belong to the ancient Greeks who knew of the special properties of the 'sackharon' or 'sweet reed' (sugarcane) from the Indian subcontinent. The advance of cane sugar into the Middle East was complete by about 700 BC. Sugar consumption continued to rise and spread, first with the expansion of the Roman Empire and later throughout medieval Europe.

Early cake recipes were probably based on the use of honey and in Roman times such confections were made for special occasions such as the Saturnalia and the New Year's fair. Recipe books of the time record the addition of honey to dough to make such cakes. In the medieval period cake recipes and their production are recorded in many European contexts. Access to sugarcane gradually improved with the voyages of discovery to the east and the Americas and the production of sweetened cakes increased and their forms proliferated through the sixteenth, seventeenth, and eighteenth centuries AD.

Types of Cakes

The term 'cake' is taken to include the forms listed in Table 1 and variants thereof. Cakes may be classified into six arbitrary categories:

- Low-fat sponges, containing less than 5% fat.
- High-fat sponges, containing more than 5% fat.

Table 1 Examples of cake formulations

	Sponge cake	*High-ratio cake*	*Chocolate cake*	*Fruited cake*
Flour	100	100	100	100
Sugar (sucrose)	105	115	130	120
Fat/oil	5	35	55	50
Baking powder	3	5	5	3
Whole eggs	50	30	30	45
Milk solids	5	6	8	5
Water	65	100	120	65
Cocoa powder			25	
Dried vine fruits				140

Recipes are based on 100 parts (e.g., 100 g, 100 kg, 100 lb) of flour.

- Low-ratio cakes, in which the levels of sugar and liquids in the formulation are individually less than the flour weight.
- High-ratio cakes, in which the levels of sugar and liquids in the formulation are individually greater than the flour weight.
- Fruited cakes, which have a proportion of dried vine fruits, fresh fruit, nuts, or other particulate materials in the formulation.
- Chocolate cakes, containing a proportion of cocoa solids.

Some examples of typical sponge and cake formulations are given in Table 1.

The Nature and Roles of the Ingredients Used

Flour

Cakes can be manufactured with most types of wheat flour. The most important contribution of the wheat flour is the starch, the gelatinization of which forms the major structural component of cakes. The hydrated wheat flour proteins form a significantly weaker gluten structure in cake batters than in bread dough because of the disruptive effects of the recipe sugars and fats in the cake formulation. In addition, the high levels of recipe liquids produce a low-viscosity batter which reduces the ability of the mixing action to impart the necessary energy for gluten formation. A protein continuum may form in the batter and this does make a small contribution to cake strength and gives a firmer eating quality.

Most commercial cake flours are characterized by the following key features:

- Particle size – improved cake quality is obtained when the particle size is reduced below that normally obtained from a standard flour-milling process. This is usually accomplished by regrinding the flour or through the application of air-classification techniques. The aim of both methods of particle size reduction is to free the starch granules from the enveloping protein matrix. Ideally, the maximum particle size of cake flours should be $< 90\,\mu m$.
- Postmilling treatment – the most common forms of treatment are exposure to chlorine gas and dry-heat treatment. Although the two treatment methods are quite different, the resulting change in flour properties is quite similar–notably, they cause changes in the hydrophobicity of the starch granules. The treatment makes the flours more suited to the production of the high-ratio type of cake. (Note that treatment of cake flours with chlorine gas is not now permitted in many countries.)

Sugars and Sweeteners

Sugar provides sweetness in cakes but also plays a significant role in batter aeration and structure formation. The influence on structural formation comes from the effect of the sugar solution formed in the batter on the gelatinization temperature of the starch. The higher the sugar concentration, the higher the starch gelatinization temperature and therefore the longer the time that the batter has to expand before it sets. Figure 1 illustrates the effects of increasing sugar level.

The most common sugar used in cake making is sucrose, though glucose and other sugars may be used. If reducing sugars are used, there is a tendency for discoloration of the crumb to occur at higher rates of addition.

Eggs

Whole egg is a common component of cakes, providing color, flavor, aeration, and structure-forming properties. The aeration and structure-forming properties come from the proteins which are present in the egg white. The addition of fat will interfere with the aeration power of egg proteins.

Some cake types, e.g., angel cake, may be made without the use of egg yolks. Using only the egg white confers a white color to the final product.

Milk

Milk products are commonly used to provide flavor and a source of water to dissolve the added sugar. Dried-milk products may also be used, provided another source of water is added in the recipe. Skimmed milk powder can be used for color and flavor. The powder should have been heat-treated before use, otherwise it may adversely affect product volume. The heat treatment is required to denature the globulins which are present, otherwise they can interfere with the stability of the gas bubbles in the batter and cause loss of product volume.

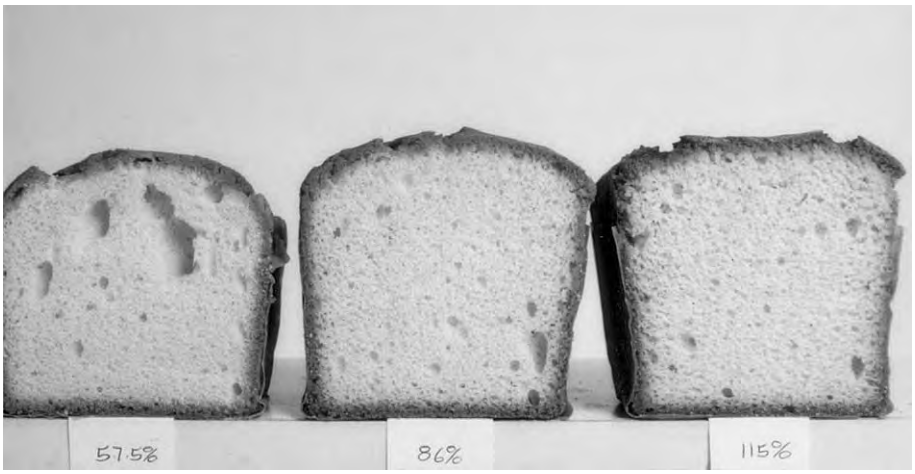

Figure 1 (see color plate 14) Cakes with (left) 57.5, (middle) 86 and (right) 115% sucrose based on flour weight.

Water

Water may be added to dissolve the recipe sugars, especially if liquid milk products are not used.

Fats and Oils

The addition of solid fat to a cake formulation is used to provide tender eating qualities and restrict the potential for gluten formation. The solid fat also aids the incorporation and stabilization of air bubbles in the batter. Polarization microscopy shows that, when subjected to agitation, the fat crystals align themselves around the air bubbles, thereby entrapping and stabilizing them. This is possible because the oil fraction in the fat allows the fat crystals to move and at the same time adhere to one another like links in a chain. It is apparent that in such a mechanism the ratio of liquid to crystalline fat and the size of the individual crystals are very important. If oil is used in the batter, the bubble stabilization effects will be absent and the cake will lack volume.

The crystalline form of the fat is important in promoting batter aeration. The three fat polymorphs of concern are the alpha, beta-prime and beta. Air incorporation in cake batters is greatest with fats in the beta-prime form, less with the alpha form, and least with the beta form.

Emulsifiers

Emulsifiers are used to aid the incorporation and stabilization of air bubbles in the batter, especially in the presence of fats or oils. The most commonly used emulsifiers for this purpose are glycerol monostearate (GMS) and polyglycerol esters, with the former being the more effective of the two on a weight-for-weight basis. Both emulsifiers are commonly used in a paste form, i.e., dispersed in water with other ingredients which promote gel stability. Emulsifiers like GMS may exist in a number of forms when dispersed in water and it is important it is in the active alpha-gel form when used for cake making.

Without GMS the egg protein will largely stabilize the air bubbles and the sponge will have a reasonable volume, but often with an area of coarse open-cell structure in the crumb. The addition of a small level of GMS somewhat unexpectedly produces a worse cake, with a dip in the top surface. It is apparent from this result that the GMS and the egg proteins do not combine their stabilizing power. At low levels the GMS is able to stabilize the bubbles at low temperatures, but it cannot continue to do so as the temperature rises and the bubbles expand during baking. Further increases in the level of added GMS eventually provide a stable batter and improved cake quality.

Baking Powders

A significant proportion of the final baked cake is air. This is a mixture of gases, partly air incorporated during mixing, and partly carbon dioxide generated from the action of sodium bicarbonate with a suitable food acid. The production of carbon dioxide gas and its release when the batter first enters the oven is an important part of the cake expansion mechanism. Without this extra release of gas the batter can only expand from the temperature effect on the air trapped in the batter and the cake will remain small in volume. Providing an extra release of gas produces a larger cake specific volume and gives it a more tender eating quality. The relative importance of mechanical and chemical aeration is shown in Figures 2 and 3.

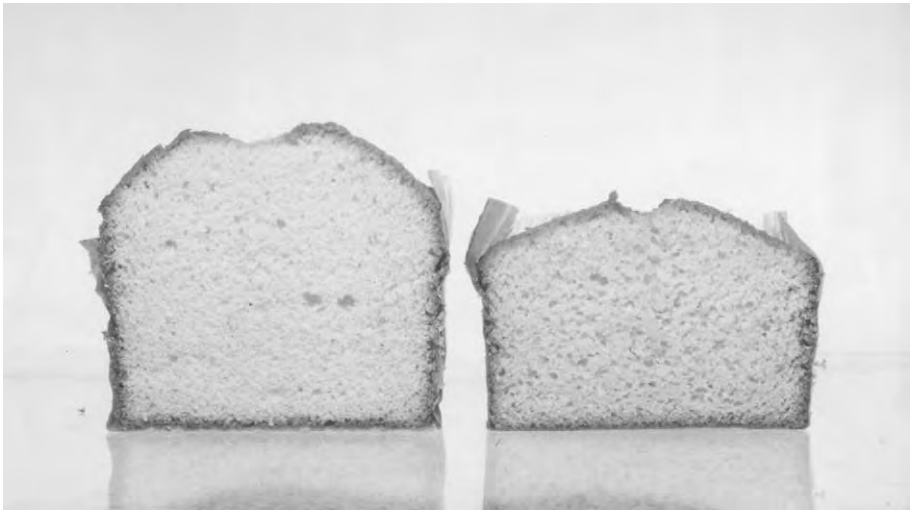

Figure 2 (see color plate 15) Cake (left) with and (right) without chemical aeration.

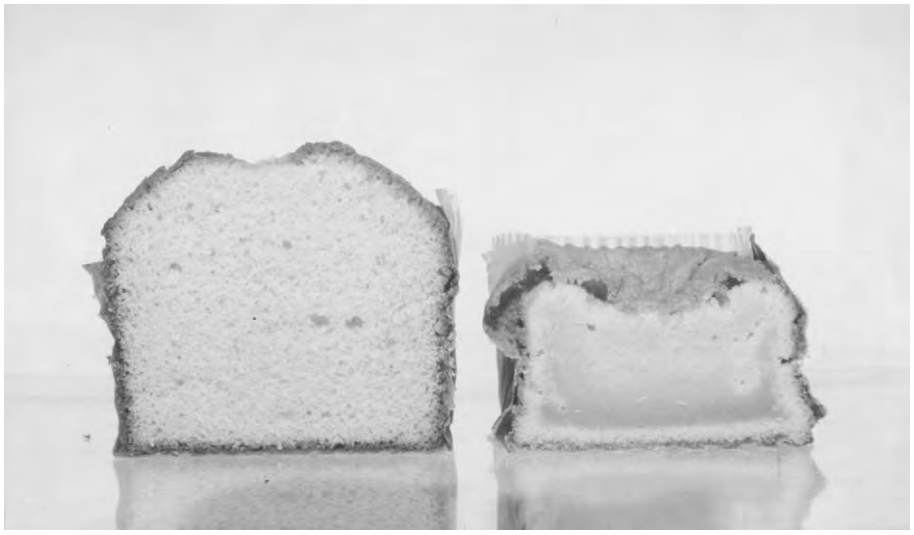

Figure 3 (see color plate 16) Cake (left) with and (right) without mechanical aeration.

The action of the baking acid on the sodium bicarbonate normally proceeds to completion, i.e., to release all of the carbon dioxide gas from the mixture. The flavor of the cake is influenced by the residual salt from the acid–base reaction. The rate at which carbon dioxide is released from the baking powder reaction is controlled by using acids of different types. The most commonly used baking acids and their rates of addition to achieve neutrality with one part of sodium bicarbonate are:

- Tartaric acid, 0.89, fast reaction
- Potassium hydrogen tartrate (cream of tartar), 2.25, fast reaction
- Acid calcium phosphate (monocalcium phosphate), 1.25, moderately fast reaction
- Glucono-delta-lactone, 2.10, moderately fast reaction
- Sodium acid pyrophosphate, 1.33, slow reaction
- Sodium aluminum phosphate, 1.00, slow reaction

Other Dry Ingredients

- Whey solids may be used for color and flavor. The powder should have been heat-treated before use otherwise it may adversely affect product volume.
- Cocoa powder is used in the production of chocolate cakes. It can come in several different forms.
- Salt may be used for flavor and improving product mold-free shelf-life.
- Humectants such as glycerol and sorbitol may be used to extend product mold-free shelf-life.

- Dried vine fruits are used in the production of fruited cake varieties.
- Candied orange and lemon peel and glacé cherries may be used in the production of fruited and speciality cakes.
- Dried nuts may be added to fruited and speciality cakes.

The Importance of Recipe Balance

The final quality of cakes is strongly influenced by the proportions of the ingredients that are used in the recipe. Since the wheat flour provides the main structure-forming component – the starch – it is common practice to construct the recipe based on the flour weight and express the mass of other ingredients as 'percentage flour weight'. This method of determining ingredient levels has the advantage that it is possible to deduce a series of 'rules' by which any cake recipe can be constructed and the causes of quality losses rectified.

Typical of the rules which are applied to cake making include the following:

- The level of sugar will lie between 95 and 135% flour weight for high-ratio cakes and 65 and 95% for low-ratio cakes.
- The level of water should be equal to and not exceed 1.25 times the sugar weight.
- The level of fat should not exceed the level of total egg used (i.e., solids and water combined).
- The level of fat should not exceed the level of sugar.

Imbalances in ingredient ratios will manifest as quality losses in the baked product. Many more specialized rules exist whereby the level of other functional ingredients, e.g., baking powder, may be determined. The range of acceptable ingredients ratios varies according to the type, size, and shape of cake being made.

Cake Shelf-Life

Water Activity

Cakes are commonly referred to as intermediate-moisture food products because the moisture content of typical cake products (approximately 18–28%) is high enough to confer soft and tender eating properties. At such moisture contents cakes are susceptible to microbial spoilage within a few days or weeks. However, it is the water activity of a cake product that controls the products microbial shelf-life rather than the moisture content alone. Examples of water activity in cakes are given in Table 2.

The formulation of the cake recipe is the main factor which affects its water activity and thus its microbial shelf-life. Particularly important in controlling water activity is the ratio of recipe water to the soluble materials. The latter will include salt and sugars. In addition, some other ingredients which do not go into solution but which have the ability to hold water and reduce its availability for microbial activity may be present. An example of the latter is flour which hydrates during mixing because of the presence of proteins and damaged starch. On baking, the flour proteins coagulate and the starch gelatinizes.

When soluble materials like salt and sugar dissolve in water they both reduce the vapor pressure of the solution. The potential effect of a particular ingredient depends on its individual chemistry. For example, salt is ionic and has a great affinity for water. Sucrose and other sugars (e.g., glucose) do not possess that same affinity of water and so for a given weight is less effective than salt at locking up water. The sucrose equivalent of an ingredient is often used to identify its likely affect on cake water activity. Some typical sucrose equivalents for cake ingredients are given in Table 3. The sucrose equivalent is based on a method which assigns a value of 1 to sucrose and compares all ingredient effects on an equal-weight basis. Thus, in Table 3 the value for salt is 11, which indicates that, weight for weight, salt is 11 times more effective at lowering product water activity than sucrose. Other materials worthy of note are glycerol four times more effective, sorbitol twice, and dextrose monhydrate 1.4. Many ingredients are much less effective than sucrose and therefore have values of less than one.

Table 2 Examples of water activity in cakes

Cake product	*Water activity range*
High-moisture cakes, such as carrot cake	0.9–0.95
Yellow, white, chocolate, and layer cakes	0.8–0.89
Fruited cakes	0.7–0.79
Celebration cakes	0.6–0.69

Table 3 Sucrose equivalent of some bakery ingredients

Ingredient	*Sucrose equivalent*
Salt	11.0
Glycerol	4.0
Sorbitol solids	2.0
Dextrose monohydrate	1.4
Sucrose	1.0
Flour	0.2

Spoilage Inhibitors

Where the microbial shelf-life of cake products is insufficient it is common practice to add a suitable mold inhibitor to add to the effect of product water

Table 4 Approximate increases in mold-free shelf-life with 1340 p.p.m. potassium sorbate in cake (pH 6.5)

Water activity	*Extra days at 21 °C*
0.92	2.5
0.86	8.0
0.80	40.0

activity. Commonly used mold inhibitors are sorbic acid and its salts (e.g., potassium sorbate). Levels of addition will vary according to the shelf-life requirements, with upper limits being controlled by legislation. In practice, high levels of addition will lead to changes in product flavor which may make the product unacceptable to consumers.

The effect of mold inhibitors in cake making is enhanced by the effect of water activity. An example of this relationship is given for potassium sorbate in Table 4.

Methods of Manufacture

S P Cauvain, Campden and Chorleywood Food Research Association, Chipping Campden, UK

Aims of Mixing

As discussed above, gluten formation is undesirable in cakes and is limited, in part, by the formulation, most notably high levels of sugar, liquid, and fat. Gluten formation may also be limited by the methods used to mix cake batters and the avoidance of any processing steps that may induce gluten formation. As a broad generalization, cake batters can be considered as fat, or oil, in water emulsion systems. The aqueous phase contains the dissolved sugar and suspended flour particles. In cake-batter systems, air bubbles are incorporated and held in the fat phase rather than the aqueous phase. However, as the batter warms during baking, the air bubbles transfer from the fat to the aqueous phase foam and expand. Later in the baking process, the foam sets to yield the familiar cake structure.

The aims of cake-batter mixing can be summarized as follows:

- to uniformly disperse the ingredients;
- to incorporate and stabilize the necessary air bubble nuclei; and
- to minimize gluten formation.

The main manufacturing methods for cakes are mostly based on the mixing process that is used. There are two main types:

- *Multistage*, in which various ingredients are mixed together as subcomponents before blending into the final batter. The aims of multistage mixing methods are to minimize gluten formation and to aid with the incorporation and stabilization of air

bubbles in batter. Such methods are traditional and probably derive from days when ingredient qualities were less reliable than today.

- *All-in*, in which all of the ingredients are placed in the mixing bowl at the same time and beaten together. All-in or single-stage mixing relies on standardized ingredients being available.

Mixing Methods

Sugar–Batter Processes

The essential features of this process are:

1. Creaming of the fat and sugar together. The sugar crystals aid the incorporation of air bubbles into the mixture, and the density falls as the mixing continues. This will be seen as a progressive 'whitening' of the mixture. The ideal creaming time depends on the type of fat being used, with higher-melting-point fats requiring longer creaming times. A medium speed, about 150 rpm, is typically used.
2. The addition of egg to the fat–sugar mixture in four to six individual portions with some blending between the addition of each portion. The aim should be the uniform dispersion of the egg without de-aeration of the mixture. It is important that the egg should not be at a lower temperature than the mixture, otherwise separation of the fat from the mixture may occur – this is known in the baking industry as 'curdling.' Additions of egg are usually made at low speed, typically around 50 rpm, with subsequent blending on a medium speed for short lengths of time.
3. The addition of the flour and other 'dry' ingredients with subsequent blending. The mixing time at this stage will be short and only sufficient to blend in the flour. A low speed is used.
4. The addition of final liquids, e.g., milk and water, blended in at low speed.
5. The addition of dried fruit, if required.

Flour–Batter Process

1. The fat and a portion of the flour (typically three-quarters of the flour mass) are creamed together at low speed for about 10 min, during which time, air is incorporated into the mixture, and the density falls.
2. The egg and sugar are whisked separately at high speed.
3. The fat–flour and egg–sugar are blended at low speed.
4. Any water or other liquids are blended into the mixture at low speed.
5. The remaining flour and other dry ingredients (e.g., skimmed milk powder, salt, and baking powder) are blended into the mixture at low speed.

Egg-separated Process

1. The fat, a portion of the flour (typically three-quarters of the flour mass), salt, and other dry ingredients are creamed together at low speed.
2. The egg is separated into its white and yolk components.
3. The egg white and sugar are whisked together at high speed to form an aerated foam.
4. The egg yolk and additional water or milk are blended into the egg white foam before being blended with the fat cream.
5. The remaining flour is blended into the mixture at low speed.

Boiled Process

1. The egg and sugar are whisked at high speed to form a foam.
2. The fat is heated.
3. The flour and other dry ingredients are blended into the hot fat.
4. The egg foam and the fat-flour blend are mixed together.

The final batter temperature is around 35–40 °C. The method is not usually considered suitable for recipes that contain baking powder because the high temperature causes premature release of carbon dioxide.

All-in Process

Using this method, all of the ingredients are placed into the mixing bowl and blended together at low and medium speed. The all-in method is particularly suitable for use with recipes that contain an emulsifier.

Sponge Cakes

Sponge cakes may be made with a simple formulation of flour, whole eggs, and sugar. The eggs and sugar are whisked together at high speed, typically 200–300 rpm. During this whisking process, large numbers of minute air bubbles are incorporated into the batter. Without some form of stablization, the air bubbles occluded during mixing would rapidly coalesce, rise to the surface of the batter, and be lost. In this sponge system, the surface-active proteins of the egg white and the lipoproteins migrate to the interface with the air occluded during beating, and form a protective film around the nascent gas bubbles and prevent them coalescing. When a stable foam has

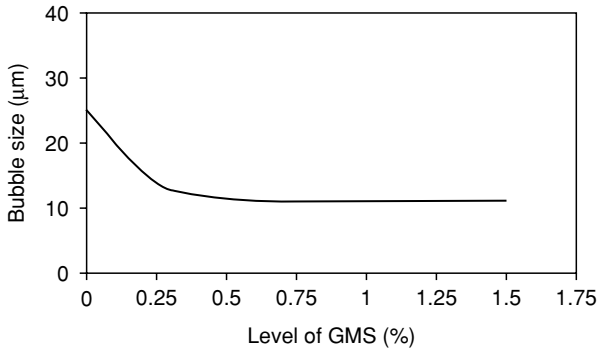

Figure 1 Effect of glycerol monostearate on gas-bubble size in sponge cake batter.

been formed, the flour is added carefully, trying not to de-aerate the foam. After depositing, the bubbles expand as the batter temperature rises in the oven, and eventually, just as the mass of the batter begins to set, the bubbles burst into one another to form the porous cake structure.

The addition of a small level of fat or oil to the recipe disrupts the interfacial films and prevents the egg proteins from stablizing the air bubbles. The result is a less well-aerated batter and restricted cake volume. To overcome this potential loss of volume, the fat can be melted and carefully added at the end of the mixing process once a stable foam had been formed. More commonly fat-enriched sponge cakes are made with the addition of glycerol monostearate (GMS), which displaces the egg proteins at the gas-bubble interface and provides the stabilizing role.

GMS controls not only the size of the air bubbles (see Figure 1) but also the quantity of air mixed into the batter. High levels of GMS allow large quantities of air to be incorporated into the batter in the cold, but unless there is a sufficient amount to stabilize the bubbles during baking, the sponge inevitably will collapse. Measurement of bubble sizes in cake batters at ambient temperatures shows that this property is governed, in part at least, by the amount of GMS present. However, an excess of GMS above an optimum restricts bubble coalescence during baking so that the foam remains intact and tends to shrink back on cooling. This gives the cakes an unacceptable wrinkled surface.

Delayed Soda Process

In some more traditional sponge making processes using fast-acting baking acids, the addition of the sodium bicarbonate in the recipe may be delayed to the end of the mixing cycle. This delayed addition of sodium bicarbonate insures that losses of carbon dioxide before baking are minimized.

Mixing Equipment

Planetary Mixers

The most common form of cake batter mixer is the vertical form that comprises a removable bowl in which the mixing tool describes a planetary motion. Typically, the mixing tools are removable, with the most common forms being a flat beater or a wire whisk. The former is commonly used with batters containing higher fat levels in the recipe, whereas the latter is mostly used with sponge batters. Planetary mixers can operate over a range of mixing speeds (usually three).

Horizontal Mixers

The mixing chamber of this type of mixer is fixed within the mixer frame but can be rotated through a limited arc to allow for the discharge of the cake batter. The mixing tools revolve around a horizontal axis within the mixing chamber. The chamber comprises two U-shaped sections with a single mixing blade operating in each section. Two mixing speeds are usually possible with this type of mixer. Ingredients are fed in from the top of the mixer.

Pressure Whisks

In this type of machine, the mixing is based on a rotating whisk, vertically mounted, and moving within a sealed mixing chamber. Since the chamber is sealed, it is possible to vary the pressure of the air within the mixer headspace during the mixing cycle. This increases the quantity of air that can be incorporated into the batter and so reduces batter density. Pressure whisks are most commonly used in the production of low-density sponge batters. The pressure whisk may be operated over a range of mixing speeds. Discharge of the batter from the mixing chamber may be under pressure direct to a depositor.

Continuous Mixers

Continuous mixers are most commonly used in larger-scale cake-batter production. The mixing chamber is small compared with other cake mixing machines, because the batter residence time for mixing is in the order of 10–20 s. The mixing tool comprises a form of round-sectioned, double-sided rotor covered in small, rectangular pins able to rotate in a round-shaped mixing chamber with similar-shaped pins projecting from the inner walls. The effect is to create a series of very narrow gaps through which the batter can pass, and the action provides an intimate mix. At the same time as being thoroughly mixed, the batter is aerated by the injection of air under pressure. The high shear of the mixing action

aids the dispersion of the air and the formation of smaller and more uniformly sized gas bubbles in the batter.

Mixing and batter aeration in continuous mixers are far more controlled than with any other type of cake mixer. All of the ingredients must be blended to form a slurry on a separate mixer before being fed to the holding tank of the continuous mixer. Aeration of the slurry is avoided. The residence time of the batter in the mixing head is a function of the throughput rate. The speed of the rotor may be varied. Levels of aeration can be varied by adjusting the air flow rate into the mixing chamber.

Continuous mixers may be used with most forms of cake batter, except fruited varieties, and also for the aeration of creams, meringue, and some forms of sugar confectionery.

High-speed, Vertical Mixers

High-speed, vertical mixers are most commonly used in the production of bread and other fermented doughs. However, they may be used in the production of pastes and cake batters. Mixing times are very short, typically less than 3 min, and the levels of aeration are lower than those achieved with most other mixer types.

Batter Handling and Depositing

The low viscosity and fluidity of most cake batters make them relatively easy to handle. However, batter handling should be kept to a minimum, because, while in motion, there is the potential for de-aeration of the batter, especially the loss of carbon dioxide gas from the baking powder reaction.

Individual portions of many cake batters are deposited into some form of container for baking. Typically, the baking container will be lined with greaseproof or silicone paper to provide easy release of the product after baking. Product shapes can vary, though round or rectangular are the most common. Some cake batter types, e.g., Swiss roll and sponge drops, may be deposited directly on to the oven band or sheet for baking.

Cake Baking

Cake batters may be baked in most oven types, e.g., deck, rack, and continuous. The baking temperatures are lower than used for bread baking and vary according to the type and size of cake. In many ovens, heat input will be greater at the bottom of the product than at the top. High heat inputs directed on to the top of the baking product commonly lead to problems with product shape and surface color.

Secondary Processing

While many cake types may be eaten in their baked form, a large number of cake products are combined with other food products to present consumers with a wide variety of products. Examples of other food products that may be used as a filling or topping with cakes include, dairy and nondairy creams, chocolate, icing and fondants, jams, and jellies.

Packaging

Some form of packing is required to hold cakes, protect them from microbial contamination, and prevent moisture losses that would have an adverse effect on the cake-eating qualities. Product packs take many forms, but most often, the material used will be impermeable to moisture to prevent drying out of the product. Wrapping composite cake products in moisture impermeable film may lead to problems of moisture migration between components, unless steps are taken to adjust the water activities of individual components.

Storage

The shelf-life of cake products is directly related to the storage conditions: the warmer the storage temperature, the shorter the microbial shelf-life and the greater the problem with moisture migration between the cake and other components (e.g., cream). Low-temperature storage is particularly important for dairy cream-filled cakes because of their susceptibility to bacterial growth. Refrigerated storage does not accelerate cake staling (unlike the situation with bread). Cake staling proceeds fastest with cake at temperatures around 25 °C.

Chemistry of Baking

J L DesRochers, K D Seitz and C E Walker, Kansas State University, Manhattan, KS, USA

Principal Ingredients in Cake Batter

Flour is the most important ingredient in cakes, functioning primarily to establish crumb structure. Cake flour is milled from soft white or red wheat with low protein and ash (mineral) levels and has a fine particle size. In the USA, cake flour is commonly treated with chlorine gas, causing hydrolytic depolymerization of the starch molecules, which increases the water-holding capacity of the flour. During mixing, proper gluten development is critical, to insure a fine foam structure without excessive toughening. Protein level and type and mixing procedure are key factors for producing cakes with desirable crumb texture. The optimal specifications for a typical cake flour are: protein content $8.5 \pm 0.5\%$, ash content $0.36 \pm 0.04\%$, pH 4.7 ± 0.2, and average particle size $10 \pm 0.5\,\mu m$. (*See* **Flour**: Roller Milling Operations; Analysis of Wheat Flours; Dietary Importance.)

Shortening performs three basic roles in cakes. First, it aids in aeration or leavening of the batter and finished cake by entrapping air during the creaming process. These minute air cells provide the nucleus for bubble expansion via steam and carbon dioxide during baking. Second, shortening coats the protein and starch particles, preventing hydration and formation of a continuous gluten–starch network. Third, it emulsifies liquids in the batter, which increases the moisture of the crumb. The last two functions contribute to a soft, tender crumb texture. (*See* **Fats**: Uses in the Food Industry.)

Eggs perform a variety of functions in cake production, providing structure, volume, tenderness, and nutritional quality to the product. They act as a binding agent due to their high protein content and ability to form a complex network with gluten. They contribute to cake volume and structure by their ability to be whipped into a relatively stable foam. Upon heating, the proteins are denatured, thus setting and stabilizing the crumb structure. The yolk portion of the egg imparts an emulsifying and tenderizing effect because of the high lipid and lecithin content. Eggs help stabilize the emulsion, retain gas generated by the leaveners, and prevent air cell coalescence in the batter, resulting in a uniform crumb grain and desirable texture. Eggs also add a mild but distinctive flavor and color (from the yolk) and enrich cake's nutritive value. (*See* **Eggs**: Dietary Importance.)

Chemical leavening agents are added to aerate the batter and produce a light, tender, porous product. The porosity of the batter directly translates into good volume, uniform cell structure, bright crumb color, tender texture, and overall eating quality of the finished cake. In lieu of yeast, chemically leavened cakes utilize sodium bicarbonate (baking soda) plus an acidic agent to generate carbon dioxide (CO_2) gas when combined in the presence of water. (*See* **Leavening Agents**.)

Baking powders are a combination of sodium bicarbonate and the salt of a weak acid (see Table 1 for examples). Baking powder should yield no less than 12% carbon dioxide based on the weight of the product. Starch or flour may be added as a diluent to standardize the baking powder's strength.

Baking powders are classified by their reaction rates as fast, slow, or double-acting. The fast-acting types release most of their available carbon dioxide within the first few moments of contact with liquid. If these batters or doughs are not processed very quickly, the gas will be lost before the structure is set and the volume will decrease significantly.

Slow-acting baking powders do not react at low temperatures and therefore require oven heat to release gas. Double-acting types react partially at low temperature, but need higher temperatures to complete the reaction. The double-reacting powders are most commonly used in commercial cake production.

Table 1 Acidic agents used in leavening

Acid	*Formula*	*Neutralization value*
Monocalcium phosphate (MCP)	$Ca(H_2PO_4)_2 \cdot H_2O$	80
Anhydrous monocalcium phosphate (AMCP)	$Ca(H_2PO_4)_2$	83.5
Sodium acid pyrophosphate (SAPP)	$Na_2H_2P_2O_7$	72
Sodium aluminum phosphate (SALP)	$NaH_{14}Al_3(PO_4)_8 \cdot 4H_2O$	100
Monopotassium tartrate (cream of tartar)	$KHC_4H_4O_6$	45
Sodium aluminum sulfate (SAS)	$Al_2(SO_4)_3 \cdot Na_2SO_4$	100
Dicalcium phosphate dihydrate (DCP)	$CaHPO_4 \cdot 2H_2O$	33
Glucono-δ-lactone (GDL)	$C_5H_{10}O_6$	50

The neutralization value (NV) is used to give the proper balance of the alkaline and acidic agents. The NV indicates the amount of sodium bicarbonate required to release all the available carbon dioxide from 100 units of the acid leavener (Table 1). NVs enable the formulator to achieve the desired batter pH, which is important to crumb structure and grain, color, and flavor.

Sugar acts primarily as a sweetener in cakes and aids in air incorporation during creaming. In the mid-1900s, emulsified shortenings enabled bakers to produce richer cakes with higher sugar and liquid levels. These high-ratio cakes generally contain 120% sugar based on flour weight, and have an extended shelf-life and tender texture. The type and form of sugar used are also important; liquid sugar or syrup acts as a moistener whereas crystalline or granular sugar functions as a drier. Granulation affects how quickly the sugar dissolves and generally increases cake volume as granulation becomes finer. Invert or reducing sugars, e.g., high-fructose corn syrup, honey, or molasses, can affect the crust and crumb color, and texture.

Milk, either in fluid or dry powdered form, is a source of protein and lactose, which aid in crust development and browning reactions. Milk also stabilizes the foam and contributes to cake structure.

Finally, salt is added as a flavor enhancer.

Formula balance of the major cake ingredients – flour, shortening, sugar and eggs – is important to produce a cake with good volume, grain, texture, and eating properties. Some general guidelines for high-ratio cakes are as follows:

- The weight of the sugar should be greater than the flour weight
- The weight of the eggs should exceed the weight of the shortening
- The weight of the total liquids (milk, eggs, and/or water) should be slightly greater than the sugar weight

Some exceptions to these rules include foam-type cakes, i.e., angel food or sponge which contains little or no shortening. In these cakes, whipped egg whites, sugar, and flour are the primary ingredients, along with some minor ingredients. In a typical angel food cake formulation (Table 2), the weight of the sugar is usually equal to the weight of the egg whites, and the flour is approximately one-third the weight of the sugar. Figure 1 shows the relationship between basic ingredient composition and cake type.

Sponge cakes use whole egg instead of only egg whites. To minimize the toughening effect of the eggs, an equal or slightly higher amount of sugar is added. The liquid and flour levels are balanced around the eggs and sugar. In general, the total liquids should be 25% greater than the weight of the sugar.

Table 2 Angel food cake formula

Ingredient	*Baker's %*[a]
Flour	100
Sugar	280
Egg white	280
Salt	4
Cream of tartar	4
Vanilla	5

[a]Baker's % based on 100 parts flour.

Flour level should be less than the weight of either the sugar or eggs. Combined, the weight of eggs plus flour should exceed the weight of sugar plus nonegg liquids (milk or water). A typical sponge cake formula is listed in Table 3.

Pound cake is one of the oldest types of cake, deriving its name from the original recipe which called for 1-lb (0.45-kg) increments each of flour, butter, eggs, and sugar. The expense of butter and eggs prompted commercial bakers to modify the formula, producing a lighter cake with improved volume and eating quality (Table 4).

The modified pound cake formula led to the basic yellow or white layer cake (Table 5). Unlike yellow layer cake, no yolks are used for white layer cake. These layer cakes adapt readily to many formula variations by the addition of fruits, nuts, spices, cocoa, etc. In chocolate layer cakes, the sugar level appears higher, which is due to a reduction in the flour level when cocoa is added. Functionally, low-fat cocoa acts much like flour. High-ratio cakes evolved from layer cakes through the use of emulsified shortenings and may contain as much as 140% sugar (based on flour weight).

Chemical and Physical Changes during Mixing

Mixing plays an important role in the production of quality of batter-type cakes. The objectives of mixing are to disperse the various ingredients uniformly, and to incorporate air into the batter while minimizing gluten development. There are four different basic methods of mixing: creaming, blending, single-stage, and foam-type methods.

In the creaming, or conventional method, fat and sugar are mixed at low to medium speeds until thoroughly blended and aerated. Large volumes of air are incorporated into the fat phase in the form of small air cells and the sugar crystals are encased in the shortening. Next the eggs are added with continuous beating until the mixture is fluffy and well aerated. Last, the flour and milk are added. The main advantages of this method are: (1) the large number of small

[b]In the USA, sugar would run to 120 or more.

air cells in the batter; and (2) gluten development is limited due to delayed hydration and solubilization of the fat-coated flour and sugar particles.

The blending method consists of two separate mixing steps. The shortening and flour are beaten until fluffy in one bowl and the eggs and sugar are whipped separately in a second bowl. These two mixtures are blended together followed by slow addition of the milk. This method produces a cake with a very fine grain and uniform texture. Compared with the creaming method, aeration is lessened, thus reducing cake volume, but higher sugar and liquid levels are possible.

The single-stage mixing method was devised to reduce the number of steps and shorten the mixing time requirements. All the major ingredients are mixed together at once. Although the procedure is simple, the texture and stability are sacrificed somewhat. This method is generally used for premixed box cakes, but not by the wholesale trade.

Unlike shortening-based cakes, foam cake mixing depends on air incorporation in an egg–protein matrix for volume and structure development. Egg whites plus sugar are whipped into a stiff foam, into which the flour and other dry ingredients are gently folded. In angel food cake batters, the egg whites must be fat-free to achieve maximum volume; however, in sponge cakes where whole eggs are used, a lower-volume, emulsified foam is formed.

The batter specific gravity is a measure of how much air has been incorporated into the batter during mixing. It is defined as the ratio of the weight of a known volume of batter to the weight of the same volume of water, at a given temperature. Batter specific gravity is directly related to the volume, texture, and grain of the finished cake. In general, the lower the specific gravity, the higher the finished cake volume, but optimal ranges for different types of cake batters have been established.

Chemical and Physical Changes during Baking

Air bubbles, creamed in the fat, are released into the aqueous phase as the fat is melted at approximately 40 °C. Carbon dioxide is generated by the baking powder and collects in these air bubbles. As the batter heats, the batter begins to flow due to natural convection currents, as the batter temperature next to the sides and bottom of the pan increases first and that in the center heats last.

The batter viscosity decreases initially upon heating as the fat melts and before the starch gelatinizes. Between 60 and 70 °C, the starch granules absorb several times their weight in water, increasing the batter viscosity considerably. Major swelling of the gelatinized starch granules insures that the cake structure will not collapse. The amount of sugar and some emulsifiers in the formula control the temperature at which the starch gelatinizes. The cake normally sets into a solid system well below the boiling point of water (100 °C).

As the batter temperature reaches about 80 °C, the air bubbles enlarge rapidly, causing the cake to rise. The liberation of carbon dioxide, the expansion of air cells, and the formation of steam all contribute to the leavening effect. Heat causes the gas to expand and the pressure inside the gas cells to increase. Resistance to expansion results from protein coagulation and starch gelatinization. Timing is critical for the protein film to enlarge with the expanding gases, prior to protein denaturation and starch gelatinization, which set the structure. Emulsifiers, whether occurring naturally in eggs or added, improve the elasticity of the protein film surrounding the gas bubbles, enabling them to increase without rupturing.

Moisture evaporates from the cake surface during baking, keeping it cool. However, as most of the water is removed, the surface gets hot enough to brown. Lower baking temperatures should be used for richer (high sugar and fat content) cakes, as the sugars can cause excessive browning of the crust before the interior is set. The baking time for all cakes should be kept as short as possible to avoid too much color development and formation of a thick crust.

A summary of common cake faults and possible ingredient, mixing, or baking-related causes is given in Table 6.

Role of Additives

One of the main additives in cake production is added to the flour itself. In the USA, cake flour is made by

Table 6 Troubleshooting guide for cakes

Possible causes	*Common cake faults*						
	Low volume	*Toughness*	*Lacking resilience*	*Poor crust appearance*	*Irregular grain*	*Peaked center*	*Undesirable color*
Improper chemical leavening	×				×		×
Low batter viscosity	×				×	×	
Excessive oven temperature	×	×		×	×	×	×
Insufficient oven temperature					×		×
Egg/milk protein level incorrect		×	×				
Incorrect sugar level or type		×		×			×
Overmixed batter		×		×	×		
Undermixed batter			×		×		

adding chlorine gas to soft wheat flour at a rate of 0.5–2.5 oz per 100 lb (0.3–1.5 g kg^{-1}) of flour. This lowers the pH and improves overall baking performance by increasing the volume, and improving grain, texture, and symmetry. The optimal pH range is between 4.5 and 4.8. The mechanism of chlorine on flour is not completely understood: various researchers have shown that it affects the gluten, starch, and/or lipid components of wheat flour.

Overchlorinated cake flour will cause the batter to set too quickly around the sides of the pan before full expansion has been reached. The center continues to rise, and the result is a cake with a strong peak. If the flour is underchlorinated, the structure sets too slowly, allowing the leavening gases to escape, and the center of the cake collapses upon cooling.

Emulsifiers promote air incorporation in the form of fine bubbles and disperse the shortening into small-sized particles. Emulsifiers' unique behavior is due to their ability to bridge the inseparable oil and water phases at the interface. When their concentration exceeds the solubility limit, they form an interfacial membrane whose hydrophilic portions extend into the aqueous phase. The membrane surrounds the dispersed oil and prevents the emulsion from breaking.

Hydrogenated shortenings typically contain 3% emulsifiers, with glycerol mono- and distearate being the most common, although many others, including blends, are also used. (*See* **Emulsifiers**: Uses in Processed Foods.)

Antioxidants are sometimes added to cake mixes to retard the development of oxidative rancidity during storage. All fats are subject to oxidative and hydrolytic rancidity, which causes objectionable odors and flavors, but antioxidants delay these reactions from occurring within the products' shelf-life. Four compounds commonly used as antioxidants are butylated hydroxyanisole, butylated hydroxytoluene, t-butyl hydroquinone, and propyl gallate. Citric and phosphoric acids have a synergistic effect when combined with the antioxidants. The levels are limited by law, economics, and functionality, and vary with the additive and product application, but generally fall between 0.005 and 0.1% of the product weight. Natural antioxidants, e.g. tocopherals, offer a desirable alternative to synthetic varieties, but have other usage issues such as heat lability. (*See* **Antioxidants**: Synthetic Antioxidants.)

Color additives are used in many baked products, including cakes and their icings. Added color can help the product fulfill consumer perceptions and expectations regarding quality, richness, and overall visual appeal. There are two types of color additives – certified and uncertified. The certified colors are synthetic and strictly regulated, whereas the uncertified usually come from natural sources and usage level varies greatly. The certified colors used in the USA include FD&C blue no. 1, FD&C red no. 3, FD&C yellow no. 5 and FD&C red no. 40. Uncertified color additives include annatto extract, β-carotene, beet powder, β-apo-8-carotenal, xanthins, caramel, carmine, carrot oil, cochineal extract, toasted partially defatted cottonseed flour, fruit and vegetable juices or concentrates, paprika and paprika oleoresin, riboflavin, saffron, titanium dioxide, tumeric, and tumeric oleoresin. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; Properties and Determinants of Synthetic Pigments.)

Many flavoring agents are used in cake batters, icings, and/or fillings. Spices are processed from different parts of aromatic plants, including fruits, barks or seeds. Some spices commonly used in cakes include allspice, anise, caraway seed, cardamom, cinnamon, cloves, coriander, ginger, mace, nutmeg, poppy seed, saffron, and sesame seed. Some of these act as both flavoring and coloring agents.

Alcohol extracts can also be used to enhance the flavor of cakes. The sapid and odorous volatile components are extracted from aromatic plants or parts of the plant and solubilized in ethanol or propylene glycol. For example, vanilla extract is a ubiquitous flavoring in cakes, derived from the vanilla bean.

Chocolate and cocoa from the cacao tree bean are also popular flavoring agents. However, defatted cocoa powder also adds bulk to the cake, often replacing up to 10% of the flour weight. Often in chocolate cakes, the sugar level and leavening system must be adjusted to compensate for the cocoa. (*See* **Cocoa**: Production, Products, and Use.)

Properties and Determination

K A Cockell, Sir F.G. Banting Research Centre, Ottawa, Ontario, Canada

Calcium

Calcium is an alkaline earth element and a mineral nutrient essential for plant and animal life. This article covers the basics of calcium chemistry, its occurrence in foods, influences of food processing on calcium content and bioavailability, and methods for analysis of calcium in foods and biological samples.

Chemistry of Calcium

The chemical element calcium, symbol Ca, atomic number 20, is a group IIA metal (alkaline earth metal), first isolated by British chemist Sir Humphry Davy in 1808. The name is derived from '*calx*,' Latin for lime (calcium oxide), which was used by the Romans in mortar for construction. Calcium has an atomic weight of 40.08 and six stable isotopes, with ^{40}Ca predominating at over 96% relative abundance (**Table 1**). There are several calcium radionuclides available, including ^{41}Ca, ^{45}Ca, and ^{47}Ca. For practical reasons, ^{45}Ca is the most commonly used calcium radionuclide for biological investigations.

The electron configuration of calcium is $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$. Calcium thus has two valence electrons and commonly occurs as a divalent cation (Ca^{2+}). Calcium does not occur as a free metal in nature, being found rather in several common mineral compounds including carbonates (e.g., limestone, marble, chalk), sulfates (e.g., gypsum, alabaster), fluorides (e.g., fluorite), phosphates, silicates, or as ionic calcium in seawater ($\sim 400\,mg\,l^{-1}$). Calcium is the fifth most abundant element, and third most abundant metal, in the earth's crust (comprising almost 4%), and ranks seventh in terms of content in seawater.

In living organisms, calcium occurs in the form of solid mineral salts as well as dissolved in solution, in contrast to the other major alkali and alkaline earth metals (sodium, potassium, and magnesium) where solution chemistry predominates. Calcium in solution has an affinity for oxygen-containing ligands such as carboxy and phosphate groups.

Calcium as an Essential Nutrient

Calcium is an essential nutrient for all plants and animals including man. It is the most abundant

^{43}Ca	0.135					
^{44}Ca	2.086	^{47}Ca	β^-	4.536 days	1.98	16
^{46}Ca	0.004				0.68	84
^{48}Ca	0.187		γ		1.30	75

metal and fifth most abundant element (after oxygen, carbon, hydrogen, and nitrogen) in the human body. In both plants and animals, calcium plays key structural and metabolic roles.

In plants, calcium forms salt bridges between pectin molecules in the middle lamella, providing the 'glue' that holds the walls of adjacent cells together. Calcium in solution regulates the activity of many enzymes in plant cells, and protoplasmic calcium concentrations are regulated by sequestration of calcium in vacuoles where it is precipitated in an inert form such as calcium oxalate.

In animals, calcium in mineral form is plentiful as the carbonate ($CaCO_3$) in shell and coral and as hydroxyapatite ($Ca_5(PO_4)_3(OH)$) in bone and tooth enamel. Calcium in solution acts an important intracellular signal mechanism in animals, essential for muscle contraction, blood clotting and many other functions. (*See* **Calcium**: Physiology.)

Overview of Occurrence in Foods

Roughly 70% of the calcium present in the food supply in the USA is in the form of milk and dairy products, with about 10% in fruits and vegetables, 5% in grain products, and the remainder in all other foods. Similar proportions have been reported from other Westernized countries. The relative importance of these food sources to people's calcium intakes depends upon the relative amounts consumed. Even so, the main food sources of calcium for most people consuming omnivorous diets in Western countries are milk and dairy products, typically accounting for over 50% of total calcium intake. Although the concentration of calcium in cereal products and vegetables is typically much lower than in dairy products, the amount of these foods eaten means that foods of plant origin do make a significant contribution to total calcium intakes for most people (20–25% from cereals in the USA and the UK, with about 14% from bread due to calcium fortification of white flour). It is commonly estimated that the total contribution of nondairy foods eaten over the course of a day provides 200–300 mg of calcium to those consuming a mixed diet, or about the equivalent of one glass of milk. Other foods that contain considerable amounts of calcium include tinned fish such as sardines or salmon (largely due to the calcium in the bones and skin), tofu (especially if it has been processed with calcium) and certain seeds and nuts, but typical eating habits indicate that these do not contribute much to total calcium intake for most people. Vegans, or others who do not consume milk and dairy products, may need to take particular care to ensure adequate calcium intake from their diet or may require a supplemental source of calcium, particularly during periods of rapid growth. Lactovegetarians, who do not avoid milk and dairy products, generally have little difficulty in attaining adequate calcium intakes.

Factors Influencing Calcium Bioavailability

Knowledge of the calcium content of a food must be tempered to some extent by understanding the dietary and physiological factors that can influence the bioavailability of calcium. Calcium bioavailability can be operationally defined as the amount of calcium that is available to be absorbed and used for normal metabolic functions in the body. Physiological factors influencing calcium bioavailability include rate of growth, calcium status and age (*See* **Calcium**: Physiology). A number of dietary factors can influence the bioavailability of calcium, including the level of calcium intake and its chemical form, whether calcium is taken with food or as a supplement on an empty stomach, and the presence of inhibitory or enhancing compounds coingested with the calcium. Calcium is more bioavailable when taken with food than on an empty stomach, due at least in part to the longer passage time through the GI tract. Oxalate and phytate are well-known inhibitors of calcium uptake through the formation of insoluble complexes within the gut. With the exception of vitamin D, which is involved in the active transport uptake of calcium from the gut (*See* **Calcium**: Physiology; **Cholecalciferol**: Physiology), potential enhancers of dietary calcium absorption are generally less well defined than the inhibitors, and may have only limited influence on the intestinal absorption of calcium ingested with a meal. Absorption from the gastrointestinal tract is not the only consideration in bioavailability; dietary sodium and protein (particularly proteins high in sulfur amino acid content due to the physiological acidification effect) influence the amount of calcium excreted in urine and consequently not available for essential functions in the body.

Sources of Calcium Intake

As alluded to previously, calcium is quite unevenly distributed in the diet of humans. Some foods are rich sources of calcium, whereas others contain relatively little. With developments in food processing and fortification policies and practices, the increasing availability of calcium-fortified foods and dietary supplements containing calcium salts is leading to a wider range of rich dietary sources of calcium.

Foods of Animal Origin

Milk and many dairy products are good sources of bioavailable calcium (Table 2). Removal of the milk fat fraction from fluid milk leads to slight increases in the calcium concentration as one proceeds from whole milk to skim milk. Fluid milk with added modified milk ingredients is a relatively new entry into selected marketplaces, containing some 20–25% more calcium than regular milk due to the addition of whey calcium concentrates. Naturally, foods containing milk or milk products, whether 'hidden' in the recipe as in cakes or other baked goods or more obviously added as with cream or cheese sauces, will also provide a fair amount of calcium.

Soft cheeses and cream cheese generally contain less calcium on a wet-weight basis due to their higher water content. The calcium content of cheeses also depends on the process used in preparation and whether the calcium precipitates with the milk solids or remains in the whey. Cheeses precipitated with lactic acid, such as cottage cheese or cream cheese, contain lower calcium levels in the curd, as most of the calcium remains soluble in the acid whey. Rennin coagulation (e.g., in production of cheddar or mozzarella cheese) yields cheeses with a higher calcium content as the curd is formed before significant acidification takes place.

Meat and fish are not typically rich sources of calcium (Table 2). Mechanically deboned meats can contain much higher levels of calcium due to the abrasion of bone during the deboning process. Tinned salmon provides higher levels of calcium than fresh salmon fillet (Table 2), because the bones and skin tend to be consumed along with the flesh. Similar reasoning applies to small fish consumed whole, such as sardines and anchovies. Calcium is generally somewhat higher in crustaceans than in fin fish.

Foods of Plant Origin

Foods of plant origin are not generally very rich sources of calcium, and some contain significant levels of calcium absorption inhibitors such as phytate or oxalate. However, due to the large amounts consumed, this class of foods typically makes a fairly significant contribution to total calcium intake. Whole grains and seeds generally provide more calcium than most fruits or vegetables. Fortification of refined flours and breakfast cereals can significantly increase the contribution of these foods to total calcium intake. Similarly, the high calcium content of baking powder and the variety of calcium-containing food additives used (e.g., as dough conditioners or yeast nutrients – see below) adds to the amount of calcium in baked goods.

While spinach appears to contain a reasonable amount of calcium (129 mg per 95-g serving, see Table 3), the high oxalate content of spinach renders much of the calcium insoluble and much less

Table 2 Calcium content of selected animal-source foods[a]

Food name	*Serving size*	*Weight (g)*	*Calcium (mg)*	*Concentration (mg g^{-1} as is)*
Milk and dairy products

Turnip greens	72	99	51.6	1.9
Tofu, calcium set	126	258	31.0	1.2

[a]Selected data from Weaver CM and Plawecki KL (1994) Dietary calcium: adequacy of a vegetarian diet. *American Journal of Clinical Nutrition* 59 (supplement): 1238S–1241S.

bioavailable, so that it has been estimated that over 15 servings of spinach would be required to obtain the same level of absorbable calcium as one glass of milk (Table 4). Turnip greens contain a similar level of calcium to that found in spinach, but without the oxalate, so that about 2 servings of turnip greens provide a similar level of absorbable calcium to one glass of milk (Table 4). However, these types of food calcium absorption values are often determined under laboratory conditions while feeding only the single food. Calcium bioavailability from a given food source can be substantially modified by other foods eaten at the same time. For example, milk calcium absorption has been shown to decline from 33 to 27% when coingested with spinach, whereas spinach calcium absorption showed an increase from 3% when fed alone to 11% when coingested with milk. In a Western mixed diet, the overall calcium absorption by adults typically averages about 25–30%.

Processing Effects on Food Calcium

There are numerous food additive uses of calcium salts that may add appreciable amounts of calcium to some foods. The Food Chemicals Codex, fourth edition (1996) lists over 30 calcium compounds used as food additives or processing aids. Some of the common functions of calcium-containing food additives (and examples of the calcium compounds used) include: dough conditioners such as calcium carbonate, calcium iodate, calcium lactate, calcium oxide, calcium phosphate or calcium sulfate; pH adjusters such as calcium hydroxide or calcium phosphate; antioxidants such as calcium ascorbate; preservatives such as calcium propionate, calcium disodium EDTA

or calcium sorbate; anticaking agents such as calcium stearate, calcium phosphate or calcium silicate; and thickeners such as calcium gluconate or calcium alginate. The percentage composition of calcium in these compounds ranges considerably, e.g., calcium gluconate is 9% calcium, calcium carbonate is 40% calcium, and calcium oxide is 71% calcium by weight. Solubility also differs considerably between compounds, with some such as calcium carbonate being relatively insoluble at neutral pH, whereas others like calcium acetate or calcium chloride are highly soluble.

Tofu set with calcium sulphate contains considerably more calcium than tofu set with magnesium chloride (Table 3). Firm tofu contains a higher concentration of calcium than does regular tofu due to the lower water content (and consequently higher solids). Fermentation (including leavening of bread) or germination of selected plant foodstuffs can increase the availability of calcium due to breakdown of complexing compounds such as phytic acid. The calcium content of meat can be increased by processing or cooking in acidic solutions due to the dissolution of calcium from bone. For example, pork spare ribs or chicken cooked with vinegar contain more calcium than the uncooked flesh.

Tap water typically contains calcium and many other elements, and may make some contribution to total calcium intake particularly in hard water areas. Water hardness is measured as milligrams of calcium carbonate equivalents per liter, and hard water may be over 300 mg of $CaCO_3$ per liter. Calcium carbonate is 40% elemental calcium by weight. Thus, a 250-ml glass of water may provide 30 mg of elemental calcium in some areas. The hardness of water added in processing may also influence the calcium content of foods to some extent. Conversely, losses through soaking and/or boiling may amount to 5–25% of the calcium content of a variety of vegetables that are commonly prepared in this way.

Foods may have nutrients added for a variety of reasons including restoration of processing losses, or to provide similar nutrient levels in substitute foods (e.g., soy 'milk' and other plant based beverages, which may be fortified with calcium in some countries, as they are used as a substitute for dairy products in the diet of their consumers), for fortification (which, in this context, refers to addition of calcium with the intent of raising the calcium content of the food for the consumer, e.g., enriched flour or infant cereals), or for special purpose foods such as meal replacements or formulated liquid diets (*See* **Legislation**: Codex). Regulations and practices concerning food fortification may vary considerably between countries.

Supplements

Nutritional supplements and antacid medications can make a significant contribution to calcium intakes for some people. Calcium supplements are available in a number of forms, including carbonate, phosphate, lactate, or citrate salts of calcium, among others. Calcium carbonate is found in many over-the-counter antacid preparations. Multivitamin and multimineral supplements may also contain calcium, though frequently in smaller amounts. Natural source supplements include oyster shell and dolomite, though it should be noted that concerns have been raised with the potential for lead contamination of these forms. It has been estimated that, among supplement users in the USA (who represent approximately 20% of the population), an average of 300 mg of Ca per day is consumed from supplements. In addition, calcium-containing antacids, supplying 200–400 mg of Ca per tablet, are consumed by about 18% of USA adults.

Analysis of Calcium in Foods and Biological Samples

There is no satisfactory routine biochemical method for assessing calcium nutritional status (*See* **Nutritional Assessment**: Biochemical Tests for Vitamins and Minerals). Serum calcium concentration varies very little, even across a wide range of dietary calcium intakes, because of adaptive alterations by which the endocrine system regulates the level of this mineral in blood (*See* **Calcium**: Physiology). Deviations of calcium concentration from this narrow range are medically significant, and in this setting, the measurement of total plasma or serum calcium or specific measurement of the ionized calcium fraction is important. Total calcium in plasma or urine can be measured by atomic absorption spectrophotometry, either directly on the diluted sample or following sample mineralization ('ashing' – see below), or by colorimetric assay (e.g., using arsenazo III or orthocresolphthalein complexone) on a clinical autoanalyzer. Ionized calcium in plasma (the fraction that is not bound to proteins or low-molecular-weight ligands, and consequently is most physiologically active) represents about 45% of plasma calcium under normal conditions and can be assessed using an appropriate ion-sensitive electrode. Assessment of intracellular calcium levels in the research laboratory can be addressed using fluorescent probes such as FURA 2 or QUIN 2, among others. Calcium nutritional status is more often assessed indirectly through balance studies or by measurement of bone mineral concentration or bone mineral density, reflecting the major structural role played by this mineral nutrient.

Sample Preparation

Most foods and biological tissue samples can be prepared for analysis of their calcium content either by dry ashing (in a muffle furnace) or wet ashing (acid digestion) techniques or some combination of the two. Dry ashing techniques typically involve combustion at elevated temperature (e.g., 500–550 °C) until organic matter is fully destroyed, followed by dissolution of the ash in a suitable acid for subsequent analysis. Wet ashing techniques typically involve destruction of organic matter by heating in concentrated nitric acid until a pale straw color is attained, and may feature additional oxidation steps with perchloric acid or hydrogen peroxide to clarify the sample solution. In wet ashing procedures, particularly for samples with a high calcium content such as bone meal, sulfuric acid is generally to be avoided due to the ready precipitation of calcium from solution by sulfate, forming plaster of Paris (calcium sulfate hemihydrate) or gypsum (calcium sulfate dihydrate).

Determination of Calcium Content of Foods and Tissues

Determination of calcium content of foods and tissues is commonly done by atomic absorption spectrophotometry, though a number of alternative methods exist including titrimetric methods using EDTA or $KMnO_4$, neutron activation analysis, or inductively coupled plasma emission spectrometry. Details of sample preparation and analytical procedures for a variety of food sample types are published by the Association of Official Analytical Chemists.

Atomic Absorption Spectrophotometry

For atomic absorption spectrometric analysis of calcium, 0.1–1.0% (w/v) lanthanum is included in the analytical working solution as a matrix modifier to reduce anion interferences due to phosphate or sulfate, which otherwise can form refractory complexes and depress the absorption of light by atomic calcium. Absorbance is measured at the 422.7-nm calcium spectral line, following atomization in a reducing air–acetylene flame, and compared with certified analytical standard calibration solutions. A reducing flame gives a higher sensitivity, though an oxidizing flame may give a higher precision where this is critical. Typical analytical working ranges are obtained up to $5\,mg\,l^{-1}$ in the analytical working solution when using a standard nebulizer assembly, and may be approximately doubled with the use of a high sensitivity nebulizer. (*See* **Spectroscopy**: Atomic Emission and Absorption.)

$KMnO_4$ Titrimetric Method for Calcium in Wheat Flour (Method from the Association of Official Analytical Chemists)

After dry ashing and dilution of the ash to a suitable volume with demineralized water, bromocresol green indicator is added along with enough 20% sodium acetate solution to change the pH to 4.8–5.0 (blue). The sample solution is covered and heated to boiling. The calcium is precipitated by slow addition (1 drop every 3–5 s) of 3% oxalic acid solution (w/v) until pH is 4.4–4.6, as indicated by a distinct green shade. The solution is then boiled for 1–2 min and allowed to settle overnight. The supernate is filtered through quantitative paper, Gooch, or fine fritted glass filter, and the beaker and precipitate are washed with small portions of ammonium hydroxide (1 + 50). A mixture of 125 ml of water and 5 ml of sulfuric acid is added to the precipitate with heating to 80–90 °C. The solution is finally titrated at 70–90 °C with 0.01 M $KMnO_4$ to a slight pink endpoint, 1 ml of permanganate solution equating to 1 mg of calcium.

Physiology

M R L'Abbé, Nutrition Research Division, Ottawa, Ontario, Canada

Background

Calcium (Ca, element number 20, atomic weight 40.08, oxidation state + 2) is the most abundant cation in the human body and is a nutritionally essential mineral. More than 99% of body calcium is in the skeleton, accounting for 1.5–2.0% of body weight (approximately 1.5 kg). Calcium has two main types of functions: structural and metabolic. It is responsible for the mechanical and structural functions of bone and teeth as well as many metabolic functions involving numerous regulatory enzymes that require calcium. The physiological functions of calcium are so vital that total serum calcium is maintained in a very narrow range through a highly integrated system of hormones (parathyroid hormone, calcitonin, and vitamin D). If dietary sources of calcium are inadequate, bone reserves are mobilized; inadequate dietary calcium has long been associated with osteoporosis – a disease characterized by low bone mineral density.

Calcium Metabolism

Absorption

Intestinal absorption of calcium proceeds by two independent routes, a saturable, active absorption pathway regulated almost exclusively by vitamin D and a nonsaturable passive pathway that depends on the concentration of calcium in the intestinal lumen. Most calcium absorption occurs in the duodenum and jejunum, but minor amounts can also be absorbed in the colon. The active absorption pathway is located primarily in the duodenum and upper jejunum. Absorption by this pathway varies with age, calcium and vitamin D status, and total calcium intake. It constitutes the mechanism whereby the body increases relative absorption during periods of low dietary calcium intakes or low calcium status. Most calcium is absorbed by the nonsaturable passive route in adults with a mature skeleton, and active transport is of relatively minor importance to the total calcium absorbed. Thus, the major factor that determines the amount of calcium absorbed is the quantity ingested. Although the efficiency of calcium absorption declines with increasing calcium dose, there is evidence that the total amount absorbed may continue to rise.

The absorption of calcium from food can vary from 5 to 60%. It is influenced by calcium status, vitamin D metabolites, pH of the gut lumen, and dietary factors such as protein, phosphorus, sodium, phytate, and oxalate (see sections on Bioavailability Dietary Factors Affecting Calcium Balance, for more details).

Bioavailability

Foods vary in both calcium content and bioavailability. Together, these two factors determine how much calcium a particular food source will provide per serving. Information on the content and bioavailability of calcium in various food products is given in **Table 1**. Milk and milk products have a high calcium content and bioavailability, and thus are major food sources of calcium in Western diets. Many vegetables have a higher fractional absorption (bioavailability) of calcium but a lower content of calcium than is found in milk and milk products. In addition, some vegetables and plant products contain inhibitors of calcium absorption, such as oxalate (e.g., spinach), or phytate (e.g., wheat bran, legumes, nuts, oats, soy beans, maize), which reduce the bioavailability of calcium.

Balance

Calcium balance is controlled through an integrated response to calcium-regulating hormones that affect calcium transport at three primary sites of regulation: intestine, bone, and kidney. The most important calcium-regulating hormones are parathyroid hormone (PTH), calcitonin and vitamin D, and the effects of these are briefly described below. Glucocorticoids, thyroid hormones, growth hormone, insulin, estrogen, and testosterone also affect bone turnover and calcium metabolism.

Table 1 Content and bioavailability of calcium in various food products[a]

	Serving size (g)	*Calcium[b] content (mg)*	*Fractional absorption (%)*	*Estimated absorbable Ca/serving (mg)*	*Servings needed to = 1 cup of milk*
Milk (1 cup)	240	300	32.1	96.3	1.0

[a]Selected data from Weaver CM and Plawecki KL (1994) Dietary calcium: adequacy of a vegetarian diet. *American Journal of Clinical Nutrition* 59(5): 1238S–1241S.
[b]Based on a half-cup serving size unless otherwise noted.

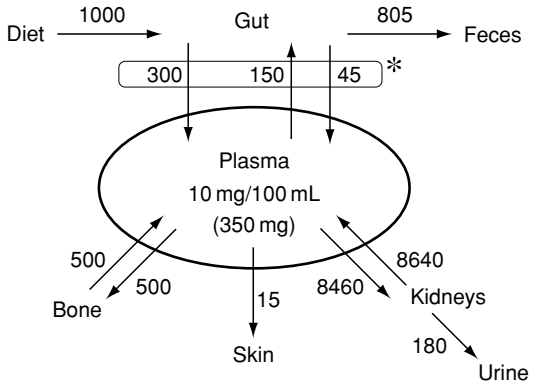

Figure 1 Outline of calcium balance (mg per day) under equilibrium conditions (input = output) in adult humans. *Assuming equilibrium conditions and 30% absorption, 300 mg of the daily dietary intake of 1000 mg are absorbed from the gut. Endogenous calcium secretion returns 150 mg per day to the gut lumen. Using the same assumption of 30% absorption, 45 mg per day of the endogenously secreted calcium are reabsorbed. Net calcium uptake is therefore 195 mg per day under these conditions, which offsets the net loss of 195 mg per day through the skin and in urine.

At equilibrium, calcium balance is maintained through regulation of plasma calcium levels, with the calcium influx/efflux occurring at several sites, as illustrated in Figure 1. If dietary calcium intakes are insufficient, or in the case of malabsorption syndromes, calcium is mobilized from bone to maintain blood concentration.

Hormonal Regulation

Vitamin D is an important nutrient for regulating plasma calcium concentration and bone metabolism. The two most physiologically active forms are vitamin D_2 (ergocalciferol), found mainly in yeast and plant foods, and vitamin D_3 (cholecalciferol), synthesized by skin and the most common form added to foods. Vitamin D is hydroxylated first in the liver at the 25-carbon position to form the 25-hydroxyvitamin D (25(OH)D), which enters the circulation. Circulating (25OH)D is a good measure of vitamin D status. In the kidney, the 25(OH)D is further hydroxylated to form the dihydroxy compound (1,25 $(OH)_2D$), which is the most active metabolite. The production of $1,25(OH)_2D$ in the kidney is tightly regulated via PTH (see below). The $1,25(OH)_2D$ increases calcium absorption in the intestine and is absolutely critical during growth as well as during times of low calcium intake. In calcium deficiency, $1,25(OH)_2D$ production is increased, causing enhanced intestinal absorption and renal reabsorption of calcium, and increased bone resorption.

PTH is released in response to a decrease in extracellular fluid calcium concentration. PTH directly stimulates bone and renal tubular calcium resorption and indirectly increases intestinal absorption through

enhanced formation of $1,25(OH)_2D$ in the kidney from the monohydroxy form, 25(OH)D.

Calcitonin is synthesized by the C cells of the thyroid in response to a rise in serum calcium; it inhibits bone resorption and agents that have resorptive effects on bone (PTH, vitamin D, prostaglandins, and vitamin A).

Excretion

The kidneys filter 8–10 g of Ca per day, with almost all of it reabsorbed; only about 100–200 mg per day is excreted in urine. Tubular reabsorption therefore plays an important part in the conservation of calcium, and a reduction in the number of functional nephrons or in their capacity to reabsorb normally can result in hypocalcemia.

Under ideal conditions (i.e., in calcium balance), excretion via the urine (and, to a lesser degree, via sweat and feces) is matched by the influx into the extracellular fluid compartment, usually through intestinal absorption.

Dietary Factors Affecting Calcium Balance

Vitamin D

As mentioned above (see section Hormonal Regulation), adequate vitamin D is critical to the absorption of calcium D; yet, there is little or no natural vitamin D in most foods that humans normally eat, except some fish. Vitamin D is present in the flesh of fatty fish such as sardines and herring, and in the liver oils of other fish such as cod and tuna. Meat such as poultry, pork, and beef contain small amounts of vitamin D. In Canada and in many other countries, vitamin D fortification of milk and/or margarine provide the major sources of dietary vitamin D.

The other major source of vitamin D for humans is synthesis by skin exposed to ultraviolet or sunlight irradiation, and most people could obtain sufficient vitamin D from this source. However, this vital photosynthetic process can be affected by anything that limits the amount of solar ultraviolet B photons to reach the skin's surface and penetrate into the viable epidermis. In northern latitudes, the photosynthetic production of vitamin D is negligible during the winter months (e.g., from November to March, or virtually half the year in much of Canada). The elderly also have a reduced capacity for vitamin D synthesis, and deficiency is most prevalent among the elderly, particularly among institutionalized or house-bound individuals. Factors such as pollution in the air and melanin of the skin can affect the cutaneous synthesis of vitamin D. In addition, sunscreens block the absorption of the sunlight spectrum that helps the cutaneous synthesis of vitamin D, and there has been a marked increase in the use of sunblocks in recent years in many countries. Thus, providing a reliable, safe, and adequate source of vitamin D in the diet is essential for optimum calcium absorption.

Phosphorus

There is some controversy concerning the effects of high phosphorus on calcium balance. In the past, considerable emphasis was placed on the Ca:P ratio of the diet, particularly in infant nutrition. In the most recent review of calcium and phosphorus requirements done by the National Academy of Sciences, this concept was considered to have no demonstrable relevance in adults, although the report stated: 'The concept still has some utility under conditions of rapid growth (in which a large share of the ingested nutrients is converted into tissue mass).' The ratio of calcium to phosphorus by itself does not take into account the differing bioavailabilities of the two nutrients, but estimates of optimal Ca:P ratios have frequently been based on the calcium and phosphorus needs of bone building. It was estimated that an absorbed Ca:P ratio sufficient to support the sum of bony and soft tissue growth would be approximately 1.3:1, and correcting for the relative net absorptions, this would be met by Ca:P intakes in the range of about 2:1.

Currently, in the USA, the intake of phosphorus is high relative to calcium. Furthermore, an individual's actual phosphorus intake may be higher than estimated due to inaccurate nutrient composition tables for phosphorus values, coupled with underreporting of processed foods. In recent years, the usage of phosphate salts as food additives has increased by nearly 20%. Currently, there are more than 45 phosphorus-containing compounds approved for use in food processing as nutrients, dietary supplements, or for functional purposes such as to preserve moisture or color, and as emulsifiers. Cola beverages and root beer beverages can be a significant source of phosphorus, containing about 70 mg of phosphorus per serving. One study has suggested that high intakes of phosphoric acid-containing cola beverages were associated with slight reductions in serum calcium in Mexican children, but it is unclear to what extent the effect was due to the acid load of the cola beverages, low calcium intakes, or the phosphorus itself.

Because phosphorus absorption is not strictly regulated, a high-phosphorus diet will directly increase the level of serum phosphate, which in turn lowers

serum calcium, a signal for PTH release. Current research describing diets in terms of the Ca:P ratio has suggested that diets with low ratios (i.e., high phosphate intakes where Ca:P equals 0.25:1) cause serum calcium to drop, thereby increasing PTH secretion, and inducing secondary hyperparathyroidism. This increase in PTH is often thought to be harmful to bone. Other researchers, however, have shown that calcium and phosphorus have no effect on each other in the healthy adult population. For example, balance studies in human adults with Ca:P ratios ranging from 0.08:1 to 2.40:1 had no effect on either calcium balance or calcium absorption.

Protein

North Americans consume considerably more calcium than people in developing countries; yet, the incidence of osteoporosis is much higher in North America. Recommended intakes for calcium in developed countries is much higher than for countries that consume a plant-based diet. One possible reason for this is the high amount of processed foods and animal protein found in Western diets that are not present in diets from primarily cereal-based food economies. With regard to processed foods, phosphorus has been discussed above, and salt and caffeine will be discussed below. Animal proteins contain a high proportion of sulfur amino acids, and the oxidation of these sulfur amino acids to inorganic sulfate generates endogenous acid, which in turn increases urinary excretion of acid and calcium. Increasing urinary calcium excretion will result in bone loss when there is insufficient capacity to replace the loss by absorbing more dietary calcium. High-protein-induced hypercalciuria is a misnomer, in that simply comparing high protein with low protein does not show hypercalciuria unless phosphorus is controlled or the amount of protein added is exceedingly high, or there is a change in the type of protein from one low in sulfur amino acids to a protein that is high in sulfur amino acids. In general, for every gram of total protein consumed, urinary calcium increases by approximately 1 mg.

Salt

High intakes of sodium chloride (NaCl) result in increased renal calcium loss, which promotes negative calcium balance. Urine calcium level increases by approximately 26 mg for every gram of salt ingested. Habitual excessive sodium chloride intakes have been suggested as a factor in promoting bone loss. However, given the small amount of calcium loss for every gram of salt consumed, the overall impact from dietary salt on calcium metabolism is likely minimal unless excessive amounts are consumed.

Caffeine

Oral doses of caffeine increase the urinary excretion of calcium for at least 3 h after consumption. Calcium balance studies have been performed in which caffeine was shown to have no effect when dietary calcium levels were adequate. The amount of caffeine in a small cup of coffee could raise urinary calcium excretion by approximately 4 mg, an effect that is less than that for salt. However, for persons with a low calcium intake, caffeine ingestion can be a significant predictor of low bone mineral density. Caffeine is found in only a small number of food products (e.g., colas, coffee, tea); its consumption would be unlikely to have a negative impact on calcium status, as urinary losses would be more than compensated for by a teaspoon of milk.

Methods for Assessment of Calcium Status

Serum concentration of calcium varies very little, even across a wide range of dietary calcium intakes, because of the adaptive alterations by which the endocrine system regulates the level of this mineral in blood. Therefore, there is no satisfactory routine biochemical method for assessing nutritional calcium status. If serum calcium levels are found to be outside the normal range, it is usually due to underlying disease conditions rather than nutritional problems. Calcium is found in several forms in serum: ionized, protein bound, and other minor blood components, with the ionized form of calcium being the functionally regulated form. Numerous biological markers or techniques have been used to assess calcium status. These can be classified into several groups: serum calcium or ionic calcium, urinary excretion of calcium, bone mineral density measurements or other techniques to measure the degree of bone loss, quantification of markers of bone resorption or bone remodelling, and finally calcium balance or absorption studies. Information on each of these measures is given in the following section.

Serum Calcium

Serum calcium concentration cannot be used as an index of calcium status, as it is homoeostatically controlled. Calcium concentration is serum varies very little, despite large changes in dietary calcium, because of the adaptive alterations by which the endocrine system regulates this mineral (see section Hormonal Regulation). Calcium in serum is distributed in the following forms: ionized 47.5%, protein bound 46%, Ca citrate 1.7%, $CaHPO_4$ 1.6%, and unidentified complexes 3.2%.

Serum-ionized Ca Concentration

This test measures 'physiologically active' calcium and thus better reflects calcium metabolism than total calcium values. It is useful in determining calcium changes in patients with altered proteins (e.g., chronic renal failure, nephrotic syndrome, hyperparathyroidism, malabsorption, multiple myeloma) but is not well correlated with dietary intakes of calcium.

Urinary Calcium Excretion

Urinary excretion of calcium can be elevated following high intakes of dietary calcium, although urinary excretion of calcium accounts for only 0.2% of the calcium filtered by the kidneys, because 99.8% of filtered calcium is reabsorbed. Many conditions can be associated with hypercalciuria, including metabolic disturbances such as hyperparathyroidism, bone metastases, osteoporosis (especially after immobilization), Cushings syndrome, and vitamin D intoxication. High dietary sodium or high dietary protein can also promote increased excretion of calcium. Hypercalciuria usually occurs prior to hypercalcemia.

Bone Mineral Density

Bone mineral density (BMD) is used as an index of body calcium stores, and techniques such as radiography, single or dual energy X-ray absorptiometry, and computerized tomography have been developed to measure BMD. The standard technique for diagnosing the presence or absence and severity of osteoporosis is based on BMD and a comparison with reference ranges established for normal BMD in young adults (see section Osteoporosis).

Markers of Bone Resorption

Blood biochemical markers of bone resorption rates tend to be less sensitive and specific than those for bone remodeling and include: urinary hydroxyproline, a measure of total collagen turnover, and pyridinoline and deoxypyridinoline, which are 3-OH-pyridinium derivative cross-links more specific to bone collagen. These measures indicate the degree by which bone reserves of calcium are being depleted.

Markers of Bone Formation

Markers of bone formation include serum osteocalcin (bone gla-protein), bone alkaline phosphatase, and urinary nephrogenous cyclic AMP.

Calcium Balance

Calcium status has been assessed indirectly by assessing calcium balance data, as increased retention is usually seen when status is poor. Techniques used include stable isotope or radiolabeled absorption and calcium retention measures to estimate calcium balance.

Function

Calcium has two main types of functions: structural and metabolic. It is responsible for the mechanical and structural functions of bone and teeth as well as many metabolic functions involving numerous soft tissue regulatory enzymes that require calcium. These include such processes as neuromuscular transmission of chemical and electrical stimuli, enzyme activation, membrane transport of inorganic ions, muscle contraction, hormone and cellular secretions, signal transduction, blood clotting, and reproductive functions such as sperm motility and fertilization of the ovum. Calcium regulates release and storage of neurotransmitters and hormones, the uptake and binding of amino acids, absorption of vitamin B_{12}, and gastrin secretion. The activities of many enzymes are affected by calcium, either acting directly (e.g., glyceraldehyde phosphate dehydrogenase, pyruvate dehydrogenase, α-ketoglutarate dehydrogenase) or indirectly through its activation of calmodulin (e.g., adenylate cyclase, cyclic nucleotide phosphodiesterase, Ca, Mg-ATPase, myosin light chain kinase, phosphorylase b kinase, NAD kinase, ornithine decarboxylase). Calcium therefore plays a role in normal cardiac function, renal function, respiration, blood coagulation, cell and membrane capillary permeability, cyclic nucleotide metabolism, glycogen metabolism, microtubule and microfilament function, and cell division.

The physiological functions of calcium are so vital to survival that total serum calcium is maintained in a very narrow range (2.2–2.5 mmol l^{-1}). Calcium in bone is in constant exchange with calcium in plasma. When calcium absorbed from the diet is insufficient to balance obligatory fecal and urinary losses, it is drawn from bone to maintain plasma levels of ionic calcium within this tightly controlled range.

Calcium Requirements

Recommended intakes for calcium for North America were recently released by the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes (DRI), US National Academy of Sciences, Food and Nutrition Board, Institute of Medicine, under a program jointly commissioned by federal government departments in the USA and Canada. These revised standards encompass both recommended dietary allowances (RDA) and tolerable upper intake levels for nutrients. It should be noted

Table 2 Adequate intakes (AI) and tolerable upper intake levels (UL) for calcium by life stage group for Canada and the USA[a,b]

Age	*AI (mg per day) (1997)*	*Criteria on which AI was based*	*UL (mg per day)*
Children (male and female)			
0–6 months	210	Human milk content	nd
7–12 months	270	Human milk content + solid food	nd
1–3 years	500	Extrapolation of desirable calcium retention from 4 through 8 years	2500
4–8 years	800	Calcium accretion/ΔBMC/calcium balance	2500
9–13 years	1300	Desirable calcium retention/factorial/ΔBMC	2500
14–18 years	1300	Desirable calcium retention/factorial/ΔBMC	2500
Adult males			
19–30 years	1000	Desirable calcium retention/factorial	2500
31–50 years	1000	Calcium balance	2500
51–70 years	1200	Desirable calcium retention/factorial/ΔBMD	2500
> 70 years	1200	Extrapolation of desirable calcium retention from 51–70-year group/ΔBMD/fracture rate	2500
Adult females[c]			
19–30 years	1000	Desirable calcium retention/factorial	2500
31–50 years	1000	Calcium balance	2500
51–70 years	1200	Desirable calcium retention/factorial/ΔBMD	2500
> 70 years	1200	Extrapolation of desirable calcium retention from 51–70-year group/ΔBMD/fracture rate	2500

[a]As set in National Academy of Sciences, Institute of Medicine, Food and Nutrition Board, Standing Committee on the Scientific Evaluation of Dietary Reference Intakes (1977) *Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D and Fluoride*. Washington, DC: National Academy Press.
[b]The AI is a recommended average daily nutrient intake level based on observed or experimentally determined approximations of estimates of nutrient intake by a group (or groups) of apparently healthy people that are assumed to be adequate – used when an RDA cannot be determined. The UL is the highest average daily nutrient intake level likely to pose no risk of adverse health effects to almost all individuals in the general population. As intake increases above the UL, the potential risk of adverse effects increases.
[c]For pregnancy and lactation: no additional requirements for pregnancy and lactation; requirements are the same as for the corresponding age group.
nd, not determined due to a lack of data of adverse effects in this age group and concern with regard to lack of ability to handle excess amounts. The source of intake should be from food only to prevent high levels of intake.

that although the DRI Panel revised calcium recommendation levels upwards, the panel set adequate intake levels (AIs) rather than RDAs 'because reducing the risk of chronic disease was the intended endpoint [but] there were many uncertainties about the epidemiologic and experimental data. Other than for breast fed infants, the AI is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.' The AIs for calcium were determined mainly from the intakes necessary to achieve maximal calcium retention. Table 2 list the AIs for calcium by life stage group for the USA and Canada.

Current Intakes of Calcium

Dietary Intakes

No national data on the calcium intakes of Canadians are available, although several provincial surveys have reported relatively recent data for calcium intakes (data were obtained from surveys conducted in the 1990s). Mean calcium intake data as well as percentile distributions for Canada and the USA (from the 1994 CSFII survey) are shown in Table 3. It should be noted that these data do not reflect consumption of the recently introduced orange juices with added calcium, milks with added milk solids (approx 30% more calcium), fortified soy beverages or the increased level of calcium in enriched flour. These additional sources of calcium reflect recent changes in fortification policy and industry practices in Canada and the USA since these data were collected.

Supplement Use

In the Quebec survey (1990), 8–13% of men and 15–29% of women reported taking nutritional supplements containing calcium. In the National Health Interview Survey conducted in 1986, 25% of women in the USA took supplements containing calcium compared with 14% of men and 7.5% of children.

Calcium and Osteoporosis

Definition of Osteoporosis

Osteoporosis is a disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a

Table 3 Intake of calcium from foods by age and gender for the USA and Canada (mg per day)[a]

Age	USA				Canada (data from province of Quebec)[b,c]			
	Mean	25th	50th	75th	Mean	25th	50th	75th
Infants (males and females)								
0–6 months	461	343	457	569	na

consequent increase in fracture risk. The World Health Organization expert committee on osteoporosis has defined four different diagnostic categories: *normal* if BMD or bone mineral content (BMC) is within one standard deviation (SD) of young adult values; *osteopenia* (low bone mass) if the BMD or BMC is between 1 and 2.5 SD below young adult values; *osteoporosis* if the BMD or BMC is 2.5 SD or more below young adult values; and *severe osteoporosis* if the individual is osteoporotic and has suffered at least one fragility fracture.

Bone Structure

Bone tissue is a matrix of collagen and other proteins into which minerals are deposited, calcium and phosphorus being the most abundant. Calcium in bone is primarily (>90%) in the form of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$], and amorphous calcium phosphate, which lacks a coherent structure, found in areas of active bone formation. Bone is composed of two different types of structural tissue: cortical (the outer, denser envelope which plays a major structural support function) and trabecular or cancellous tissue (the metabolically more active form which is structurally like a fine sponge with numerous small voids). Cortical bone is found primarily in the appendicular skeleton (bones of the limbs), whereas trabecular bone is found mainly in the axial skeleton (skull and vertebral bones). The total skeleton is composed of approximately 80% cortical bone and 20% trabecular bone.

Bone contains two types of cells, osteoblasts and osteoclasts. The osteoblasts secrete an organic matrix composed largely of collagen, which is then hardened by hydroxyapatite. Osteoclasts are active at numerous sites within bone, secreting enzymes that dissolve bone before it is reformed. Bone remodeling, or turnover, is the cycle of bone breakdown by osteoclasts and bone rebuilding by osteoblasts and continues throughout life. In the normal young state, total osteoblast activity exceeds osteoclast activity, resulting in bone accretion.

Risk Factors for Osteoporosis

Osteoporotic fractures are multifactorial and may result from a variety of causes, either singly or in combination. For this reason, no single risk factor can identify all potential fracture cases. Peak bone mass is the major factor determining the risk of developing osteoporosis. By about age 20, the human skeleton reaches 90–95% of its peak bone mass. Then, over the next 10 years, the final 5–10% of bone mineral is added. People who have achieved a greater peak bone mass are less susceptible to osteoporosis. Numerous factors have been identified as the major risks for osteoporosis, including low calcium intakes and other dietary factors, BMD, estrogen status, as well as use of alcohol and some drugs (see Table 4).

Table 4 Major risk factors for osteoporosis

Low bone mineral density; BMD is the most useful risk factor for stratifying people by level of fracture risk
Estrogen deficiency due to menopause (natural or surgical), ovulatory disturbances among premenopausal women
Inadequate dietary calcium and vitamin D
Excessive intakes of caffeine
Excess dietary sodium intake
Alcohol abuse
Extended periods of immobility
Long-term use of corticosteroids
Other medications (heparin, anticonvulsants, excess thyroid hormone, and others)
Hereditary factors

Adapted from Ross PD (1996) Osteoporosis. Frequency, consequences, and risk factors. *Archives of Internal Medicine* 156: 1399–1411.

Physiologic Relationship Between Dietary Calcium and Osteoporosis

While it seems reasonable to predict that calcium intake and bone loss would be linked, the evidence showing this relationship has been less than obvious. Studies comparing calcium intakes and osteoporosis incidence or fracture rates among different countries with varying cultures tend to show no relationship or a negative association between calcium intakes and osteoporosis. However, within countries or population groups, a large body of evidence has accumulated that shows that higher calcium intakes at various times in the life cycle are linked with increased BMD or BMC. Controlled clinical trials of calcium supplementation have been conducted for almost every age group (children and older) and, for the most part, support the benefits of calcium for increasing BMD or BMC, or in some groups reducing losses. Fewer studies have investigated the impact of calcium on osteoporosis or fracture rates.

In children, clinical trials have shown a modest but positive effect of calcium supplementation, particularly in those children with intakes < 1000 mg per day, on bone mineral accretion. In general, supplementation resulted in 1–5% greater gains in bone mineral density or bone mineral content compared with controls. However, the long-term benefits of such an increase and whether the increase is sustained remain unclear at the present time.

Data concerning the role of calcium in bone health of young adults are particularly lacking compared with other age groups. Physical activity appears to be a significant determinant of bone health in this age group.

Studies show several consistent effects regarding the role of calcium in bone loss in postmenopausal women. Early postmenopausal women are less responsive to calcium supplementation than late postmenopausal women; where effects were seen, they tend to be in cortical bone, with spine being less responsive to calcium. Late menopausal women with low calcium intakes tend to gain more BMD from calcium supplementation than do women with higher usual intakes of calcium. Observational studies in postmenopausal women and one study that included men generally indicated a positive effect of calcium on bone density. Several studies also suggested that higher intakes of calcium earlier in life were related to reduced incidence or fractures or increased BMD in postmenopausal women.

Many studies conducted in the elderly have shown a benefit of supplements or higher intakes of calcium on the clinically important outcome – fracture rate. Almost half of the trials in the elderly found decreased fracture incidence, in addition to changes in BMD. More studies in this age group than in any other have included male subjects, and benefits appeared to apply equally to men. In the elderly, most studies have provided a supplement of vitamin D along with calcium. Given that vitamin D deficiency is most prevalent among the elderly, particularly among institutionalized or house bound individuals, it is important that the elderly have adequate vitamin D in order to utilize calcium or to benefit from additional calcium.

CAMPYLOBACTER

Contents

Properties and Occurrence

M B Skirrow, Gloucestershire Royal Hospital, Gloucester, UK

Introduction

Campylobacters are the leading cause of infective diarrhea in most industrialized countries. Yet, they have hitherto enjoyed a low public profile that belies their importance as a cause of foodborne disease. There are several reasons for this. First, their role as enteric pathogens was not discovered until the late 1970s; second, infection is rarely fatal; and third, they seldom cause spectacular outbreaks that catch the attention of the media. Yet, they cause much morbidity and constitute a huge economic burden to society.

After a brief description of campylobacters and their properties, this article describes their wide distribution in wild and domestic animals, notably birds, and shows how they are introduced into the food chain from these sources. It attempts to define the foods of greatest importance as a cause of human infection, and the circumstances that allow infection to arise. Although there must be many sources and modes of transmission that remain hidden, there can be no doubt that poultry are the most important single source. It has been estimated that poultry account for about half of all recorded cases.

Classification

Campylobacters are small, spirally curved, flagellated, microaerophilic Gram-negative bacteria that were formerly classified in the genus *Vibrio*. Together with *Arcobacter*, *Helicobacter*, and *Wolinella*, they form a phylogenetic group distantly related to other eubacteria. Several species are associated with human disease, but only *Campylobacter jejuni* ssp. *jejuni* and *C. coli* are of major importance as a cause of campylobacter enteritis. *C. upsaliensis* and *C. jejuni* ssp. *doylei* are associated with diarrheal disease in children in developing countries, but to only a minor extent in industrialized countries. *C. lari* is present in abundance in birds (notably gulls) and natural water, but most strains appear to be nonpathogenic, as they seldom cause human disease.

C. fetus, the type species of the genus, is an uncommon cause of systemic (bloodstream) infection in people with impaired immunity. Although *C. fetus* infection has been caused by eating raw lambs' liver, its low virulence for healthy people makes it of minor concern to the food microbiologist.

Arcobacters were initially regarded as aerotolerant *Campylobacter* species (unlike campylobacters, they grow freely in air), but in 1991, the new genus *Arcobacter* was created to accommodate them. Although they cause abortion in pigs and cattle and are commonly found in poultry (24–96% of fresh carcasses) and meat (80% of ground pork samples in one study), arcobacters (usually *A. butzleri*) have only occasionally caused intestinal infection in humans. Until more is known about their role in human disease, arcobacters remain a research topic. Our main concern is with *C. jejuni* and *C. coli*.

Helicobacter pylori, which colonizes the stomach of roughly half of the world population and causes gastric and peptic ulceration, can probably be transmitted via food and water. Evidence is currently indirect and inconclusive, but progress needs to be monitored.

Growth Factors and Properties

Campylobacters are strictly microaerophilic bacteria that require oxygen for growth yet are poisoned by concentrations much above 10%. Unlike most other campylobacters, *C. jejuni*, *C. coli*, and *C. lari* have an optimum growth temperature of 42–43 °C, a feature that has earned them the informal title of 'thermophilic campylobacters.' They do not grow below a temperature of 28 °C.

Campylobacters are more sensitive to physical and chemical agents than enterobacteria such as *Escherichia coli*. Dense saline suspensions (10^{10} cfu ml^{-1}) dried on hard surfaces survive for 2–10 h at 37 °C, but suspensions in broth or skimmed milk dried and held at 4 °C survive for several weeks. Campylobacters have a pH growth range of 6.0–8.0, but they are inactivated below pH 5.5 or above pH 9.0. Hypochlorites, phenols, iodophors, and quaternary ammonium compounds kill campylobacters within 1 min at standard working dilutions.

These factors combine to prevent their multiplication in food. Unlike salmonellas and other enterobacteria, they tend to die in food stored at ambient temperatures, owing to exposure to air and overgrowth by other bacteria. Their survival is prolonged by refrigeration.

Occurrence in the Environment

C. jejuni and *C. coli* live mainly as commensals in the intestinal tract of a wide variety of warm-blooded animals, notably birds (Table 1). Carriage rates in wild mammals are generally lower than in birds, but a rate of 24% has been found in urban rats (*Rattus norvegicus*). Domestic and food-producing animals are commonly colonized and constitute the main source of human infection. Poultry are a particularly important source (see below). *C. jejuni* is generally the predominant species, but in pigs, virtually all the thermophilic campylobacters are *C. coli*. Horses are seldom colonized.

Table 1 Occurrence of campylobacters (*C. jejuni* and *C. coli*) in wild birds from five continents[a]

[a]The data are given as the mean percent positive, with the number of surveys from which the data were extracted in parentheses.

The fecal shedding of campylobacters by domestic and wild animals results in widespread environmental contamination, notably surface water, even in remote areas. Campylobacters survive well at temperatures below 15 °C in fresh water, sea water, and sewage. In these conditions, they can adapt to aerobic metabolism, which is presumably a defense strategy. Surface water is probably the chief vehicle of infection for farm animals, and drinking untreated water carries a high risk of infection for human beings.

Occurrence in Foods

Although carriage rates in food-producing animals vary widely, both seasonally and between herds or flocks, average figures compiled from numerous surveys give an idea of the high prevalence of these bacteria in poultry and animals produced for red meat.

Table 2 shows the occurrence of campylobacters in eviscerated poultry, in poultry processing plants and

Table 2 Occurrence of campylobacters (*C. jejuni* and *C. coli*) in poultry[a]

at the point of retail sale. The initial high contamination rates persist in the retailed product, with only a modest fall brought about by freezing and thawing. This high persistence is not surprising, considering that cecal contents of chickens may contain as many as 10^8 campylobacters per gram. Cuts of chicken with skin are significantly more contaminated than those without skin.

Table 3 shows the occurrence of campylobacters in cattle, sheep, and pigs together with the meat products derived from them. Butchered carcasses in the abattoir reflect the high intestinal colonization rates in the live animals, but in contrast to poultry, there is a sharp reduction of campylobacters between the abattoir and the retailed product. This is largely due to the forced air chilling process used on these large carcasses (see below). Thus, contamination rates on red meat are generally low, as are the campylobacter counts on the positive samples. Note that offal, which is not subjected to the same treatment, remains more contaminated.

Table 4 shows the occurrence of campylobacters in milk and other foods. Raw milk is clearly a major potential source of infection, and there are many instances of campylobacter enteritis resulting from its consumption. Pasteurization or other conventional heat treatment renders it safe from this threat.

Food Poisoning from Campylobacters

The proportion of campylobacter infections attributable to the consumption of food is not precisely known, but it is believed to be the great majority. A few infections are acquired through direct contact with infected animals or their products. These are mostly occupational, for example, in workers in poultry-processing plants, but some arise through contact with domestic pets, notably puppies and kittens that are themselves suffering from campylobacter diarrhea. Animal contact is more important in developing countries, where transmission rates are far higher than in industrialized countries, and the disease is virtually confined to young children.

Most campylobacter infections are sporadic. Unlike salmonella infection, outbreaks of campylobacter enteritis are uncommon. In the UK, for every campylobacter outbreak reported, there are 34 salmonella outbreaks. Large campylobacter outbreaks are mostly milkborne (see below) or waterborne. Five waterborne outbreaks, affecting a total of nearly 7000 people, have arisen from the distribution of contaminated supplies, including unchlorinated water from oligotrophic lakes in Scandinavia.

Incidence

As diagnosis depends on the identification of campylobacters in patients' feces, measurement of incidence depends on laboratory reports. This in turn is dependent on the availability and use of medical and laboratory services, which are highly variable. Laboratory reports give incidences of 100/100 000 per year in the UK, 25/100 000 in the USA, and 318/100 000 in New Zealand. However, extrapolations from community surveys and outbreaks give figures of 1100/100 000 and 1000/100 000 for the UK and USA, respectively. The costs in terms of health care and lost productivity are immense. World Health statistics for foodborne

campylobacter enteritis in the USA cite estimates of US$ 1.2–6.6 billion annually.

Foods Implicated in Campylobacter Enteritis

Having identified the foods that are regularly contaminated with campylobacters (Tables 2–4), we need to define which of them are actually implicated as sources of infection. This is not easy. As already mentioned, outbreaks of campylobacter enteritis, which provide good opportunities to pinpoint sources, are uncommon. There are several approaches to the problem:

1. Comparison of the campylobacter strains commonly found in foods with strains found in patients. For example, strain identification tells us that pigs are a relatively minor source of campylobacter enteritis, as almost all strains in pigs are *C. coli*, yet in most regions, *C. coli* accounts for only about 5% of human infection. The common serotypes of *C. jejuni* found in man are well represented in poultry, cattle, and sheep. In the UK, about 70% of the strains most commonly isolated from patients are also found in chickens. (*See* **Essential Oils**: Isolation and Production; **Pork**.)
2. Identification of foods that have been implicated in outbreaks of campylobacter enteritis. These foods are listed in Table 5, from which it can be seen that poultry feature prominently. The locations of these outbreaks are shown in Table 6.
3. Identification of foods that are statistically associated with infection in case-control studies. Such studies provide two valuable indices: the relative risk of consuming or handling a food (usually expressed as the odds ratio); and the etiological fraction, i.e., the proportion of infections attributable to that food. Table 7 shows the foods or activities that have been associated with a risk of acquiring campylobacter infection. Again the consumption of chickens, especially if they are undercooked, stands out as a prominent risk factor.
4. Observation of the effects of eliminating or reducing campylobacters from a food on the incidence of infection in the community that consumes the food. In a UK study, the control of *C. jejuni* serotype HS4:HL1 in a heavily colonized chicken farm was followed by a fall in the proportion of human infections with this serotype from over 30% to 5% in the community supplied with the chickens. Likewise, in Tasmania, the escalation of a salmonella control program in chickens, which incidentally would have controlled campylobacters, was followed by a 50% reduction in human campylobacter infections.

The role that these various foods play in causing campylobacter infection will now be considered in more detail.

Poultry Poultry feature prominently in all of the above categories, especially if undercooked. It is notable that any meat cooked by barbecue, char-grill, stir-fry, or fondue methods feature in these lists. These hot rapid methods of cooking are liable to leave the deeper parts of meat uncooked, even when the outside is well browned. Handling and preparing chicken were found to carry a much higher risk of infection than eating chicken, in a case-control study in the USA.

Broiler chickens are consumed in vast numbers, so even though the relative risk (odds ratio) of eating chicken is only around 3 (Table 7), the total number of cases resulting from their handling and consumption is large. Extrapolating case-control data to estimate the proportion of sporadic infections attributable to poultry must be viewed with caution, but two studies, one in the USA and the other in the UK, came up with similar figures, namely 48 and 50%, respectively.

Table 5 Foods other than milk implicated or suspected as the source in 83 outbreaks of campylobacter enteritis (average attack rate 41%)[a]

						Miscellaneous		
Poultry		*Red meat*		*Seafood*		*Salads*	*foods*	*Specific meal*
Chicken	8	Raw beef	2	Raw clams	1	12[b]	7[c]	36
Undercooked chicken	7[d]	Vinegared pork	1	Prawn, salmon vol-au-vent	1			
Chicken liver	2[e]	Red meat products	3					
Turkey	2[f]							

[a]The figures shown are the numbers of outbreaks reported in publications from 11 countries.
[b]Evidence of cross-contamination from raw chicken in 7.
[c]Includes pâté vol-au-vent (1), tuna/egg vol-au-vent (1), mayonnaise (1), frozen egg (1), undercooked egg (1), cake icing (1).
[d]Barbecued (2), char-grilled (1), stir-fried (1).
[e]Fondued (1), pâté (1).
[f]Processed and sliced (1), boned, stuffed, and rolled (1).

Table 6 Places where 67 outbreaks of foodborne campylobacter enteritis arose (excluding milkborne outbreaks)

Place	*Number of outbreaks*
Restaurant, hotel	34
Institution (e.g., colleges, military barracks)	13[a]
School (residential and nonresidential)	8
Private home or function	4
Home for aged	3
Outdoor camps	3
General community	2

[a]Includes one hospital.

Table 7 Foods identified as carrying a risk for acquiring sporadic campylobacter enteritis, as determined by case-control studies

Food	*Number of studies*	*Odds ratio, mean (range)*
Chicken (any)	8	2.6 (0.44[a]–5.2)
Chicken (raw/undercooked)	5	6.0 (2.7–9.0)
Chicken eaten in restaurants	1	3.8
Poultry liver	1	5.7
Game hens	1	3.3
Barbecued sausages	1	7.6
Raw/rare fish	1	4.0
Raw/rare shellfish	1	1.5
Mushrooms	1	1.5
Raw (unpasteurized) milk	5	5.8 (3.9–9.3)
Raw (unpasteurized) cream	1	12.0
Milk from bird-pecked bottles	1	42.1

[a]This odds ratio of 0.44 ostensibly shows a protective effect from eating chicken. A possible explanation for this exceptional result is that many of these chicken eaters habitually consumed chicken and had thereby developed immunity to infection.

Milk and Dairy Products Raw milk commonly contains campylobacters (Table 4). The distribution of inadequately pasteurized milk was responsible for the largest outbreak of campylobacter enteritis on record. In 1979, in England, an estimated 3500 people, mostly primary-school children, were affected over a period of 3 weeks. Since then, at least 58 milkborne outbreaks have been reported in the UK and 26 in the USA, affecting over 8000 people. The average attack rate in exposed persons in 14 outbreaks in which data were available was 54% (range 24–79%).

In the USA, milkborne outbreaks accounted for 50% of all reported foodborne campylobacter outbreaks. Roughly one-half the milkborne outbreaks arose in the general community, 20% in schools or other institutions, 17% on school visits to farms, and 8% in holiday or rural camps. In all but two instances, the implicated milk was drunk raw; in the two exceptions, the milk was distributed as pasteurized, but there had been unsuspected processing failures. It is notable that four of 10 people who drank their raw milk in coffee became infected.

Most milkborne infections are associated with cows' milk, but raw goats' milk has occasionally been implicated. In a survey in the UK, only one out of 2493 (0.04%) goat's milk samples in the UK was found to contain *C. jejuni*.

Cheese Most cheeses are too acidic for the survival of campylobacters, but a soft cheese made from unpasteurized sheep's milk was incriminated in an outbreak of campylobacter enteritis in Czechoslovakia, and there is a single instance of infection associated with home-made ricotta cheese prepared from unpasteurized goats' milk.

In several case-control studies, the consumption of dairy products was associated with a reduced rate of infection.

Eggs The various egg-containing foods listed as suspect sources of infection in Table 5 may have been cross-contaminated from other foods. However, shell eggs may become externally contaminated with campylobacters from chicken excreta and may thus contaminate egg contents when broken. Campylobacters do not penetrate intact shell or membranes into the egg contents. Vertical transmission to eggs from laying hens has not been proven, but there is indirect evidence to support it.

Seafood Raw seafood may harbor campylobacters (Table 4) as well as other pathogens. In temperate zones, contamination may be highly seasonal – high in winter and low in summer. A study in Australia showed that Sydney Rock Oysters (*Crassostrea commercialis*) allowed to feed in waters containing about 10^4 cfu campylobacters per milliliter concentrated them to 10^2–10^3 cfu g^{-1} in their tissues within 1 h, but they were effectively cleared by depuration for 48 h. Yet, depuration does not always eliminate campylobacters. A high proportion of mussels have been found to harbor campylobacters, but conventional steaming completely inactivates them. Seafood kept in sea water may be contaminated from the water rather than containing campylobacters itself.

Campylobacters survive for several months in frozen oysters and for 8–14 days in refrigerated oysters. (*See* **Shellfish**: Contamination and Spoilage of Molluscs and Crustaceans.)

Introduction of Campylobacters into Food

Contamination of Meat at Slaughter

The contamination of animal carcasses with intestinal contents at slaughter and the persistence of the bacteria in raw meat are the most important sources

of campylobacters in food. Because these are inextricably bound with processing methods, they are considered below in the section on the effects of food processing on campylobacters. (*See* **Meat**: Slaughter.)

Contamination of Milk from Milk-producing Animals

At any one time, an average of about 25% of milking cows excrete campylobacters in their feces. Carriage in individual animals is variable, and several strains may circulate in a herd over a period. Some degree of fecal contamination is unavoidable, even in well-run milking parlors, and several outbreaks have been caused by drinking top-grade certified milk in the USA. Table 4 shows that, on average, 4.8% of bulked milk contains campylobacters. Positive samples usually have high counts of *E. coli*, but occasionally, campylobacters have been found without *E. coli*, probably through excretion from the udder. High counts of *C. jejuni* have been found in milk from cows with campylobacter mastitis, an uncommon naturally occurring infection. In experimental mastitis, many campylobacters may be excreted from an infected quarter before the milk appears obviously granular.

Contamination of Milk by Wild Birds

In the UK, where it is common practice for fresh milk to be delivered to the doorstep in metal-foil-topped bottles, magpies (*Pica pica*) and jackdaws (*Corvus monedula*) have developed the habit of pecking through the foil tops and contaminating the contents. This is a seasonal activity when the birds are raising fledglings (April to June), which is also a time when they frequently probe cow dung for invertebrates. The habit is geographically variable; in areas of highest prevalence, case-control studies have shown it to account for a high proportion of campylobacter infections at that time of year.

Cross-contamination in the Kitchen

Items of food, such as raw poultry that are heavily contaminated with campylobacters, provide a reservoir of bacteria in the kitchen from which other foods can become contaminated. This may come about through direct contact (e.g., from the liquor of a thawing chicken), or via common utensils, counter tops, chopping boards, and the hands of kitchen staff. Campylobacters have been isolated from all of these sites in working kitchens and from 76% of the hands of staff who had held contaminated chicken.

A frequent finding in campylobacter outbreak investigations is a failure to separate raw meats from other foods in food preparation areas – and often a disturbing ignorance on the part of the staff of the need for this separation. Although it is seldom possible to prove cross-contamination, it is probably the most frequent event leading to infection.

Insects Theoretically insects could be passive vectors of infection via food. Campylobacters have been isolated from houseflies (2.4% of flies caught in houses and gardens in the UK; 5.5% in Pakistan) and cockroaches, but substantial carriage has been found only in the close vicinity of chicken sheds and piggeries. Campylobacters failed to survive for more than 2 days in flies artificially fed with campylobacter broth cultures. (*See* **Insect Pests**: Problems Caused by Insects and Mites.)

Fate of Campylobacters During Food Processing

Animal Slaughter and Meat Processing

Contamination of animal carcasses with intestinal contents during slaughter and preparation is universal and, to some degree, unavoidable. Fortunately, in the case of large animals (cattle, sheep, pigs), conventional forced air evaporative chilling with frequent mechanical spraying greatly reduces the numbers of live campylobacters remaining on the surfaces of carcasses, mainly through the effect of drying. Cooling without mechanical assistance causes only about a 50% reduction in campylobacter numbers.

Broiler chickens and other poultry pose a greater problem owing to the high degree of mechanization required for processing birds at rates that satisfy public demand. Two stages of processing are particularly problematic:

1. Mechanical defeathering, which is preceded by immersion in hot water ('scalding') to facilitate plucking. 'Hard scalding' at temperatures above 58 °C causes a reduction in bacterial counts, but 'soft scalding' at 50–52 °C, used for birds that are to be sold fresh, has little effect; thus, leakage of intestinal contents, which is common, results in gross cross-contamination.
2. Mechanical evisceration, which often results in the rupture of the gut of birds that are not of consistent size. Again, widespread cross-contamination is the inevitable consequence; birds that are initially clean become contaminated during processing. Contamination can be reduced, but not eliminated, by chilling in well-designed reverse-flow systems containing chlorinated water (10 p.p.m. chlorine). Uneviscerated ('New York dressed') birds are the most heavily contaminated; campylobacter

counts of up to $2.4 \times 7\,10^7$ per chicken have been recorded. Frozen birds are least contaminated, owing to the damaging effect on the bacteria of freezing and thawing.

Effects of Storage

The most critical factors in the survival of campylobacters are temperature and oxygen concentration: cold and reduction of oxygen tension are protective. Campylobacter counts have been shown to decline on stored meat by 1–2 $\log_{10}$ at 4 °C and 2–5 $\log_{10}$ at 23 °C over 2 weeks, but much depends on the particular campylobacter strain and the type of meat – minced beef, for example, is unusually protective, probably on account of its reducing properties. Reduced conditions, such as are present in vacuum or modified-atmosphere-packaged (MAP) foods, are certainly protective. In one study, campylobacters were detected in 22% of MAP salads from supermarkets (Table 4), although counts were mostly below 80 cfu g^{-1}. Freezing and thawing cause a 1–2 $\log_{10}$ reduction in campylobacter counts, but once frozen, survival is measured in months or even years. (*See* **Storage Stability**: Mechanisms of Degradation.)

Salting

C. jejuni and *C. coli* do not grow in the presence of salt at concentrations greater than 1.5%. They can survive for 3–5 days at room temperature in 4.5% NaCl and for 3 weeks at 4 °C in 6.5% NaCl, albeit with a several $\log_{10}$ fall in viable counts. However, the addition of 2.5% NaCl to aerobically packaged turkey hams reduced *C. jejuni* counts from about 6.0 $\log_{10}$ cfu g^{-1} to below detectable limits within 6 days at 4 °C. Campylobacters can survive on washed pig intestines after overnight salting.

Acidification

Campylobacters cannot grow at pH values of 5.5 or less and are inactivated at pH 5.0 or below.

Irradiation

Campylobacters are considerably more sensitive than *E. coli* to gamma (D_{10} values 0.12–0.25 kGy) and ultraviolet irradiation, so they are destroyed by conventional irradiation regimens. A gamma irradiation dose of 1.5 kGy is sufficient to cause a 7 $\log_{10}$ reduction in *C. jejuni*. (*See* **Irradiation of Foods**: Basic Principles.)

Survival in Milk, Dairy Products, Spices, and Fruit

Milk Most campylobacter strains are recoverable from raw milk held at 4 °C for 7 days if the initial concentration is heavy, e.g., 10^7 cells ml^{-1}. Inactivation of strains parallels a rise in the aerobic plate count and fall in pH. Thus, survival in raw milk is about half that in sterilized milk. The lactoperoxidase system also reduces survival in milk. Survival becomes progressively shorter as the temperature is increased, so that at 20 °C, it is only 1–2 days. Campylobacters are readily destroyed by conventional pasteurization and give *D*-values of 1 min or less at 60 °C in raw, pasteurized, or skimmed cows' milk.

Cheese and Yogurt In one study, campylobacters were not recovered from cheddar cheese curd after 30 days of curing, or from whey or curd of cottage cheese after cooking for 30 min at 55 °C. In another study, no strain survived for more than 25 min in yogurt. (*See* **Yogurt**: The Product and its Manufacture.)

Egg Campylobacters can grow in egg yolk and yolk–albumen melanges, but albumen alone is toxic. The major factor in the sensitivity of egg white is apparently conalbumen.

Spices and Fruit The spices oregano, sage, and ground cloves are mildly inhibitory to *C. jejuni*, but not sufficiently to reduce numbers in refrigerated food. A study showed that *C. jejuni* survived for 6 h on cubes of water melon and papaya at 25–29 °C (8–62% survivors), but much less readily when lemon juice was added to the surface of the cubes (0–14% survivors).

Detection

M B Skirrow, Gloucestershire Royal Hospital, Gloucester, UK

Introduction

The conventional means of detecting campylobacters is by isolation in culture. In this article their microaerobic growth requirements and special needs for isolation from foods are described, including selective enrichment and plating on selective agar. Direct detection of campylobacters by immunological and DNA probe techniques are becoming more sensitive and specific by the application of polymerase chain reaction (PCR) methods, but they are as yet too complex to be adopted routinely. Campylobacters can be provisionally identified by phenotypic methods in most laboratories, but definitive identification requires molecular methods that are available only in reference laboratories. Strain typing of campylobacters (serotyping, phage typing, molecular typing) is also best performed in reference laboratories. Advances in molecular typing in particular are paving the way for better source tracing and understanding of the epidemiology of campylobacter infection.

Principles of Campylobacter Cultivation

The failure of traditional cultural methods to provide the conditions necessary for the growth of campylobacters was the main reason why their role in human disease remained hidden for so long. The main peculiarity of campylobacters is that they are strictly microaerophilic and require specially prepared atmospheres for satisfactory growth. Specific selection, either by means of selective media or filtration, is essential for their isolation from feces or other specimens containing mixed organisms. Moreover, they only grow well on supplemented media, and *Campylobacter jejuni, C. coli*, and *C. lari* – the so-called thermophilic group that causes campylobacter enteritis – have an optimum growth temperature of 42–43 °C.

Oxygen Sensitivity

Oxygen sensitivity is the most critical factor in the cultivation of campylobacters. Campylobacters have a respiratory type of metabolism based on the krebs cycle, so oxygen is necessary for growth; yet oxygen at atmospheric pressures is toxic. This toxicity is due to superoxides and free radicals that form in unsupplemented media exposed to air, particularly in the light. Campylobacters are especially vulnerable to these compounds despite being able to produce superoxide dismutase and catalase. They are most vulnerable in the resting phase; once they have started to grow they become more oxygen-tolerant, probably owing to the production of nicotinamide adenine dinucleotide (NAD) or nicotinamide adenine dinucleotide phosphate (NADP), which forms a physiological barrier that protects oxygen-sensitive enzymes. The practical points that arise from this are twofold:

1. Heavy inocula are required to initiate growth on unsupplemented media. Large populations usually have a few bacteria that are able to start growing and thereby create conditions suitable for other cells to grow. The result of seeding campylobacters on unsupplemented media tends to be either confluent growth or none at all.
2. The key supplements for growing campylobacters are agents that neutralize superoxides and free radicals; any nutrient value they have is incidental. Blood, hemin, hematin, activated charcoal, dihydroxyphenyl, and iron compounds are examples of such agents. A simple and widely used supplement is the triple combination of ferrous sulfate, sodium metabisulfite, and sodium pyruvate, each at a final concentration of 0.025% (FBP).

Detection in Food by Culture

The isolation of campylobacters from food is more difficult than from the feces of a patient with campylobacter enteritis, as there are usually far fewer organisms present. For fecal specimens direct plate culture is normally adequate – indeed, organisms may be so plentiful that a presumptive diagnosis can be made by direct microscopy – but for food, selective enrichment cultures are essential. Possible exceptions are raw poultry products, which may be so heavily contaminated that enrichment is not critical; indeed, for some chicken samples enrichment has proved to be less sensitive than direct plating.

The principle of the enrichment method is to incubate the food (after stomaching or other treatment to break it down) in a selective broth for 24–48 h and then subculture on a selective agar for the isolation and identification of individual colonies. However, for campylobacters that have been subjected to hot or cold stress, which causes sublethal injury, other techniques may be necessary. As the treatment the foods have received is not always known, there is much to be said for including the more sensitive techniques routinely.

When properly carried out, cultural methods are able to detect 1 campylobacter colony-forming unit (CFU) in 2 g food that contains at least $10^6\,g^{-1}$ of other bacteria.

Specimen Handling and Transport

The correct handling and preservation of specimens are crucial for food specimens; incorrect handling negates the value of sensitive isolation procedures. The three most important factors are refrigeration (as near to 4 °C as possible), exclusion of oxygen, and prevention of drying. Oxygen may be excluded by gassing with 100% N_2, but this is not always practicable. Provided specimens are not unduly large, they can be placed in a semisolid transport medium, such as Cary-Blair medium (0.16% agar), or directly into a campylobacter-selective broth, each containing either FBP or sodium bisulfite 0.01%. The choice of medium may be critical, and it is often better to use a highly selective formulation, as campylobacters do not compete well with other microorganisms. The choice will be influenced by the nature of the sample, the physical state of the target organisms, and the time likely to elapse before cultures are set up.

Milk and liquid foods should be held refrigerated after adding sodium bisulfite 0.01% and either sodium thioglycollate 0.15% or 100% N_2. Under these conditions there is little loss of viability over several days, but the sooner specimens are cultured the better.

Enrichment Techniques

Campylobacters that have been frozen, chilled (4 °C), or subjected to mild heating become sublethally injured. This is manifested by increased susceptibility to antibiotics (notably rifampicin and polymyxin), deoxycholate, oxygen radicals such as peroxides, and high incubation temperatures. This susceptibility is thought to be due to damage to the outer membrane of the bacterial cell and it can significantly reduce the efficacy of detection by culture.

Thus the first stage of an isolation procedure is designed to allow the organisms time to recover. Ideally this is done in a nonselective broth incubated at 37 °C. This is feasible with samples such as water containing few competing flora, and in which campylobacters are often severely injured. However, for samples such as chicken, preincubation in nonselective media often results in a reduced isolation rate because the high numbers of competing flora overwhelm *Campylobacter*. Given the unpredictability of bacterial contamination levels, it is better to use selective media for the routine examination of food, water, and environmental samples. The broth should be at about room temperature when inoculated, and if the volume is large, incubation is best done in a water bath.

In choosing a liquid-selective medium it is important to take one that is able to suppress the growth of competing flora adequately, particularly *Pseudomonas* and *Proteus* spp. The choice will depend partly on the type of sample being examined, as some of the many available formulae perform better with some materials than others. A good all-round highly selective medium is Exeter broth (Table 1).

Various protocols have been laid down for incubation procedures. In general, maximum sensitivity can

[c]Commercially available as MAST SV59 Campylobacter-selective supplement.
[d]Only for solid plating medium.

be attained by initial incubation at 37 °C for 18 h followed by incubation at 42–43 °C for 30 h. This latter period can be extended for a further 24 h, and with some lightly contaminated samples the use of this extension has been shown to improve isolation rates. With highly selective media like Exeter broth it is possible to incubate samples at 37 °C throughout. In general, as large a volume of broth as is practicable should be used in order to accommodate as much of the sample as possible; a minimum of 25 g in 225 ml broth is recommended.

For liquid samples such as milk, it may be convenient to add the sample to an equal volume of double-strength medium. For maximum sensitivity, however, it is necessary to examine large volumes (around 200 ml) and this can present problems. Alternative methods of testing large volumes are to culture gauze or cotton wool pads through which the milk has been filtered, or to culture centrifuged deposits.

It is generally acceptable to incubate fluid cultures in closed vessels containing air. Slight increases in sensitivity can be attained by the use of Erlenmeyer flasks with stoppered side-arms, so that air can be partially extracted and replaced with a mixture of 10% carbon dioxide, 10% hydrogen, and 80% nitrogen. Best results are obtained if there is a constant flow of gas mixture with agitation of the broth.

Subculture to Agar Plates

Mature enrichment cultures are subcultured on a campylobacter-selective agar. There are numerous formulae, but either charcoal, cefoperazone, deoxycholate (CCDA) or Exeter agars are recommended. Hydrogen peroxide and other potentially toxic oxygen metabolites can accumulate in agar even if the plates are stored in the dark under refrigeration. It has been shown that these compounds act synergically with antibiotics, such as rifampicin, to inhibit campylobacter growth severely. Thus for maximum sensitivity it is important to use fresh plates and include FBP supplement in the agar, even if blood is also included.

Plates are incubated at 42–43 °C in a microaerobic atmosphere containing 5–10% oxygen and preferably some hydrogen. If cylinder gases are available, the easiest method is to extract two-thirds of the air from a closed container, such as an anaerobic jar (without catalyst), and replace it with a mixture of 10% carbon dioxide, 10% hydrogen, and 80% nitrogen. If there is no cylinder gas, an anaerobic-type gas-generating envelope can be used, and the jar partially evacuated after closure. Alternatively, special gas-generating envelopes for campylobacters are commercially available for use in jars with a catalyst.

Growth is usually visible after 24 h, but occasional strains do not appear until incubation has been maintained for 48 h.

The foregoing protocols are designed to detect the main causes of campylobacter enteritis, namely *C. jejuni* and *C. coli* (they will also detect *C. lari*). Other species of campylobacter and related bacteria, such as *C. uppsaliensis*, *C. hyointestinalis*, and *Arcobacter butzleri*, which have been implicated to a lesser degree, are unlikely to be detected. Those wishing to isolate these bacteria, for research or whatever reason, must use special selective media incubated at 37 °C rather than 42 °C. Alteratively, nonselective media may be used in conjunction with membrane filters placed on the agar.

Fecal Indicator Bacteria and Campylobacters

It will be evident from the foregoing account that the culture of campylobacters from food is time-consuming and costly, especially if regular monitoring is undertaken. Campylobacters are rarely found in the absence of fecal bacteria, so for processed foods it is reasonable to screen for the latter rather than look for campylobacters. Most raw meats have fecal coliforms on them, and it must be assumed they also have campylobacters. In short, it pays to think carefully about the value of screening for campylobacters before undertaking a monitoring program; it could be unproductive and uneconomic.

Identification

In general, most *Campylobacter* colonies are typically flat, effuse, and wet-looking, although other morphotypes can occur. Identity is confirmed by a positive oxidase reaction and the presence of characteristic motile, spiral, or S-shaped Gram-negative organisms in wet preparations and Gram-stained smears. Additional basic identification tests are shown in Table 2. Sets of these tests are available from commercial sources and one includes simple resistogram typing. Latex agglutination tests for identification are also available commercially, but they need careful assessment. Molecular methods that depend on the analysis of DNA fragments can perform well in identification tests, but they tend to be too complex for general use. In choosing a test appropriate to one's needs it is important to know whether it discriminates between groups of species, single species, or strains within a species.

Meat samples, especially chicken meats, are likely to carry *Arcobacter* spp. These bacteria closely resemble *Campylobacter* spp. on agar plates. *Arcobacter* spp. can be distinguished by their ability to grow in air at 25 °C (Table 2). Not all *Arcobacter* spp. grow at 42 °C.

Table 2 Basic differential characters of campylobacters likely to be found in food

Species	Growth at 25 °C	Hippurate hydrolysis	Indoxyl acetate hydrolysis	Sensitivities	
				Nalidixic acid	Cephalothin
C. jejuni	−	+	+	S	R
C. coli	−	−	+	S	R
C. lari	−	−	−	R	R
C. fetus	+	−	−	R	S
Arcobacter spp.	+[a]	−	+	S	R

−, negative; +, positive; R, resistant (no zone of inhibition to 30 μg disk); S, sensitive (any zone of inhibition to 30 μg disk).
[a]Growth in air.

Typing

Serotyping on the basis of heat-stable lipopolysaccharide antigens (Penner system) and heat-labile flagellar and outer-membrane protein antigens (Lior system) is the main typing method in current use. There are several hundred designated serotypes, but only a limited number are found frequently. The discriminatory power of serotyping can be enhanced by the parallel use of biotyping and/or phage typing. Typing facilities are only available at reference laboratories.

In recent years a plethora of molecular-typing methods have appeared based on the analysis of fragments of DNA split by specific enzymes. Their discriminatory powers and complexity vary widely. Some are simple enough for wide application, but all suffer from a lack of standardization. Until this problem is resolved, serotyping, supplemented with phage typing, remains the basic typing method.

Detection in Food by Noncultural Methods

Immunological methods that make use of high-affinity monoclonal antibodies were the first noncultural methods to be used for the direct detection of campylobacters. The antibody/bacterial antigen reaction was detected by latex agglutination or enzyme-linked immunosorbent assay (ELISA). Work on these techniques was largely foresaken in favor of molecular methods, in which fragments of DNA specific to the bacterium are recognized by specific probes and then amplified by PCR. A sensitivity of 3–15 *C. jejuni* cells in 100 ml water and $3\,g^{-1}$ has been claimed. These methods work better with samples that do not contain an excess of other bacteria or biological material, but they have recently been made to work with feces. The main problem is that they need specialized skills and reagents. False-positive results are likely unless scrupulous care is taken to avoid contamination with DNA. These methods are likely to come into their own as they become refined and easier to use.

Detection in Suspected Food Poisoning

Outbreaks of campylobacter enteritis usually come to light through the recognition of a sudden excess of campylobacter isolations in a clinical laboratory, or, less often, by the recognition of an excess of diarrhea in a community. Either way the laboratory plays a key role, as the infection cannot be diagnosed clinically. Unfortunately, outbreak investigations are hampered by the long time that elapses between food consumption and awareness of an outbreak: the average incubation period is 3 days; people tend not to seek medical attention until they have been ill for several days; sampling, testing, and reporting may take 2–3 days; and several more days may pass before someone realizes that cases are epidemiologically connected. Thus, the investigation may only start 2 weeks or more after ingestion of the food, long after suspect items have been discarded. Even if foods are available, the vulnerability of campylobacters mitigates against their survival in detectable numbers. (*See* **Food Poisoning**: Tracing Origins and Testing.)

For the above reasons reliance must often be placed on statistical associations of infection with foods eaten. Such evidence can be powerful and prove beyond all reasonable doubt that a particular food was the vehicle of infection. Protocols for investigating such outbreaks can be complex and require close cooperation between community doctors, public health workers, microbiologists, veterinarians, and food producers. The prime essential is to have all efforts directed and coordinated by one person.

Campylobacteriosis

M B Skirrow, Gloucestershire Royal Hospital, Gloucester, UK

Introduction

Campylobacteriosis, or *Campylobacter* enteritis, is an infection of the intestines manifest by acute diarrhea and abdominal pain. It is the most frequently reported form of infective diarrhea in the human population in most industrialized nations. Although the illness seldom lasts more than a few days, occasional patients develop complications, such as reactive arthritis or Guillain–Barré syndrome (GBS), a serious neurological disorder that can result in permanent disability or even death. The burden of campylobacteriosis on society in terms of health care, economic costs, and suffering is immense. This article describes the clinical manifestations, pathology, and treatment of the disease, and ends by considering options for its prevention and control. There are many approaches to control, but ultimately the only one that will have lasting impact is the control of infection in food-producing animals, especially broiler chickens.

Clinical Features

Campylobacter enteritis is caused mainly by *Campylobacter jejuni* and *C. coli* (*See* ***Campylobacter***: Properties and Occurrence), but before describing the disease due to these organisms, brief mention is made of an uncommon low-grade septicemic form of infection known as systemic campylobacteriosis, usually caused by *C. fetus*. Although blood stream invasion by *C. fetus* may arise from intestinal colonization, diarrhea is not a common feature. This form of infection is limited to patients with disease of the immune system, cancer, or some other chronic disease compromising their immunity. It is of minor importance relative to *Campylobacter* enteritis, but it earns a place here because *C. fetus* infection has been acquired by eating raw calves' liver. *C. fetus* is a common inhabitant of the intestinal tract of sheep and cattle, in which it may cause septic abortion.

Campylobacter enteritis is an acute self-limiting diarrheal disease clinically indistinguishable from *Salmonella* enteritis, although minor differences become apparent when groups of patients are compared.

Infection can be established with as few as 500 organisms. The average incubation period is 3 days (range 1–7 days). In most patients the illness starts with abdominal pain and diarrhea, but in about one-third of patients there is an influenza-like prodrome of malaise, headache, and fever, sometimes with rigors, for a period ranging from a few hours to a day or so before the onset of gastrointestinal symptoms. Profuse diarrhea lasts for 2–3 days and is almost invariably accompanied by abdominal pain, which is sometimes severe enough to simulate acute appendicitis and cause some patients to undergo emergency surgery. Occasionally there is genuine appendicitis. Children sometimes have abdominal pain without diarrhea. Surveys of patients affected in community outbreaks show that, on average, about 50% have fever, 40% myalgia, 8% rigors, 14% frank blood in their stools, but only 15% vomit, even though nausea is common.

Some patients present with acute colitis that is difficult to distinguish from an acute attack of idiopathic ulcerative colitis (inflammatory bowel disease). Acute

complications are rare but include intestinal haemorrhage, toxic megacolon, hemolytic–uremic syndrome, pancreatitis, and septic abortion.

After a few days the diarrhea eases and about 80% of patients recover within a week, irrespective of any treatment they may receive. Minor relapses have been reported in about 20% of patients after a day or two without diarrhea.

Young and middle-aged adults seem to be most severely affected by the infection. Unlike salmonellosis, *Campylobacter* enteritis in infants is often mild, and although infection in old people tends to be more invasive, it is seldom dangerous. Death is rare and virtually limited to frail patients debilitated from other causes.

Late Complications

There are two late complications that typically arise 1–2 weeks after the onset of illness: reactive arthritis and GBS.

Reactive Arthritis

Reactive (aseptic) arthritis affects about 1% of patients, particularly those possessing the human leukocyte antigen (HLA) B27. The ankles, knees, wrists, and the small joints of the hands are most frequently affected, often in migratory fashion. It can cause painful debility lasting for several months, but it is ultimately benign. Clinically it is the same as the reactive arthritis that sometimes follows other forms of acute bacterial enteritis.

Guillain–Barré Syndrome

Another name for GBS is postinfective polyneuropathy. It is a serious, though fortunately rare complication causing paralysis that does not always resolve completely. Severely affected patients develop respiratory paralysis and have to be nursed on a ventilator. Surveys indicate that *Campylobacter* infection is the antecedent event in 14–41% of patients with GBS – it is the most commonly identified trigger for the disease.

The mechanism of this distressing condition, in which the myelin in peripheral nerves becomes lost or damaged, is thought to be immunological. Certain *C. jejuni* strains are particularly associated with GBS, and some have been found to possess cell wall epitopes that cross-react with proteins in peripheral nerve myelin. It is believed that this triggers immunological attack and destruction of the myelin.

Convalescent Excretion

Excretion of *Campylobacter* in feces falls off exponentially after illness. About 50% of patients are culture-negative after 3 weeks, and virtually all are negative after 3 months. Long-term carriage is unknown except in patients with severe immune deficiency, such as hypogammaglobulinemia or acquired immune deficiency syndrome (AIDS). Spread of infection from a healthy excreter is a remote risk. In the case of food handlers, provided they have formed stools there is no need to exclude them from work.

The basic features of *Campylobacter* enteritis are summarized in Table 1.

Table 1 Basic features of *Campylobacter* enteritis

Feature	*Duration and details*
Incubation period	3 days (range 1–7 days)
Main symptoms	Diarrhea, abdominal pain, fever
Mean duration of illness[a]	
Incapacity	3.8 days
Symptoms	14.6 days
Mean duration of fecal *Campylobacter* excretion[a]	38 days (maximum 69 days)
Exclusion from food handling	Until stools formed

[a]Figures taken from a Norwegian study of 135 sporadic cases.

Pathology

The essential lesion in *Campylobacter* enteritis is an acute inflammation of the jejunum and small intestine, which progresses to the cecum, colon, and rectum. The histopathology of the intestinal mucosa is one of acute inflammatory cellular infiltration indistinguishable from that seen in *Salmonella, Shigella*, or other acute bacterial infections of the gut. The terminal ileum and cecum are often particularly affected, and it is this feature that causes the symptoms that mimic acute appendicitis.

Campylobacter are invasive and may be present in the blood stream at the onset of illness, as indicated by the high fever and rigors experienced by some patients. Unlike *C. fetus, C. jejuni* and *C. coli* are sensitive to the natural killing power of normal serum, so any bacteremia is likely to be transient and hence seldom detected in blood cultures (bacteremia reported in only 0.15% of infections). Regional lymph nodes are often enlarged and inflamed. A cholera-like enterotoxin and at least one cytotoxin are produced in modest quantities by many strains of *C. jejuni* and *C. coli*, but the role played by these in pathogenesis is unclear.

Immunity

Circulating (humoral) antibodies are produced within a few days of illness and for at least several months patients are refractory to reinfection with the same strain. People regularly exposed to infection develop

solid immunity. Children in developing countries, where transmission rates are high, become immune within the first 2 years or so of life, and occupationally exposed groups in industrialized countries also become immune. For example, in a milkborne outbreak of *Campylobacter* enteritis in the USA, 76% of people exposed for the first time were ill, whereas no person who habitually drank raw milk became ill. In the UK significant amounts of *Campylobacter*-specific antibody were found in 18% of veterinary assistants, 36% of cattle abattoir workers, and 27–68% of workers in poultry-processing plants, compared with 2–5% in nonexposed adults. Infection with one or two strains may be sufficient to give broad immunity, although there are patients who have had two attacks of *Campylobacter* enteritis several months apart; in each case the second infection has been with a different strain. It is not known how long immunity lasts, but regular exposure is probably necessary for its maintenance.

Treatment

As *Campylobacter* enteritis almost always resolves spontaneously, treatment is primarily symptomatic and supportive. The most important element, as with all forms of acute diarrhea, is the correction of dehydration and electrolyte loss, particularly in infants and old people, who are least able to do this of their own accord. In many cases simply getting patients to increase their fluid intake with assorted drinks is sufficient, but giving a balanced electrolyte preparation such as Dioralyte is ideal.

Antimicrobial therapy is effective if given within a day or two of the onset of illness, but a bacteriological diagnosis has seldom been made at this stage. If a patient is still suffering from acute symptoms when a positive report is received, antimicrobial therapy is justified. Erythromycin is the antibiotic of choice for both children and adults. In patients with severe diarrheal illness, who might be put at risk if treatment were delayed until a bacteriological report was available, there is a case for treating empirically with an antimicrobial agent effective against the common enteropathogenic bacteria. Ciprofloxacin, or an equivalent quinolone drug, was once the ideal agent here, and it still may be in some places. Unfortunately, in recent years resistance rates in *Campylobacter* (as well as *Salmonella*) have soared to around 50% in some European countries, so that its use has been drastically compromised. This is almost certainly a result of the widespread use of quinolones in poultry.

Fortunately erythromycin resistance is less of a problem. In industrialized countries resistance has remained at about 1–5% of strains, but higher rates have been found in some developing countries, notably 65% in Thailand. Erythromycin resistance is much more common in *C. coli* than *C. jejuni*, probably due to the use of tylosin, a similar macrolide antibiotic, in pig rearing.

Prevention

Basic measures for the prevention of any communicable intestinal infection apply equally to *Campylobacter* enteritis. These include the treatment and safe disposal of sewage, the provision of potable water, the pasteurization or equivalent heat treatment of milk, and the general hygienic processing and handling of food. An important aspect of the prevention of *Campylobacter* infection is the interruption of transmission from food-producing animals, particularly poultry, to the final food product. Each of these is now considered.

Sewage Disposal

Campylobacter are plentiful in raw sewage. The discharge of untreated sewage is undesirable as it helps to maintain the *Campylobacter* population in the environment. Conventional sewage treatment is effective in eliminating *Campylobacter*. In one study over 78% were removed after primary sedimentation, and less than 0.1% remained in the final effluent.

Water Purification

Campylobacter are ubiquitous in natural surface waters, including sea water. They are capable of surviving for several weeks in cold water (below 15 °C). Survival is increased in waters that have an autochthonous microflora. *Campylobacter* also appear to be capable of forming viable but nonculturable forms, which are alleged to survive for several months or longer. However, the potential role of such dormant cells in the epidemiology of *Campylobacter* has yet to be established. Conventional treatments are fully adequate for removing *Campylobacter*, which are generally more sensitive to chlorine and other disinfecting agents than *Escherichia coli*. Contact with monochloramine 1.0 mg l^{-1} for 15 min or free chlorine 0.1 mg l^{-1} for 5 min causes more than 99% inactivation. *Campylobacter* are also sensitive to ultraviolet light and are destroyed by protocols designed to kill *E. coli*.

Major community outbreaks of *Campylobacter* enteritis have been caused by the distribution of unchlorinated or inadequately chlorinated water (*See* ***Campylobacter***: Properties and Occurrence), which serves to emphasize the importance of proper treatment. This applies equally to remote oligotrophic lakes and surface waters, which become contaminated from wild

birds and other animals. A number of outbreaks have arisen as a result of the failure of outdated, overloaded, or inadequately maintained water works or distribution systems. (*See* **Water Supplies**: Water Treatment.)

Heat Treatment of Milk

Pasteurization and other orthodox treatment processes are fully effective in destroying *Campylobacter*. Despite this, milkborne outbreaks of infection regularly occur, even where it is illegal to sell raw milk to the public. Some of the largest outbreaks of *Campylobacter* enteritis on record have been milkborne, mostly from the distribution of raw milk, but a few of them from ostensibly pasteurized milk. Thus, although compulsory pasteurization is a highly desirable goal, it is unlikely to eliminate all risks of milkborne infection. Bad design, malfunctioning of machinery, or those running the machinery, the difficulty of designing satisfactory small pasteurizing units at reasonable cost are all factors that need attention in order to minimize risks. Electricity supply failures putting pasteurizing machinery out of action and bad weather preventing the delivery of milk to central pasteurizing plants have also been precipitating factors in outbreaks of milkborne infection.

Food Hygiene

Measures taken to maintain good hygiene and food-handling practice in restaurants and other catering establishments are fundamental to the prevention of *Campylobacter* enteritis. Much infection is believed to be transmitted through the cross-contamination of cooked or ready-to-eat foods, such as bread and salads, from raw poultry or other raw meats. The separation of raw from cooked foods and the use of dedicated equipment for each, such as chopping boards, mixers, knives, and other utensils, is the single most important principle to be observed. If raw meats cannot be stored separately they should always be placed on a bottom shelf so they cannot drip juices on to other foods.

Raw poultry should be handled as little as possible; handling and even washing carcasses only spreads organisms around work areas. The discipline of washing hands after touching raw meats of any sort should be rigorously observed.

It has been shown that *Campylobacter* can be isolated from the flesh of chicken carcasses even when the surface has been disinfected by immersion in boiling water. Chicken muscle affords the organism some protection from the effects of heat and this is the probable explanation for the implication of barbecued chicken in outbreaks of *Campylobacter* enteritis. It is therefore particularly important that chicken and other poultry meat is properly cooked.

These rules must be taught to all professional food handlers and it is the responsibility of health authorities to see that correct instruction is carried out and maintained to satisfactory standards. Analysis of outbreaks shows that many arose through ignorance of these basic rules. (*See* **Poultry**: Chicken.)

Control of *Campylobacter* in Poultry

Elimination of *Campylobacter* from food-producing animals is clearly impracticable owing to the wide natural distribution of the organisms. Yet there are ways of reducing colonization in farm animals, especially in poultry.

Campylobacter colonization in broiler chicken flocks does not usually appear until 2 weeks or more after hatching. This is taken to indicate horizontal transmission of *Campylobacter* from the environment either within or outside the broiler house. Thus there is the possibility of preventing colonization, or at least extending the *Campylobacter*-free period, by improving hygienic practice among broiler-house attendants and proofing houses against intrusion by birds and rodents. Such interventions have met with partial success, notably in Scandinavia and The Netherlands.

In some cases water has been shown to be a crucial factor in promoting colonization. Many broiler houses are served by unchlorinated private borehole supplies that are suspect. Even in mains-supplied houses *Campylobacter* can become established in distribution systems beyond header tanks. Experimental interventions, in which header tanks and distribution pipework have been thoroughly cleaned and disinfected, have been followed by dramatic falls in colonization rates in the broilers. Unfortunately such measures are difficult to sustain under agricultural conditions and further research is needed.

It is generally believed that, unlike *Salmonella* infection, vertical transmission of *Campylobacter* from parent flocks does not occur. This view has been challenged by the results of a 5-year study in the UK, in which the distribution of *C. jejuni* serotypes in broiler flocks supplied with day-old chicks from two hatcheries pointed to vertical rather than horizontal transmission. *C. jejuni* readily survives in embryonated eggs. If vertical transmission is confirmed, there is the possibility of preventing *Campylobacter* colonization of broilers by ensuring that breeder flocks are kept free from infection.

The principle of competitive exclusion, in which normal intestinal flora is artificially established in newly hatched chicks in order to exclude pathogens such as *Salmonella*, is not applicable to *Campylobacter* control, as the intestinal flora has already become established by the time *Campylobacter*

make their appearance. An experimental oral vaccine has been used with some success in broiler chicken flocks. This is a sound approach that could have major benefit.

The total elimination of *Campylobacter* from broiler flocks is probably not practicable, but reducing the extent of colonization may be sufficient to curtail transmission to the human population. The logistics, precise methods, and costs of such measures have yet to be worked out, but they are urgently needed if there is to be any hope of reducing the present unacceptable burden of the disease. These measures need to be studied in relation to the problems of cross-contamination during the mechanical processing of poultry, which are discussed elsewhere (*See* ***Campylobacter***: Properties and Occurrence.)

Terminal irradiation of dressed poultry is an option that removes all pathogens, including *Campylobacter*, but there are problems with this, not least public acceptability. (*See* **Irradiation of Foods**: Basic Principles.)

Waste disposal from poultry farms An added advantage of controlling *Campylobacter* colonization of poultry is that fewer bacteria would be returned to the environment and to surface waters. Heavily colonized flocks have a prodigious output of *Campylobacter* that are likely to be recycled in farm stock via surface water and wild or feral animals that are closely associated with farms, such as magpies, jackdaws, starlings, pigeons, sparrows, rats, and mice. Cattle with access to surface water are commonly colonized, whereas those with access only to mains water have been found to be free of *Campylobacter*.

Public Education

It has been said that if everyone handled their foods properly, foodborne *Campylobacter* enteritis would virtually disappear. This is probably true, but it is an unrealistic expectation. Yet much could be done to improve matters. Surveys to assess public knowledge of the rudiments of food hygiene have revealed abysmal ignorance. It should not be difficult to remedy this. Even to impart the simplest facts about handling poultry could have an impact that far outweighs the effort – and it would help control salmonellosis as well as *Campylobacter* enteritis. Television is the most influential medium and a substantial impact could be made by broadcasting high-quality entertaining yet informative spot 'advertisements.' The understandable fears of the poultry and retail industries could be allayed by inviting their participation and ensuring that the content of such spots was sensibly balanced. With appropriate professional skills, it could even be turned to their advantage. Public moneys used to fund such a venture should be amply offset by the savings from infections prevented.

Nutritional Epidemiology of Cancer

Methodological Complexities

Epidemiological studies exploring the role of diet in the etiology of cancer have several methodological complexities, which may be classified into partially overlapping categories as follows:

- Instruments for ascertainment of past diet are inherently weak; therefore, random misclassification of dietary factors of causal importance may be extensive, leading to substantial underestimation of genuine effects and to false-negative results.
- Random misclassification may be so extensive as to substantially reduce the power of a study, to the extent that an apparently positive result may be as likely to reflect a statistical artefact (alpha error) as a biologically genuine association.
- Mutual confounding among nutritional factors is extensive and complex, because there are many nutritional factors, and many of them have a common dietary origin (**Figure 1**).
- Random misclassification of nutritional factors may substantially reduce the ability to control their confounding influences.
- Most nutritional factors implicated in human carcinogenesis are considered to be late-stage agents (promoters or growth enhancers) rather than early stage agents (initiators). All of them, however, have their own specific latent periods. This poses theoretical and practical difficulties in the definition of a common latency when the effect of more than one nutritional factors are considered in relation to a specific cancer in any particular study.
- The exposure–response curve describing cancer risk in relation to a particular nutritional variable may be sigmoid, implying the existence of thresholds below or above which no association could be documented between the two variables.
- When a particular cancer has several independently operating nutritional causes, the relative risk associated with any particular nutritional cause decreases with the prevalence or the abundance of the other nutritional causes.
- On the contrary, when two factors are jointly necessary for the causation of a particular cancer, for example, an unknown initiator and a particular

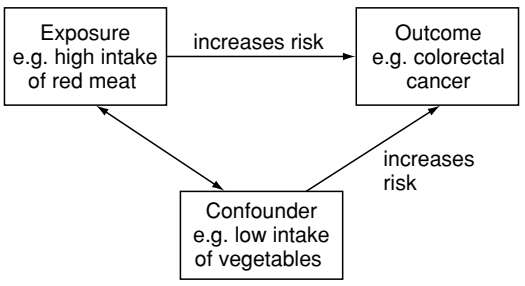

Figure 1 Confounding.

food item or nutrient as promoter, the relative risk associated with the nutritional factor increases with the prevalence or the abundance of the unknown initiator.

- When many nutritional factors are examined in the context of a particular study, multiple comparisons can generate both false-positive and false-negative results.
- Food patterns, for instance the Mediterranean diet, may have effects that are considerably different to those of the constituent foods or nutrients because of complex interactions.
- Interindividual variability of certain food items or nutrients may be too small in comparison with the corresponding intraindividual variability, thus considerably reducing the power of analytical epidemiological studies. Indeed, in many populations, the diet may be too uniform and etiologically important food items may be too common or too rare to allow statistical substantiation of risk differentials with standard analytic epidemiological studies.
- Energy intake may be an important cause, an equally important confounder or an indicator of bias, particularly in case-control studies. Control of energy intake is thus necessary whenever particular foods or nutrients are evaluated.

Epidemiological Evidence on the Nutritional Etiology of Cancer

The effect of diet on cancer occurrence is poorly understood in molecular or mechanistic terms, although it is generally assumed that dietary factors act at a late stage in the long process of carcinogenesis. Several patterns have emerged, however, from the many epidemiological studies that have been undertaken during the last 30 years on the relation between diet and cancer, and these are summarized in Tables 1–4. The associations are distinguished into convincing, probable, and possible, and can be either positive (increasing intake of the dietary factor increases cancer risk) or inverse (increasing intake of the dietary factor reduces cancer risk).

Table 1 refers to the cancer risk implications in relation to the intake of major food groups. Vegetables and, to a slightly lesser extent, fruits are inversely associated with risk for several forms of cancer. There is also evidence that intake of red meat increases the risk for some forms of cancer, particularly cancer of the large bowel.

The collective evidence for macronutrients, as summarized in Table 2, is considerably weaker for obvious reasons. In the absence of long-term randomized intervention studies, the evidence concerning macronutrients is derived from the evidence concerning food groups with additional uncertainties introduced by variability in food composition tables and analytical methods, as well as by uncontrollable confounding due to the possible operation of unidentifiable or immeasurable factors that tend to coexist with some of the macronutrients.

Table 3 summarizes the risk implications for major forms of cancer by intake of selected micronutrients. Although the study of micronutrients shares the same constrains as that of macronutrients,

this table appears more informative than Table 2 for three reasons, two of which are purely artificial. First, of the many micronutrients, only those for which some evidence exists are included. Second, several carotenoids are included in the single column dedicated to these compounds. Thus, the evidence for lung cancer mostly refers to β-carotene, whereas the evidence for prostate cancer refers almost exclusively to lycopene. The third reason, which is more substantive, is that the physiologic and pathophysiologic effects of certain micronutrients have been extensively studied, so that the criteria of biologic plausibility can be more successfully relied upon for micronutrients rather than for macronutrients. For instance, several carotenoids, vitamins C and E, and selenium have been intensively studied on account of their experimentally documented antioxidant potential.

Table 4 refers to nonnutrients and nutritional correlates like height, obesity, and physical activity. Entries in the same column do not imply identical products or processes. For instance, alcohol causes liver cancer through cirrhosis and cancer of the esophagus and larynx, mostly through interaction with tobacco smoking, and cancer of the breast possibly by increasing levels of estrogens. Moreover,

Table 4 Risk implications for major forms of cancer by exposure to selected nonnutrients and nutrition-related indicators

coffee and mate are mixtures that have both similarities and differences. Lastly, the effect of obesity may refer to stages of carcinogenesis that are not necessarily identical in the various forms of cancer. At the extreme, obesity among premenopausal women reduces the risk of breast cancer, whereas it considerably increases this risk among postmenopausal women.

Additives and Contaminants

Some readers may be surprised by the absence of a table referring to additives and contaminants that are frequently reported as carcinogens in the lay press. There are several reasons for this. First, the intake of additives and contaminants cannot be documented in most epidemiological research. Second, additives and contaminants are extensively scrutinized in laboratory assays, and whenever evidence incriminates them as carcinogens, these are removed from the diet. Third, the alleged breast carcinogenicity of organochlorine compounds, which can be measured in the blood or adipose tissue, has not been documented in large and sophisticated epidemiological investigations; nor has there been any direct epidemiological support for a role of nitrosamines in human carcinogenesis. At this stage, the only additive that is likely to play a major role in human carcinogenesis is salt. Among dietary contaminants, only aflatoxin has been conclusively linked to hepatocellular carcinoma and may be causing a nonnegligible fraction of liver cancer in developing countries. The suspicion that chlorination byproducts in drinking water may be involved in urinary bladder carcinogenesis has not been documented but is currently under investigation.

Prevention of Diet-related Cancers

On the basis of studies in migrants and ecologic investigations, it has been estimated that diet may be responsible for up to 30% of cancer mortality in developed countries. Although we know little about the mechanisms of diet-related carcinogenesis, we have a very good idea of what a prudent diet that reduces cancer in humans should be. This diet should be high in vegetables, fruits, pulses, and cereals, low in red meat and salt, and low in saturated fat of animal origin. Added lipids should be of plant origin, and, among them, olive oil has a safety record of several thousand years. Obesity should be avoided, preferably by increasing physical activity, which, in itself, can reduce the incidence of colorectal cancer and, perhaps, other forms of cancer as well. Regular physical activity during childhood and adolescence may also slow down excessive growth, as reflected in attained height, and may have beneficial consequences on several cancer types. Alcohol, which is known to protect against cardiovascular diseases, should be consumed in moderation, particularly by women, because it contributes to the causation of cancer at several sites, including the breast.

Carcinogens in the Food Chain

M J Prival, United States Food and Drug Administration, Washington, DC, USA

Background

It has become increasingly clear in recent decades that food can have a substantial effect on cancer risk. This conclusion is based on the results of both human population studies and animal studies. Presently available evidence indicates that dietary fat may be a risk factor for cancer and that fresh fruits and vegetables may have a protective effect. In addition, the human diet contains specific carcinogenic substances, most, but not all of which are present at such low levels that their effects on human cancer rates, if any, are likely to be small. This article summarizes current information on carcinogens in the diet that are (1) naturally occurring components of food, (2) produced by the processing of food, or (3) added intentionally to food. Carcinogenic contaminants of food, including mycotoxins and pesticides, are discussed elsewhere. (*See* **Carcinogens**: Carcinogenic Substances in Food: Mechanisms; Carcinogenicity Tests; **Fatty Acids**: Dietary Importance; **Contamination of Food**; **Mycotoxins**: Occurrence and Determination.)

Naturally Occurring Components of Foods

Bracken Fern

The toxic effects of bracken fern on livestock have been observed for a century or more. Bracken fern is not only toxic, but also carcinogenic when fed to rats and other experimental animals at high levels. Both the toxicity and the carcinogenicity are attributed to the same chemical constituent, ptaquiloside (**Figure 1**).

Young bracken fronds in the fiddlehead or crosier stage are used as a salad green in some countries, including Japan. In Japan, bracken fern is boiled or pickled before eating to remove the astringent taste; this reduces, but does not eliminate, its carcinogenicity. Milk from cattle that were fed bracken fern has been found to be carcinogenic to rats. This raises the possibility that there may be a risk associated with the drinking of milk in areas where dried bracken fern is used for bedding in winter or where range-fed cattle may consume bracken fern; this occurs, for example, in Turkey and Bulgaria.

Pyrrolizidine Alkaloids

Pyrrolizidine alkaloids occur in a variety of plants used as food and herbal medicines in many parts of the world, particularly in Africa and Asia. The first natural substances shown to cause liver tumors were pyrrolizidine alkaloids from plants. Among the pyrrolizidine-alkaloid-containing plants used by humans are *Petasites japonicus* Maxim (a kind of coltsfoot), which is used as a food and herbal remedy in Japan, and *Symphytum officinale* L. (comfrey), which is widely used as a medicinal herb, salad ingredient, or 'tea.' Both of these plants have been shown to be carcinogenic when fed to rats. Senkirkine (**Figure 1**), which is found in *P. japonicus* M., induced liver tumors when injected intraperitoneally into male rats, as did symphytine (**Figure 1**), extracted from roots of comfrey (*S. officinale*). Both alkaloids can also induce mutations in the bacterium *Salmonella typhimurium*; this is an indication of their ability to react with deoxyribonucleic acid (DNA) and may be relevant to the mechanism of their carcinogenicity. (*See* **Alkaloids**: Toxicology.)

Mate

Mate (pronounced 'mah-taý') is a beverage that is widely consumed in southern Brazil, Paraguay, Uruguay, and northern Argentina. It is made by brewing the toasted, dried, and aged leaves of a particular type of tree, *Ilex paraguariensis*, which is indigenous to this area. Several studies have compared mate consumption among patients with cancers of the esophagus, larynx, oral cavity, or pharynx with that of comparable individuals who did not have these cancers. Taken as a whole, these studies indicate that consumption of hot mate is probably carcinogenic to the upper gastrointestinal tract. There is currently no way of knowing to what extent the

chemicals present in the mate contribute to its apparent carcinogenicity and to what extent the high temperature of the consumed beverage is the problem. Experiments on the carcinogenicity of mate on animals might help to resolve this question, but unfortunately, no such experiments have been reported.

Coffee

The many studies on the possible association between coffee consumption and cancer in people have given conflicting results. Overall, the evidence suggests that coffee consumption may increase the risk of bladder cancer in humans, but this conclusion is by no means definitive because of the possible failure to account properly for other factors that can affect cancer rates. Some studies, but not others, have linked high levels of coffee consumption to cancer of the pancreas, but again, the positive findings may result from methodological problems. Unfortunately, currently available studies on the carcinogenicity of coffee to experimental animals do little to shed light on the issue owing to the inadequacy of these studies. Caffeine, which is found in tea, cola drinks, and cocoa as well as coffee, has not been found to be carcinogenic when tested in animals. (*See* **Caffeine; Coffee**: Physiological Effects.)

Alkenylbenzenes and Benzene

Several alkenylbenzene compounds have been shown to induce liver tumors in experimental animals. One of these compounds, safrole (Figure 1), constitutes 80–90% of the volatile oil of sassafras and is also present at much lower concentrations in certain spices and flavoring ingredients such as sweet basil, cananga oil, nutmeg, pepper, tamarind, and ylang ylang oil. As a result of the carcinogenicity of safrole, the US Food and Drug Administration (FDA) prohibited the use of safrole or sassafras oil in food, which resulted in the cessation of its use as the principal flavoring ingredient in root beer. Furthermore, sassafras extracts or leaves can only be sold in the USA if the safrole has been removed from them.

Another carcinogenic alkenylbenzene related in chemical structure to safrole is estragole (Figure 1; also called methylchavicol), which is found in

tarragon, sweet basil, anise, West Indian bay, fennel, chervil, and marjoram. The level of estragole from these sources in a typical diet is very low, and the resulting risk is, at most, vanishingly small.

Benzene is a well-established human and animal carcinogen, inducing leukemia in occupationally exposed workers and several types of cancer in benzene-treated rodents. Traces of benzene have been detected among the volatile components of a variety of foods, including oat groats, processed pork and ham, cooked meats and baked potatoes, and in the aromas of coffee and cocoa.

Mushrooms and Hydrazine Derivatives

Gyromitra esculenta is one of the mushrooms known as false morels. It is harvested and eaten by many people in northern Europe and also in the USA, although it is poisonous, even fatal, unless properly dried and boiled. The principal poisonous ingredient is gyromitrin (Figure 1), which is carcinogenic to animals and can give rise to the carcinogen methylhydrazine under acidic conditions, such as exist in the stomach. Both methyl-hydrazine and another carcinogen, *N*-methyl-*N*-formyl-hydrazine, appear to form during the preparation of false morel for consumption. In fact, cooking must be performed in an open vessel to allow methylhydrazine to escape; otherwise, poisoning can occur.

The widely available edible mushroom cultivated in countries with a temperate climate is *Agaricus bisporus*. The principal hydrazine derivative in *A. bisporus*, agaritine, has not been shown to be carcinogenic, but there are reports of carcinogenicity for some hydrazine derivatives related to compounds that have been identified in this mushroom. When uncooked *A. bisporus* was fed to mice as their only food for 3 days per week throughout their lifetimes, tumors developed in several organs. No adequate study has yet been performed on the carcinogenicity of cooked mushrooms, and cooking may inactivate carcinogens that may be present. Additional studies are needed to determine the significance of the results with uncooked *A. bisporus* and the hydrazine derivatives.

Carcinogens Produced by the Processing of Food

Alcoholic Beverages

Alcoholic beverages probably constitute the most widely consumed class of substances for which human carcinogenicity is definitively established. The most clearly affected sites are the mouth, pharynx, larynx, esophagus, and liver. Smoking of tobacco and consumption of alcohol, each of which is carcinogenic independently, appear to have a far greater additive effect in inducing human cancer at these sites, excluding the liver. There are also studies implying that alcoholic beverages increase the risk of breast cancer, but the data in this regard are not nearly as definitive as those for the other sites mentioned.

It is not clear which components of the alcoholic beverages are responsible for the human cancers. Animal experiments have failed to show that ethanol (alcohol) itself is carcinogenic, although the major metabolite of ethanol, i.e., acetaldehyde, induces respiratory-tract tumors when inhaled by experimental animals. Alcoholic beverages contain numerous chemicals that may contribute to the carcinogenicity of the beverages, including traces of acetaldehyde, *N*-nitroso compounds (including *N*-nitrosodimethylamine), and urethan (ethyl carbamate). Urethan has been found in the highest concentrations in 'stone fruit' (i.e., cherry, plum, apricot, etc.), brandies, sake, and rice wine; at lower levels in various other types of distilled spirits and wines; and at even lower levels in beer. Urethan is also found in other fermented food products such as soya sauce, bread, yogurt, and some cheeses. The carcinogenic risks from urethan appear to be extremely low and are probably negligible, but may be somewhat increased among those who frequently consume alcoholic beverages with the highest levels of this carcinogen. (*See* **Alcohol**: Metabolism, Beneficial Effects, and Toxicology; Alcohol Consumption; **Smoking, Diet, and Health**.)

Carcinogens Produced by Cooking

Under most circumstances, the cooking of meat, fish, or eggs results in the formation, at very low concentrations, of a group of heterocyclic amines that are very potent mutagens when tested on bacteria. A few of these mutagens, all of which are carcinogenic when fed to experimental animals, are shown in Figure 2 with their commonly used abbreviated names.

The formation of mutagenic activity has been observed in beef, pork, ham, bacon, lamb, chicken, fish, and eggs after broiling (grilling), frying, and barbecuing. Other high-protein foods, such as tofu, beans, and cheese, gave little or no mutagenic activity when cooked under similar conditions. Beef extract is also mutagenic. (*See* **Browning**: Nonenzymatic.)

While the cooking-induced mutagens that have been isolated are extraordinarily potent mutagens when tested on bacteria, these chemicals tend to be only moderately potent as carcinogens. The fact that the mutagens are found in foods in the parts per billion range, and the fact that their carcinogenic

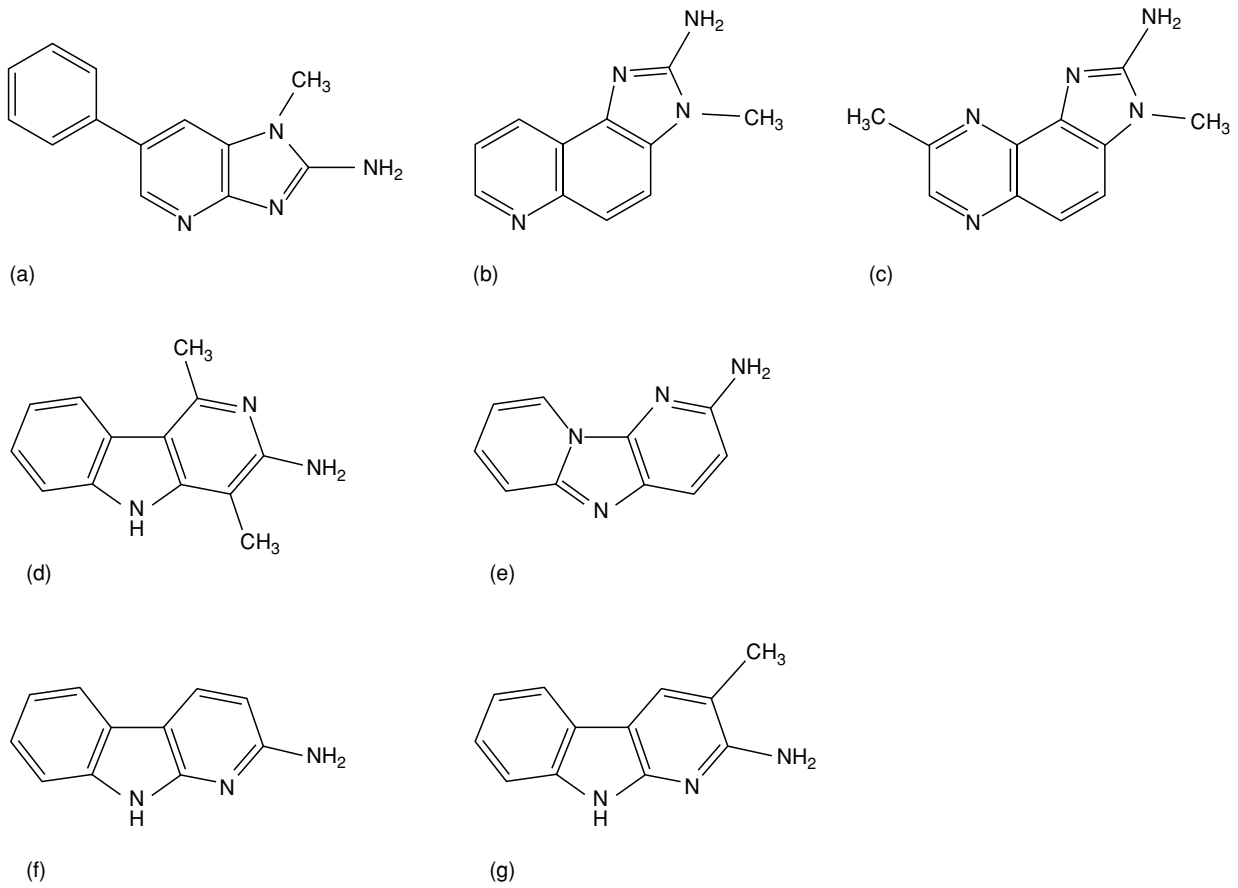

Figure 2 Chemical structures of some cooking-induced heterocyclic amine carcinogens. Their commonly used short names are (a) PhIP, (b) IQ, (c) 8-MeIQx, (d) Trp-P-1, (e) Glu-P-2, (f) A-α-C, and (g) MeA-α-C. potency, in animals at least, does not seem to be particularly great, are factors that minimize the anticipated risk from these substances. However, exposure to them occurs each time a person eats cooked meat or fish, and such exposure often occurs at a high frequency over the lifetime of the individual. While it is possible to reduce the level of carcinogenic heterocyclic amines by reducing the temperature or time of cooking, the reduction in carcinogenic risk thus effected must be weighed against the very real possibility of increased risk from bacterial or parasitic infection from undercooked meat or fish. Recent reports concerning the isolation of an anticarcinogen from fried ground beef also imply that caution is necessary before recommending any reduction in the degree of cooking. Microwave cooking without surface browning apparently does not result in the formation of heterocyclic amine mutagens or carcinogens. (*See* **Mutagens**.)

Another class of chemicals containing a number of carcinogens, the polynuclear aromatic hydrocarbons, are also introduced into food when meat or fish are grilled, but not when cooking is performed by the lower-temperature processes of frying, roasting, or microwave cooking. The pyrolysis of fat dripping on to the heat source appears to be a major source of this class of carcinogens. Benzo[a]pyrene and other polynuclear aromatic hydrocarbon carcinogens appear to be relatively weak carcinogens when administered orally to experimental animals, but much more potent when applied to the skin. Whether this is also true for humans is unknown, and the risks associated with these carcinogens are difficult to evaluate. (*See* **Polycyclic Aromatic Hydrocarbons**.)

Salting of fish

The salting of fish in southeastern China is carried out for several days using sea salt, followed by drying in direct sunlight. Sometimes, the fish is permitted to soften by decomposition. Several studies have found that the consumption of such salted fish contributes to the high incidence of cancer of the nasal passages and pharynx (nasopharyngeal carcinoma) among Chinese people in southeastern China, Hong Kong,

and Malaysia. Nasopharyngeal carcinoma is rare in most populations but accounts for about 15% of all cancer deaths among males in Guangdong Province, China. Feeding of salted fish to children and to babies during weaning seems to be a particularly strong risk factor.

The conclusions of these population studies have been confirmed by animal studies in which feeding of Cantonese-style salted fish to rats resulted in the induction of nasopharyngeal carcinomas. *N*-Nitroso compounds formed as a result of the salting process may be responsible for the carcinogenicity of the salted fish. Nitrate, which contaminates the salt used to prepare the fish, can be reduced to nitrite during the processing, and the nitrite can react with amines in the fish to form *N*-nitroso compounds. Since salted fish consumption appears to account for most of the nasopharyngeal carcinoma cases among Chinese populations, it must be considered to be a very high risk factor when consumed regularly, particularly by children and infants.

Chemicals Added to Foods

Saccharin

Saccharin has been used as a nonnutritive sweetening agent since 1907, and its safety has been a subject of debate by scientists and public health officials from that time. Experiments conducted in the 1970s and 1980s have demonstrated that high levels of sodium saccharin in the diets of rats resulted in the appearance of tumors of the urinary bladder. In spite of this, the controversy concerning the safety of saccharin continues. (*See* **Saccharin**.)

Studies on human populations have failed to show any association between bladder cancer incidence and the consumption of saccharin or other artificial sweeteners, but such studies have a limited ability to detect such associations, even if they exist. The fact that saccharin is generally not mutagenic, or is very marginally mutagenic, in a variety of test systems may imply that saccharin does not interact with DNA and, therefore, that it may not pose a significant carcinogenic risk at the usually consumed human doses, which are far below the doses fed to the rats in the positive carcinogenicity studies. Saccharin continues to be widely used in food products around the world.

Cyclamates

Other widely used nonnutritive sweeteners include sodium cyclamate and calcium cyclamate. In a study performed in the 1970s, rats that were fed high doses of a mixture of sodium cyclamate and saccharin had an increased incidence of bladder tumors. Some additional studies reported that rats receiving sodium cyclamate alone developed bladder tumors, but the results were not statistically significant. Based on these findings, cyclamates were banned in some countries, including the UK and the USA. However, many consider the experimental reports of carcinogenicity to be of questionable value, and cyclamates continue to be approved for use in many countries. As mentioned above, there are no data from human populations indicating that consumption of nonnutritive sweeteners are associated with increased cancer risk, although such studies are, by their very nature, insensitive. (*See* **Cyclamates**.)

Nitrate and Nitrite

Sodium nitrate and sodium nitrite are used as preservative agents in cured meats, such as bacon, sausage, and ham, and in some cheeses. While neither salt has been shown to be carcinogenic, there is some concern because nitrite can react with (nitrosate) amines present in food to form *N*-nitroso compounds, many of which are carcinogens; this reaction can occur under the acid conditions in the stomach. Since nitrate can be converted to nitrite either in a food product or in the mouth or gastrointestinal tract, both nitrate and nitrite must be considered together in assessing any possible hazard. (*See* **Curing**; **Nitrosamines**.)

There are several dietary sources of nitrate and nitrite other than cured meats, including vegetables and some drinking waters. Over the past few decades, the levels of nitrate and nitrite in cured meats have been reduced considerably, and the potential for formation of *N*-nitroso compounds has been further mitigated by the addition to cured meats of antioxidants such as ascorbic acid, which inhibit the nitrosation of amines.

The addition of nitrate and nitrite to food is only one of many sources of *N*-nitroso compounds to which humans are exposed; salt-preserved fish and smoked foods are among the other sources of *N*-nitroso compounds in the human diet. While there are some data indicating that nasopharyngeal, esophageal, and stomach cancer are more common in populations that consume high levels of nitrate or certain types of preserved meat or fish, the specific role of *N*-nitroso compounds or of added nitrate or nitrite in human cancer remains to be clarified. It is possible that the presence of inhibitors of nitrosation in fresh fruits and vegetables is a factor in explaining why consumption of these foods appears to have a protective effect against cancer in human populations.

Butylated Hydroxyanisole

The antioxidant butylated hydroxyanisole (BHA) has been used since 1947 to prevent rancidity in edible

fats and oils and in fat-containing foods. Experiments performed since 1982 have shown that BHA in the diet can cause tumors of the forestomach in rats and hamsters. However, the relevance of this finding has been questioned because humans do not possess a forestomach, and their stomachs do not contain the type of tissue (squamous epithelium) found in the rodent forestomach. Although humans have squamous epithelium at other sites along the digestive tract, no tumors have been noted in such sites in experimental animals. The possibility that BHA may be a carcinogenic hazard at normal human dietary levels, which are much lower than the experimental tumor-inducing levels, has also been questioned on the grounds that it is not mutagenic in a variety of test systems. Because of the questions that have been raised concerning the relevance of the experimental forestomach tumors induced by BHA to human exposure at low dietary levels, and the effectiveness of BHA as an antioxidant in fatty foods, it continues to be approved for use in many countries around the world. Diet in Cancer Prevention

I T Johnson, Institute of Food Research, Norwich, UK

Introduction

Cancer is primarily a disease of old age. In societies where infant mortality and infections have ceased to be major causes of death, a large proportion of the population will survive to die eventually of cancer. Nevertheless, the age-specific incidence of many common types of cancer varies by a factor of 10-fold or more between populations, the age-standardized incidences of particular cancers change within populations over time, and the risks alter consistently in populations migrating between countries. Since only a small proportion of human cancers are directly attributable to inherited susceptibility, most must be caused by environmental factors that are, in principle, avoidable. In their 1981 review of the causes of cancer, Sir Richard Doll and Richard Peto showed that, apart from tobacco, which at that time was the direct cause of 30% of deaths from cancer in the USA, the largest proportion of avoidable cancer (approximately 35%) could be attributed to diet. However the uncertainty attached to this estimate was very high (10–70%). Surprisingly little has changed in the intervening years. The American epidemiologist WC Willet has recently suggested that the true proportion of cancers avoidable by dietary change is probably between 20 and 42%, but the means by which such reductions might be achieved remain stubbornly obscure. There are two major sources of difficulty. First, there are many different types of cancer, and the various mechanisms by which they arise have only recently begun to be understood. Second, human diets are immensely complex and difficult to measure. The biology of cancer, and the epidemiological evidence for effects of diet, will be briefly reviewed here, and the current state of knowledge regarding the role of dietary factors in the prevention of cancer will be discussed.

The Nature of Cancer

Cell division is fundamental to all life. The human body begins life with the fertilization of a single cell, yet by the time maturity is reached the total number has risen to about 10^{13}. Throughout the earliest stages of development all the embryonic cells divide constantly and undergo differentiation to form the specialized tissues and organs. Cell division is minimal in many adult tissues but those of the blood-forming organs, the reproductive tissues, and the epithelia lining the gut continue to divide at a high rate throughout life. A tumor can be defined as a localized increase in the number of cells in an organ, beyond what is necessary for tissue growth and repair, or for the reproductive needs of the host. Benign tumors grow relatively slowly, and retain an approximately normal anatomical location, whereas malignant tumors acquire the ability to invade surrounding tissues and form secondary tumors in remote organs such as the liver or brain. Until relatively recently it was assumed that the crucial abnormality of cancerous cells was their loss of proliferative control, but their ability to evade apoptosis, the internal pathway which obliges damaged cells to undergo suicide, is at least as important.

Carcinogenesis occurs in stages that can be broadly characterized as initiation, promotion, and progression. The earliest event is thought to be the acquisition of an unrepaired mutation by a single cell. DNA damage and repair occur constantly, but a mutation which remains unrepaired, fails to trigger apoptosis, confers some growth advantage on the cell, and can be passed on through successive cellular divisions, is potentially carcinogenic. During the promotion stage, the normal constraints on proliferation and spatial location are disrupted by the acquisition of further mutations within genes essential for the normal growth and differentiation. At the progression stage the lesion has made the transition to malignancy and can give rise to secondary tumors at remote sites. This multistage model of carcinogenesis is exemplified by colorectal cancer, which in most cases develops through the adenoma–carcinoma sequence. Around 40% of all males over 50 in the UK and other western industrialized countries have one or more colorectal polyps. Only a few percent of these will ever progress to carcinomas, but regular screening and removal of such polyps are an effective, though costly means of preventing cancer.

Cancer and Populations

Some examples of the geographical variations that occur in the incidence of important cancers of the alimentary tract are given in Table 1. These data are of comparable reliability, and have been selected to illustrate some important features of cancer incidence across the globe. For example, colorectal carcinoma is about 12 times more common in New Zealand than in India. This cancer is consistently more common in richer, westernized countries than in the developing nations of Asia and Africa that have primarily agrarian economies. Cancer of the stomach is much less consistently related to economic development. The highest incidence of gastric cancer in the world occurs in Japan, but rates are also high in other much poorer countries of eastern Asia, and in Central and South America. Within countries, gastric cancer tends to decline with increasing socioeconomic status. The third example, esophageal cancer, shows an extraordinary degree of geographical variation. In general it tends to be more common in poorer societies, but there is a recognized "esophageal cancer belt" which runs from China through central Asia to Iran with incidence rates hundreds of times higher than the least affected countries of the world. Such extremes cannot be attributed to general economic conditions. They suggest that the esophagus is exquisitely sensitive to some combination of environmental conditions amongst which diet must play a major role.

Table 1 Geographical variations in the incidence of major cancers of the alimentary tract

Country	*Incidence of carcinoma for both sexes (cases/100 000)*		
	Esophageal	*Gastric*	*Colorectal*
Brazil	13.6	31.3	27.3
Denmark	8.3	12.6	69.3
Germany	7.0	25.3	77.0
India	12.7	8.5	8.0
Israel	3.1	22.1	78.1
Japan	11.6	97.8	68.5
New Zealand	7.9	16.2	98.7
South Africa	22.6	12.6	23.0
Uganda	24.5	12.5	14.4
UK	13.2	17.9	60.7
USA	6.3	11.2	71.2

Data are predicted age-specific incidence rates for the year 2000. Source: Globocan 2000 database of the World Health Organisation, Geneva (http://www.who.int).

Cancer and Diet

Three types of interaction between diet and the carcinogenic process can be envisaged.

1. The diet may contain specific carcinogens or promoters that initiate or accelerate carcinogenesis.
2. The provision of known nutrients and /or energy may be a key determinant of the body's susceptibility to cancer.

3. Biologically active nonnutrients may modulate the initiation or progression of carcinogenesis at various stages.

Carcinogens and Promoters

The Swiss toxicologists Lutz and Schlatter analyzed the contribution of various dietary factors to the risk of human cancer. They compared human exposure to known carcinogens with the activity of these substances in animal models, and concluded that only a small proportion of the human cancer cases attributed to diet by Doll and Peto were likely to be caused by foodborne carcinogens. Certainly there is very little evidence that food additives and pesticide residues impose any carcinogenic risks on the general public in industrialized societies. Food additives are rigorously screened to eliminate any risk of carcinogenic effects, and synthetic pesticide residues are no more likely to be mutagenic than natural plant constituents. In contrast, food supplies in developing countries are often at risk of contamination with carcinogenic toxins derived from fungi. Aflatoxin, a product of the fungus *Aspergillus flavus*, frequently contaminates groundnuts stored in hot climates. Dietary exposure to aflatoxin is associated with increased risk of hepatocellular carcinoma, a form of liver cancer. Food supplies in western countries are screened for the presence of aflatoxins, but socioeconomic conditions make this difficult to achieve in developing countries where locally produced groundnuts are a dietary staple. Another potent class of carcinogens known to be present in foods are the nitrosamines. The best established example of a probable link between these compounds and disease is the high risk of nasopharyngeal cancers in southern Chinese populations consuming high levels of salted fish. In Japan, a high intake of various pickled and highly salted vegetable and meat products is believed to be one cause of the very high incidence of gastric cancer.

Epidemiological evidence derived from both case-control and cohort studies suggests that regular consumption of more than about 80 g of red meat (beef, pork, or lamb) per day leads to an approximately 2.5-fold increase in the risk of colorectal cancer. Around half of these studies show a statistically significant effect. The strongest evidence of an adverse effect comes from North America. However at the time of writing, the European Prospective Investigation of Cancer and Nutrition (EPIC) has begun to publish its first findings, and preliminary reports suggest a moderate adverse effect of red meat consumption on colorectal cancer risk, and a somewhat stronger effect of processed meat products. Cooked meat contains carcinogens, particularly heterocyclic amines, but at rather low levels. A second hypothesis is that heavy meat consumption increases the formation of nitrosamines by colonic bacteria. It is not entirely clear why processed meat should entail a higher risk, but one possibility is that the iron-containing protein heme is the risk factor, and that processed meats contain a higher concentration. In any case meat consumption is only one among many nutritional factors that influence colorectal carcinogenesis.

Alcohol is not a genotoxic carcinogen but there is good evidence that even moderate consumption increases the risk of breast cancer. Heavy consumption is an important cause of oropharyngeal, esophageal, laryngeal, and hepatic cancers. The risk is dose-related but also strongly linked to smoking.

Nutritional Factors

A large proportion of human diet-related cancers appear to be due to the effects of overconsumption of energy. Evidence that restricting energy intake would inhibit tumor growth in experimental animals first began to appear in the early part of the twentieth century. More recent studies have confirmed the relationship, and shown that increased physical exercise, leading to greater energy expenditure, has a similar effect. There are several plausible mechanisms of action, including a suppression of endogenous DNA damage caused by reactive oxygen species, enhanced DNA repair, and suppression of tumor growth, mediated by insulin and other endocrine factors. Direct evidence that similar mechanisms are at work in humans is difficult to achieve, but restricted energy intakes may well contribute to the reduced risk of colorectal cancer observed in agrarian communities of Asia and Africa. It is difficult to see how deliberate restriction of energy intake could be made to work as a cancer prevention strategy in the west, but regular exercise and avoidance of obesity are likely to be beneficial. An understanding of the mechanisms involved may eventually lead to other biological strategies for suppression of carcinogenesis.

It has long been thought that dietary fat may have an effect on the risk of cancer, independently of any effect of energy intake. International comparisons suggest positive links between fat intake and breast and colon cancer, and there is evidence that total fat intake is positively related to induction of tumors by chemical carcinogens in animals. However, the evidence is much less convincing when comparisons are made within populations, and there is no clear scientific consensus that total fat intake is an important risk factor. There is stronger experimental evidence to show that the fatty acid composition of the diet is

important. Polyunsaturated fatty acids (PUFA) of the *n*-6 series tend to promote mammary carcinogenesis in experimental animals, whereas *n*-3 PUFA such as eicosapentaenoic acid, which is found in fish oils, tend to suppress mammary and colorectal carcinogenesis. Epidemiological evidence has begun to emerge for protective effects of fish consumption against cancer of the colon, breast, and prostate, but these findings require validation.

Micronutrient status is another aspect of general nutrition that has received a great deal of attention in relation to several types of cancer. Small quantities of many minerals and organic micronutrients are essential to normal growth and function. Substances for which a specific deficiency condition has been identified are classified as nutrients, but many have biological effects beyond their classical function. Vitamin C (ascorbic acid) is one example. Ascorbic acid is essential for the prevention of scurvy in humans but it is also a strong antioxidant and numerous studies have shown that a relatively low level of ascorbate in the serum is a risk factor for several forms of cancer. However the evidence that supplementation with vitamin C reduces the risk of cancer is much less convincing. It is possible that plasma vitamin C is a biomarker for a high intake of fruit and vegetables. Similar arguments apply to a number of other antioxidant nutrients, including β-carotene, but strong protective effects against several types of cancer have been demonstrated in a human intervention study with selenium.

Low intakes of folate, one of the B-group vitamins, have been linked to increased risk of cancers of the colon, pancreas, lung, and breast. Individuals with one or more common inherited abnormalities of methylenetetrahydrofolate reductase, one of the principal enzymes involved in folate metabolism, may be at higher risk. The relationship is biologically plausible because folate is essential for normal synthesis of DNA, and for other aspects of cell proliferation. Folate deficiency causes misincorporation of nucleotides and DNA breaks similar to those caused by ionizing radiation.

Of all human cancers, squamous cell carcinoma of the esophagus seems the most likely to be caused, at least partially, by one or more deficiencies of known micronutrients. Populations characterized by a very high incidence of the disease often consume restricted diets, with low intakes of protein and many micronutrients, including riboflavin, niacin, vitamins C and E, β-carotene, and retinal. It seems probable that in high-risk communities, specific nutrient deficiencies act synergistically with other factors, such as specific foodborne carcinogens or the irritating effects of very hot or abrasive foods and drink.

Dietary fiber

The dietary fiber hypothesis has complex origins, but its best-known advocate was the colonial medical officer Dennis Burkitt, who sought to explain the rarity of colorectal carcinoma and other bowel disorders amongst rural Africans. Burkitt proposed that the various nondigestible polysaccharides of plant cell walls, collectively termed dietary fiber, are protective against cancer of the large bowel. His original hypothesis was based largely on the concept of fecal bulk. Working from clinical observations, Burkitt deduced that populations consuming traditional rural diets, rich in vegetables and cereal foods, produced frequent bulky stools. The increased risk of colorectal cancer in western populations eating low-fiber diets was attributed to a low volume of feces and infrequent bowel movements, causing prolonged exposure of the colonic epithelial cells to mutagens. The mildly laxative effects of dietary fiber are now well recognized, and numerous human intervention trials have confirmed that dietary supplements containing wheat bran or other types of dietary fiber can increase fecal volume and reduce transit times. Reports from such bodies as the World Cancer Research Fund, the European Cancer Prevention Organization, and the UK Department of Health have agreed that the evidence for a protective effect of dietary fiber against colorectal cancer is at least moderately convincing. The fecal-bulking hypothesis provides the principal rationale for the current dietary reference values for nonstarch polysaccharides in the UK, which recommend that adults should consume an average of 18 g of fiber per day.

Apart from the simple dilution effect of increased fecal bulk, the nonfermentable particulate components of plant cell walls may sequester bile acids, thus reducing their concentration in the aqueous phase of the fecal stream. This hypothesis is consistent with the results of human intervention studies with high-fiber low-fat diets, which have been shown to reduce fecal bile acids and slow the appearance of large adenomas.

In the three decades or so that have elapsed since the original work of Burkitt, great progress has been made in our understanding of the gradual transition from a normal colonic epithelium to a malignant tumor. Apoptosis is thought to provide a defense mechanism against the appearance and survival of cells carrying unrepaired mutations, and it is probably also important at a later stage in the adenoma–carcinoma sequence because the speed at which tumors grow depends upon their relative rates of cell production and death. The colonic microflora is rich in bacteria that can break down carbohydrates to yield the short-chain fatty acids acetate, propionate, and butyrate, and these are absorbed and metabolized by human tissues. Butyrate

is utilized preferentially by the colonic mucosa, and besides supplying metabolic energy, it suppresses proliferation, increases differentiation, and induces apoptosis of tumor cells *in vitro*. Thus the principal role of fermentable carbohydrate may be to regulate mucosal cell turnover and death by providing a constant endogenous supply of butyrate.

The dietary fiber hypothesis has never been disproved. Some large North American cohort studies have failed to confirm an inverse relationship between fiber intake and colorectal cancer, but it is doubtful whether the highest levels of fiber consumption in such studies were great enough to provide the protective effects seen in international comparisons. Preliminary reports from the EPIC study do provide some evidence of beneficial effects of dietary fiber in Europe, where the range of fiber intakes may be greater.

The colon is perhaps the most obvious site for fiber to exert anticarcinogenic effects, but there is evidence that it protects against other cancers. One analysis of a series of case-control studies on breast cancer and diet has suggested that a 20-g increase in daily fiber intake was associated with a statistically significant reduction in risk of breast cancer of about 15%. Diets containing this rather high level of fiber may be associated with low levels of body fat, reduced plasma estrogen levels, and improved insulin sensitivity, all of which might inhibit the growth of hormone-dependent tumors. Furthermore, fiber-rich plant foods contain a variety of other biologically active plant cell constituents, including antioxidants and phytoestrogens, which probably exert a variety of anticarcinogenic effects in their own right.

Phytochemicals

The strongest association between dietary factors and cancer in industrialized societies is a protective effect of high intakes of fruit and vegetables. The phenomenon extends to most carcinomas (cancers of epithelial tissues) but is not consistently observed for leukemia, nor for cancers of lymphoid or neural tissues. Fruits and vegetables are rich in a variety of important micronutrients, including antioxidants and folate, and they probably contribute to the protective effects of these foods (Table 2). However, studies with experimental animals have shown that plant tissues also contain a variety of nonnutrient phytochemicals that can act as blocking agents, which interfere with the mutagenic effects of carcinogens at target cells, or suppressing agents, which slow or reverse the development of precancerous lesions or tumors, after the initial mutagenic effect of the carcinogen has occurred. Some compounds can act in both ways.

Although much of the epidemiological data is relatively nonspecific in that it simply indicates that a variety of vegetables and fruits are protective against an equally diverse range of cancers, there is also a growing body of evidence relating specific plant foods, and hence specific types of chemical compound, to particular disease processes. Evidence of this type forms the starting point for focused mechanistic studies. Some examples of potentially anticarcinogenic phytochemicals and their principal sources are given in Table 1. A thorough discussion of these compounds cannot be given here but one group, the glucosinolates, will be discussed in some detail.

Table 2 Some examples of potentially anticarcinogenic phytochemicals

Class of compound	*Dietary source*
Isothiocyanates	Brassica vegetables and condiments
Flavonoids	Apples, onions, broccoli, tea infusions, chocolate
Isoflavonoids	Soy beans, soy products
Carotenoids	Tomatoes, carrots and other colored vegetables
Protease inhibitors	Legumes

Many cohort and case-control studies indicate that a high consumption of brassica vegetables is associated with a decreased risk of carcinomas of the lung, stomach, colon, and rectum. Probably the most important common characteristic of cabbages, broccoli, cauliflower, and Brussels sprouts is that they all contain glucosinolates, a large family of sulfur compounds linked to glucose, and bearing a side chain derived from various amino acids. Following tissue damage caused by pests, harvesting, food processing, or chewing, glucosinolates are broken down by the endogenous enzyme myrosinase. Hydrolysis of the glucosidic bond releases glucose and an unstable intermediate, which spontaneously degrades to form a variety of breakdown products, the most important of which are the isothiocyanates. These hot and bitter compounds, commonly termed "mustard oils," provide much of the flavor of brassica vegetables.

Isothiocyanates such as phenethyl isothiocyanate, benzyl isothiocyanate, and sulforaphane modify the balance of phase I and II xenobiotic-metabolizing enzymes that are expressed in liver, and in epithelial cells including those of the colon. Phase I enzymes such as the cytochrome p450 family metabolize procarcinogens, often converting them to highly carcinogenic products in the process. Phase II enzymes such as the glutathione transferase family (GST) convert these products to inactive, water-soluble conjugates, readily excreted in urine. In one animal study in which a carcinogenic nitrosamine and phenethyl isothiocyanate (a constituent of watercress) were administered simultaneously, lung tumors were induced in

70% of the control rats given only the carcinogen, but only 5% of those cotreated with isothiocyanate.

One problem with such animal models is that the concentrations of both carcinogens and anticarcinogens used are often unrealistically high. However there is also evidence from epidemiological studies to show that this work has real implications for human health. In a recent study by London *et al*. the excretion of isothiocyanates in urine was used as a marker of brassica vegetable consumption in a large cohort of Chinese men. The presence of inherited defects in two phase II enzymes, *GSTM1* and *GSTT1*, was recorded at the same time as the urinary analysis, and the cohort was followed up for 10 years. Individuals with detectable levels of isothiocyanate metabolites in urine were found to be at a reduced risk of cancer, but the effect was only observable in subjects who lacked *GSTM1* or *GSTT1*, and strongest in those with deletion of both enzymes. The GST enzymes play a major role in the detoxification of carcinogens, but they also break down the isothiocyanates themselves. These observations provide evidence of a very complex interplay between environmental factors, genotype, and risk of cancer. The protective mechanisms may include suppression of the carcinogenic process by induction of apoptosis. Like butyrate, glucosinolate breakdown products block the cell cycle *in vitro*, and induce apoptosis in the rat colon after treatment with a chemical carcinogen. It is interesting to note that a protective effect of broccoli consumption against precancerous adenomatous polyps of the colon has been observed in individuals with the *GSTM1* null genotype.

Conclusion

Clearly there is still a huge disparity between the proportion of human cancers that are theoretically avoidable, and the small number of well-established dietary strategies for actually reducing the risk of cancer in practice. By far the most important cause of human cancer is cigarette smoke. Its avoidance is the surest way for individuals to minimize their risk of cancer. Nevertheless, there are subtle interactions between dietary components, genetic profile, and exposure to carcinogens that shape the individual's risk of disease to an important degree. Understanding such mechanisms in greater depth is the key to harnessing the protective effects of diet more effectively in the future. The current rapid developments in genetics and molecular biology will do much to facilitate this process. In the meantime, the best advice available is to eat large quantities of fruit and vegetables. The current recommendation in many countries is to eat five portions (80 g) of leafy vegetables and fruits per day from a variety of sources. This is already well in excess of the average intake in the UK, but even higher quantities may be of additional benefit. The bulk of such a diet, coupled with quantities of complex carbohydrates sufficient to provide around 18 g of dietary fiber per day, will ensure a relatively low energy density. If combined with regular exercise, this should help to maintain body weight within the desirable range. The most recent evidence suggests that moderating the consumption of red and processed meat products in favor of oily fish and poultry may also help to reduce the risk of bowel cancer. Alcohol consumption should be maintained within current Department of Health guidelines. There is no convincing evidence that very large doses of any particular vitamin are protective against cancer, but in view of the evidence linking suboptimal micronutrient status to some forms of carcinoma, consumption of a daily multivitamin supplement may be prudent.

Diet in Cancer Treatment

J W T Dickerson, University of Surrey, Guildford, Surrey, UK

Introduction

The nutritional requirements of persons with cancer, and hence the diet required to meet them, may be affected by the body's response to the disease itself, a condition known as 'cancer cachexia,' and by the methods used to treat the disease. Assessment of the factors involved and their interrelationships can help towards the adequate nutrition of cancer patients and the maintenance of their maximum possible quality of life. Furthermore, it is now becoming evident that some food components may be able to modify the cachectic process, whilst others may have a direct effect on some kinds of cancer cells. This latter effect raises the possibility that diets may be used in the future to treat, or at least to control the growth of some kinds of cancer.

Cancer Cachexia

Weight loss occurs in many but not all patients with cancer. Thus, whilst patients with cancer of the gastrointestinal tract may become progressively wasted, those with breast cancer may maintain or even increase their body weight. Variability in weight change both within the same patient and between different patients has been reported in patients with lung cancer. In some patients, weight loss may be the first indication of the presence of a tumor. This is particularly so in patients with gastrointestinal cancer in whom protein-energy malnutrition (PEM) may develop somewhat insidiously owing to a decrease in food intake, though this may be denied by the patient.

In healthy individuals the body adapts to starvation by conserving protein and reducing energy expenditure. In many patients with cancer these adaptations do not adequately occur and a wide spectrum of changes in nutrient metabolism occur, similar to those found in the so-called 'metabolic response to trauma.' Some of these changes are mediated by cytokines released by macrophages. At least four of these have been described: tumor necrosis factor-α, interleukins-1 and -6 (IL-1 and IL-6 respectively) and interferon-γ. In addition, tumors themselves elaborate catabolic factors which cause direct breakdown of host lipid and skeletal muscle protein stores with the production of acute-phase proteins, such as C-reactive protein. The cachexia syndrome is characterized by anorexia, early satiety, changes in taste perception, weight loss, weakness, anemia, and edema.

Anorexia

A failure of appetite is the most important cause of a low food intake. The etiology of anorexia is, however, often complex with a number of interacting etiological factors, rather than one single factor.

The factors responsible for anorexia in the cancer patient may be psychological, physical, and metabolic. Moreover, the anorexia may be one of three types:

1. Transient anorexia is caused by emotional distress such as during a diagnostic work-up, or when recurrence or metastases are diagnosed, or when pain or discouragement is experienced.
2. Iatrogenic anorexia is related to treatment by surgery, the result of radiation sickness, or a side-effect of chemotherapy.
3. Pathological anorexia is related to the disease, particularly gastrointestinal or bronchial cancers, or part of the anorexia–cachexia syndrome of advanced disease.

The importance of psychological factors may decrease with the progress of the disease as physical factors become more prominent; nevertheless, they may make a substantial contribution to appetite failure. Feelings of worthlessness, loss of self-esteem, pessimism, guilt, and suicidal ideas may be experienced. Anorexia and cachexia may be the physical result of the patient's own beliefs and attitudes towards the disease and its treatment. Patients may become quite unable to overcome a sense of fear and hopelessness, leading to withdrawal.

We know little about the pathology of disturbed appetite control in cancer patients. It is part of the cachexia syndrome and it seems certain that the release of cytokines and associated acute-phase proteins is involved but the mechanism of their action is not clear. In hospitalized cancer patients a low food intake has been found to be significantly associated with a lower quality of life, but whether by cause or effect is not known. Consuming insufficient food to meet energy requirements leads to weight loss and a low body mass index (BMI). In the community, cancer patients with a BMI below $20\,kg\,m^{-2}$ have been found to have higher rates of consultation with their doctor, higher rates of prescription, and higher death rates during the follow-up period compared with those with a BMI of $20–<25\,kg\,m^{-2}$.

Taste Changes

There is strong evidence that taste changes and associated alterations in food preferences occur during the development of neoplastic disease. These can occur irrespective of the location of the primary tumor or

the therapeutic management of the patient. Measurements of taste detection thresholds (TDTs) have shown the threshold for bitterness to be reduced, that is, that patients could taste bitterness at lower concentrations than their noncancerous counterparts. Conversely, patients with cancer had elevated thresholds for sucrose and could only taste sucrose (sweet) at higher concentrations than noncancerous subjects. The changes in TDT were more common in patients with weight loss and in early reports there was a suggestion that they decreased as the energy intake increased. The metabolic cause of the taste changes is not at present clear but studies in end-stage cancer patients with low thresholds to bitter have been found to have an ongoing metabolic response with higher levels of the acute-phase reactant protein, C-reactive protein, when compared with an age-matched group. Moreover, patients with the lowest bitter thresholds had the highest plasma levels of the cytokine, tumor necrosis factor-α. Heightened recognition of household odors has also been reported in patients with end-stage disease.

Attempts to correlate changes in TDT with plasma vitamin A (retinol) and plasma zinc in patients with cancer are complicated by the interpretation of such levels. Plasma retinol levels depend on the availability of retinol-binding-protein (RBP), the levels of which are susceptible to nutritional status, and plasma zinc concentrations are an uncertain measure of tissue zinc status. Magnesium status has been found to correlate with salt detection thresholds.

Taste changes can have important consequences for the feeding of cancer patients. Reduced threshold for bitter taste (as determined with urea) results in beef and pork becoming less acceptable, poultry and fish rather intermediate, and cheese and eggs pleasurable. Taste abnormalities vary between patients and this is one aspect of the condition which needs to be individually assessed.

Taste changes may result in aversions, but aversions may also develop in patients who do not have disturbances in taste. There is some evidence that food aversions may be associated, or learned, by the association of certain foods with side-effects of drug treatment. Whatever the mechanisms by which they develop, aversions to foods may be persistent, lasting for several months, and ignoring them will have a definite effect on food intake.

Energy Expenditure

The resting energy expenditure (REE) of cancer patients has been reported to be increased, decreased, or the same as that of control subjects. Some of this variation is due to the subjects' different kinds of cancer, the cross-sectional nature of the studies, and to the different body composition of the subjects. The resting metabolic rate (RMR) of a group of lung cancer patients has been found to be 108% of predicted values at diagnosis, with a range of 96–151%. In those who experienced a partial or complete remission, maintenance of body weight was associated with a significant decrease in RMR. In contrast, patients who did not respond to treatment and who had lost weight had an unchanged RMR. It seemed that the elevated RMR in those with active disease was a response mediated by cytokines and acute-phase proteins rather than to the metabolic activity of the small tumors themselves.

However, RMR is only part of the total energy expenditure (TEE) and changes in physical activity can exert a greater influence on TEE. It is a matter of common observation that sick people reduce their physical activity and this could counterbalance the increase in RMR. This, indeed, seemed to be so in patients with lung cancer, and this meant that the energy requirement of lung cancer patients is unlikely to be higher than their preillness levels.

Glucose Metabolism

Altered glucose metabolism in the patient who is losing weight is the result of glucose intolerance, changed β-cell function, and decreased sensitivity and responsiveness to insulin. The causes of these changes are not clear but it seems likely that decreased food intake, protein loss, and hormone changes contribute, as do specific characteristics of the tumor. Increased glucose turnover is a composite of increased Cori cycle activity (80%), glucose oxidation (15%) and lipid synthesis, and ketone formation (5%). (*See* **Glucose**: Function and Metabolism.)

Protein Metabolism

Muscle wasting is clear evidence of altered protein metabolism. Most studies on this subject have been performed using experimental animals but insofar as similar studies have been carried out in patients, they have confirmed those in animals. Cancer increases whole-body protein turnover, with an increased rate of protein synthesis in the liver, but a decreased rate of synthesis in skeletal muscle with a simultaneous increase in skeletal muscle degradation. It is likely that a number of factors affect protein metabolism in the cancer patient, e.g., tumor specificity, the staging of the tumor, age, sex, and previous nutritional condition of the patient. (*See* **Protein**: Digestion and Absorption of Protein and Nitrogen Balance; Synthesis and Turnover.)

The biggest challenge in the nutritional management of a patient with cancer is to reverse the changes in protein metabolism which result in the severe muscle wasting so characteristic of cachexia.

Hypoalbuminemia is common in cancer patients and is often interpreted as evidence of malnutrition. However, this is only so if the other causes have been eliminated. These other causes are decreased albumin synthesis, increased plasma volume, and passage of protein-rich fluid into the gut, i.e., protein-losing enteropathy.

Fat Metabolism

Loss of subcutaneous fat is an obvious feature of cancer cachexia. Patients with progressive disease metabolize more fat than those with nonprogressive disease. If a rise in plasma free fatty acids (FFA) can be taken as an index of the mobilization of fat stores, then a significant increase has been found to correlate with the clinical activity of a tumor. However, these findings have not been confirmed. There does seem to be a failure of normal homeostatic mechanisms, possibly owing to insulin resistance, because glucose does not depress FFA oxidation to the same degree in cancer patients as it does in control subjects.

Whatever their cause, loss of body fat, inappropriate energy consumption, and loss of lean body mass can only contribute to a negative energy balance and continuing weight loss. (*See* **Fats**: Digestion, Absorption, and Transport; **Fatty Acids**: Metabolism.)

Vitamins and Minerals

Overt vitamin-deficiency diseases are rare in western societies but their absence is no guarantee of satisfactory status with respect to any vitamin. Patients with malignant disease are, indeed, likely to suffer some degree of deficiency with respect to a number of vitamins which may affect their continuing resistance to the disease and determine their response to treatment. Poor food intake and abnormal losses through the alimentary and renal tracts, possibly coupled with increased requirements which may be drug-induced, may contribute to vitamin depletion. If such deficiencies are suspected during recovery from active treatment, or during palliative care, patients should be given appropriate supplements. However, patients receiving anticancer treatment are advised not to take vitamin supplements, unless under medical supervision, as they may interfere with the action of the drugs.

Some vitamins, particularly those that are antioxidants (vitamin C, β-carotene, vitamin A and α-tocopherol) have been suggested, on the basis of epidemiological studies in humans and experimental studies in animals, to give protection against the development of some kinds of tumors, particularly lung cancer. However, large-scale trials with supplements of these substances have so far yielded adverse and contradictory results and it is considered at present that there is no place for supplements of these vitamins in the prevention or treatment of cancer.

Of the essential minerals investigated in relation to cancer, selenium has attracted most attention, largely because of its antioxidant properties. Though in rodents dietary supplementation has been found to inhibit colon, mammary gland, and stomach cancer, there is as yet no evidence for such an effect in humans. Iron transferrin and ferritin have been linked to cancer risk and cancer cell growth, possibly because many cancer cells require iron for growth. The relevance of this to dietary management seems unclear.

Diet in the Chemoprevention of Cancer

Epidemiological studies have provided evidence that diets low in fat and high in vegetables, whole-grain cereals and fruits are associated with lower risk of colon, breast, prostate, and endometrial cancer. Although such diets are rich in antioxidant vitamins, it seems that their role in cancer prevention is due to the presence in these foods of other substances with anticancer properties. Foremost amongst those at present being investigated are the phytoestrogens (coumestans, isoflavonoids, flavonoids, and lignans). A number of these compounds have been identified in fruits, vegetables, and whole grains commonly consumed by humans and research is under way to determine the quantities present. Studies in humans, animals, and cell culture systems have suggested a number of possible mechanisms for their anticancer action, including estrogenic and antiestrogenic effects, induction of cancer cell differentiation, and suppression of angiogenesis (i.e., extension of existing blood vessels).

Good sources of phytoestrogens are legumes (particularly soybeans), dark green leafy vegetables, nuts (including peanuts), seeds (especially linseed), whole grains and fresh fruits (including apples and bananas) and dried fruits (especially dates, prunes, and raisins). Antibreast-cancer diets including rich sources of phytoestrogens have been proposed. Genistein, a prominent isoflavonoid in soy products, may be responsible for lowering breast cancer risk in Asian women. Other plant constituents which are under investigation for their anticancer properties include indole-3-carbinol and glucosinolates. Indole-3-carbinol is found in vegetables of the *Brassica* genus and

has been found to induce cell cycle arrest of breast cancer cells. Glucosinolates are often responsible for the bitter taste of condiments (e.g., in mustard and horseradish) and are found in turnips, cabbage, and Brussels sprouts. Some glucosinolates are effective inhibitors of cancer induction in rodents by modifying the metabolism of carcinogens. The use of these compounds in humans as anticancer agents may be limited by the fact that some of them are goitrogenic.

Effects of Antineoplastic Treatment on Nutritional Status

Surgery

Not only are cytokines produced as a result of the presence of cancer in the body, they are also produced as a result of surgery, and a decrease in muscle mass characteristic of the cachectic process also occurs as part of the neuroendocrine response to surgery. The initial effect of the cytokines produced by macrophages is on the hypothalamus and this can cause anorexia, even in a previously noncachectic patient. The hypothalamus produces corticotropin-releasing factor which stimulates the pituitary to secrete adrenocorticotropic hormone which causes the adrenals to produce glucocorticoid hormones, and it is these hormones that stimulate the breakdown of muscle proteins. Some of the amino acids produced by muscle proteolysis, principally alanine, are converted to glucose by gluconeogenesis, whilst others are used to synthesize acute-phase proteins, one of which, C-reactive protein, is also produced during the cachectic process caused by cancer. The glucose produced by gluconeogenesis following surgery causes a rise in blood glucose levels which has been described as the 'diabetes of trauma.'

Largely experimental studies have shown that the production and suppression of cytokines can be manipulated by nutritional means, particularly fats, and this offers scope for their potential use in the treatment of severely ill patients.

The extent of these changes, their duration, and the period of convalescence are directly proportional to the severity of the surgery. This is important for the patient with cancer in whom surgery may need to be extensive in order to remove all cancerous tissue. Moreover, surgery is the treatment of choice for cancers of the alimentary tract and may have direct nutritional consequences (Table 1) which will be superimposed on the general 'metabolic response to injury' experienced by all surgical patients. Nutritional management of these patients requires careful attention to specific problems, possibly over an extended period of time.

Table 1 Possible nutritional effects of gastrointestinal surgery

Surgical procedure	*Possible effects*
Resection of the oropharyngeal region	Chewing or swallowing difficulties Prolonged dependence on tube feeding
Esophagectomy	Gastric stasis
Esophageal reconstruction	Reduced acid secretion (both these effects are due to cutting the vagus nerve) Fat malabsorption Diarrhea
Gastric resection (partial or total)	'Dumping syndrome' Malabsorption Reduced acid secretion Reduced absorption of vitamin B_{12} Low blood glucose level
Small intestine: duodenum	Reduced secretion of pancreatic juice and bile
Jejunum	Reduced efficiency of absorption
Ileum	Reduced absorption of bile salts Reduced absorption of vitamin B_{12} Increased urinary excretion of oxalate
Massive resection	Severe malabsorption Malnutrition Metabolic acidosis
Colon	Fluid and electrolyte imbalance
Removal of pancreas	Reduced secretion of pancreatic enzymes Reduced secretion of insulin – diabetes mellitus

Radiation Therapy

The purpose of radiation therapy is to kill cells and the effects may be dramatic. As the cells are destroyed, toxic waste products are liberated, causing an inflammatory response with consequent edema. Cells may be lost from tissue surfaces which then become ulcerated and clinically the patient shows symptoms such as mucositis and stomatitis, nausea, vomiting, cystitis, or diarrhea. Irradiation may have both immediate and late effects on tissues and hence on nutritional status. Normal and tumor cells are affected in similar ways and cell death may be immediate, delayed, or 'natural':

1. Immediate cell death is the result of irreversible damage to DNA; this mechanism is responsible for the immediate side-effects.
2. Delayed cell death occurs after mutation of DNA; limited functions usually continue until the M phase in the multiplication process, when the cells are unable to divide; this mechanism is responsible for late effects.
3. 'Natural' cell death involves the formation of giant (sterile) cells which function but cannot divide.

Some of the nutritional consequences of radiation therapy may be severely disabling, even life-threatening,

Table 2 Effects of radiation and drug treatment of cancer and their palliative treatment

Treatment	*Undesirable effects*	*Possible palliative treatment*
Radiation		
Mouth and throat	Nausea	Small frequent meals; reduced fat
	Vomiting	Total parenteral nutrition (TPN)
	Anorexia	Small meals, served attractively
	Severe anorexia	Tube feeding
	Loss of taste	Emphasis on aroma of food
	Dental deterioration	Reduced sugar intake
	Sore mouth	Bland soft foods; tube feeding
	Lack of saliva	Avoidance of dry foods
	Swallowing and chewing difficulties	Soft, semisolid small meals at correct temperature; between-meal supplements
Upper abdomen	Nausea and vomiting	As above
	Sense of fullness	Small frequent meals; reduced fat
	Reduced secretion of digestive enzymes	Soft, moist, easily digested foods
Lower abdomen	Intestinal cramping	Soft, bland, low-residue diet
	Diarrhea – dehydration	Low-residue foods, high fluid intake
	Malabsorption	Low-fat (?), lactose-free (?), elemental diet; TPN
Drugs		
General effects	Nausea, vomiting, anorexia, diarrhea	As above
Particular effects		
Nitrogen mustard	Metallic taste in mouth	Elimination of any food accentuating this taste; individual tolerance
Cyterabine	Abdominal pain	Bland low-residue diet
Hydroxyurea	Intermittent constipation	Prune juice, large fluid intake (at least 3 l day^{-1})
Vinca alkaloids	Intermittent constipation	As above
	Abdominal pain	As above

Adapted from Dickerson JWT and Williams CM (1988) Nutrition and cancer. In: Dickerson JWT and Lee HA (eds) *Nutrition in the Clinical Management of Disease*, 2nd edn, pp. 350–373. London: Edward Arnold.

and occur in patients whose nutritional status is already compromised. Food intake is substantially reduced and malabsorption resulting from treatment of tumors in or near the gastrointestinal tract may be very difficult to control. The severity of these problems means that aggressive, symptom-related nutritional support (Table 2) is an essential adjunct to radiation therapy in order to prevent deterioration of nutritional status and to allow compensatory hyperplasia of undamaged bowel.

Chemotherapy

Anticancer drugs have profound cytotoxic effects and since they cannot discriminate between 'normal' and 'cancer' cells they may seriously affect 'normal' tissues. Contributions to host malnutrition may be by both direct and indirect mechanisms that cause many symptoms. Current medical practice is to administer drugs cyclically in multiple combinations, sometimes called 'cocktails.' This increases the possibility of 'killing' cancer cells at different stages of cell multiplication, but it can increase both the range and severity of side-effects. Different anticancer drugs cause a slightly different pattern of side-effects (Table 2), but the general effect is to reduce food intake and since this may occur over prolonged periods it will lead to weight loss and debility.

Indirect effects of chemotherapy that may contribute to a reduced food intake include moniliasis or candidiasis. These are particularly common in patients with leukemia and lymphoma and affect the oral cavity, pharynx, or esophagus, causing a sore, painful mouth, odynophagia, and dysphagia.

Possible palliative treatment for some of these problems is shown in Table 2.

Nutritional Management of Cancer Patients

The feeding of cancer patients should be seen as part of their total care. Provision of food for these patients requires the following:

1. Understanding. Carers and providers should appreciate the clinical problems and difficulties experienced by individual patients so that the 'diet,' whether oral, enteral, or parenteral, is suited to the patients' needs, including the effects of the anticancer treatment.
2. Flexibility. Dietary provision must be flexible, with menus to cater for a wide range of needs with respect both to the nature of the food and the timing of its availability.
3. Psychological importance. The provider should be sensitive to the psychological condition of patients and the importance of food to them. This involves

the way in which food is provided, as well as its nature. Food can be a 'messenger' between the carer and the patient.

Oral food is always the first choice and considerable skill may be needed to obtain an appropriate intake. Detailed suggestions for dealing with specific problems are given in some of the works quoted in the Further Reading section. Practical suggestions for increasing energy and protein intakes are as follows:

1. Plan a definite eating schedule and then adhere to it. Do not omit meals or between-meal snacks.
2. Add cereal with banana or other fruit, sugar, and cream to the breakfast menu.
3. Butter toast or bread when it is hot because more butter can be used.
4. Use jam, marmalade, or cheese with toast or bread.
5. Add cream to milk beverages.
6. Add skim milk powder to milk, soups, pudding, mashed potatoes, etc.
7. Add icecream or whipped cream to desserts (cake and icecream, apple pie with whipped cream, etc.).
8. Use mayonnaise, salad dressing, butter, or margarine with sandwiches, salads, and vegetables.
9. Serve thickened gravy with meat and potatoes.
10. Have bacon, ham, or sausages with eggs at breakfast.
11. Add eggs to beverages or recipes to increase the protein.
12. Use milk instead of water to prepared canned condensed cream soups.

Oral food can be supplemented with 'sip' feeds. These may be homemade, milk- and egg-based, or commercially available complete feeds such as Ensure, Clinifeed, or Fortisip. If elemental feeds such as Flexical or Vivonex are needed due to malabsorption, they should never be given orally because of their taste. Patients with inadequate oral intake should be fed through a fine-bore tube (1–2 mm in diameter) inserted nasogastrically, or directly into the stomach or intestine. Feeds used as sip feeds should be introduced from a reservoir either by gravity or with a pump. If the gastrointestinal tract cannot be used, or if the patient cannot tolerate a tube, complete nutrition can be given parenterally through a central vein. Parenteral feeds (for TPN) contain energy (usually fat and glucose), amino acids, vitamins, and minerals. Given under expert supervision, their use in cancer patients before surgery has been found to reduce complications and in some reports to reduce the length of hospital stay. Usually, the greatest benefit has been in the most malnourished individuals. TPN may also widen the scope for radiation and drug treatment. Indeed, the survival of some cancer patients may depend on this kind of treatment. A potential problem with TPN is that it results in a decrease in the barrier function of the gut, but this can be prevented by giving some food enterally.

Conclusions

The feeding of cancer patients is part of their total care at all stages of the disease and its treatment. It is at different times 'supportive,' 'adjunctive,' and 'definitive.' It is supportive as part of the preparation for definitive treatment. It is adjunctive as a part of the overall therapy. In some individuals it becomes definitive as the therapy that permits survival. In the future, it is envisaged that diets containing foods with anticancer properties may be used to treat specific tumors.

Introduction

Canning is the general term applied to the process of packaging a food in a container and subjecting it to a thermal process for the purpose of extending its useful life. An optimal thermal process will destroy pathogenic (disease-causing) bacteria, kill or control spoilage organisms present, and have minimal impact on the nutritional and physical qualities of the food. Although we think of canning in terms of steel or possibly aluminum cans, the principles apply equally well to a variety of food containers such as glass jars, plastic and foil-laminated pouches, semirigid plastic trays or bowls, as well as metal cans of any one of several shapes, including cylindrical, oval, oblong, or rectangular. The concept of aseptic packaging (sterilizing the food and the container prior to filling and sealing) also follows the same principles.

Basic Concepts

In 1810, Nicolas Appert reported the first methods on the thermal treatment of food. His method of preservation was primarily aimed at the elimination of the use of large quantities of sugar, salt, and vinegar as preserving agents because they detracted from the natural flavor and quality of the food. His methods of food preservation developed over the years into procedures that not only prevented the large economic loss associated with microbial spoilage, but also destroyed the food-borne microorganisms that are capable of causing illness, or even death, in humans.

Heat processing coupled with hermetic packaging is used to preserve a wide variety of products. Microbial control processes at temperatures in the 65–95 °C range are often called pasteurization, those from 100 to 150 °C, sterilization. Pasteurization processes are designed to kill pathogenic microorganisms and extend product life under refrigerated storage; sterilization processes make possible indefinite product life at ambient temperatures. Whereas the principles of thermal process design are the same for all conditions, the concepts for process establishment that will follow are those for the sterilization of foods known as low-acid canned foods (LACFs) packaged in hermetically sealed containers. Low-acid foods have a pH greater than 4.6 and a water activity (a_w) greater than 0.85 – a combination capable of supporting the growth of *Clostridium botulinum*, a spore-forming bacterium that produces an exotoxin which is one of the most deadly neuroparalytic toxins known. *C. botulinum* is ubiquitous; it occurs in both cultivated and forest soils, sediments of streams, lakes, and coastal waters, the intestinal tracts of fish and mammals and gills and viscera of crabs and other shellfish. For many years, canning industry laboratories have devoted much attention to *C. botulinum*. Early in the 20th century, thermal-processing technologists divided high-moisture foods into acid (pH less than 4.6) and low-acid (pH greater than 4.6). The basis for this decision was that, at a pH of less than 4.6, *C. botulinum* will not grow and produce toxin. At a pH above 4.6, in a favorable medium *C. botulinum* will multiply and produce toxin. Examples of

foods with a pH greater than 4.6 are vegetables, fresh meats, and seafood. Tomatoes normally have a pH that is less than 4.6 and require a less severe heat treatment (pasteurization) to achieve preservation.

a_w is a measure of the amount of available water in the food. The a_w of fresh fruits, vegetables, and meats is normally greater than 0.85. Dried fruits, honey, and salami have insufficient water content to support the growth of most hazardous microorganisms and thus do not require a sterilization process to produce a shelf-stable product.

Establishment of the Thermal Process

The establishment of the thermal process for sterilization of canned foods results from a successful marriage of microbiological science and physical science, specifically thermobacteriology and heat penetration testing, their validation and iteration, as shown diagrammatically in Figure 1.

Thermobacteriology

Thermobacteriology is the science that studies the potential microbiological contaminants in foods, the relationship between temperature and time levels required to destroy them, and the influence of the food itself on the destruction rates.

There are three microbiological parameters which are involved in all process establishment work, namely D_T, z, and F. These variables define the thermal resistance of bacteria and indicate how much of an effect a particular thermal process is likely to have. The D_T value, which is defined graphically in Figure 2a, is the time in minutes at constant temperature (T) to inactivate 90% (one log reduction) of the target organisms present in a food. The D_T value is also known as the 'death rate constant' or 'decimal reduction time.'

Thermal resistance, or thermal destruction tests (TDTs), that measure D_T are conducted using small food samples inoculated with known levels of microorganisms. The samples, contained in specially designed, low-profile TDT cans or glass tubes, are heated in chambers capable of rapidly heating the sample to a precise temperature, holding for a precise time period, and rapidly cooling to sublethal temperatures. Common heating devices are the TDT retort and the thermoresistometer.

A plot of the thermal resistance (or survival) data must approximate a straight line on semilogarithmic graph paper (as in Figure 2a) for the D_T value to be meaningful. Each TDT curve is unique for the microorganism, food medium, and exposure temperature. The D_T value describes the time effect of heat on a population of microorganisms exposed at constant temperature for a precise time period, without influence of a heating (come-up) or cooling period effect.

The $D_{121.1^\circ c}$ value for *C. botulinum* is normally taken as 0.2 min. This is based on thermal resistance studies conducted in the early 1920s on spores harvested from the most heat-resistant strains known. These studies demonstrated that, by extrapolation from the semilogarithmic survival curve, it was necessary to heat a spore suspension in phosphate buffer for 2.78 min at 121.1°C to reduce the survival population from about 10^{11} spores per unit to less than one spore per unit (12-log reduction). Later, correcting the data for come-up time resulted in a reduction of the heating time to 2.45 min to achieve the same lethal effect, hence, a $D_{121.1^\circ c}$ value of 0.2 min.

The time–temperature data in Figure 3 (see Thermal Process Calculations, below) are typical of the way in which cans of food heat, and illustrates that food in containers does not heat (or cool) instantly. To be efficient in the thermal process design, we must take advantage of the microbial kill at each step along the thermal process path. The thermal resistance curve shown in Figure 2b is the vehicle that makes this possible. A series of TDT tests are conducted to determine the effect of different temperatures (D_T values) on the thermal resistance of an organism. By plotting the measured D_T values on a logarithmic scale against temperature on a linear scale (Figure 2b), a thermal resistance curve is constructed. The thermal resistance curve relates time for a one log kill with the kill temperature. From this plot, the z value can be obtained; it is the inverse slope of the curve and represents the number of degrees of temperature required for the curve to traverse one log cycle. In other words, the z value denotes the number of degrees of temperature required to effect a 10-fold change in the time to achieve the same lethal effect. A higher z value means that a greater change in process temperature is required for the same change in the destruction rate of an organism. The z value makes it possible to quantify the microbial kill at the product temperature that exists at all times during a thermal process.

A range of z values from 7 °C to 12 °C have been measured over the years for *C. botulinum*. These differences are attributed to the spore type (strain), heating system, test substrate, and method of calculation. Much effort has been expended on determining the appropriate z value for LACF process establishment. Consensus led to the conclusion that the use of a single z value of 10 °C – which has been in general use for 80+ years – is still the best recommendation for calculating LACF sterilization processes that are to be safe from a public health standpoint. It is

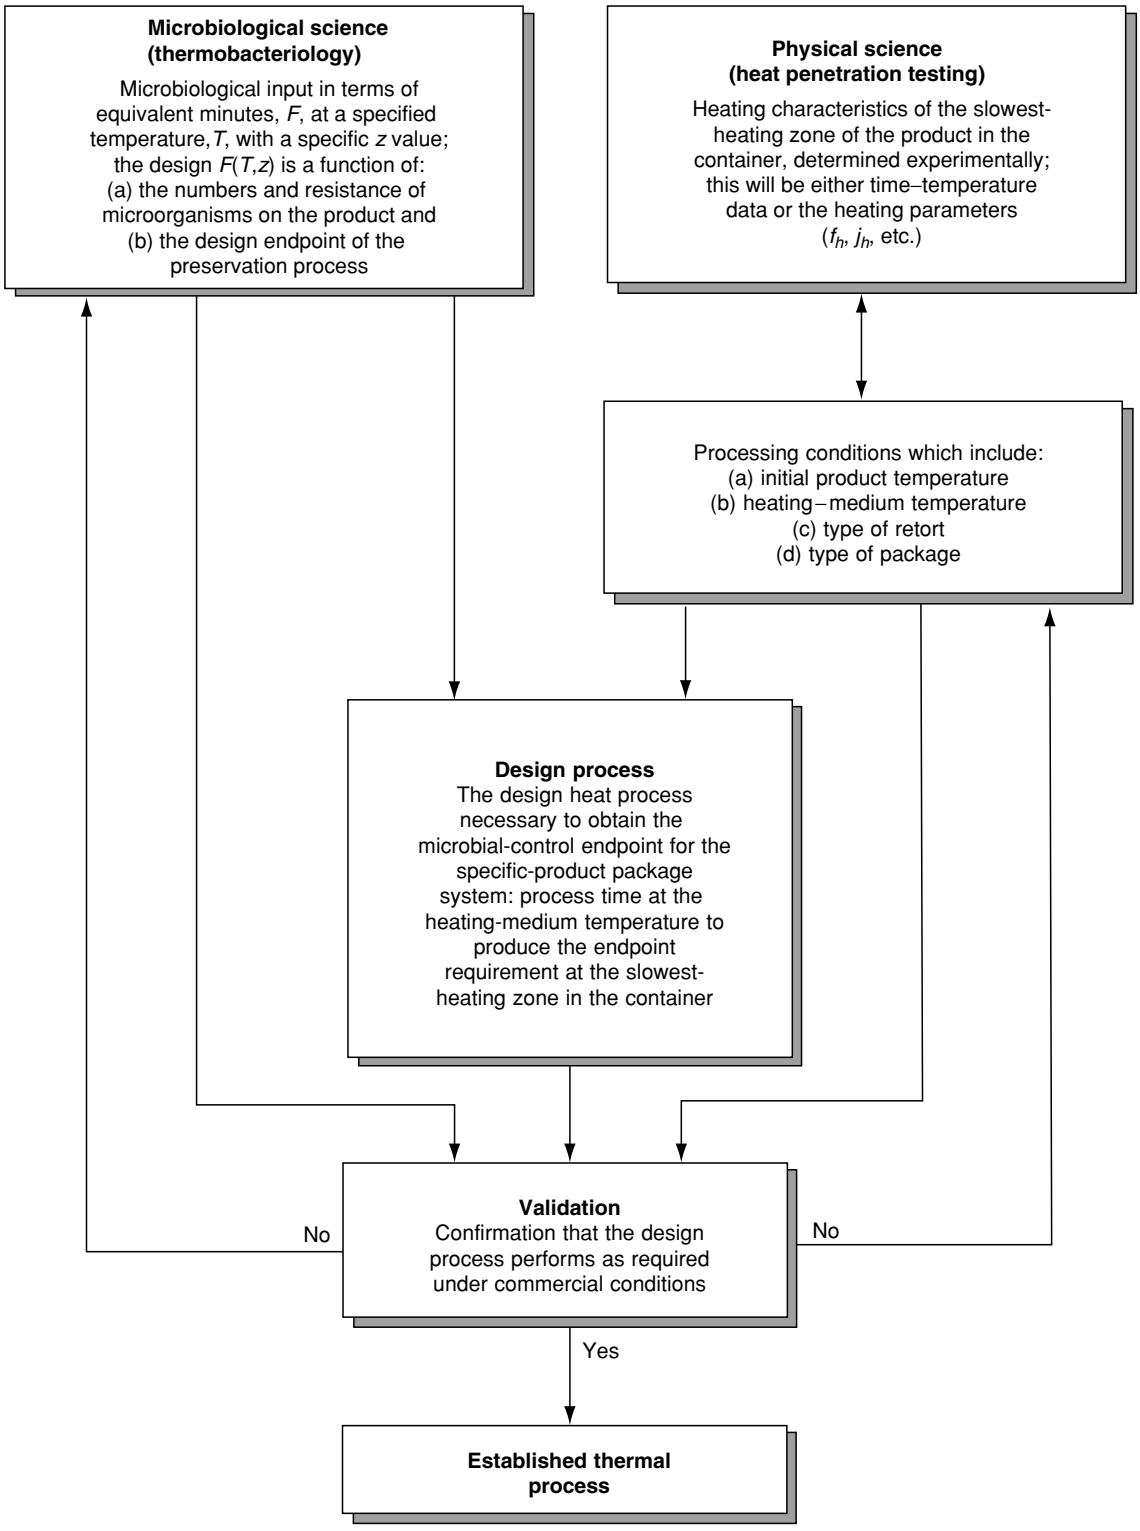

Figure 1 Establishment of the thermal process.

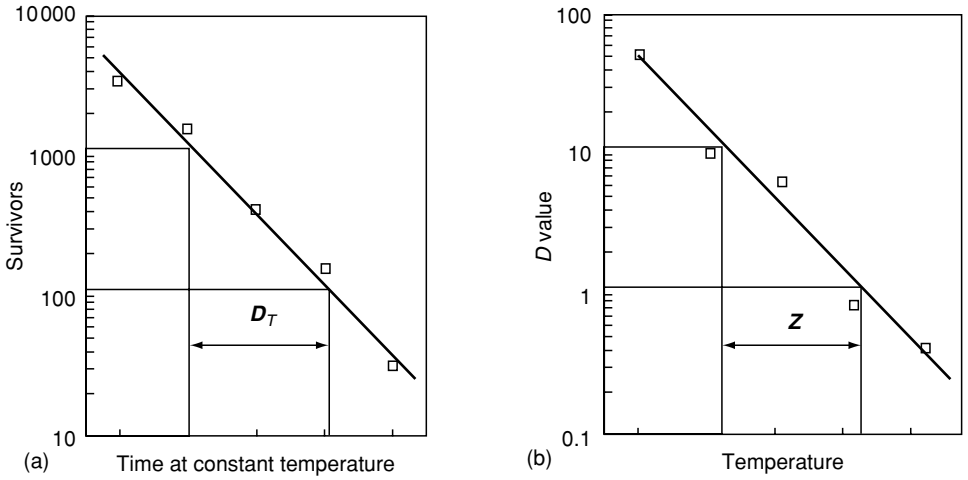

Figure 2 Graphical representations of *D* and *z* values. (a) *D* value; time required at temperature to reduce survivors by 90%; (b) *z* value; temperature change required for a 10-fold change in destruction rate.

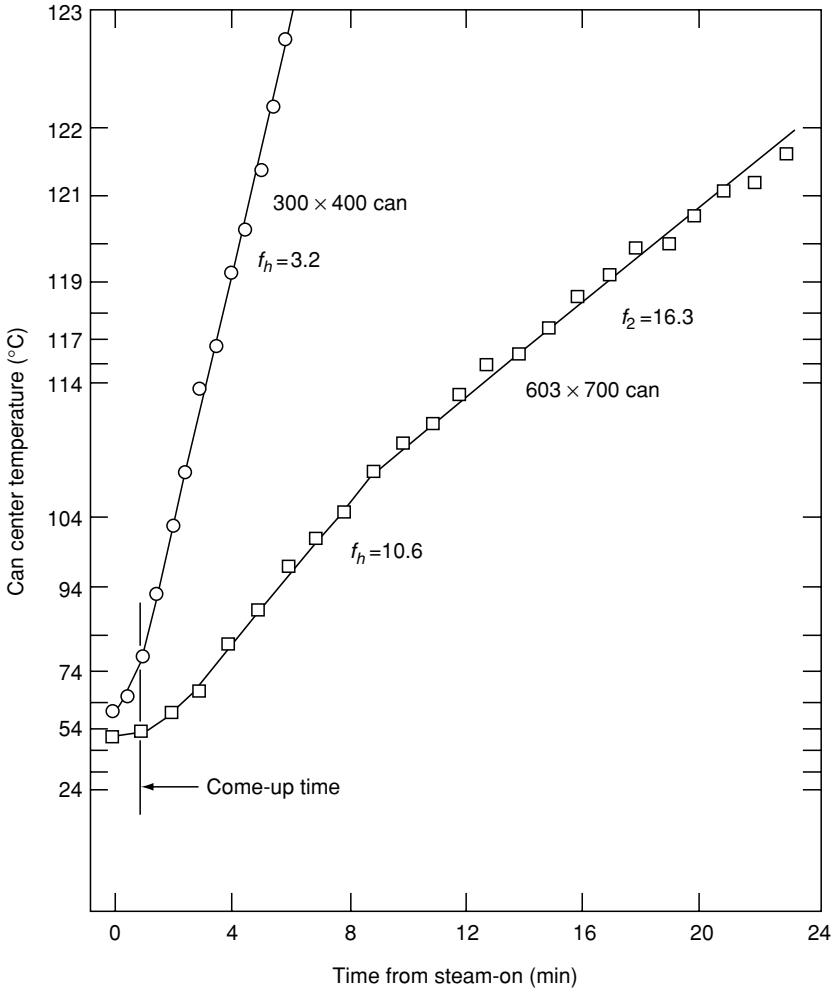

Figure 3 Typical simple and broken heat penetration curves. Tests were for two can sizes of mushrooms in brine, heated simulating the FMC Sterilmatic continuous agitating retort. Can sizes are American designations: 603 × 700 implies an outside diameter of 6 3/16 in (approx. 16 cm) and a height of 7 in (approx. 18 cm). From Berry MR, Bradshaw JG (1982) Heat penetration for sliced mushrooms in brine processed in still and agitating retorts with comparisons to spore count reduction. *Journal of Food Science* 47: 1699, with permission.

possible that this choice was fortuitous; on the other hand, it may have been the purposeful result of research by the canning industry pioneers of the 1920s and 1930s.

Lethality

Containers of food do not heat instantaneously, and since all temperatures (above a minimum value) have a lethal effect and contribute to the destruction of microorganisms, a mechanism to determine the relative effect of a changing temperature while the food is heated and cooled during thermal processing is necessary. The z value is the parameter that allows us to calculate the lethal effect of various temperatures on the destruction of microorganisms. The lethal rate (L) describes, through use of the z value, the relative effect of temperature on microbial destruction with respect to the effect of a certain reference temperature (T_{REF}). In descriptive terms, L is the equivalent minutes at the reference temperature per minute at any temperature T:

$$L = 10^{\frac{T-T_{\mathrm{REF}}}{z}} \qquad (1)$$

Table 1 shows lethal rates at five temperatures for *C. botulinum* assuming a reference temperature of 121.1 °C and a z value of 10 °C, and times required at each temperature for a 12-log spore reduction. If the initial *C. botulinum* population per container (N_0) is 10^3 and we desire a final probability (N_{F}) of 10^{-9}, then a 12-log spore reduction is required. The difference in each temperature in Table 1 is one z value (10 °C), which illustrates that changing the exposure or processing temperature by one z value will require a 10-fold change in processing time.

Sterilization Value

The parameter that accumulates the lethal effect as a function of time (t) during the thermal process is the sterilization value, defined as

Table 1 Lethal rates and times required for a 12-log reduction, applicable to the destruction of *Clostridium botulinum* spores (reference temperature 121.1 °C; z 10 °C)

Temperature, T (°C)	*Lethal rate (min at 121.1 °C/min at T)*	*Time (F_T)[a] required for a 12-log spore reduction*
101.1	0.01	4 h
111.1	0.1	24 min
121.1	1	2.4 min
131.1	10	15 s
141.1	100	1.5 s

[a] $F_T = D_T\, Y_n$ where $D_{121.1} = 0.2$ and Y_n is the spore log reduction ($\log N_0 - \log N_F$) where N_0 and N_F are 10^3 and 10^{-9}, respectively.

$$F^z_{T_{\mathrm{REF}}} = \int_0^t 10^{\frac{T-T_{\mathrm{REF}}}{z}} dt \qquad (2)$$

Or, in terms of lethal rate, L (eqn 1),

$$F^z_{T_{\mathrm{REF}}} = \sum L\Delta t \qquad (3)$$

When temperature (T) characterizes the slowest-heating zone in the container of food and when the reference temperature and z value are 121.1 °C and 10 °C, respectively, then the sterilization value is known as the F_0 value for the thermal process. The F_0 value is specific for the food, container, processing conditions, processing system, and thermal process (processing time, temperature, and other physical factors affecting the process). The F_0 value is the equivalent value of the process in terms of minutes at 121.1 °C, as if no time is involved in heating to 121.1 °C and cooling to sublethal temperatures. An F_0 value of 3.0 min ($z = 10$ °C) is generally accepted as a realistic, minimum botulinum thermal process that will produce LACFs that are safe from a public health standpoint.

Commercial Sterility

Commercial sterility of food means the condition achieved by application of heat which renders such food free of viable forms of microorganisms having public health significance, as well as any microorganisms of nonhealth significance capable of reproducing in the food under normal nonrefrigerated conditions of storage and distribution.

Several additional considerations go into the decision as to the design F_0 for commercial sterility which may be as much as 20 F_0 units higher than the minimum *C. botulinum* public health thermal process. By convention in North America, the F_0 used in calculating a thermal process includes the processing equipment heat transfer safety factor along with the requirement for killing the microbial contaminations. These considerations include: initial bacterial level of the food product, physical parameters of the food itself (style, consistency, particle size, liquid-to-solid ratio, etc.); food container; processing system (still, hydrostatic, continuous agitating retorts, etc.); conditions of storage and distribution; natural or added ingredients that prevent spoilage; economics and the general experience of the food processor. As examples, foods that will be distributed to a high-temperature geographical area may require an F_0 of 15–20 min to afford the same protection from economic loss due to spoilage as an F_0 of 5–7 would afford for a moderate temperature area. An F_0 of 8–12 min is recommended for products heated with induced agitation.

The initial bacterial level of the food has a direct effect on the outcome of a specific process; the same thermal process (F_0) does not guarantee the same process endpoint. The F_0 value is a measure of processing conditions necessary to affect a specific process condition, for example, the level of *C. botulinum* spores by a certain number of log reductions, such as 12 $D_{121.1^{\circ}c}$ values. The higher the initial spore concentration, the higher the spore concentration after processing for a process delivering the same F_0 value.

There is a potential hazard in expressing process requirements as '12*D*,' in that only the spore-log reduction is specified. A spore-log reduction of 12 will yield a probability of a spore surviving of 10^{-9} (one spore per 10^9 containers) only when the initial spore contamination level is 10^3. To provide all consumers of canned food with equal protection, regardless of the initial numbers of *C. botulinum* spores, the heat process F_0 value should always satisfy a constant, agreed endpoint value of probability of a surviving spore.

Heat Penetration Testing

The purpose of the heat penetration (HP) test is to determine, accurately, the temperature of the slowest-heating zone in the food container during thermal processing. The results of the HP test are experimentally determined time–temperature relationships describing the heating and cooling of the product. These data are derived from tests which duplicate commercial processes with a high degree of reliability. The HP data are normally collected in the laboratory because of difficulty in making accurate measurements and having close temperature control in plant equipment. This is especially true for products that heat by natural or forced convection by conduction (i.e., no product movement). The HP test provides the temperature history of the product during the process which, when combined with the thermal resistance information for the organism of concern (the required F_0 value), allows us to calculate the length (process time) of the thermal process at the specified processing temperature.

The factors which affect the HP results are numerous and tend to be more complex as the food product, package, and processing systems (retorts or autoclaves) become more complex. The following factors must be considered by the HP technician during the conduct of a HP test because they may influence the resulting heating and cooling temperature profiles:

- Processing (retort) temperature
- Processing time
- Processing medium (steam, water, etc.)
- Initial temperature and temperature distribution within the container
- Size and shape of container
- Container orientation and distribution within retort
- Agitation of containers during processing*
- Container fill and head space*
- Product formulation and preparation procedures*
- Proportion of solids to liquid*
- Size, shape, arrangement, and composition of food particles
- Consistency of product*
- Product drained weight after processing
- Style of container (plastic or metal; rigid, semirigid, or flexible)
- Vacuum or air remaining in container
- Temperature distribution (uniformity) in processing vessel
- Operating conditions during processing (come-up time, sequence of events, controller function, rotational speed, etc.)*
- Location and type of temperature sensor in container
- Ability of test retort to duplicate commercial conditions*

Items marked with an asterisk are particularly significant when processing with agitation.

Every thermal process will have factors that are critical for delivery of the design F_0. For example, the critical factors of retorting systems that are designed to agitate the contents of the container during processing, to increase the rate of heat penetration, will differ from those of a still retorting system for the same product. It is the responsibility of the person establishing a thermal process to understand all the factors that may influence the way the product heats and cools. It has been repeatedly observed that the HP testing program must continue until all parameters are fully understood. Only accurate and applicable HP factors are meaningful for thermal process establishment.

The instrument of choice for measuring food temperature during HP testing has historically been the thermocouple (TC) with recording potentiometer. Normally nonprojecting style TC receptacles are attached to the container and hard-wired to the potentiometer. The TCs are placed to measure the temperature at the slowest-heating zone within the container; this is determined *a priori* by ancillary testing. Since the objective of the HP test is accurate time–temperature data, care must be exercised in the selection and use of the TC. For products that have considerable natural or induced convection, such as whole-kernel corn in brine, a TC of small diameter is

used in order to avoid interfering with product movement. For conduction-heating foods that remain motionless during processing, such as a viscous stew, the TC support material is selected to have thermal properties similar to the food to minimize the conducting of heat to or from the TC junction. If the TC and/or container are not adequately grounded, especially in water processes, stray voltages may cause large temperature errors.

Temperature measuring systems in use today usually use personal computers as the output device and include resistance temperature devices (RTDs) and miniature telemetry or data logger systems. These systems have allowed HP testing in systems that were previously not possible since they have removed the requirement of direct wiring to the container.

The accuracy of the measuring instrument is extremely important. A 0.5 °C difference in the temperature of the thermal process results in more than a 10% difference in F_0. For minimally processed foods, this could result in severe underprocessing and survival of numerous pathogenic or spoilage organisms.

Thermal Process Calculations

The methods for calculating the sterilization value (F_0) from the HP and TDT data can be classified as either a general or formula method. The two methods use similar principles but the procedures are distinctly different.

The general method is essentially a graphical or numerical integration of eqn 2, using the time–temperature data obtained during the HP test. It is the most accurate and simplest method of determining the F_0 delivered by the thermal process. The disadvantage is that the method affords little or no ability first, to change the process time, heating parameters, or initial product temperature and predict their influence on F_0, or second, to use F_0 as an input to predict required process time. An example of calculating F_0 using the general method is given in Table 2. In this example, eqn 3 is numerically integrated using typical time–temperature data at 2-min intervals from a HP test. The resulting F_0 for the 30-min combined heating and cooling phases (Table 2) is 9.8 min at 121.1 °C. In the general method, improved accuracy may be achieved by reducing the HP data measurement time interval.

The various formula methods are mostly iterations and improvements of the formula method first proposed by C.O. Ball in 1923. The HP data are first plotted on semilogarithmic paper as either simple- or broken-heating curves, as shown in Figure 3. The shapes of the respective heating curves are defined in terms of parameters, commonly known as HP factors: a heating lag factor (j), a temperature response parameter that is a function of the slope of the heating curve (f_h), and the second slope and time of the break point (f_2 and X_{bh}) when the heating curve has a change of slope and can be better represented by two straight-line segments.

The simple (single, straight-line) heating curve normally occurs for food product heating by conduction, or by forced convection induced by mechanical agitation of the container. Broken-heating curves normally occur for product heating by natural convection in still retorts, and for products that undergo a change in their thermophysical properties during processing (such as a rapid increase in viscosity as temperature increases).

In the formula methods, the temperature of the food during the process is described by equations that utilize the HP factors for the heating, cooling, and transitional phases of the processing cycle. When these expressions are substituted into eqn 2, the equivalent minutes at heating medium temperature of the process can be calculated. F_0 values are calculated by either numerical procedures that use high-speed computing equipment or by classical 'cookbook' procedures using supplemental tabulated data. The versatility of the formula method makes it possible to vary the heating time, process temperature, design F_0, and even can size, using the same HP data, and to determine the influence of each of these factors on the thermal process delivered to the product.

Sterilization values calculated using the original Ball formula method are reported to be conservative. Numerous investigators have offered modifications which have improved the method, resulting in F_0 values nearer those calculated by the general method.

Process Validation

The delivered F_0 in the process establishment procedure is a value calculated using experimental data that can be related to the reduction in microorganisms that occurs when the process is used for the commercial production of canned foods.

The final step in the process establishment process is the validation or confirmation of the design process to provide assurance that the design F_0 will be delivered to the product under the commercial processing conditions (Figure 1). It is not possible to measure the design level of sterilization processes (microbial survival probability of about 10^{-9} spores for *C. botulinum* or 10^{-6} for nonpathogenic organisms) using the organism for which the process is intended to destroy. Process validation is normally performed

Table 2 Example heat penetration data and calculation of the sterilization value by the general method (reference temperature 121.1 °C; *z* 10 °C)

Time[a] *t (min)*	*Temperature*[a] *T (°C)*	*Lethal rate L (eqn 1)*	*Lethality* $(L \times \Delta t)$	*Cumulative lethality* F_0 *(eqn 3)*

[c]Begin cooling.

using microbial techniques involving the inoculation of calibrated bacterial spores into the cans before the containers are sealed and processed. After the cans receive the thermal process, they are incubated. At the end of 2 to 4 weeks incubation, all cans are examined, the number of cans that show evidence of microbial growth is determined.

The bacteria used in biovalidation have a heat resistance higher than *C. botulinum* and are typically spore-forming, putrefactive mesophiles or thermophiles. A commonly used organism is PA3679 which is nontoxic and, therefore, safe for use in food plants and not hazardous to microbiologists conducting the validation tests.

Experience in commercial processing indicates that the microbial kill measured by biological methods does not always agree with the measurements of physical parameters (HP and TDT). This is why each process must be validated biologically. If the bacterial spores have been adequately calibrated, they give an indication of the actual killing power of the thermal process as delivered by the commercial processing equipment. A common biological validation is to carry out an inoculated pack where 10 000 resistant PA3679 spores ($D_{121.1°c}$ of between 1.0 and 1.5 in phosphate buffer) are added to each container of product before processing. After processing inoculated containers are incubated. An acceptable process should produce a greater than 5-log reduction of the PA3679. The test must be carried out with good technique and appropriate controls. If the results of the validation tests do not agree with the physical process design, it is an indication that the critical processing parameters were not adequately understood and the differences should be resolved, typically using the iterative process depicted in Figure 1.

Cans and their Manufacture

M de F Filipe Poças, Escola Superior de Biotecnologia, Universidade Católica Portuguesa, Portugal

Cans

Cans for food and drinks may be manufactured in tin plate, tin-free steel, or aluminum. Depending on the metal to be used and on the type of can, different production methods may also be used to manufacture cans. The characteristics of the metals and the operations to produce and close the cans are described below. Additionally, information is given on the polymeric coatings used to avoid undesirable interactions between the product and the metal surface.

Types of Cans for Foods and Drinks

Metal cans for foods and drinks are usually classified in three-piece cans and two-piece cans. The can components and the terms commonly used to designate different parts of a can are shown in **Figure 1**. Cans in the first group are composed of a welded body and two seamed ends and are usually made in tinplate. The two-piece cans have the body and the bottom end in a single piece and a seamed top end. They are made in tinplate, aluminum, or tin-free steel, and are produced by the Draw–Redraw (DRD) process or by the Draw-Wall-Ironing (DWI) process. The DRD process is used to produce shallow cans, with a low height/diameter ratio, whereas the DWI process is typically used for drink cans, commonly with a high height/diameter ratio. These cans have a very thin wall, thus lacking mechanical resistance. They are used for carbonated drinks where the high pressure from the product (very often around 4 atm) imparts the required resistance. In still drinks, the application of liquid nitrogen in the headspace yields a high internal pressure.

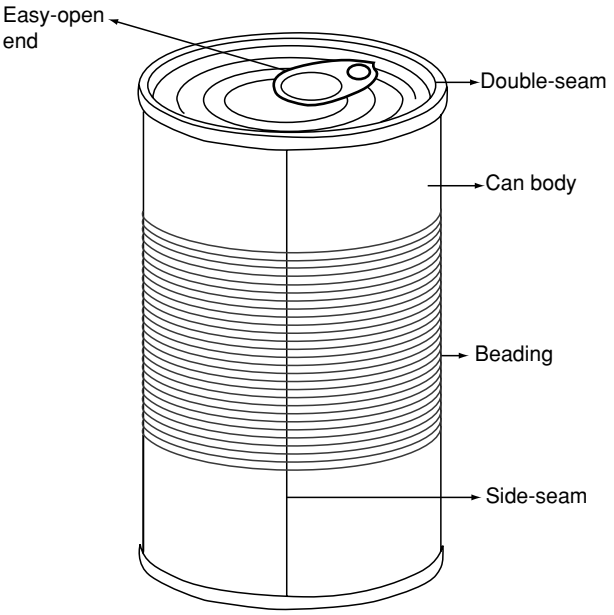

Figure 1 Can terminology.

A wide variety of can shapes are available: round, rectangular, oval, trapezoidal, etc. The circular can is the most popular shape because it is the easiest shape to seam and uses the least metal sheet area for a given volume content. Rectangular shapes are common for processed fish because this format benefits the product presentation when the consumer opens the can.

For a given can capacity, the surface area of metal required for round cans is minimal when the can diameter equals its height. The dimensions of cans are designed taking into consideration this diameter/height ratio so as to maximize the efficiency of metal usage. However, it is easier and less expensive to reset a production line to make a can with a different height than to change its diameter, and thus a standard can diameter system was developed (**Table 1** shows the standard diameters of round cans in both imperial and metric units). Therefore certain can dimensions have been commonly used for certain capacities of cans. The nominal size of round cans is given as diameter × height. The dimensions of rectangular cans are given as three sets of numbers: the first two sets are base dimensions, and the third is the height dimension. The units conventionally used are millimeters for metric units; imperial dimensions are given in three digits: the first digit is in whole inches, and the second two digits indicate 16ths of an inch. For example, a can designated as 307 × 403, is 3–7/16 inches in diameter and 4–3/16 inches in height. **Table 2** shows some of the more widely used cans for foods.

Metallic Materials

Tinplate is the material used more widely in cans for foods. The term tinplate refers to a low-carbon mild steel sheet with a coating of tin on each surface of the material (Figure 2a). The steel varies from around 0.12 to 0.5 mm in thickness. The thickness and hardness of the tinplate are selected as a function of the can size and format, as well as taking into consideration the mechanical solicitations during the thermal processing and handling. In general, the smaller the diameter of the can, the thinner the body wall and ends may be to withstand the imposed loads. Larger cans with thinner walls may be used if wall beading is provided. Double-reduced steel (steel that has undergone a second cold reduction before tinplating) also enables downgauging with no loss of performance. This steel has additional strength, but is less ductile compared with the single reduced plate, which may impose some limitations to the can-manufacturing process.

The tin coating is applied in weights from 1.0 to 11.2 g m^{-2}, with the same or different amounts of tin on each surface. Differentially coated tinplate is identified by marking a set of parallel lines, the line pattern being related to the differential weight combination. Normally, the pattern is applied on the more heavily coated surface, inside the can, where greater protection is needed. Figure 3 shows the tin coating weights used and, in the case of differentially coated steel, the pattern of marking lines.

The steel strip usually has a passivation treatment to render its surface more stable and resistant to the atmosphere, as well as to improve lacquer adhesion. Passivation treatment results in the formation of a top layer of chromium and chromium oxides and tin oxides. After the passivation, the plate is given a light oiling to help preserve it from attack and to assist the passage of sheets through container-forming machines without damaging the soft tin layer.

Tin-free steel (TFS) or electrolytic chromium-coated steel (ECCS) is low-carbon steel coated with metallic chromium and chromium oxides with a weight of around 80 and 20 mg m^{-2}, respectively (Figure 2b). The surface of TFS has a better adhesion to protective lacquer coatings or printing inks and varnishes than tinplate. It requires shorter times in curing enamels (since higher temperatures may be used, due to the lack of a low-melting-point tin

layer) but is less resistant to corrosion than tinplate. TFS is not used in three-piece cans, because it cannot be soldered by traditional techniques, nor in DWI two-piece cans because its hard and rough surface makes drawing operations in uncoated metal impracticable. Therefore, TFS is frequently used for can ends and DRD two-piece cans.

Aluminum is a light metal, easy to work throughout most of the conventional can-forming processes. Aluminum is used for two-piece containers only, DWI and singly or multiply drawn cans, but it is also formed into easy-open ends. Aluminum cans may also be formed by impact extrusion, this type of can normally being used for monobloc aerosols.

Aluminum body stock is available in a range of thicknesses from 0.25 to 0.30 mm, whereas end stock covers the range from 0.30 to 0.38 mm. Most commercial applications of aluminum require special properties that the pure metal cannot provide. Therefore, alloying agents are added to impart strength, improve formability, and influence corrosion characteristics. A wide range of alloys are commercially available for packaging applications, depending on the container design and fabrication method being used. The alloys are identified by four-digit numbers where the value of the first digit indicates the alloy type and the principal alloying ingredient. For example: 2xxx for copper, 3xxx for manganese, 4xxx for silicon, and 5xxx for magnesium. Series 1xxx represents aluminum with 99.00% or higher purity. Commercially pure aluminum (types 1100 and 1050) is used for the manufacture of foil and extruded containers since it is the least susceptible to work hardening. For rigid packaging, the alloy elements used are manganese and magnesium (alloy types 3004 and 5184). When the aluminum surface is exposed to the atmosphere, a layer of aluminum oxides is naturally formed, which protects the metal from further oxidation. This self-protecting characteristic gives the aluminum its high resistance to corrosion, unless it is exposed to some substance that destroys this passivation layer. Aluminum will corrode on contact with products with a pH lower than 4 or higher than 9, and when used for manufacturing cans for food and beverage products, it is always coated with a organic lacquer in the internal surface.

Manufacturing Processes

Steel and aluminum are initially in coil form, so sheet cutting is often the first manufacturing process. This operation can be performed by the can-maker if coil cut-up lines are available in the plant. Otherwise, material must be acquired already in sheet form. Sheets to be used for the production of can ends or round DRD cans are scroll-cut (Figure 4). This is a method used to cut coil into sheets in a pattern, which reduces metal wastage. It enables circular blanks to be packaged more densely: skeleton scrap is reduced by a third compared with straight-cut sheet.

Three-piece Cans

Starting with metal sheets, rectangular in format and with dimensions suiting the can body size (Figure 5a),

the sheets are coated on the side that will become the internal surfaces of the finished cans (Figure 5b). This special lacquer protects the can itself from corrosion and limits the interaction between the contents and the metal. However, welding margins should be left uncoated since the polymeric nature of the lacquer would influence the electric current passage through the metal (see details below). The lacquer is cured as sheets pass in an oven (Figure 5c). The sheet may also be printed for decoration on the other side, unless a paper label is to be used.

The sheets are fed into a slitter, where they are cut into body can blanks (Figure 5d). The blank is then fed to the forming rolls, which generate a cylinder with the edges of the side seam (Figure 5e). The cylinder edges are welded by squeezing them together whilst passing an electric current through them (Figure 5f). This heats up the metal sufficiently for a sound join to be made. To protect the weld seam, a coating is applied immediately after the can body exits the welder, in both sides of the side seam (Figure 5g). Powder coating is usually applied electrostatically to the interior of the side seam.

The cans are passed through a flanger, where the top and bottom of the can are flanged outwards to accept the ends (Figure 5h). Ends, produced elsewhere, are seamed to the can bodies to close one end (called the 'maker's end') of every can (Figure 5i).

Depending on the can design, cans are passed through a beader, where the walls of the cans have circumferential beads formed (Figure 5j). Beading of the can body wall, although reducing the top-load resistance of the can, allows for a reduction in wall thickness without sacrificing paneling performance.

Testing is performed with high-pressure air to detect pinholes and poor seams on every can, and the finished can bodies are then transferred to the warehouse to be automatically palletized before delivery to the filling plant.

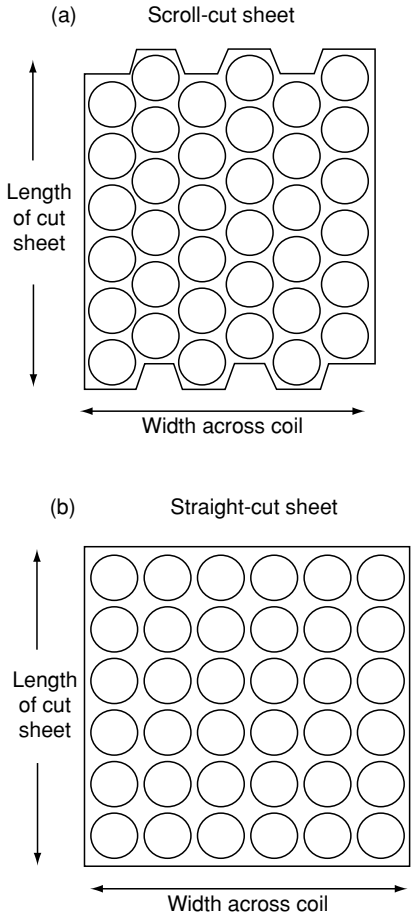

Figure 4 Comparison between scroll and straight cut sheet.

DWI Two-piece Cans

Aluminum or steel coil (Figure 6a) is lubricated with a thin film of oil and then fed continuously through a cupping press (Figure 6b), which stamps and draws disks into cups at a rate of more than 1500 cans per

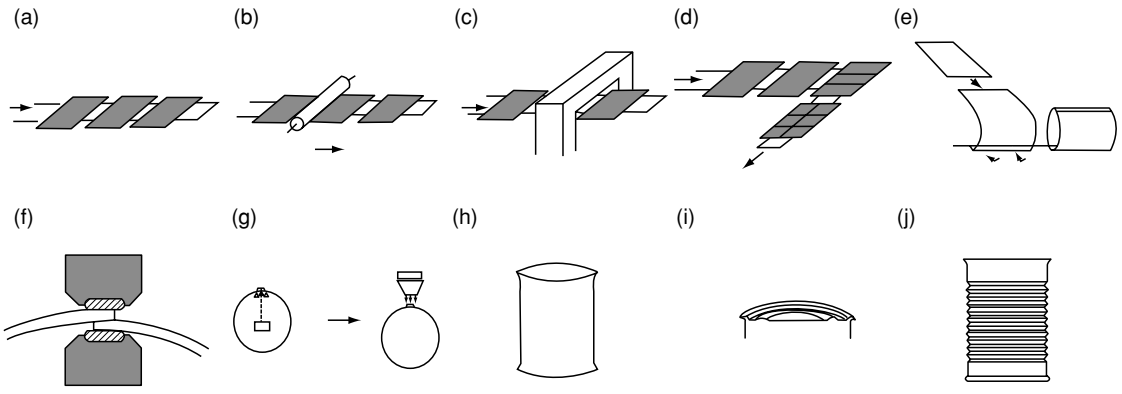

Figure 5 Three-piece can-manufacturing process.

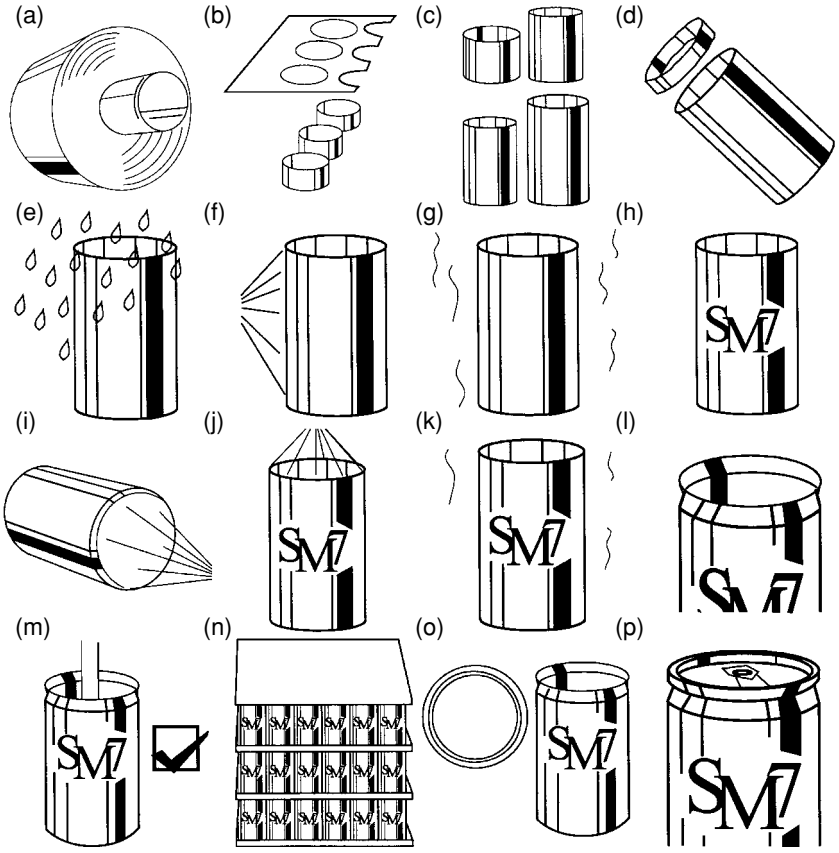

Figure 6 Two-piece DWI can-manufacturing process.

minute. Each cup is rammed through a series of tungsten carbide rings for drawing and ironing. This process redraws the cup to smaller diameter and thins the walls, whilst increasing the height leading to untrimmed cans (Figure 6c).

Trimmers remove the surplus irregular edge and cut each can to a precise specified height (Figure 6d). The trimmed can bodies are passed through washers (Figure 6e) for removal of all traces of lubricant and then dried in preparation for internal and external coatings. The clean cans are coated externally (Figure 6f) with a clear or pigmented base coat, which forms a good surface for the printing inks. The cans pass through a hot air oven to dry the lacquer (Figure 6g).

The next step is the application of the print design in up to six colors, and a varnish, by a highly sophisticated printer/decorator (Figure 6h). A coat of varnish is also applied to the base of each can by the rim coater (Figure 6i). The cans pass through a second oven, which dries the ink and the varnish. Spray machines apply an internal coating of protective lacquer (Figure 6j) to maintain product quality, and the cans are then dried in the final oven (Figure 6k).

The cans are passed through a necker/flanger (Figure 6l), where the diameter of the body is reduced (necked in), and the tops of the cans are flanged outwards to accept the ends after the cans have been filled.

Every can is tested at each stage of manufacture. At the final stage, they pass through a light tester, which automatically rejects any can with pinholes or fractures (Figure 6m). Cans are then moved to the warehouse for palletizing and delivery to the filling plant together with the ends.

DRD Two-piece Cans

This process is similar to the DWI process, except that the final height and diameter of the container are produced by sequentially drawing cups to a smaller diameter, i.e., causing metal to flow from the base to the wall of the container rather than ironing the container wall. The wall and base thickness of DRD cans, as well as the surface area, are identical to the original blank, as opposed to the DWI cans, where the wall thickness is much lower than the base thickness (Figure 7).

The process starts with blanking and cupping, in which cups are produced from prescrolled sheets, lacquered, and/or decorated. The cups then go

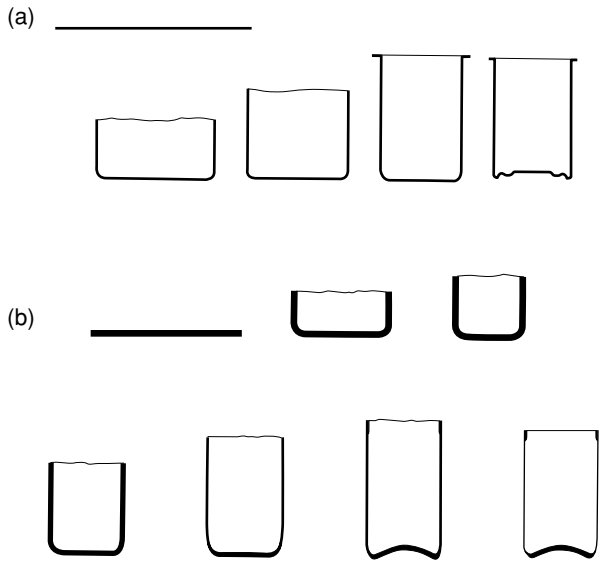

Figure 7 Comparison between (a) DRD and (b) DWI processes. From Bakker M and Eckroth D (1986) *The Wiley Encyclopedia of Packaging Technology*. New York: John Wiley with permission.

through the first drawing operation, where they are drawn by a punch through a die. The cups produced at this stage may undergo a similar redraw process for further diameter reduction as the height is progressively increased (Figure 7b).

There is a linear relationship between the maximum height to which a container can be drawn in a single operation and its diameter. The taller the can, the more drawing operations are required. Also, single-reduced steels can be drawn more than double-reduced, which can be used in lower gauges for the same strength.

The bottom end is the thickest region and governs the material gauge, often resulting in an excessive side wall thickness. Typically, a prelacquered tinplate and TFS with a thickness of 0.2 mm, is used for the DRD process. DRD cans are currently used in the packaging for food rather than beverages, where a greater wall thickness is required to withstand pressure reversals. The body is beaded, and TFS is used more than tinplate because a better enamel adhesion is achieved with the former.

Ends

The can end is designed for optimum deformation behavior during the food-heating process, thereby preventing permanent distortion: it should resist the high relative internal pressure achieved in the heating process that tends to deform the can ends outwards, and it must also be sufficiently flexible to return to its original profile as the internal pressure becomes slightly negative inside the processed can. This behavior depends on

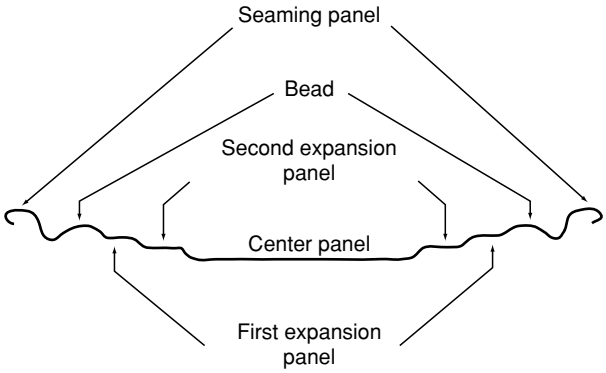

Figure 8 Can end profile.

the metal thickness, the profile of the expansion rings, and the countersink depth (Figure 8).

The scroll-cut sheet, previously lacquered, is fed through a press that stamps the ends. After stamping, the edges are curled and passed through a lining machine, which applies a precise amount of a sealant compound around the inside of the curl. This sealant assists the formation of a hermetic seal by providing a gasket between adjacent layers of metal in the double seam.

Easy-open ends are produced, from a previously stamped shell (Figure 9a), in a press comprising four basic operations: a bubble-like structure is drawn (Figure 9b), a cylindrical button is drawn from the bubble (Figure 9c), the score line is performed (Figure 9d), and the tab is attached at the rivet station by compression of the button, the tab being formed on a separate operation (Figure 9e). In this way, the tab is affixed to the end without any loss of end integrity. Figure 9 illustrates the basic operations.

Double Seaming

The end is joined to the can body by a double-seaming operation that is carried out in two stages (Figure 10): in the first operation, the end curl and the body flange are brought together and rolled inwards so that the end hook is well tucked up underneath the body hook. The shape of the seaming roll determines the contour of the seam at the end of this stage; in the second operation, the seam is tightened by a second set of seaming rolls. The final quality of the double seam is defined by its length, thickness, and the extent of the overlap of the end hook with the body hook (Figure 11). Rigid standards are laid down for an acceptable degree of overlap and seam tightness.

Welding Side Seams of Three-piece Cans

The side seam is made by a resistance-welding process, using the lost-wire-electrode principle. After the can body blank has been formed into a cylinder over

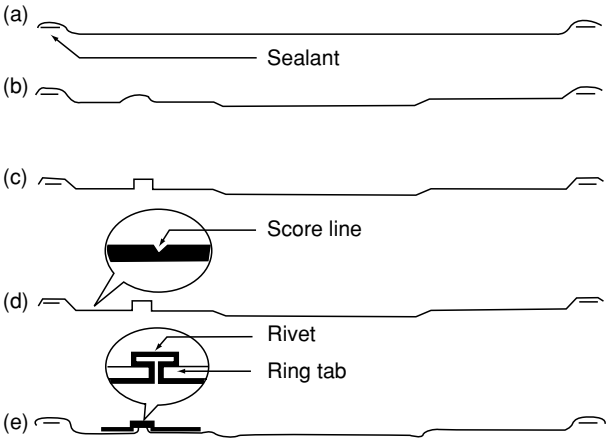

Figure 9 Easy-open end production.

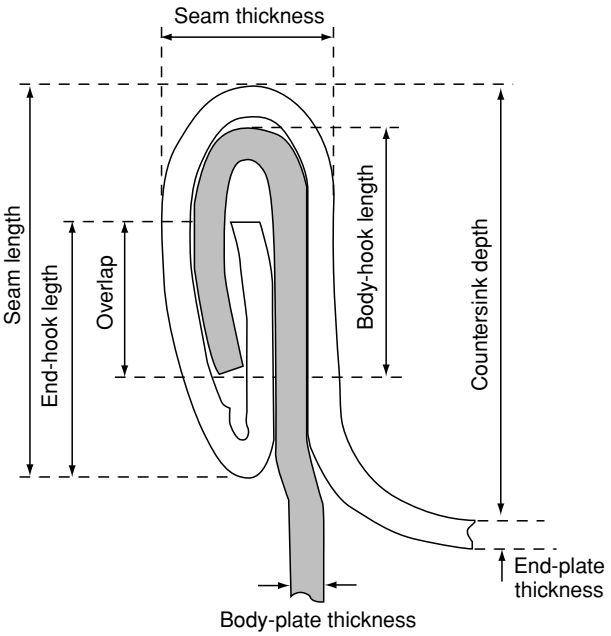

Figure 11 Main components of a double seam.

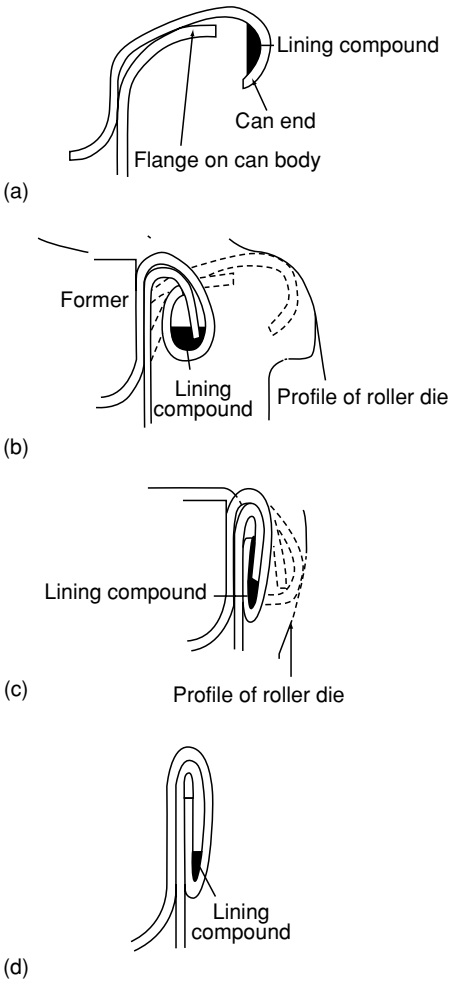

Figure 10 Double-seaming: (a) and (b) first seaming operation; (c) and (d) second seaming operation.

the welding arm, the overlapping seam (0.4 mm for most cans) passes between two copper weld rolls where the weld is formed (Figure 12).

The two layers in the seam are squeezed together between the upper weld roll located outside the can body and a smaller-diameter inner weld roll. An alternating current is passed to the upper roll, and high electrical resistance causes the interface temperature to rise rapidly to at least 900 °C, resulting in solid-phase bonding. As the can body moves continuously between the two weld rolls, a spot weld is created at each peak of the alternating current. By adjusting the frequency of the current to the linear speed of the can body, the correct number of spot welds per unit of can length can be achieved. In a good weld, the individual spots should merge into a continuous weld. Although the welded seam is free from the danger of lead pick-up, the weld has to be effectively coated to prevent any traces of iron being picked up by some types of beverages and acidic foods. The external side of the seam is also coated for protection.

Protective Organic Coatings

The primary function of interior can coatings, enamels or lacquers, is to prevent any interaction between the can and its contents, although some enamels have special properties, and others are used merely to improve the appearance of the pack. Exterior can coatings may be used to provide protection against the environment, as well as for decoration and product labeling.

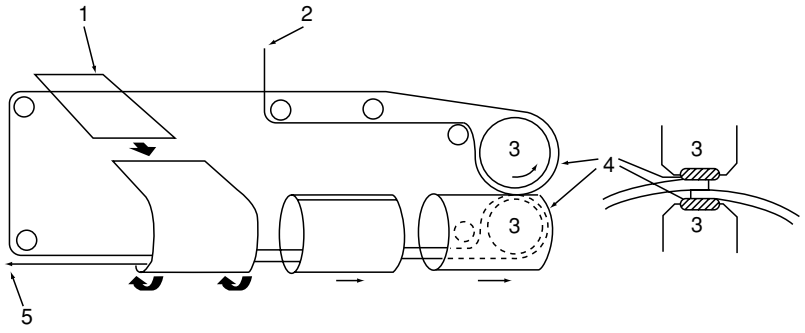

Figure 12 Welding side seam of a three-piece can: 1, blank feed; 2, wire fed; 3, welding rolls (electrodes); 4, copper wire (welding contact); 5, used wire. From Bakker M and Eckroth D (1986) *The Wiley Encyclopedia of Packaging Technology*. New York: John Wiley, with permission.

Internal lacquers must be inert, must provide a good barrier, and must also have a good mechanical resistance, as well as thermal resistance if the product is to be thermally processed. The lacquer must comply with the regulations for materials intended for food contact, i.e., only approved substances that had sustained successful migration or extraction tests and that do not impart any flavor to the contents, may be used.

The barrier provided by the lacquer depends on its chemical composition and on its porosity (which must be as low as possible) and which in turn depends on the thickness of the lacquer. Control of the amount of lacquer applied, usually measured in terms of the mass of dry film per area of metal sheet, is very important since a thin layer will not cover the surface completely, and a layer that is too thick will lead to brittleness, lack of flexibility, and poor adhesion, as well as being uneconomical.

The lacquer must be resistant to mechanical solicitations during can and ends manufacturing operations, as in the case of three-piece cans and most DRD two-piece cans that are produced from a precoated metal sheet. Flexibility and adhesion are also important characteristics of lacquers, as during retorting, the can tends to deform, due to a pressure imbalance.

The lacquer is usually applied by roller coating to the metal in the flat form sheet or coil before fabrication. Spraying is used for coating the internal surface of DWI two-piece cans that cannot be produced from prelacquered sheets, owing to the considerable amount of metal deformation and surface disruption occurring during ironing operations. Powder coating, where the resin is applied dry in the form of a fine powder, usually under the direction of an electrostatic field, is used for the protection of welded side seams (internal side), where heavy coatings are required. A postfabrication repair lacquering is applied to cans used to pack products with very demanding protection requirements, to compensate for natural application imperfections and layer damage during can fabrication.

After application, the lacquer must be dried by solvent removal, oxidation, and/or heat polymerization. This process is usually performed in a forced convection oven using hot air up to 210 °C for up to 15 min. Recent developments include resin formulations, which need lower temperatures and shorter curing times, often through the use of ultraviolet radiation (these ultraviolet-curing resins are virtually solvent-free).

The more common chemical families of protective lacquers are the phenols, epoxy, polyesters, and vinyl. The resins are rarely used pure. They are modified and/or combined with other resins and additives that confer specific characteristics. Table 3 summarizes the major lacquers' characteristics and applications.

Phenolic resins are produced by the action of formaldehyde on phenol and are characterized by having a high degree of reticulation enhancing barrier, hardness and chemical inertia, but limited flexibility due to the presence of the bulge phenolic ring.

Epoxy resins are produced by polymerization of bisphenol A with glycerol epichlorohydrine. Epoxy is highly reactive, allowing for combination with other resins, and it has a good chemical resistance. It is very flexible because of its linear structure, without reticulation, and it is often combined with phenolics giving the epoxy-phenolic family, one of the most widely used families of resins for lacquering. A three-dimensional structure is formed during curing, either by straight blending of a solid epoxy resin with a solid phenolic resin or by condensation of a mixture of two resins in appropriate solvents. Epoxy-phenolic lacquer combines the good adhesion properties of the epoxy resin with the high chemical resistance properties of the phenolic resin. The balanced properties of

Table 3 Application and characteristics of lacquers

Family	*Application*	*Flexibility*	*Adhesion*	*Resistance to heat-processing*
Phenolic	Fruits, vegetables, meat: very good barrier	Bad	Bad	Very good
Epoxy-phenolic	Wide use, can be pigmented with Al, ZnO; characteristics depending on formulation	Good	Good	Good
Vinylics	Beverages	Excellent	Good	Bad
Organosols	Large use in two-piece cans	Very good	Very good	Good
Acrylics	Pigmented with TiO_2	Good	Very good	Medium
Epoxy-urea	Beverages	Good	Good	Medium
Polyesters	Pigmented with TiO_2	Medium	Good	Good

epoxy-phenolic coatings have made their use almost universal in food-can applications. Epoxy may also be combined with amines to produce epoxy-urea and with fatty acids to produce epoxy-esters.

Vinyl coatings are based on copolymers of vinyl chloride and vinyl acetate. They can be used with or without pigmentation, and they can be blended with alkyd, epoxy, and phenolic resins to enhance their performance. Their main disadvantage is the high sensitivity to heat and retorting processes, restricting their application to cans that are hot-filled and to beer and beverage products.

Vinyl organosol coatings are dispersions of PVC (homopolymer), sometimes reinforced with soluble thermosetting resins, such as epoxy or phenolic, to enhance thermal resistance and adhesion. Plasticizers are also added to aid film formation. These coatings are typically white due to the addition of titanium dioxide.

Polyesters have an excellent resistance to high temperatures and are often used for can external coating. When used for heat-processed foods, they are modified with phenolic resins and often white pigmented with titanium dioxide.

The choice of lacquer depends on the nature of the food and the can to be used. Products that contain sulfur-containing amino acids require sulfur-resistant lacquers to prevent staining of tinplate surfaces. Sulfur compounds may break down during heat processing to release sulfides, which react with tin to form brown–violet tin sulfide (SnS) that affects the global can surface or with iron to form iron sulfide (FeS) in spots where, due to lacquering and tin-coating imperfections, iron may be in contact with the food. These compounds do not affect the product safety or quality but are suspicious to the consumer. To overcome this problem, lacquers offering a good physical barrier, such as phenolic or epoxy-phenolic, are used. In addition, these are pigmented with zinc oxide, which reacts preferentially with the sulfur compounds, thus acting as a chemical barrier. Lacquers may also be pigmented with aluminum powder or white pigments, to obscure any tin sulfide that might be formed.

Acidic foods require a very good protection to prevent can corrosion. A vinyl organosol with a high thickness, pigmented with aluminum powder or titanium dioxide, or a double coating of epoxy-phenolic plus vinyl organosol may be used for this purpose.

Beer and other drinks susceptible to flavor contamination by metallic traces require very good protection as well. DWI cans are coated after fabrication, usually with two coats of lacquer: epoxy-phenolic plus vinyl, epoxy-urea plus vinyl or a double layer of epoxy-urea.

Recent Developments in Can Design

M de F Filipe Poças, Escola Superior de Biotecnologia, Universidade Católica Portuguesa, Portugal

Short History of the Can

Metal cans have been on the marketplace since the early nineteenth century, and this early-born packaging system keeps its relevant position in the food packaging area owing to constant developments and

innovation to meet the demands from the food and beverage industry, distribution, and the consumer. Recent developments in can design include lightweighting, shaping cans, double seams, the use of polymer coated metals, and new can opening features.

The start of the history of the can is attributed to Nicholas Appert as a result of the method he developed for storing and sterilizing food using glass bottles. This was followed by the registration of the first patent, by Peter Duran, for food processing using iron and tin containers. Since then, the modern can has evolved from a simple cylinder with two flat ends into a sophisticated package, with a design that incorporates features to improve performance, convenience, and appearance, as well as to reduce costs. Environmental protection has also played a role as a driving force in can design, particularly in issues related to the reduction of metal and energy usage, and air emissions and liquid effluents on can-manufacturing operations. Table 1 summarizes the major landmarks on food and drink can history, and Figure 1 shows, as an example, changes in Coca-Cola beverage can design over decades. These include changes in the easy-open end, can body neck-in, and innovations in can shape.

Table 1 Brief history of can making

Period	*Innovation*
1809	Nicolas Appert wins Napoleon's prize for his method of processing food
1810	Peter Durand patents the idea of using tinplate for making a container
1853	The canned condensed milk is introduced
1900s	The first can with soldered side-seamed and double-seamed ends is produced
1930s	Cans for beer and soft drinks appear
1942	Electroplating for applying tin coating is introduced
1940s	The draw–redraw process is developed
1947	Draw-wall-ironing aluminum cans are introduced
1959	The Soudronic Company is founded (side-seam welding machines)
1962	Aluminum easy-open ends for beverage cans are produced
1965	Tin-free steel is available
1975	The Wima (wire mash) welding system is developed by Soudronic

Lightweighting

Lightweighting means the reduction in the amount of material used in the can-making process. This may be achieved at the expense of a reduction in the metal thickness and/or improvements in can construction, leading to savings on the metal sheet surface required for each can. Statistics show that lightweighting is a fact. For example, over the last 20 years, a typical 33 cm^3 steel beverage can has become on average 30% lighter (Figure 2). In general, the steel thickness of the can body has decreased by around 4.5 μm per year, and the steel thickness of can ends has decreased by 2 μm per year, i.e., a 40 and 18% reduction, respectively, in thickness over the last 20 years.

Downgauging has been possible through the use of double-reduced steels and through can wall beading. Double-reduced steel has suffered a second cold-reduction process, between annealing and tinplating, where the thickness is reduced by about 35%, whereas the elastic limit of the steel has increased to more than 500 $N\,mm^{-2}$. Therefore, double-reduced steels have additional strength although at the expense of their ductibility and formability properties. This process allows for a 3/100 mm reduction in steel thickness without compromising mechanical performance. Double-reduced steels have been used for can bodies and more recently for can ends.

Beading has the effect of reinforcing the side wall, thus allowing for a reduction in metal thickness without compromising paneling performance. The

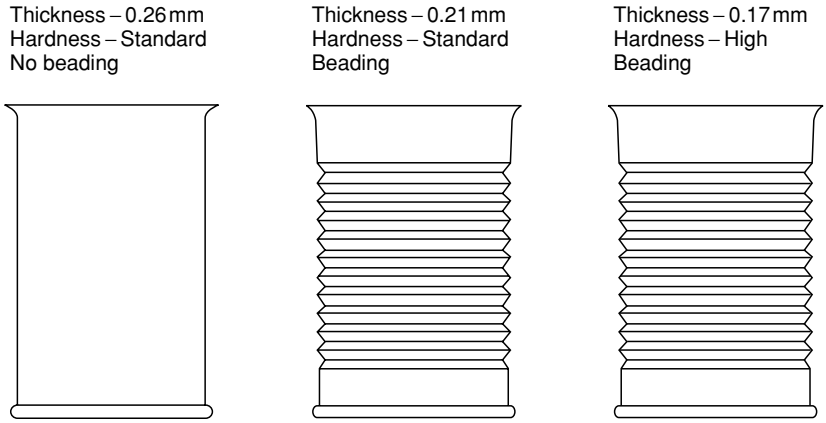

Figure 3 Relationship between beading and metal thickness and hardness in can design.

retorting process of thermal processed food induces positive and negative pressures within the can at different stages. The can must withstand high internal pressures that occur when the product is heated, this resistance being mostly conferred by the expansion rings of the can ends. It must also withstand external pressure to paneling owing to the pressure difference during the early stages of retorting, while there still is a slight vacuum inside the can, and the steam pressure acts outside the can. Circumferential beads on the walls greatly increase can resistance to implosion. However, beading also reduces the resistance to vertical load, which is important during filling, storage, and handling, and so a compromise between beading profile, pitch, and depth must be achieved. Beading, thickness, and hardness of the metal sheet are three variables that the can designer may use to optimize the can performance. Figure 3 shows how these three factors can be combined in the design of a specific can.

Beading was first introduced in 1970 and was commonly used in 1975–80. More recently, a new beading design was developed by Hoogovens and Impress Metal – The Varybead (Figure 4). This design has a constant bead depth of 0.4 mm and a varying bead pitch from 3.67 mm at the extreme ends of the 20 beads to 2.68 mm in the middle. The end beads control the mode of axial collapse, and the middle smaller beads maximize the paneling resistance.

Aluminum drink cans have also been reduced in weight. The number of cans produced from a kilogram of aluminum increased by 35% between 1975 and 1995. Figure 5 shows the net weight of aluminum required to make 1000 cans from 1990 to 2000. Lightweighting has been possible by decreasing the starting gauges of the aluminum coil (Figure 6), by improvements in the draw-wall-iron process, and by using smaller diameter can ends, which is related to the can body neck-in. Downgauging of the aluminum coil requires refinement in dome design as the starting gauge of the metal determines the can bottom dome thickness, critical to the performance of the can in terms of its resistance to internal pressure.

Double Seam

A double-seam fixes the end to the can body and provides a hermetic seal. It is one of the most critical elements in the safety of canned shelf-stable foods, and great effort is devoted to controlling the double seam dimensions, in compliance with rigorous standards and tight tolerances.

Developments to reduce costs have led to smaller seam profiles. The Microseam was developed by Kramer in Brazil, and has a structure similar to the conventional double seam. However, the dimensions of the seam height, body, and cover hooks are 50% of a conventional seam. The design is only possible when using double-reduced steel (0.16 mm or less) for can body and ends. When applied to a 73-mm-diameter three-piece can, it allows for the end diameter before seaming to be reduced from 88.5 to 81.5 mm, and the blank body height to be reduced from 98.7 to 93.5 mm (Figure 7). The main advantages claimed

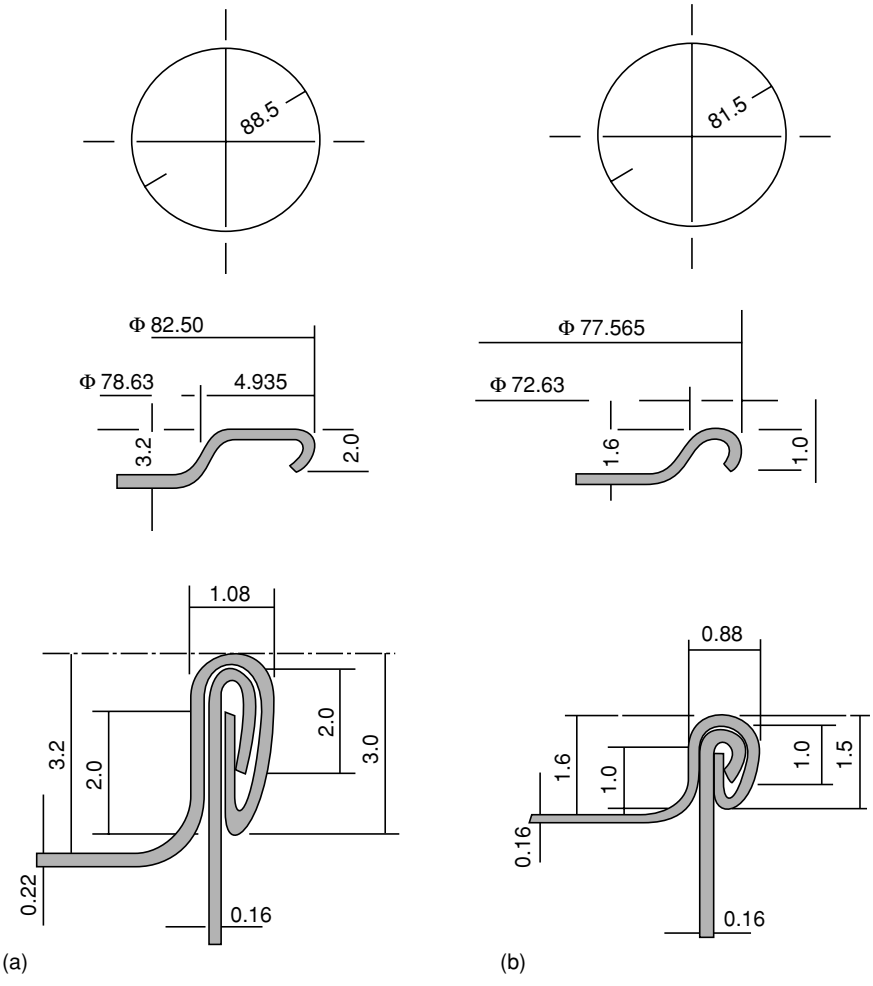

Figure 7 Comparative dimensions of (a) conventional and (b) microseam three-piece can double-seam. From The CanMaker September 1992, Copyright 1992 Mayo Sayers Ltd. Reprinted with permission.

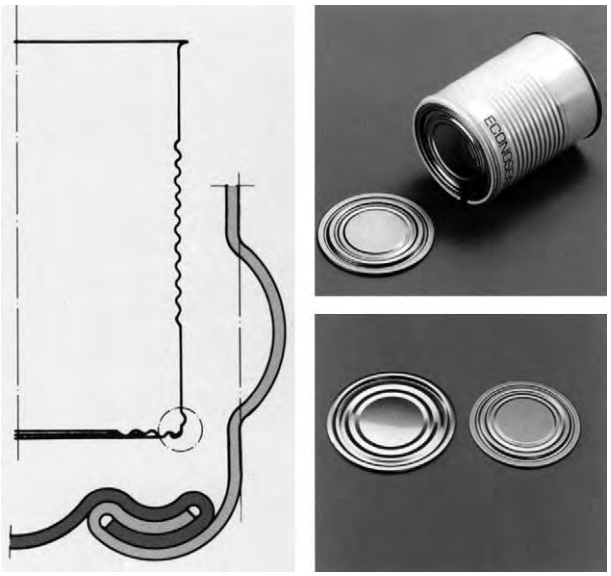

Figure 8 Novel seam design – Econoseam.

Figure 9 Hexacan with honeycomb beading. From The Can-Maker January 1997, Copyright 1997 Sayers Publishing Group Ltd. Reprinted with permission.

are a stronger marketing appeal, metal savings of around 15%, depending on the can diameter, and a significant cutback of end sealing compound. Tests have shown no significant differences in the performance between cans closed by the conventional double-seam and those closed by the Microseam. More recently, Alcan has also developed smaller seam designs, using specifications similar to those developed for Microseam, but for beverage aluminum can ends: Mini and Reduced seams.

The Econoseam is another novel seam design developed by Krupp (Figure 8). This is a method of seaming in which the folds are made in the horizontal rather than in the vertical plane. The material consumption for can ends to be fixed through Econoseam is around 28% lower for 73-mm-diameter cans, as compared with conventional seams. Besides metal savings, the elimination of the base rim may be an advantage in preventing transit damage resulting from rim-riding impact. However, this design did not achieve widespread acceptance in commercial terms, because of competition with two-piece cans.

Shaped Cans

Recently, new styles of cans appeared in the market. Odd-shaped cans were developed because of marketing factors, as their novelty leads to product differentiation. However, other issues such as material saving and performance improvements are also behind innovations regarding shaping cans.

As mentioned previously, beading provides extra strength to the can wall. Although circumferential beads are commonly used, other beading designs have been developed. The honeycomb beading (Figure 9) is claimed to offer at least 15% material savings, because it supports thinner gauge steel at all levels of performance. These cans are marketed as Hexacan and are commercially available in diameters of 73, 83, 99, 127 and 153 mm.

Another enhanced can design is the fluted can. The food steel three-piece can developed by CMB Foodcan in the early 1990s and designated as the Quantum can is an example of a fluted can. It has vertical body flutes that act as a support to provide a strong, high-quality, thin-walled can, with enough elasticity to withstand the expansion and contraction stress experienced during the product thermal treatment (Figure 10a). More recently, Anheuser-Busch developed a similar design for aluminum beer cans. This development was marketing-driven, since the fluted can assists in product differentiation (Figure 10b).

Shaped aluminum draw-wall-ironed cans often require thicker starting metal gauges, as in the case of the 500-ml beer-glass-shaped can of Heineken beer. The can is manufactured by CMB UK, using the high-pressure gas expansion technique. The can is produced in a conventional manufacturing line and then expanded in the radial direction at the top and bottom to form a shape common to glasses used for drinking beer. The shape, together with the printed decoration showing a typical gold yellow beer color with white foam on the top, yields an attractive and different image (Figure 11).

Figure 10 Two examples of fluted cans. From The CanMaker November 1992 and January 1998, Copyright 1998 Sayers Publishing Group Ltd. Reprinted with permission.

Figure 11 Beer-glass-shaped can. From The CanMaker June 1997, Copyright 1997 Sayers Publishing Group Ltd. Reprinted with permission.

Another marketing-driven innovation on can design is the Coca-Cola contour can, a bottle-shaped two-piece aluminum can (shown in Figure 1). The can's external dimensions are similar to the industry standards, thus requiring no significant changes in filling lines. The can is higher to compensate for the loss in volume resulting from the ribbed body. The can requires 15% more aluminum to impart the strength required during the filling and seaming operations.

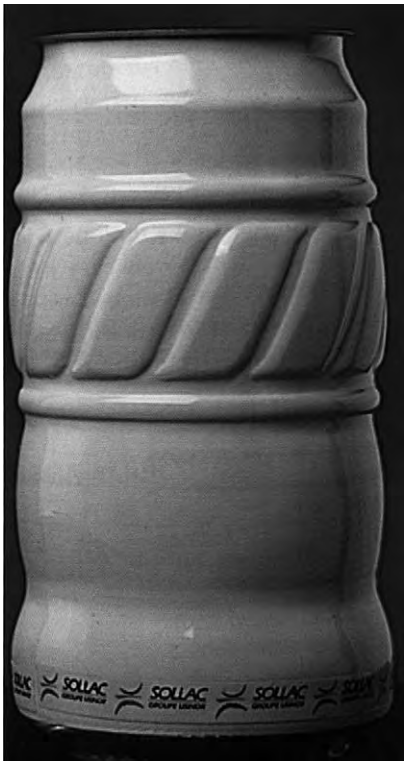

Figure 12 New shaped steel can-making process from Sollac. From The CanMaker September 1998, Copyright 1998 Sayers Publishing Group Ltd. Reprinted with permission.

Sollac has recently launched a new shaped steel can-making process – the full body necking process. Unlike other can-shaping systems, this process uses standard gauge steel and centers on a necking process that first reduces the diameter of a standard can, which is then expanded into the desired form (Figure 12). The finished can shape is formed by high-pressure water jets forcing the reduced can diameter out into a shaped mold. The major advantages of this process are claimed to be the possibility of fitting into the existing draw-wall-ironing production lines whilst maintaining identical productivity, no increase in the quantity of steel, and costs similar to those of straight-walled aluminum cans.

Can performance may also be optimized by using a design that allows for a greater amount of product to be packed. The Caronde can from Carnaud Metalbox (Figure 13) is one such example. This can is manufactured from a cylindrical can body wall, which is shaped into a squared body, affording around 18% more volume of product.

The stackability of three-piece cans is a feature introduced only recently and is becoming increasingly important, because of the risk of products tipping over in retailers' displays. The design of the base of most two-piece cans and the typical neck-in in

Figure 13 Caronde can from CMB Packaging (France). Reprinted with permission.

Figure 14 Stackable three-piece can from Ferembal (France). Reprinted with permission.

two-piece drink cans allows these cans to be stacked. This does not apply to regular three-piece cans, in which the dimensions of the top and bottom of the can are the same, and so the bottom of the upper can does not fit in the top of the underlying can. The formation of a neck-in in just one end of the can reduces the diameter and allows that end to fit in the opposite end of the next can, thus forming a stable pile (Figure 14). Furthermore, the use of one end smaller in diameter contributes to a reduced can weight and hence reduced costs. Stackability and weight reduction are the major drivers for the increased use of neck-in in three-piece cans.

Polymer-coated Metal Cans

Changes in can coatings have been influenced by environmental legislation, food-contact legislation, and trends in can making. Laminates and extruded coatings are currently under development, some of them having already been introduced on to the market. These new types of can coatings imply new can-manufacturing technologies and are related to can design and decoration.

In laminates, the metal sheet is coated by lamination with prefabricated thermoplastic polymeric films. The metal substrate, whether tinplate, tin-free steel, or aluminum, is coated on both surfaces with one layer of polyethylene terephthalate (PET) or polypropylene (PP). The advantages of laminates over traditional wet coatings include the good properties for food contact and the negligible emission of volatile materials. Also, laminates confer an excellent appearance and abrasion resistance to the external layer, combined with very good barrier properties between the food product and the metal of the internal layer. Cost is the major drawback, and some laminates require the use of a tie adhesion layer (epoxy, phenoxy, or phenolic) between the PET and the metal substrate, which may raise problems regarding the suitability of the can for food contact.

Ferrolite is a laminate produced by Corus Packaging Plus under license from Carnauld Metalbox. The metal substrate (tinplate or tin-free steel) is heated before application of PET to the external surface of the steel and PP to the internal surface. PET film imparts a high resistance to abrasion and a glossy appearance, whereas PP provides a protective barrier between contents and metal. The system allows for different types of film, colors, and thickness to be applied to each opposite surface. The resultant composite sheet passes through a second induction heater, which melts the polymeric films. After holding for a few seconds at high temperature (260 °C), the

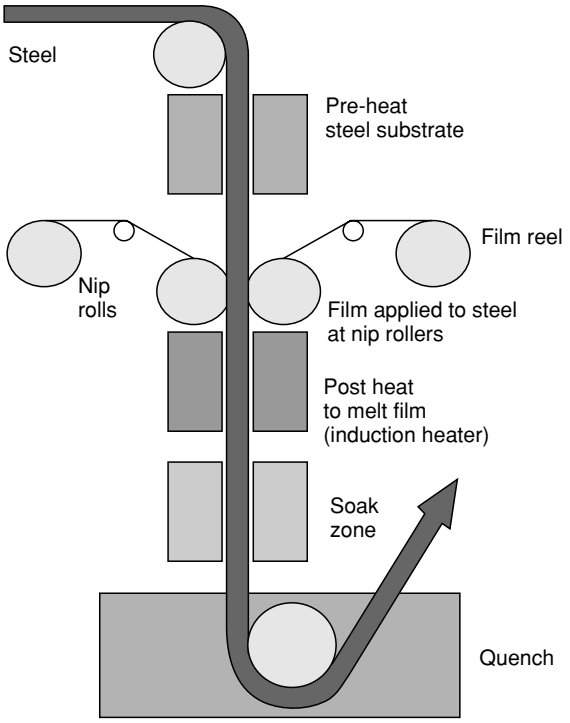

Figure 15 Ferrolite-producing process.

composite sheet is cooled down by quenching in controlled conditions in a water bath (Figure 15).

The other major laminate, Andrafol, is produced by Toyo Kohan (Japan). This is a tin-free steel laminated with PET and/or PP. The polymeric film may also be combined with lacquer on the opposite metal surface. The production system has three alternative methods for application of the polymeric film. The first method is a solvent-free process, where the PET film is thermally laminated (as described earlier for Ferrolite). The second method uses a PET film to which a tie layer was previously applied, promoting adhesion between the PET and the metal surface. Alternatively, the adhesive may be applied to the metal surface prior to laminating the polymeric film. When lacquer is used in one surface, this is applied by a roller system. The lacquer must be dried and cured in an oven.

Polymer-coated steel is used for steel aerosol components, such as tops, bottoms, and valve cups, but also for food and beverage applications. In this segment, it is used for easy-open ends and for containers such as food trays and drink cans. Food trays in polymer-coated steel are microwaveable, strong, and remain rigid when hot. Fabrication of two-piece drink cans from laminated steel requires specific technologies, but developments in this area have led to a considerable growth on the interest for this new type of cans.

Figure 16 RBS cans and TULC can. From The CanMaker November 1998 and June 1997, Copyright 1998 Sayers Publishing Group Ltd. Reprinted with permission.

The TULC can (Toyo Ultimate Can) and the RBS can (Redicon British Steel) are examples of this type of cans. The TULC can is a development of Toyo Seikan Kaisha, and it has been on the Japanese market since 1992, currently representing around 14% of the Japanese can manufacturing market. The RBS can was launched by Corus Packaging Plus and Redicon Corporation in 1997 (Figure 16). These are two-piece cans made from PET laminated tin-free steel, in the TULC case, and from Ferrolite, in the RBS case. The cans are produced by a draw–stretch–redraw technique, an improvement on the draw–redraw process, in which body-stretching operation is included. The RBS production line includes a mechanical body-shaping machine. Recent developments in the TULC can manufacturing process have led to the use of wall ironing, which implies considerable can lightweighting. Another recent innovation in the TULC can is the new wall design in a triangulated pattern (the Diacut pattern), which using slightly more material thus providing a much better resistance to denting and allowing for a global weight reduction. The polymer-coated steel cans weigh more than a regular draw-wall-ironing steel can, but further weight reductions are expected by producers of these cans.

Polymer laminated steel is also used for three-piece cans, as the Crystal can from the Japanese producer Hokkai. In this case, tin-free steel is coated on both surfaces with PET. The lamination requires an adhesive layer and therefore a curing operation. The sheets are cut into can body blanks and welded. The external layer of PET is preprinted with a high-definition decoration, providing a very appealing image.

An alternative to laminated metal, using a polymer coating, is extrusion coating. This technology is commonly used in other areas of the packaging industry, such as polyethylene extrusion coating of paper and paperboard. In extrusion coating, the polymer is

extruded and applied, in the melted state as it leaves the extruder die, on to the metal substrate. Advocates of this technology claim that, compared with the laminates, extrusion coating has the following advantages: thinner coatings, a wider range of materials available, better adhesion and flexibility, and lower costs. This technology is, however, still under development and, besides some unsolved issues such as can decoration, still lacks consolidation and proven results at the industrial level.

Alcoa has been developing its Flex-Coat extrusion coating system, devoted to aluminum coating for beverage draw-wall-ironed cans. Hoogovens developed the Protact, a multilayer coated steel intended for aerosol components, full aperture easy-open ends, and twist-off caps, although applications in shallow cans and trays are also expected. The composite has three layers of polymer on each side of chromium-coated steel applied by coextrusion. The top layer provides wear resistance, gloss, and ink adhesion, the center layer gives strength and coloring, and the third layer provides adhesion to the metal substrate.

Can Opening

One of the most remarkable features introduced in metal cans is the easy-open end. Easy opening is considered by consumers to be a major advantage and marketing argument for the metal can, and its rate of use is increasing. Easy-open ends are of two broad types: those that provide a pouring aperture for dispensing liquids, used in beverage cans, and those that give a full aperture to remove solid products, used in food cans.

The ring-pull easy-open end for drink cans was first introduced in 1962. The tab was detachable, causing litter problems. To overcome this, stay-on tabs were incorporated later on. Easy-open ends for food cans, full aperture ends, were introduced in 1965. The first ends were made of aluminum (since this is an easily workable material), and only in the middle of the 1980s were steel easy-open ends being widely used.

The importance of this feature in selling cans has led producers to invest great effort and economic resources in optimizing the concept. Easy-open ends must accommodate a compromise between easy opening and resistance during the product's thermal processing and can handling during the distribution operations. Balancing these opposite requirements is a technical challenge, and the design of an easy-open end includes several aspects that should be precisely detailed:

- the levering tab (produced separately and attached to the end) should not be too hard to lift for breaking the can end (initial pop); the tab ring should also allow easy access to the consumer's finger at the peeling back stage;
- the rivet formed in the end panel through which the tab is attached without loss of the end integrity; if the rivet is not strong enough, when peeling the end, the consumer might remove the ring without opening the can;
- the panel profile that is responsible for the end behavior both during the thermal processing (providing the required reversible deformation) and when peeling off the end; and
- the score line that allows for the end to be torn off; the depth of the score line has very tight tolerances, as it controls the force needed to tear the end off but also constitutes a weak region of the can.

Current developments and improvements focus on making ends safer and easier to open (that is avoiding sharp edges that might hurt the consumer and requiring less effort to open the can) while maintaining the required mechanical strength and reducing cost by reducing thickness and diameter.

The Eole II from Carnauld Metalbox Food, the Top Can from Impress and the Meteor from Usinor Packaging are some examples of recent developments in steel easy-open designs for food cans. The first two are manufactured from single-reduced steel, and the last is produced with double-reduced steel.

Eole II is an update of the Eole first version, and the producer claims that improvements in the panel design and in the score line profile have led to an end that is 30–40% easier to open, with equal or better performance in mechanical and seaming load tests. The initial pop force required is lower, and the size of the finger well is larger for easier access. The Eole family of ends is supplied with a printed diagram on the panel, to inform the consumer of the best way to open the can.

The Top Can follows a different philosophy: instead of reducing the initial pop force, the end is designed to reduce the amount of energy globally expended in the opening process (pop plus tear). The panel profile insures that the end does not bend during the peeling part of the opening process, which is claimed to reduce the tearing force. The total energy expended is reduced, even with an increased pop force.

The Meteor design uses double-reduced steel combined with a new method of producing the rivet. Producers claim that this allows for an increased ease of opening, and for the possibility of reducing the thickness of the end without compromising strength.

In the beverage area, Crown Cork & Seal introduced very recently the SuperEnd. This new design is

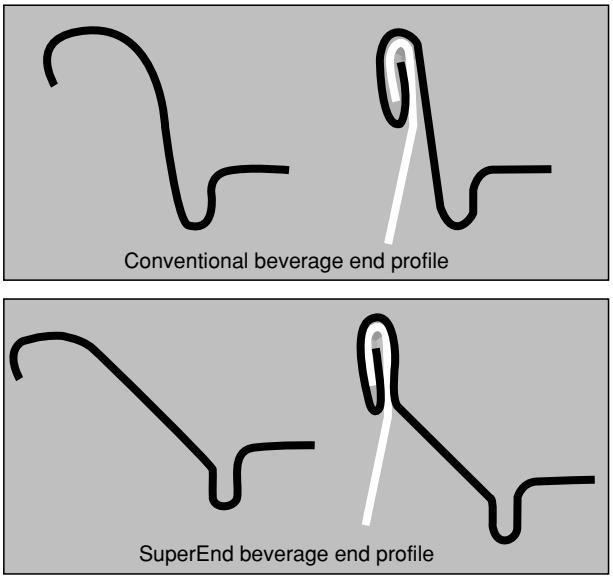

Figure 17 Recent developments in easy-opening. From The CanMaker November 1998, Copyright 1998 Sayers Publishing Group Ltd. Reprinted with permission.

claimed to provide a better seam integrity, to be stronger, to be easier to open and to drink from, and to have better pouring characteristics. Figure 17 shows the profiles of the current industry standard and that of the new end design, before and after seaming.

Other developments in cans opening and closing systems are resealable drink cans (screw-top cans) that allow closure between uses, and the peelable end, where a foil end is heat-sealed to a metal ring, which is then double-seamed on to the can body.

Food Handling

P Rutledge, Food Processing Consultant, NSW, Australia

Introduction

There is a large variety of affordable, canned foods available on supermarket shelves. These foods comprise the full range of the food groups which include meat, fruit, vegetables, cereals, and dairy products. Preparation methods and canning technology vary depending upon the product. Vegetables and fruits are canned directly after harvest and require washing, blanching, and sometimes peeling before canning. Meat, once it is butchered, is cut into chunks or minced, while cereals are often used as the ground flour.

Farm produce is generally seasonal and is only available for a matter of weeks each year. Canneries require enough produce during this short time to maintain stock in the supermarket from season to season. This means the scale of operation is in tonnes per hour for sometimes 24 h day^{-1} to process enough product while it is available. Mechanical handling and processing systems are essential under these conditions.

Preparation of Vegetables

Vegetables are normally mechanically harvested. Mechanical harvesters do not distinguish between the wanted vegetable material and other extraneous plant material and soil. Some of this is removed by fans and belts on the harvester before the crop is transported to the cannery. Cannery cleaning operations must be very thorough to removed the unwanted material and wash the vegetable.

Cleaning

The preparation of vegetables harvested from under the ground, such as carrots and potatoes, requires the removal of adhering soil and stones. Several systems are available to remove the soil, and they start with dry brushing or soaking to remove the bulk of the dirt, followed by washing. Washing involves wet scrubbing with rotary brushes or rubber fingers, followed by rinsing in a rod washer. In the rod washer, the vegetables are tumbled in a cylinder made from steel rods while being washed by water sprays from inside the cylinder. These vegetables are usually peeled in a subsequent operation, which insures a clean product.

Legumes, such as green peas and beans, are mechanically harvested and transported in bulk ready for

canning to the processing plant. Specialized equipment is used, for example, to carry out operations such as husking corn and breaking up clusters of green beans. Dry cleaning with air blowers to remove extraneous leaf material from this type of vegetable is followed by washing in tanks which removes mud balls and stones. Some systems use froth flotation cleaners to remove small pieces of vegetable material. A final rinse with water follows the cleaning treatment to remove the last of the soil.

Leaf vegetables, such as spinach, are difficult to clean as extraneous material lodges between the leaves. Leaves are cleaned by floating them in tanks of water where the water is agitated with air or water injection. This separates the leaves and removes the soil.

Inspection of the washed vegetable by instruments, such as color sorters or electronic sorters, at this stage will remove any remaining unwanted material. Manual inspection is still carried out where the removal of specific material cannot be achieved mechanically.

Peeling

Vegetable peeling may be by mechanical cutting or abrasion, by the use of high-pressure steam, or by chemical treatment. Abrasion peeling uses carborundum-covered rollers or disks which come in contact with the skin of the tumbled vegetable. The abraded skin is removed with water sprays. To remove material from depressions in the vegetable, some of the flesh of the vegetable is also removed with abrasion and, as such, gives the lowest yield of the three methods.

Vegetables are steam-peeled by holding them for a short time in high-pressure steam. This superheats a layer of tissue under the skin. When the pressure is suddenly released, the tissue explosively boils, releasing the skin from intimate contact with the vegetable. Typical conditions for steam peeling are 17 atm steam pressure for about 30 s. The skin is washed from the vegetable. This system is the most efficient in removing the skin and in yield of peeled vegetable.

A hot lye (sodium hydroxide) solution is used for chemically peeling vegetables and some fruits. It is important that the vegetable is thoroughly washed after peeling to remove all traces of the lye. The treatment varies depending upon the skin to be removed, but a boiling solution of 10% lye will remove most skins in less than 1 min. The skin is removed by rotating brushes or rubber fingers and water sprays. Caustic waste, both liquid and solid, has to be neutralized with acid before disposal, which increases the cost of peeling.

Slicing and Dicing

Cutting operations are used to supply the required size of vegetable for canning. Asparagus spears are sawn to the correct length for the can, and carrot and potato are sliced or diced to give an attractive piece of canned vegetable. Canned food in which the particles are of uniform size generally has a superior appearance to that with large variations in particle size. Some dicers are designed to give an irregular-shaped dice so the product looks home-made. The size and shape of the canned vegetable depend upon the style of pack that the market requires.

Preparation of Fruit

Washing

Generally fruit is more easily damaged than vegetables. Therefore, fruit is washed by submersion in tanks of water, which is agitated, followed by water sprays on the elevators as the fruit is removed from the tank. Rod washers may be used with fruit, such as citrus, which are not easily damaged.

Peeling and Pitting

Pome and some stone fruit require peeling and pitting before canning. Pitting is a mechanical operation, and each type of fruit has specialized equipment designed for pit removal. Mechanical apple and pear peelers remove the core section and skin before halving the fruit. Stone fruit that is peeled for canning is usually chemically peeled with lye followed by washing. Other fruit with stems, such as cherries, are rolled over sets of small rotating rollers which pick up the stems and remove them.

Blanching

Blanching is a heat treatment in a near-boiling water or steam followed by rapid cooling given to vegetables and some fruit. Blanching removes gases from within the tissue and softens the product. Blanching makes the product easier to fill into the can and to obtain the correct fill weight. The removal of the gas also reduces the oxidation of the product, maintains the vacuum in the can, and prevents excessive can corrosion.

Blanching gives the product another washing treatment and inactivates enzymes which may cause deterioration of the food. Enzyme inactivation is not as important for canned foods as it is for frozen foods, as canned foods receive a far greater heat treatment during thermal processing of the can. It can be important if there is a long delay between filling the can and retorting. Typical blanch times in near-boiling

water are 60–90 s for small objects, such as green peas and diced carrot, and up to 3 min for larger pieces.

Preparation of Juices

Juices are the liquid which may be squeezed from fruits and vegetables. The major methods of extracting juices are to apply a force to the whole or pulped material followed by screening out pulp from the resultant liquid. This can be carried out continuously in screw presses and belt presses, and there are many different types of batch presses. Citrus fruit is reamed on mechanical reamers or crushed in such a way as to remove the edible portion from the skin. Unwanted material is removed from the juice in paddle or brush finishers, or in some cases small screw presses. These machines push the juice through a screen while separating and removing the pulp which is too large to pass through the screen.

Citrus juice is pasteurized, which is a heat treatment of 95 °C, immediately after extraction to inactivate pectinase, which will cause the cloud in the juice to 'fall.' The cloud in the juice is held by naturally occurring pectin which, when attacked by pectinase, allows the juice to separate into a clear serum and a solid deposit. Conversely, pectinase may be added to other juices, such as apple juice, to manufacture a clear juice. If the juice is not hot-filled it will receive another heat treatment during the canning process.

Meat Preparation

Meat preparation, after slaughter and deboning, mainly consists of removing unwanted tissue such as fat, skin, and visible arteries. Meat shrinks by about 30% when it is cooked, so for formulated products using meat it is usually precooked before filling into the cans. Some meat products are corned, which means they are cooked with a cure containing salt and nitrite. Nitrite causes the meat to turn a characteristic pink color during heating and, because of its antimicrobial action, permits a less severe heat treatment during retorting. (*See* **Curing**; **Meat**: Slaughter.)

Fish such as tuna are cleaned and then steamed to allow for the easy removal of skin and bones. The steamed fillets are filled into a machine which shapes and cuts them to the can size before filling into the can. Other fish are cut to size and filled raw. Fish are canned with brine or oil or, in some cases, a formulated sauce. (*See* **Fish**: Processing.)

Preparation of Formulated Products

There is an infinite variety of formulated products from meat stews to dairy desserts, and beverages such as beer, that are canned. Most of these products are cooked or blended or brewed prior to filling. Those that are cooked in the preparation stage are filled into the can hot.

Carbonated products, such as beer and sparkling fruit juices, are filled at temperatures just above freezing to maintain the carbonation. Soft drinks, although they are often packed in metal cans, are not 'canned products' as preservatives are used to maintain their microbiological stability. (*See* **Preservation of Food**.)

Cans

Cans are delivered to the factory on pallets. The pallets are automatically unloaded into the can race system. This delivers the correct-size can to the can filler. Canning lines operate between 200 and 2000 cans per minute, so this system must work effectively. Cans may be contaminated so they are thoroughly washed prior to filling.

Filling

There are many types of machines used to fill cans, and the type employed depends, of course, on the product to be filled. Volumetric piston fillers can be used with liquid products and liquid products with entrained solids, such as mushrooms in butter sauce. A turntable is used containing several filling 'heads' so that several cans are filled sequentially as the turntable rotates; filler speed depends upon the number of heads. A slow filler might have 12 heads, while high-speed fillers have up to 72 heads.

Tumble fillers are used to fill solid materials, such as vegetable pieces, into cans. The washed cans move through a large rotating drum containing the pieces of product. The product falls into the can and excess is removed by tilting and shaking the can at the exit of the filler. Other volumetric fillers wipe the solid products into pockets on a turntable and the products are then dumped by gravity into the can.

Hand filling is used for products that are difficult to fill by machine. The filling of asparagus into cans can be carried out by machine but in some cases the tips are damaged, so some processors prefer hand filling.

Some products are canned with syrup or brine. This is a separate operation to filling the solid food. It may take place before or after the filling of the solids. Some solid products may have pockets of air held between the pieces and, in these cases, the liquid is added prior to filling the solids so the liquid will fill these spaces. Sometimes the cans are topped up after the solids are filled.

A head space must be left in the top of the can after filling. This small space is evacuated on closing, but is important to the integrity of the can. An overfilled can prevents the expansion of the product during the thermal process, which may result in permanent damage to the can end. Also the thermal characteristics of the can change, which may invalidate the calculated thermal process.

Exhausting

Oxygen remaining in the head space of cans accelerates corrosion of the tin plate in the head space area. To prevent this occurring, the volume of gas between the product and the lid of the can (known as the head space) must contain a partial vacuum.

The conventional system of exhausting the cans is to clinch the lid on the can. Clinching is a partial, first operation seaming roll which holds the lid loosely on the can. Exhausting is carried out by passing the filled cans with clinched lids through a steam-filled compartment for several minutes to heat the can contents and displace the air in the can with steam. This is immediately followed by the completion of the seaming operation.

Another method of exhausting is by filling the product hot into the can followed by hot brining or syruping which has the same effect as steam exhausting. This is followed by 'steam flow closing.' Steam is injected between the can and the lid as they come together in the can closer. This displaces the air in the head-space region. When the steam condenses, a vacuum is formed in the head space of the can.

Alternatively, mechanical vacuum pumps can be used to reduce the air in the head space of the can. This can be done during filling, as fruit may be vacuum-syruped by pulling a vacuum on the can and air is replaced by the incoming syrup. Some closers have a vacuum chamber in which the can is seamed. This is common in meat and fish canning, where the canning lines are slowed by the relatively slow operation of the vacuum closer.

Acid products, such as fruit juices, jams, pickles, and chutneys, may be filled into the can at near-boiling temperatures. The cans are seamed, inverted to sterilize the lid, and then cooled. This is called the hot-fill process. The vacuum results from the shrinkage of the product on cooling and the displacement of air by the steam from the hot product.

Can Closing or Seaming

The modern can closer also has a turntable similar to the filler where the cans are fed into a closing 'station.' The lid is aligned over the can and the baseplate of the station raises the can and lid to engage the top chuck. The seaming rollers then roll around the seam to form the seal. The rollers retract, the baseplate is lowered, and the closed can exits from the closer. Closers with four to six stations are common.

The seaming operation is carried out by two rolling operations. The first operation roller bends the two flanges together, and the second operation roller flattens them to form a seal. The seal is insured by a thin layer of mastic-like material deposited in the flange of the can end called 'compound.'

Rates of can seaming depend more on the speed of the filler than that of the can closer. Beverages which are easy to fill can be closed at speeds of 2000 cans per minute. New fillers for semisolid foods, such as pet food, allow closer speeds of about 1300 cans per minute and vegetables are often closed at 500 cans per minute.

Thermal Processing

There are two important factors in canning which make the food safe for long-term storage. Food is sealed to prevent recontamination, and it is heated to inactivate microbes which spoil the food. The seaming operation on the can hermetically seals the food, and the thermal process provides the sterilization step.

Products which have a pH of less than 4.5 are called 'acid foods' and can be thermally processed at temperatures less than 100 °C, which is called a pasteurization process. Those with a pH above 4.5 are called 'low-acid foods' and must be thermally processed at temperatures between 110 and 125 °C in a retort or pressure vessel.

Postprocessing Operation

Cans exiting from water-cooling operations are wet with chlorinated water and must be dried before they can be handled safely. Some canners label the cans directly after processing and other palletize the cans for storage before labeling. Lithographed cans do not require further labeling.

Can stores should be maintained at a temperature designed to prevent water vapor condensation which could rust the outside of the cans. The temperature must, however, not be too high as this can, on very rare occasions, promote the growth of heat-resistant thermophilic bacterial spores which may have survived the thermal process.

Cans are held by the canner in store until an incubation period has passed. This provides added protection for the customers as it insures that only safe wholesome food is placed in the marketplace. All

cans are packed in cardboard outers to prevent damage to the cans during transport and handling, and also as a convenient package for the supermarket.

Storage of Canned Food in the Home

Canned food should be stored in a dry cupboard. Most canned food is safe for at least 2 years, but care should be taken to use the oldest cans first. Stock rotation is important at home as well as in the supermarket.

Quality Changes During Canning

R J Pither, Campden & Chorleywood Food Research Association, Gloucestershire, UK

Introduction

Canned foods are a significant component of the diet of most individuals in developed countries, offering food in a convenient form with year-round availability. The canning process relies on heat treatment for the destruction of microorganisms and preservation of the food, which is then generally considered to have an indefinite microbiological shelf-life providing that pack integrity is maintained. The extent of the thermal processing, in terms of both temperature and duration of the treatment, is dependent upon the chemical and physical composition of the product. Both physical and chemical changes occur during processing and, to a lesser extent, during storage, and it is these that determine the product quality in terms of its sensory properties and nutrient content. These changes, which can be either desirable or undesirable, are influenced by the time and temperature of the process, the composition and properties of the food, the canning medium, and the conditions of storage.

This article will consider the changes that can occur during canning and their effect on the quality of the product.

Changes in the Sensory Properties of Foods

The sensory properties of a food, its flavor, color, and texture can all be affected by thermal processing. Changes in these properties may be in the form of direct effects of heat on food constituents (e.g., starch gelatinization, protein denaturation, and cell separation; see **Table 1**) or through heat-induced reactions such as the Maillard reaction. Significant changes in all three sensory properties can also be brought about by oxidation reactions that can occur, not only during processing, but also on subsequent storage of the canned product.

Oxidation reactions in fruits and vegetables occur mainly during preparation prior to processing, due to the effects of oxidative enzymes. Heat treatments, such as blanching prior to canning and the sterilization process itself, cause inactivation of these enzymes. Along with the low oxygen tensions in canned products, this limits oxidation in all but the most oxygen-sensitive constituents.

Table 1 The effect of heat processing on sensory quality

Chemical/physical reactions or changes occurring	*Impact on sensory attribute*
Flavor	
Volatile loss (scalping oxidation)	Loss of flavor
Volatile formation	
Maillard	Roasted flavor, bitterness
Oxidation	Rancidity
Pyracaines	Roasted flavor
Texture	
Cell membrane damage	Loss of crispness
Cell separation	Loss of firmness
Protein denaturation	Gelling, firming
Starch gelatinization	Gelling
Color	
Natural pigment breakdown	Bleaching Loss of color
Maillard reactions	Browning
Others, e.g., metals and polyphenolic compounds	Discoloration

Flavor Changes

The flavor of food can be retained, modified, or, occasionally, significantly changed during heat processing, with most of the changes seen occurring in the volatile flavor components.

Lipid Oxidation

Lipids occur in almost all foodstuffs, particularly meat and fish products, and lipid oxidation can therefore occur during canning of most foods. Saturated fatty acids are relatively stable at the temperatures used in standard canning operations. However, unsaturated fats are degraded, under the conditions of oxygen and heat, to a large number of volatile compounds, which give rise to both desirable and undesirable flavors. (*See* **Fatty Acids: Properties**; **Oxidation of Food Components**.)

The first stage of the oxidation reaction involves uptake of oxygen in the presence of catalysts, such as transition metals and hemoproteins, and is initiated by heat or light. Highly reactive hydroperoxides are formed, which undergo secondary reactions giving rise to a complex mixture of low molecular compounds, including aldehydes, ketones, alcohols, acids, alkanes, alkenes, and alkynes. A certain level of volatile compounds is generally considered necessary to give characteristic odor and flavor properties to many foods, but as many of the volatile compounds give rise to typical rancid or stale off-flavors, an ideal balance needs to be achieved in the food.

Maillard Reaction

In foodstuffs, reactions that occur between reducing sugars and amino acids or proteins are known as Maillard reactions. A very important aspect of the Maillard reaction in food preparation is the production of flavors and aromas. The rate of Maillard reaction increases with temperature, although pH and water content also influence the reaction. The Maillard reaction can be split into three main stages. The first is a condensation reaction between the carbonyl group of a reducing carbohydrate and the free amino group of an amino acid or protein, followed by rearrangement of the glycosylamines. These early Maillard reactions can lead to losses in protein quality but do not give rise to flavors in the food.

The second stage, the advanced Maillard reactions, involve many complex reactions and pathways. The rearranged glycosylamines can degrade via a multiplicity of routes, including dehydration, elimination, cyclization, fission, and fragmentation, which results in a pool of flavor intermediates and flavor compounds being formed. The flavors produced by the Maillard reaction can be classified into four main groups, nitrogen heterocyclics and cyclic enolenes, which give characteristic flavors to heated foods, and monocarbonyls and polycarbonyls, which include more volatile supplementary flavors not necessarily associated with product characteristics.

The final stage of the Maillard reaction is the polymerization of the highly reactive compounds formed in the second stage, which results in the formation of brown melanoidin pigments.

Most Maillard reaction products contribute highly desirable flavors to heated foods such as bread, toast, cereal products, and meat. These flavors are often described as baked, nutty, roasted, caramel, and burnt, but even these can be considered to be off-flavors in certain other foods, e.g., the burnt caramel taste in heat processed milk.

Taints

Other types of off-flavor in canned foods can be caused by contamination of the product leading to an undesirable taint. One particularly unpleasant taint that has been found in a range of foods is the 'catty taint.' This is caused by a heat-dependent reaction between natural sulfur-containing compounds of the food and unsaturated ketones, such as mesityl oxide, which are widespread in many solvent-based products.

Examples of causes of catty taint in processed meat products include: meat that has been stored in a cold store painted with a material containing mesityl oxide as a solvent contaminant, ox tongues that have been hung on hooks coated with a protective oil, and pork packed in cans where the side seam lacquer has been dissolved in an impure solvent. Catty taint has also been a problem in canned rice pudding, where the dye used for printing on the rice sacks contained traces of mesityl oxide, which was picked up by the rice and reacted with the trace amounts of hydrogen sulfide in the milk during processing.

Texture

Canning can bring about both desirable and undesirable changes in texture of foods, primarily through starch gelatinization, protein denaturation, and pectin changes.

Starch Gelatinization

Starch gelatinization commences at a range of temperatures dependent on the type of starch, i.e., proportions of amylose and amylopectin present, and the availability of water. The two components of starch

behave differently on canning, with amylose giving an opaque solution that sets to a firm gel on cooling and with amylopectin forming a translucent paste that remains fluid when cooled. The swelling of the starch granules during canning or other heat processes causes cellular disruption, which, together with the starch gelatinization, gives a softening in texture and increased palatability to the product. During canning of vegetables, starch can often be leached into the brine making it viscous or turbid, e.g., in mature canned peas. (*See* **Starch**: Structure, Properties, and Determination.)

Pectin Changes

Canning of plant materials can lead to loss of semipermeability of cell membranes, and solubilization and breakdown of pectic substances in the cell walls and middle lamellae. The resultant cell separation leads to a loss of crispness and a softening of the product. This is generally a desirable effect, improving the palatability of foods, but overprocessing can lead to excessive softening of fruits and vegetables. Low-temperature blanching ($\sim 70\,^{\circ}C$) of fruits and vegetables can cause firming, due to enzymic demethylation of pectins followed by calcium bridges forming across the liberated carboxylate groups. (*See* **Pectin**: Properties and Determination.)

Protein Denaturation

Application of heat in meat canning causes protein denaturation, which leads to changes in texture. The hydrogen bonds maintaining the secondary and higher structure of the protein rupture and form into a predominantly random coil configuration, which affects the solubility, elasticity, and flexibility of the proteins. The sarcoplasmic and myofibrillar proteins in meat coagulate during heat processing, resulting in a firming of the texture, while the collagen proteins become more soluble, softening as they take up water. The resultant texture of canned meat is similar to that of conventionally cooked products.

Struvite

Canned seafood products such as tuna, salmon, and shrimps can occasionally contain small crystalline fragments of magnesium ammonium phosphate, commonly known as struvite. Struvite is formed during the canning process by the union of mineral elements that occur naturally in the flesh of seafood.

The formation of struvite is a rare event that appears to occur sporadically. Although struvite has no odor or taste and is harmless, it does resemble broken glass and, therefore, is undesirable from the consumer's point of view.

Color

Color changes during canning can be brought about by the breakdown of natural pigments, by the production of colors due to oxidation reactions, by the Maillard reaction, and by interactions between product constituents, e.g., metals and polyphenolic compounds.

Chlorophyl

Chlorophyl pigments are present in all green vegetables, but canning leads to breakdown with the associated color change from bright green to olive green or brown. The chlorophyl is converted to pheophytin by the loss of magnesium ions (Mg^{2+}), with heat and low pH during processing greatly accelerating this change. The addition of alkaline salts in the canning liquor to maintain a pH of 6.2–7.0 and high-temperature, short-time (HTST) processing have both been used in canning to reduce chlorophyl degradation. (*See* **Chlorophyl**.)

Heme Pigments

The red coloration in meat is due to two heme pigments, hemoglobin in the blood and myoglobin in the muscle tissue; as most of the blood is removed after slaughter, the main pigment is myoglobin. Canning causes oxidation of myoglobin to metmyoglobin, which gives the typical brown color of cooked meats. It is this reaction that is also the main cause of color change on canning of dark fleshed fish, e.g., tuna and mackerel. Green discolorations can also occur as a result of a reaction of myoglobin with sulfur compounds.

Carotenoids

Carotenoids are fat-soluble, highly unsaturated red, orange, or yellow pigments that are susceptible to oxidation and isomerization under the conditions of heat and low pH, such as those used during the canning process.

Carotenoids are generally found complexed with either proteins or fatty acids, which protect them from oxidation. It is the breakdown of these complexes during processing that leads to degradation of the carotenoids resulting in bleaching or discoloration of the product.

In crustaceans, the denaturation of carotenoprotein on heating releases the carotenoid astaxanthin, which causes a change in color from natural blue–grey to pinky red. Two types of isomerization, *cis–trans* and epoxide, can also occur, giving rise to a slight lightening in color in canned fruits, e.g., pineapple. (*See* **Carotenoids**: Occurrence, Properties, and Determination.)

Anthocyanins

Anthocyanins are water-soluble, red–violet pigments that can take part in a wide range of reactions during canning. A combination of heat and oxygen can lead to the hydrolysis of the glycosidic bonds, resulting in loss of color and formation of yellow or brown precipitates, but a low pH gives rise to greater color stability. Aldehydes, produced by the breakdown of sugars during canning, and ascorbic acid both accelerate the breakdown of the anthocyanins. These color losses are a particular problem in canned red fruits, e.g., strawberries.

Anthocyanins can also be produced, as a result of excessive thermal processing, from leucoanthocyanidins, giving rise to defects such as red gooseberries and pink pears. (*See* **Phenolic Compounds**.)

Tin and Iron

Both desirable and undesirable color effects can occur in canned goods due to reactions involving metal ions.

Tin coating of the internal can surface produces a chemically reducing environment, which minimizes oxidation and helps prevent color and flavor degradation in certain products, e.g., tomato-based products and asparagus. Asparagus canned in a lacquered can may develop a dark discoloration due to the formation of a complex between rutin (a flavanol glycoside) and iron, whereas even partial exposure to tin, such as one plain can end, will retain product color.

Certain anthocyanin pigments can form metal complexes with tin and iron produced through internal can corrosion, causing pink discoloration, especially in pears and peaches, and bluing of red fruits.

Current UK legislation limits the level of tin in canned foods to 200 mg kg^{-1}. Tin can cause short-term gastric irritation and nausea, but it is not absorbed by the gut in significant quantities, and there is no evidence of any long-term or cumulative toxic effects.

Maillard Reaction

The Maillard reaction, the principles of which are discussed earlier in this article, can cause off-colors, particularly browning on canning of a wide variety of products.

Color compounds can be grouped into two general classes, low-molecular-weight compounds and the melanoidins, which have much higher molecular masses.

The browning of navy beans in tomato sauce is primarily due to the formation of melanoidins through the Maillard reaction. Melanoidins are also partly responsible for the browning effect seen in canned apricots. Browning during canning of dark flesh fish such as mackerel and tuna is of little consequence. However, in white fish, such discoloration is a major problem, and for this reason, white fish is not routinely canned. Canning of milk can also lead to a brown tint, although cream is less affected.

Betalains

Betalains are water-soluble and split into two main groups, red betacyanins and yellow betaxanthins. The most important pigment in this group is betanin, the red pigment in beetroot which is often used as a natural colorant. Betanin is susceptible to oxidation during canning, which leads to a loss of color, although this is often not noticeable due to the large amount present.

The occurrence of a black ring discoloration in canned beetroot is due to enzymatic oxidation of polyphenols that occur during steam peeling, and not to betalain reactions.

Changes in Nutritional Properties of Foods

Both physical and chemical changes can occur during the canning of food, which may affect its nutritional status (Table 2). As well as damage to heat-labile

Table 2 The effect of heat processing on the major nutritional components

Nutrient	*Effect*
Water	Loss of total solids into canning liquor Dilution Dehydration
Proteins	Enzymic inactivation Loss of certain essential amino acids Loss of digestibility Improved digestibility
Carbohydrates	Starch gelatinization and increased digestibility No apparent change in content of carbohydrate
Dietary fiber	Generally no loss of physiological value
Lipids	Conversion of *cis* fatty acids to *trans* fatty acids Loss of essential fatty acid activity
Water-soluble vitamins	Large losses of vitamins C and B_1 due to leaching and heat degradation Increased bioavailability of biotin and nicotinic acid due to enzyme inactivation
Fat-soluble vitamins	Mainly heat-stable Losses due to oxidation of lipids
Minerals	Losses due to leaching Possible increase in sodium and calcium levels by uptake from canning liquor

nutrients and physical loss of nutrients due to leaching, there are many reactions that occur on canning that affect the availability of nutrients within the foodstuff and therefore their usefulness to the body.

If comparing the nutritive value of canned foods with that of fresh foods, it is also important to consider any changes that occur during conventional preparation and cooking techniques.

Moisture

The movement of water and solids during canning can cause major changes in the nutritional status of the foodstuff. If the complete can contents are consumed, these changes can be largely disregarded, but in products where the canning liquor is discarded, the effects of dilution, dehydration, and loss of total solids must be taken into consideration. Dilution or dehydration will affect the relative proportions of other constituents in the food, while soluble nutrients can be leached into the liquor.

Proteins

Heating of proteins, as in canning, causes denaturation, i.e., rupturing of the hydrogen bonds and other noncovalent bonds, leading to changes in the conformation of the protein. The degree of protein denaturation depends on the level of heat treatment applied, but it can also be caused by oxidation and reaction with other food constituents, e.g., reducing sugars and lipid oxidation products. The total level of crude protein is generally unaffected by canning, but both desirable and undesirable changes can occur in its nutritive quality and availability. Mild heating of proteins leads only to changes in tertiary structure, which have little nutritional effect, although there is usually a loss in solubility. More severe heating, as in canning of vegetables, results in the Maillard reaction and the consequent loss in protein quality. These reactions occur mainly between lysine and sugars and cause a loss in availability of lysine, through cross-linking, with a loss of up to 40% being seen on canning of potatoes. Canning of meat also leads to the reduction in availability of lysine and other essential sulfur containing amino acids and can lead to a reduction in the digestibility of the meat. (*See* **Protein**: Chemistry; Functional Properties.)

The losses in protein availability that occur under normal canning conditions are, however, quite small and not nutritionally significant for most people in developed countries, as lysine is rarely the limiting amino acid in the diet. Canning can, in fact, lead to improved protein availability and digestibility by denaturing antidigestive factors and by denaturing proteins. Some examples of advantageous effects of heat processing are mentioned below.

Heating of milk results in the proteins being precipitated by stomach acids as finely dispersed particles, making attack by digestive enzymes more effective than in raw milk. This can also enhance the formation of disulfide bonds, e.g., between β-lactoglobulin and K-casein, which leads to greater stability of the normally unstable β-lactoglobulin. The canning of legumes improves their digestibility by unfolding the major seed globulins, as well as increasing nutritional availability by inactivation of trypsin inhibitors.

Lipids

The nutritive value of the fat content of foods is not generally significantly altered during normal heat processing. Hydrolysis reactions can occur, resulting in separation of the fatty acids from the glycerol unit, but this does not adversely affect the nutritional value of the fat as the resulting free fatty acids are available for digestion.

Saturated lipids are relatively stable, but unsaturated lipids are prone to oxidation when heated in the presence of oxygen or air. The exclusion of oxygen or use of antioxidants prevents the oxidation of lipids during canning, so that losses in the nutritional value of fats are unlikely to be significant. It is worth considering the effects of lipid oxidation, however, as any contact with oxygen during the history of the food can be sufficient for oxidation reactions to occur.

The major effect of lipid oxidation is related to the flavor of food, but it can also result in the conversion of *cis* fatty acids to *trans* fatty acids. The nutritional value in terms of energy is similar for the two fatty acid types, but the *trans* fatty acids do not generally possess essential fatty acid activity. The availability of the fat-soluble vitamins A, D, and E, as well as vitamin C and folate, can also be reduced during lipid oxidation.

Carbohydrates

Carbohydrates have numerous characteristic properties, and the effects of canning are therefore varied. The levels of total and available carbohydrates have been found to be largely unaffected during canning of fruit and vegetables. In general, the effects of canning on carbohydrates are related not directly to their nutritional value but to their interaction with other food constituents and to the overall eating quality of the foodstuff.

Losses on canning can be caused by reducing sugars reacting with protein through the Maillard reaction, which also causes a loss in availability of certain amino acids.

Gelatinization of the starch granules improves the texture and, thereby, palatability of the food; it also

aids the digestibility of some foods (e.g., potatoes, rice) that are largely indigestible in the raw state.

The other major constituent of carbohydrate in food is the indigestible dietary fiber, which consists mainly of cellulose. Cellulose and other polysaccharides, i.e., hemicelluloses and pectins, are largely responsible for the texture and structure of plant foods.

Canning appears to have little effect on total dietary fiber levels, but the exact effects of canning on the various constituents of dietary fiber and the effect of heat-induced fiber breakdown are not fully known. (*See* **Carbohydrates**: Classification and Properties; **Dietary Fiber**: Properties and Sources.)

Minerals

Total mineral levels are not generally adversely affected by the canning process as they are relatively stable under conditions of heat, acid, or alkali (Table 3). However, minerals are susceptible to changes in bioavailability due to interactions with other food components. The bioavailability of iron can be enhanced during canning in the presence of vitamin C, or reducing sugars with which it forms available complexes. Both oxalates (which occur naturally in many acidic plants) and phytates (from cereals) can inhibit calcium bioavailability.

The major changes that can occur in mineral levels on canning are caused by movement between the foodstuff and the canning liquor. Certain minerals, especially sodium and calcium, can be taken up by the food from the canning liquor; this can be seen especially during the canning of vegetables in brine. Minerals can also be leached out from the foodstuff into the canning liquor. Potassium is particularly prone to leaching with losses of between 15 and 50% seen on canning of vegetables. Zinc, manganese, and cobalt are also susceptible to leaching.

No further substantial changes in sodium or calcium levels are seen on storage of canned vegetables, but slight further leaching of potassium and zinc does occur.

Table 3 Mineral content in freshly cooked and canned cooked peas on a wet-weight basis

	Mineral (mg per 100 g)				
Sample	*Ca*	*Na*	*K*	*Zn*	*Fe*
Fresh	48	65	179	0.82	1.4
Zero time canned	47	320	152	1.0	1.4
Canned stored					
3 months	40	315	79	0.72	1.3
6 months	31		82	0.44	0.9
9 months	28	295	84	0.53	1.5
12 months		280	108	0.55	1.2

Vitamins

Most vitamins are unstable under conditions of heat and are susceptible to loss during the canning process (Table 4). The fat-soluble vitamins are generally more stable than the water soluble vitamins, but losses can occur during canning due to oxidation. Carotenoids are particularly prone to oxidation during heat processing, but this can be greatly reduced by the addition of antioxidants, e.g., vitamin C.

Losses of water soluble vitamins during canning can be quite considerable, with vitamin C being the most labile. Vitamin C can be lost through the following processes: (1) oxidation, which can occur in the early stages of heat treatment before the ascorbic oxidase is inactivated; (2) chemical degradation, e.g., losses due to nonenzymatic browning reactions in fruit products with high vitamin C levels; or (3) through leaching into the canning liquor, which is generally the major cause of vitamin C loss in canned fruits and vegetables. The levels of vitamin C remaining in canned vegetables have been shown to be as low as 20% of the vitamin C found in the fresh raw produce; however, vitamin C is lost during all stages of fresh storage, preparation, cooking, or processing, and some canned vegetables have levels of vitamin C similar to the fresh product, which has been stored prior to cooking (Table 5). Thiamin (vitamin B_1) is the most heat-sensitive of the B vitamins, especially under alkaline conditions and in the presence of bisulfite ions. Thermal degradation of thiamin involves the cleavage of its methylene bridge, which gives rise to many volatile products, producing a meat-like aroma in cooked foods. In the presence of reducing sugars, thiamine may take part in nonenzymatic browning reactions, and it also reacts with aldehydes in the presence of ascorbic acid. Thiamin can also be lost through leaching, but it is less soluble than vitamin C, and retention levels of between 60 and 90% are usual on canning.

Folic acid is lost on canning through heat degradation and oxidation, although it is stabilized in the presence of ascorbic acid, whereas pyridoxine

Table 4 Vitamin losses on canning of vegetables

Vitamin	*Typical losses (%)*
Vitamin C	30–90
Thiamin	16–83
Riboflavin	20–70
Nicotinic acid	20–70
Folic acid	30–80
Panthothenic acid	30–85
Vitamin B_6	30–90
Biotin	0–80
Vitamin A	0–80

Table 5 Vitamin C content of fresh and canned peas and carrots (mg per 100 g)

	Carrots		*Garden peas*		
	Uncooked	*Cooked*	*Uncooked*	*Cooked*	*Pea canning liquor*
Fresh	9	8	30	16	
Stored for 7 days at ambient	3	4	17	16	
Canned	2	3	20	12	11
Canned, stored for 6 months	2	2	15	2	10
Canned, stored for 12 months	2	3	8	5	5

(vitamin B_6) can be lost through heat degradation and leaching. Losses of these two vitamins during canning of fruits and vegetables range between 30 and 80%. Losses on canning of meat can be very considerable, with up to 90% losses.

Riboflavin (vitamin B_2) and nicotinic acid are both relatively heat-stable, with minimal losses on canning of meat products; however, losses of between 20 and 50% have been found on storage of canned meats. Losses seen during the canning of fruits and vegetables, ranging from 25 to 70%, are mainly attributed to leaching. Nicotinic acid and riboflavin both show very high retention levels during milk processing, but riboflavin is lost from bottled milk as it is very sensitive to sunlight.

Heat processing generally has a detrimental effect on most vitamin levels, but mild heating conditions can have a beneficial effect due to enzyme inactivation and the breakdown of binding agents, which increases the bioavailability of certain vitamins, e.g., biotin and nicotinic acid.

Conclusions

The canning of foods has resulted in a wider choice of nutritious, good-quality foods being available all year round in a convenient form for the consumer. Although, with better global links and improved agronomy, many foods are now available fresh all year round, canned foods still form an important part of the food marketplace.

When considering the quality of canned foods, it is important to compare them with fresh or frozen foods at the point of consumption. Many of the changes that occur in both sensory and nutritional aspects do so during any thermal process, whether it is conventional cooking, blanching, or canning. For most foods, the canning process replaces a conventional cooking process, and any mild reheating stage has no further significant effect on quality.

Losses in heat-labile nutrients such as vitamins can be significant. However, as canned products are usually produced from materials at optimum maturity and immediately after harvest, levels can often be as high as the 'fresh' material purchased from the greengrocers and prepared in the home.

CARAMEL

Contents
Properties and Analysis
Methods of Manufacture

Properties and Analysis

P Tomasik, University of Zimbabwe, Harare, Zimbabwe

Introduction

Home cooks used to burn sugar to obtain so-called caramel for flavoring food. Commercial caramel differs from the domestic product by its method of preparation and consequently in many of its properties. Several products called caramel are available commercially. Tables presented in this article summarize their physical and chemical properties and analytical problems are also discussed.

Definition of the Product

Caramel is a brown product originating from various sugars when they are heated either dry or in concentrated solutions and alone or with certain additives. It is designed as a food additive or ingredient for coloring and/or flavoring food.

In some countries the name 'caramel' is reserved for products manufactured from saccharides in the absence of nitrogen-containing compounds. Such products are used as flavoring ingredients. The products resulting from heating sugars with nitrogen-containing additives are called 'sugar colors' and they serve as coloring additives. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Types and Standardization

The origin and properties of caramel are laid down in many producing countries. Also, the use of only a few, among many reported additives, is permitted in the manufacture of caramels. The World Health Organization and the Food and Agriculture Organization Joint Expert Committee on Food Additives distinguishes three general kinds of caramel: (1) caramel color, plain (CP), (2) caramel color, ammonia process or caustic (AC), and (3) caramel color, ammonium sulfite process (SAC), depending on the additive used in their manufacture. Both the European Technical Caramel Association (EUTECA) and the International Technical Caramel Association (ITCA) have standardized the properties of four classes and 10 types of caramel (Table 1).

4(5)-Methylimidazole in ammonia and ammonium sulfite caramel colors cause a special problem. This compound, which is formed from sugars and ammonia during manufacture of the caramel, is strongly neurotoxic. For this reason the daily intake of food containing ammonia caramel is controlled in some countries and in others ammonia caramel is banned.

Physical Properties

Caramel is polymeric in its character. Three main components of the plain type are called caramelan, caramelen, and caramelin. Ammonia caramels additionally contain melanoidin, which is much darker in color than the three other components mentioned above. Hence, ammonia caramels are the most intensively colored.

Depending on their isoelectric points (p*I*s) caramels may be roughly divided into positive (p*I* 5.0–7.0), negative (p*I* 4.0–6.0) and spirit (p*I* < 3.0) types. The p*I* determines the possibility of application of caramels. The average molecular weight of compounds in caramels is between 5 kDa (electropositive caramels) and 10 kDa (electronegative caramels). Other important properties are pH (Table 1), aqueous solubility (should be completely soluble), specific gravity (usually 1.315–1.345), color intensity (Table 1) or tinctorial strength, hue index (called 'redness') as well as flavor and aroma. These last two organoleptic properties consist of two components: taste arising from the acidity (modifiable) and a taste contribution attributed to the nature of caramel (nonmodifiable).

Chemical Nature

The products of caramelization are distributed among volatile and nonvolatile fractions. The volatile fraction consists mainly of water, carbon monoxide, carbon dioxide, formaldehyde, acetaldehyde,

Table 1 Classes of caramel color according to International Technical Caramel Association/European Technical Caramel Association

		SAC-2	75–100	17.5–23	55–75	0.5–2.8	0.8–3.2	0.5 (< 0.5)		0.12 (< 0.1)
		SAC-3	105–150	22.5–37		0.8–2.8	1.0–4.0	0.8		0.15
		SAC-4	210–270	40–52	47–57	2.0–4.0	1.0–5.0	1.5		0.28

The values in parentheses are Food and Agriculture Organization/World Health Organization (FAO/WHO) proposals dating from 1980. Permissible content (in mg kg^{-1}) of the heavy metals in caramel according to FAO/WHO standards are: total, 25; copper, 20; lead, 5; astatine, 3; mercury, 0.1. ε_M, Molar extinction coefficient; EBC, European Brewery Convention.

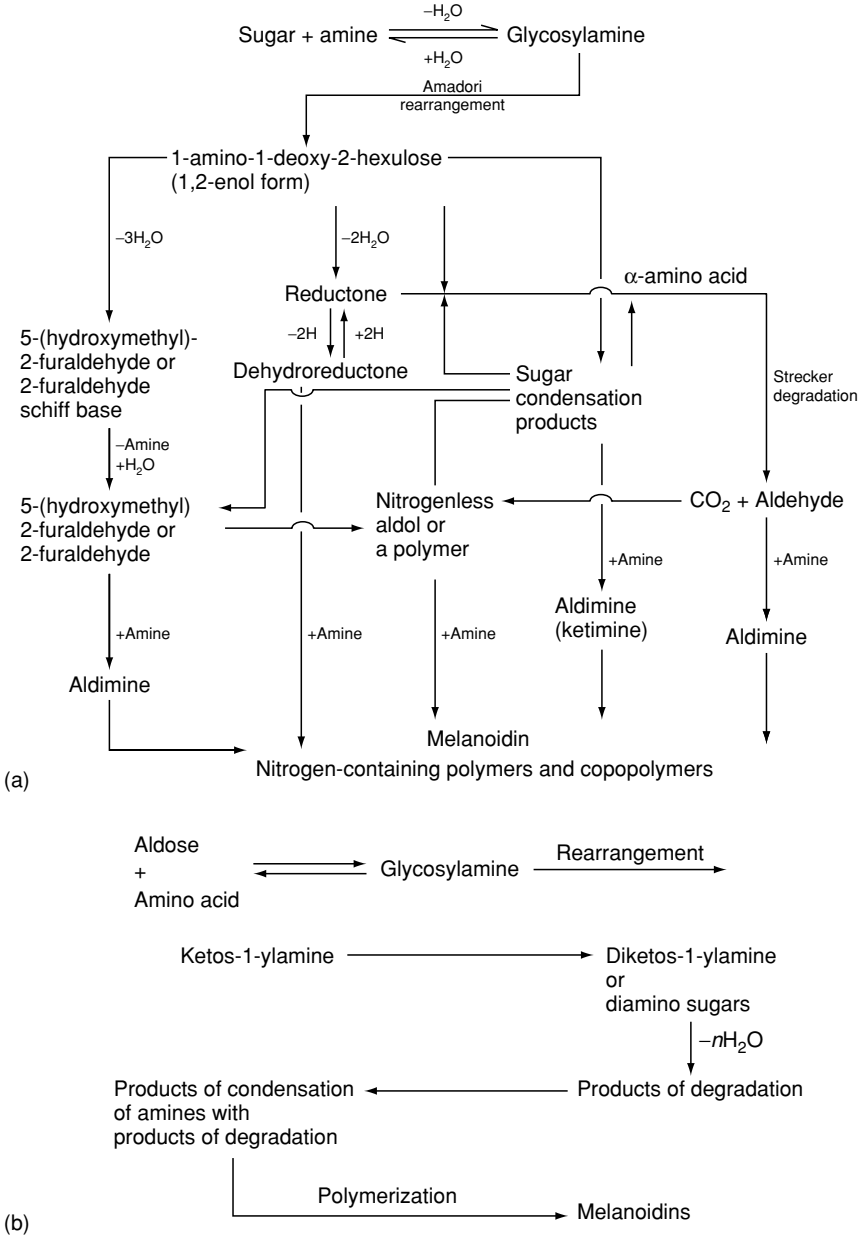

Figure 1 Theoretical schemes for the formation of melanoidins according to (a) Hodge and (b) Reynolds. Reproduced from Caramel/Properties and Analysis, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

methanol, and ethanol. The composition of the low-molecular-weight portion of the nonvolatile fraction depends on the type of caramel. The plain caramel nonvolatile fraction contains the following saccharides: D-fructose, D-glucose, kojibiose, isomaltose, nigerose, sophorose, laminarabiose, maltose, gentobiose, cellobiose, isomaltotriose, panose, and other oligosaccharides. There are also several carboxylic acids: formic acid and higher fatty acids, succinic, fumaric, pyruvic, levulinic, and furancarboxylic acids. Oxaheterocycles are represented by 2-furaldehyde, 5-(hydroxymethyl)-2-furaldehyde, 2,3-dihydro-4-hydroxy-5-methylfuran-3-one, 2,3-dihydro-4-hydroxy-2-(hydroxymethyl)-5-methylfuran-3-one, bis(5,5-formylfurfuryl) ether, and 2,3-dihydro-3,5-dihydroxy-6-methyl-4*H*-pyran-4-one. There are also various other aliphatic carbonyl compounds like glucoreductone (2-hydroxypropandial), pyruvaldehyde, and α,β-unsaturated carbonyl compounds. A number of other components which are products of reversion and polymerization remain uncharacterized. The low-molecular-weight fraction of caustic caramel

contains about 50 components. Ammonia caramel contains in this fraction a certain amount of 4(5)-methylimidazole, 2-acetyl-4(5)-(1,2,3,4-tetrahydroxybutyl)imidazole, and 3-hydroxy-6-methylpyridine, as well as at least 143 other components, including those mentioned above. (*See* **Carbohydrates**: Classification and Properties; **Fatty Acids**: Properties; **Fructose**; **Sucrose**: Properties and Determination.)

The high-molecular-weight, nonvolatile fraction of plain caramels is composed of 1,6-anhydro-α-D-glucose, caramelan (formed in the reaction shown in eqn (1)), caramelen (resulting from the reaction shown in eqn (2)), caramelin (being the product of reaction shown in eqn (3)), structures of which remain unknown, and polymers composed of furan ring units.

$$6C_{12}H_{22}O_{11} \xrightarrow{-12H_2O} 6C_{12}H_{18}O_9 \qquad (1)$$

$$6C_{12}H_{22}O_{11} \xrightarrow{-18H_2O} 2C_{36}H_{48}O_{24} \qquad (2)$$

$$6C_{12}H_{22}O_{11} \xrightarrow{-27H_2O} 3C_{24}H_{26}O_{13} \qquad (3)$$

The interpretation of carbon-13 cross-polarized magic-angle sample spinning nuclear magnetic resonance (^{13}C CP/MAS NMR) spectra of plain caramels leads to the conclusion that there are 8–9% carbonyl and aldehyde carbon atoms, 7–7.7% carbon atoms in ester groups, 33–31% heterocyclic carbon atoms, and 52.4–51.2% alkyl groups bonded to carbon atom and to oxygen. It may also be deduced that the furan system prevails among other heterocyclic systems present in caramel. (*See* **Spectroscopy**: Nuclear Magnetic Resonance.)

Two consecutive steps may be distinguished in the formation of caramels without participation of ammonia, ammonium sulfite, amines, or amino acids and their salts, which may also be used as the catalysts. They are degradation reactions which lead to colorless or yellow compounds. First, water and carbon dioxide are evolved and furan derivatives are formed (2-furaldehyde from furanoses and 5-(hydroxymethyl)-2-furaldehyde from pyranoses). This step is a function of both temperature and time; atmospheric oxygen plays some role in the final stage. This is followed by the second step, polymerization and condensation reactions forming highly colored compounds (caramelan, caramelen, and caramelin as well as furan polymers).

In caramels manufactured with basic nitrogen-containing additives, melanoidins are the most important components. Their structure is unknown, but there is evidence that they have, at least in part, an amide structure. Moreover, they contain unpaired electrons, i.e., they have a free radical character. There is a great similarity between this product and humic acids resulting from the Maillard reaction. Two consistent schemes for the formation of melanoidins are proposed by Hodge (Figure 1(a) and Reynolds (Figure 1(b)). Both theories differ in the number of steps involved in the route from the preliminary reaction between sugar and amine to give glycosylamine and the final product, melanoidin. Recent studies have revealed that the possibility of the Strecker degradation as one of the processes involved should be rejected. (*See* **Browning**: Nonenzymatic.)

Analysis of Caramels

The use of caramel is first of all limited by its type, which affects its use for a given food. For instance, a caramel may precipitate on contact with a product subjected to coloration, as a result of discharge of caramel micelles. The type and quality of caramel may easily be recognized by means of the citric acid, alcohol, and Lassaigne tests (Table 2). However, the complexity of caramel composition makes distinguishing between the different types difficult unless combined analytical methods are applied. These include chromatography of dilute solutions of caramel followed by thin-layer electrophoresis and size exclusion chromatography. Thus, full standardization of caramel may require many other determinations of chemical components as well as fractions, as shown in Table 3. This table presents several properties of certain types of caramel manufactured from sucrose. It is apparent that, for instance, two I CP-2

Lichthard	Tannin + sulfuric acid	Brown solid within 24 h
Fradiss	Dry 1-pentanol	A precipitate
Crampton–Simons	Floridin, Tonsil or Fuller's earth	Decoloration of aqueous or ethanol solutions in caramel followed by colorimetric determination of resulting color
Straub	1% aqueous $SnCl_2$ + potassium acetate	Light yellow color and precipitate
Nessler–Carles	Fresh egg white	Brown to orange color
Ihl	Pyrogallic acid in hydrochloric acid	Dark red precipitate
Magalhaes	K_2SO_4 + cotton wool	Light orange color on boiling for 10 min
Schenck	Phenol or 2-naphtol	Red brown color immediately (phenol) or after 30 min (2-naphthol)

caramels listed therein differ from one another in the majority of their properties. It is a matter of discussion whether these findings will result in further attempts to standardize caramels within subtypes. These differences may also be considered as resulting from difficulties in the strict control of the caramelization process, which tends to be rather chimeric. (*See* **Chromatography**: Principles.)

Determination of the p*I* may be carried out by means of electrophoresis, the flocculation test with tannin, ionic surface-active agents (an industrial approximate measure), the gelatin test, and other more specific methods.

Isolation and separation of caramelan, caramelen, and caramelin may be achieved by dialysis, electrofiltration through an ion exchange membrane, or by determining solubilities in different solvents (84% aqueous ethanol, 1-propanol). Fractionation by gel filtration and adsorption on either charcoal or using ion exchangers are recommended mainly for elimination and separation of overall coloring matter from caramel. Anionic resins exhibit particular selectivity towards caramelan, which is adsorbed, leaving caramelen and caramelin in the unadsorbed state.

The determination of 4(5)-methylimidazole in ammonia caramel involves chromatographic techniques. Thus, extracts of caramels are developed on silica gel F_{254}-coated plates using a 4:1:1 ether–chloroform–methanol mixture (sodium nitrite with sulfanilic acid used as a spray). Gas–liquid chromatography involves columns packed with 10% carbowax 20 mol l^{-1} with 25% potassium hydroxide on CPLA (80–100 mesh). (*See* **Chromatography**: Gas Chromatography.)

There are several methods of detection of caramel in food. These are presented in Table 4. Furthermore, physical methods based on size exclusion chromatography and spectral measurements in the ultraviolet and visible region have recently been developed.

Methods of Manufacture

P Tomasik, University of Zimbabwe, Harare, Zimbabwe

Introduction

Commercial caramels, even if manufactured from the same materials, may have different properties depending on the additives used and the conditions of caramelization. Caramelization itself is a very chimeric process and the manufacture of caramel is sometimes considered to be an art. Ready-made caramel is a rather unstable product and its storage is also a very important factor. The problems of production and storage of caramel are presented below.

Applications of Caramel

The classification of caramel into four classes results from the properties of the product and its intended food application. Thus, caramel of class I (CP-1 and CP-2) is designed as an additive to spirits, brandy, sweets, medicines, biscuits, pastries, aromas and spices. Caramel of class II (CSS-1) has very limited applications as it is used for special spirits as a flavoring rather than a coloring agent. Class III caramel (AC-1, AC-2, and AC-3) is used as brown color for beer, malt liquor, bread, biscuits, pastries, soups, sauces, canned food, meat, tobacco, and some spices. Finally, class IV caramel (SAC-1 to SAC-4) is the colorant of cola-type beverages, soft drinks, vermouths, and vinegar. The use of caramels for nonfood

purposes is of marginal importance. The data published for 1986 set the world production at the level of 60 000 tonnes: in the USA caramel of class IV was the only product manufactured to any significant extent (95% of overall production) whereas in the European Community the manufacture of both class IV (50%) and class III (45%) caramels was important (class I 4%; class II 1%). (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; **Flavor (Flavour) Compounds**: Structures and Characteristics.)

The isoelectric point and tinctorial strength are the most important criteria for selecting a class of caramel for a given purpose. However, flavor is also an important property. Incorrectly selected caramels can produce a haze in drinks and flocculation as well as nonuniform shades in finished products. Beer caramel (class III) has to withstand fermentation. The composition of caramel micelles, especially their calcium content, is another factor which can cause turbidity in some drinks finished with caramel. Caramel in brandy (0.2% v/v) accelerates its aging. Aspartame in drinks is stabilized by the addition of caramel. Oriental cuisines commonly utilize caramel for coloring and flavoring soups, gravies, and sauces, e.g., soy sauce (shoyu).

Sources for Manufacture

Some authors report that the quality of caramel depends, among other aspects, on its source. However, some authors express the opposite point of view, claiming that only parameters of caramelization (including catalyzing additives) are responsible for the quality of the final product. Undoubtedly the presence of amino acids, proteins, and hydroxy acids in materials used for caramelization contributes additional flavor and other specific organoleptic properties to the final product. As a matter of fact, such additives have a catalyzing role in the formation of the brown-colored components of caramel. There is also some relationship between the content of D-glucose in the stock and firmness of caramel. D-Glucose decreases the hygroscopicity and maltose has practically no effect on it.

Sucrose as well as D-glucose and D-fructose, both resulting from its hydrolysis, are prime sources for the manufacture of caramel. Reducing sugars caramelize more readily than nonreducing sugars. The mode of preparation of sugar for caramelization has some influence on the caramelization process. Sugar from carbonation is better than that from sulfination as residual carbonates catalyze the caramelization better than sulfites. (*See* **Fructose**; **Sucrose**: Properties and Determination.)

Other mono- and disaccharides have also been considered as sources of caramels, but they are only of theoretical importance. Molasses has attracted the attention of manufacturers as a relatively inexpensive source of caramel because of its brown components. A disadvantage in the the use of molasses is its high potassium content and the unfavorable viscosity of the resulting caramel. (*See* **Carbohydrates**: Classification and Properties.)

Many reasons, among them economic and political, make sucrose, invert sugar, and D-glucose rather unfavorable sources for the production of caramel. Oligo- and polysaccharides, which are hydrolyzed by acids, bases, or enzymes, provide a source of very stable caramels. Maize, cassava, sago, and potato starch as well as starch waste may be employed. Starch syrups from enzymatic hydrolysis deliver caramels with a higher tendency towards crystallization due to their higher content of dextrins after acid hydrolysis. Microwave heating of starch in a sealed vessel causes its hydrolysis accompanied by caramelization of the hydrolysate. Nonconventional sources such as malt and soya bean carbohydrates have also been paid some attention as the sugar syrups derived from them contain 70–85% reducing sugars. (*See* **Starch**: Sources and Processing.)

Additives and Catalysts of Caramelization

The caramelization of plain sugars produces flavoring rather than coloring caramels. Certain additives accelerate caramelization, influencing both flavor and tinctorial strength of caramel by being either reagents or catalysts. The use of the following additives has been published: acids – acetic, citric, phosphoric, sulfurous, sulfuric, and carbonic acids; bases – ammonia as well as hydroxides of sodium, potassium, and calcium; salts – carbonates, hydrogencarbonates, sulfates, sulfites or phosphates of ammonia, sodium, potassium, and calcium. Alkaline additives catalyze caramelization of furanoses more efficiently than pyranoses. Some sodium compounds, mainly biogenic amino acids and their sodium, potassium, magnesium, and calcium salts, taurine (2-aminoethanesulphonic acid) and sulfanilic acid, have also been tested. They may be of particular interest in view of the fact that the most effective catalyst, ammonia, produces caramel contaminated with the neurotoxin 4(5)-methylimidazole. Caramel sources as well as additives and catalysts are controlled by food laws of particular countries or economic unions. (*See* **Legislation**: Additives.)

Apart from chemical catalysts the possibility of catalysis of caramelization by ultraviolet, microwave

or γ-radiation or ultrasound has also been studied with inconclusive results. In particular, ultraviolet and γ-radiation introduce competing reactions such as the free radical decomposition of carbohydrate to water and carbon dioxide and a number of lower carbonyl compounds (aldehydes, ketones, carboxylic acids). In the case of caramels with poor tinctorial strength (class I CP-1 and CP-2) attempts have been made to increase their coloring ability by blending ready-made caramels with certain additives. Among possible additives enhancing the tinctorial strength of caramels the following have been tested: magnesium and calcium hydroxides, calcium phosphate as well as oxides of magnesium, calcium, zinc, and cobalt(II). Magnesium oxide appears to be a superior additive among those tested. Its application has, however, limited value. The increase of tinctorial strength of plain caramels has some limits because the most intensively colored melanoids are absent. The effect of magnesium oxide seems to be due to modification of the micellar structure of plain caramel. This effect enables further dehydration of caramelan to the darker caramelen and caramelin. Apart from such procedures, ultrafiltration, centrifugation combined with size exclusion chromatography as well as ion exchange columns have been proposed as methods to increase the tinctorial strength of caramels. Thus far, these methods have not achieved any application on an industrial scale. (*See* **Chromatography**: Principles.)

Preparation and Manufacture

The variability of the sources for caramelization causes a great deal of empiricism in this technology. Generally, the character of compounds constituting caramel depends on temperature of the process, its duration, and the concentration of reactants. Increase in the color of the product is proportional to the time of the process.

There are four aspects of thermolysis affecting caramelization and all of them have found practical industrial applications:

1. Thermolysis of plain saccharides above their melting temperatures. This can be carried out under normal, reduced, or enhanced pressure. The last approach is usually employed when syrups from the hydrolysis of starch are caramelized. The initiation of the process readily takes place, after which the pressure may be released. The process is allowed to continue open to the atmosphere to develop all the color, viscosity, and desired organoleptic properties. The temperature range is between 180 and 250 °C. Although it is commonly accepted that the contact of the reaction mixture with atmospheric oxygen does not play any role in the formation of caramel, one may see in Figures 1–4 that this is not so. Oxygen slows down the caramelization in later stages of the process. Its effect on the tinctorial strength of the final product is nonuniform and depends on the source. The elimination of nitrogen positively influences acid resistance and solubility of the final product.
2. Thermolysis in the presence of catalyst. More recent procedures allow the temperature of caramelization to be reduced to 120–130 °C. An increase of the temperature to above this range decreases the tinctorial strength of the caramel and develops an acid flavor.

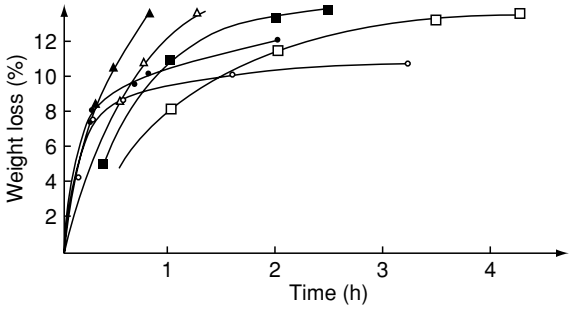

Figure 1 Course of caramelization of glucose (circles), sucrose (triangles) and maltose (squares) in air (open symbols) and under nitrogen (solid symbols). Figure 4 Solubility in water and in 96% aqueous ethanol of caramel from various sugars made in air and under nitrogen: □, solution is transparent; ▨, traces of turbidity; ▧, solution is turbid; ▩, caramel is sparingly soluble. Reproduced from Caramel: Methods of Manufacture, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

3. Thermolysis in the presence of either mineral acids or alkalis. These additives hydrolyze oligosaccharides which further caramelize. This process also requires lower temperature than these listed under (1). Increased pressures may also be used.
4. Thermolysis with ammonia, ammonium salts, amino acids and their salts as well as proteins and polypeptides. Such caramels contain nitrogen heterocyclic components (imidazoles, pyroles, pyrazines and pyridines) which enrich the flavor and aroma of the final product.

Thermolysis should be carried out in entirely stainless-steel equipment – kettles (open or pressurized), lines, storage tanks, fillers, agitators, valves, and so on.

Careful control of the process as it proceeds is very important. The parameters of the caramelization have to be precisely adjusted for a given source and to obtain the desired properties of the final product. Caramels from sucrose, D-glucose, and D-fructose with a distinct content of noncaramelized sugars have the best organoleptic quality. However, such caramels are quite hygroscopic and unstable. There are several techniques for the control of caramelization. One of the most recent developments is measuring the absorbance of free-flowing material in the near-infrared region. Lack of control of the process leads to loss of the micellar character of caramel and, in consequence, precipitation occurs. For this reason the isoelectric point has to be adjusted. This must be done at the beginning of the caramelization as attempts to change the isoelectric point in the course of the process are quite complicated and frequently unsuccessful. The pH of caramels constitutes an important property. A high pH may indicate incomplete caramelization or the presence of alkali. Above pH 6.0, caramel is readily attacked by molds and below pH 2.5 it quite easily resinifies.

The control of the viscosity of caramel is difficult. The rate of evolution of water (dehydration) significantly influences this property. The desired viscosity can be achieved by manipulation of the temperature and contact time with reagents.

Overburn caramel results from badly controlled temperature and from attempts to manufacture a highly colored product. This may occur particularly in the manufacture of ammonia caramel. The control of the temperature is important throughout the whole period of production, including the final stage of killing heat, i.e., the fast cooling of a caramel to about 30 °C.

The concentration and origin of the caramelized sources are of lesser importance. There is a relationship between the viscosity of caramel and its solubility. Less viscous caramels are usually more readily soluble and have more stable tinctorial strength, shelf-life, and retention of complete solubility. Such caramels are stored with the minimum of waste and effort.

For special use solid, dry caramels are manufactured. They are prepared by treating hot (120 °C) viscous caramel with ammonium carbonate followed by adding sucrose and orthophosphoric acid, cooling to 100 °C, and adding citric acid and sodium hydrogen carbonate. An alternative route involves addition of some cereal products, e.g., rye flour, and

conditioning of the mass at 80–85 °C at pH 3.5–5.5. Liquid caramel may also be thickened with a mixture of starch and dextrins. An extrusion of mono- and disaccharides at 150–300 °C also leads to solid caramels.

Storage

Undesirable properties of caramel may appear even if the product has been properly manufactured. Caramels are not fully stable and caramelization slowly progresses on storage. Therefore, caramel should be stored at low temperatures. Caramelization on storage may be catalyzed by metal ions. Hence tanks should be either plastic-lined or made of stainless steel. These precautions slow down resinification of the product into an amorphous gel which becomes useless as either an additive or ingredient for food and drinks. The stability of caramel stored in ideal conditions is estimated to be about 5 years.

CARBOHYDRATES

Contents

Classification and Properties

R F Tester and J Karkalas, Glasgow Caledonian University, Glasgow, UK

Background

Carbohydrates are the most abundant organic substances in the biosphere. Plants synthesize them from CO_2 and water, with energy provided by sunlight. The name originated a long time ago because of the erroneous assumption that they were hydrates of carbon having the empirical formula $(CH_2O)_n$. The simplest sugars are known as 'monosaccharides,' which can be polyhydroxyaldehydes or polyhydroxyketones. Disaccharides are formed from two monosaccharide molecules with the elimination of one molecule of water. Oligosaccharides consist of 2–10 monosaccharide units, whereas polysaccharides (glycans) may consist of a large number of monomers (e.g., over 10 000 glucose units). Oligo- and polysaccharides can be hydrolyzed by acid to the constituent monosaccharides. The structure and properties of carbohydrates are discussed in the following sections.

Configuration and Nomenclature

Chiral Molecules

The four valances of the carbon atom may be considered as directed towards the corners of an imaginary regular tetrahedron. In glyceraldehyde (2,3-dihydroxypropanal) (**Figure 1**) carbon atom 2 is

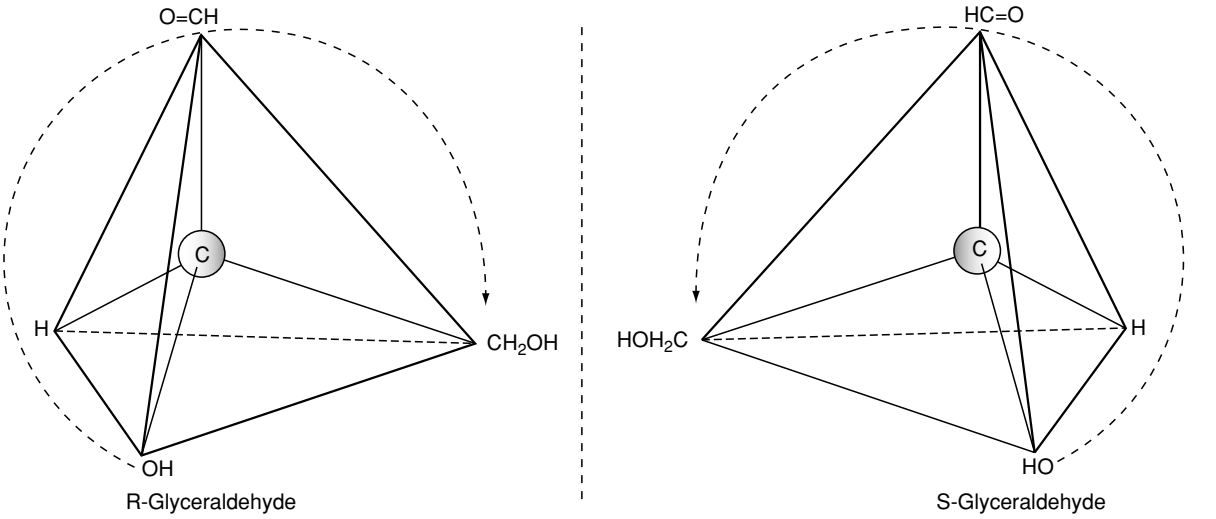

Figure 1 Enantiomers (mirror images) of glyceraldehyde drawn according to the Cahn–Ingold–Prelog rule. The direction of the arrows indicates diminishing priority of the groups OH > HC═O > CH_2OH (H always has the lowest priority). The carbon atom (chiral center) occupies the center of the tetrahedron. The four valences of carbon are directed towards the corners of the tetrahedron to which are bonded different groups. The OH groups are outside the plane of the paper directed towards the observer. If one of the figures is rotated around its vertical axis, its OH group will be moved behind the plane of the paper, thus confirming that the two figures are non-superimposable. See text for discussion.

situated at the center of the tetrahedron, and the four different substituents occupy its corners. Each molecule is asymmetric, i.e., it has no plane of symmetry that can divide it into two identical parts. The two possible molecular structures of 2,3-dihydroxypropanal are nonsuperimposable, and they are mirror images of each other. This property is termed 'stereoisomerism' (Greek *stereos* = three-dimensional or solid). The two chemical compounds are also known as 'stereoisomers,' because they have the same chemical formula and differ only in the spatial arrangement of atoms, or groups of atoms, around a stereocenter. In this example, they resemble a pair of human hands and are known as 'chiral molecules' (Greek *cheir* = hand). The asymmetric carbon atom is a chiral center or stereocenter. The two mirror images are also known as 'enantiomers' (Greek *enantios* = opposite). The position of the hydroxyl group in space determines the absolute configuration of each member of the chiral pair according to the rule explained in Figure 1. It should be noted that not all stereoisomers are enantiomers.

The letters R- and S- are derived from the Latin *Rectus* = straight (and, by extension, right) and *Sinister* = left. It should be noted that the R- and S-notation is used in modern organic chemistry to indicate the absolute configuration around a stereocenter. However, the classic D- and L-notation has been retained for the description of the chirality of carbohydrates (similarly for amino acids). D- is derived from the Latin *Dexter* (right) and L- from *Laevus* (left). The use of this notation is explained in Figure 2.

Properties of Enantiomers – Optical Isomerism

Enantiomers have identical chemical and physical properties and are indistinguishable from each other except for the direction of rotation of the plane of polarized light. They are described as optically active. One enantiomer in solution rotates the plane of polarized light to the right, whereas the other rotates it to the left. A chiral molecule that rotates light to the right is known as 'dextrorotatory,' and its chemical name is preceded by the plus sign, e.g., (+)-lactic acid. Its enantiomer, which rotates the plane of polarized light to the left, is described as 'levorotatory' and the minus sign is used, e.g., (−)-lactic acid. This property is known as optical isomerism. A solution containing equal concentrations of two enantiomers does not rotate the plane of polarized light (the two opposing effects cancel each other out) and is known as a racemic mixture. The optical properties of sugars are discussed below.

Polarimetry

The extent of rotation of the plane of polarized light is measured in angular degrees. A solution of an optically active substance is placed in a polarimeter tube (normally 20 cm long), both ends of which are made of optical glass. The tube is positioned in the light path of the polarimeter. If the solution rotates the plane of polarized light to the right, as viewed by

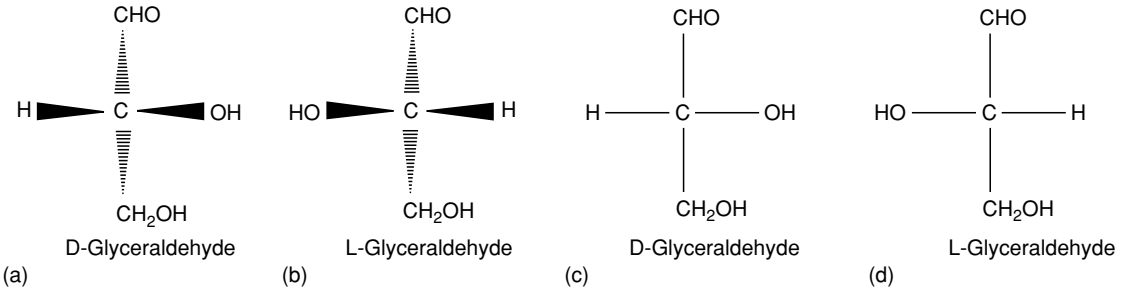

Figure 2 D- and L-notation conventionally used to indicate the position (right or left, respectively) of the OH group of glyceraldehyde (or any sugar), which is attached to the chiral center furthest from the aldehyde group. The carbon atoms are written vertically with the aldehyde group always at the top. In formulae (a) and (b), the carbon atom lies on the plane of the paper. The dark bonds with the respective groups are directed out of the plane of the paper towards the observer. Light bonds and respective groups are directed behind the plane of the paper. Formulae (c) and (d) are known as Fischer projections. They are commonly used to represent sugars, amino acids, organic acids, and other chiral compounds. The respective chiral molecules (mirror images) (a) and (b) or (c) and (d) cannot be superimposed. The rule is that these formulae may be rotated 180° on the plane of the paper only, but they should never be rotated around the imaginary axis that passes through the carbon atoms on the plane of the paper.

an observer facing the light source, the substance is dextrorotatory. The opposite effect is observed with a levorotatory substance. The following equation defines the specific rotation of a substance:

$$\text{Specific rotation} = [\alpha]_{\text{D}}^{\text{T}} = \frac{\alpha \times 100}{l \times c},$$

where: α = the observed angle of rotation (in degrees); l = length of the polarimeter tube in decimeters (dm); and c = concentration of the optically active substance in grams per 100 ml. The specific rotation of a pure substance of known concentration is measured with sodium light ($\lambda = 589.3$ nm; the subscript D stands for the sodium D line) at a specified temperature (superscript T), normally 20 °C. Specific rotation depends (to a lesser extent) on the concentration, which is usually reported in brackets. In addition, the polarimeter is used for the quantification of optically active substances by means of the equation given above. It is necessary, of course, to know the specific rotation of the substance being analyzed. All sugars are optically active, and therefore, their concentration can be conveniently measured by means of the polarimeter. However, it is not possible to measure mixed sugars by this technique.

Monosaccharides

Aldoses and Ketoses (D- and L-configuration)

D-Aldoses are sugars containing an aldehyde group and, for classification purposes, may be considered as derived from D-glyceraldehyde (a triose with three carbon atoms). As shown in Figure 3, sequential addition of carbon atoms (by the Kiliani–Fischer cyanohydrin reaction) leads to (aldo)tetroses, (aldo)-pentoses and (aldo)hexoses, with four, five, and six carbon atoms, respectively. Similarly, Figure 4 gives the formulae of D-ketoses derived from dihydroxyacetone. Simple sugars belong either to the D-series or the L-series. This is clear from the Fischer projection formulae, whereby the hydroxyl group attached to the asymmetric carbon atom furthest from the aldehyde (or ketone) group is projected to the right (shown in bold characters in the figures) or to the left.

The Fischer projection formulae (Figure 3 and 4) are widely used to represent the basic structure of sugars because of the convenience they offer. The aldehydic carbon atom (reducing end) is numbered 1, and the remaining carbon atoms are consecutively numbered (vertically) towards the nonreducing end of the molecule. Bonds in the vertical direction are behind the plane of the paper, whereas horizontal bonds are directed out of the plane of the paper. The Fischer formulae give an exact picture of the stereochemical arrangement of atoms in a carbohydrate molecule, as projected on the plane of the paper. The projected molecular structures may be rotated 180° on the plane of the paper but should never be rotated around their longitudinal axis by lifting them 'off the plane of the paper.' It should be stressed that D- and L-forms have nothing to do with the direction of rotation of the plane of polarized light, which is always denoted by (+) or (−) signs. Indeed, as seen in Figures 3 and 4, not all D-sugars are dextrorotatory. The fact that R-glyceraldehyde (D-glyceraldehyde) is dextrorotatory is coincidental. A clear picture of the architecture of sugars can be gained by the use of atomic models (preferably the ball-and-stick type). Computer-generated models are also useful, especially programs that allow interactive rotation of the molecules for three-dimensional viewing.

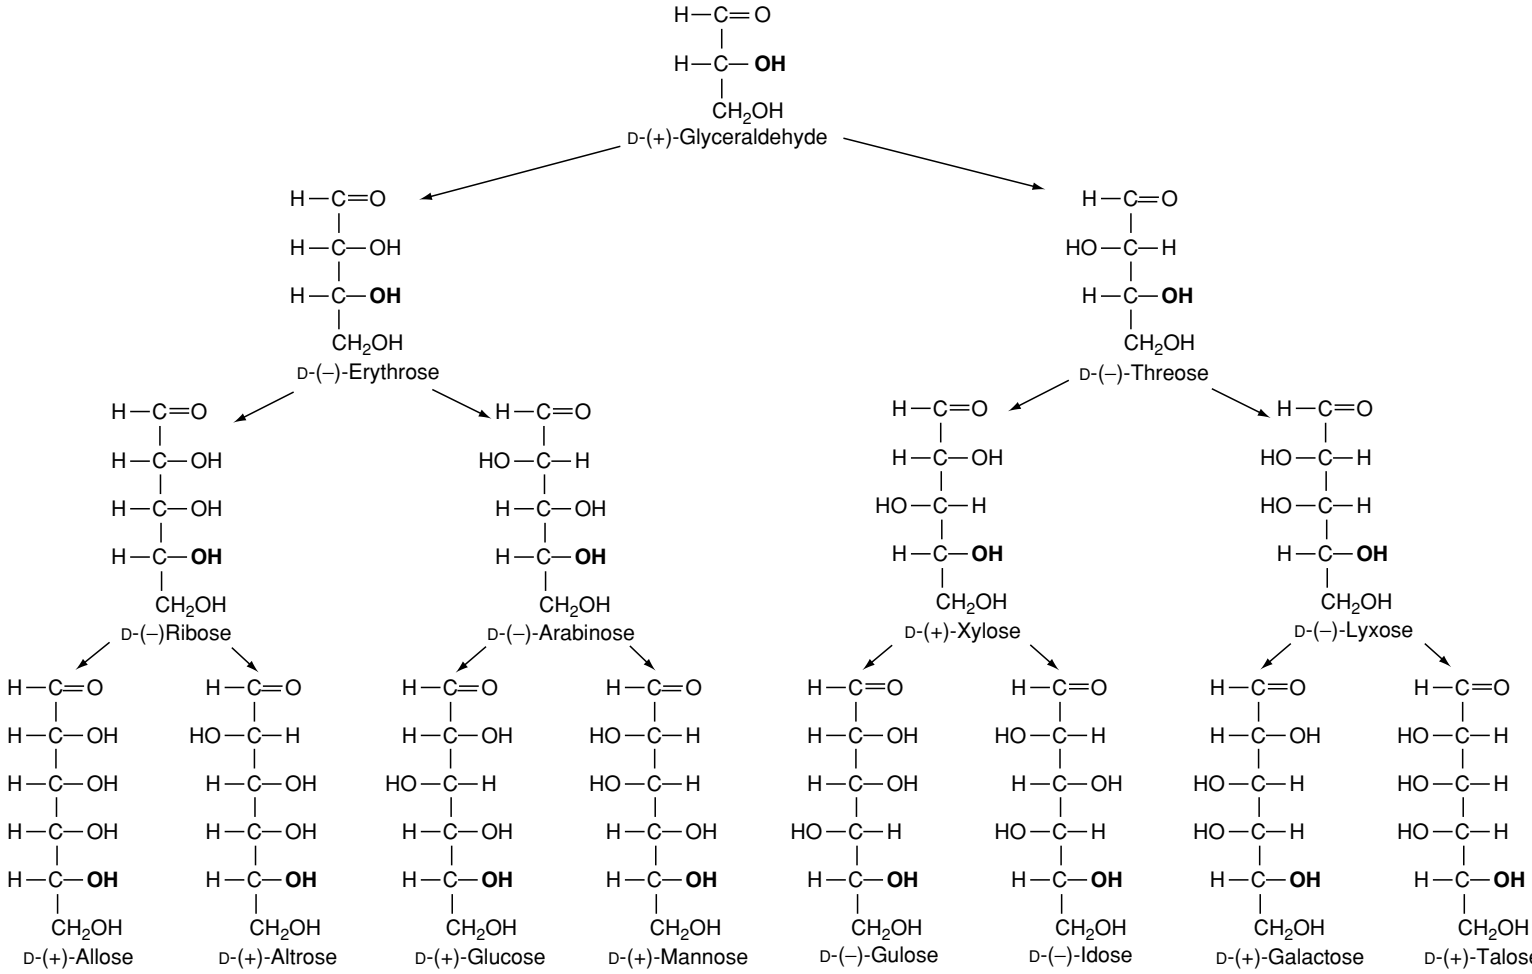

Figure 3 D-series of aldoses derived from D-glyceraldehyde (a triose). Sugars containing four, five and six carbon atoms are known as aldotetroses, aldopentoses, and aldohexoses, respectively. These Fischer projection formulae have the penultimate OH group (bold characters) attached to the highest numbered chiral center, on the right-hand side of the projection formula.

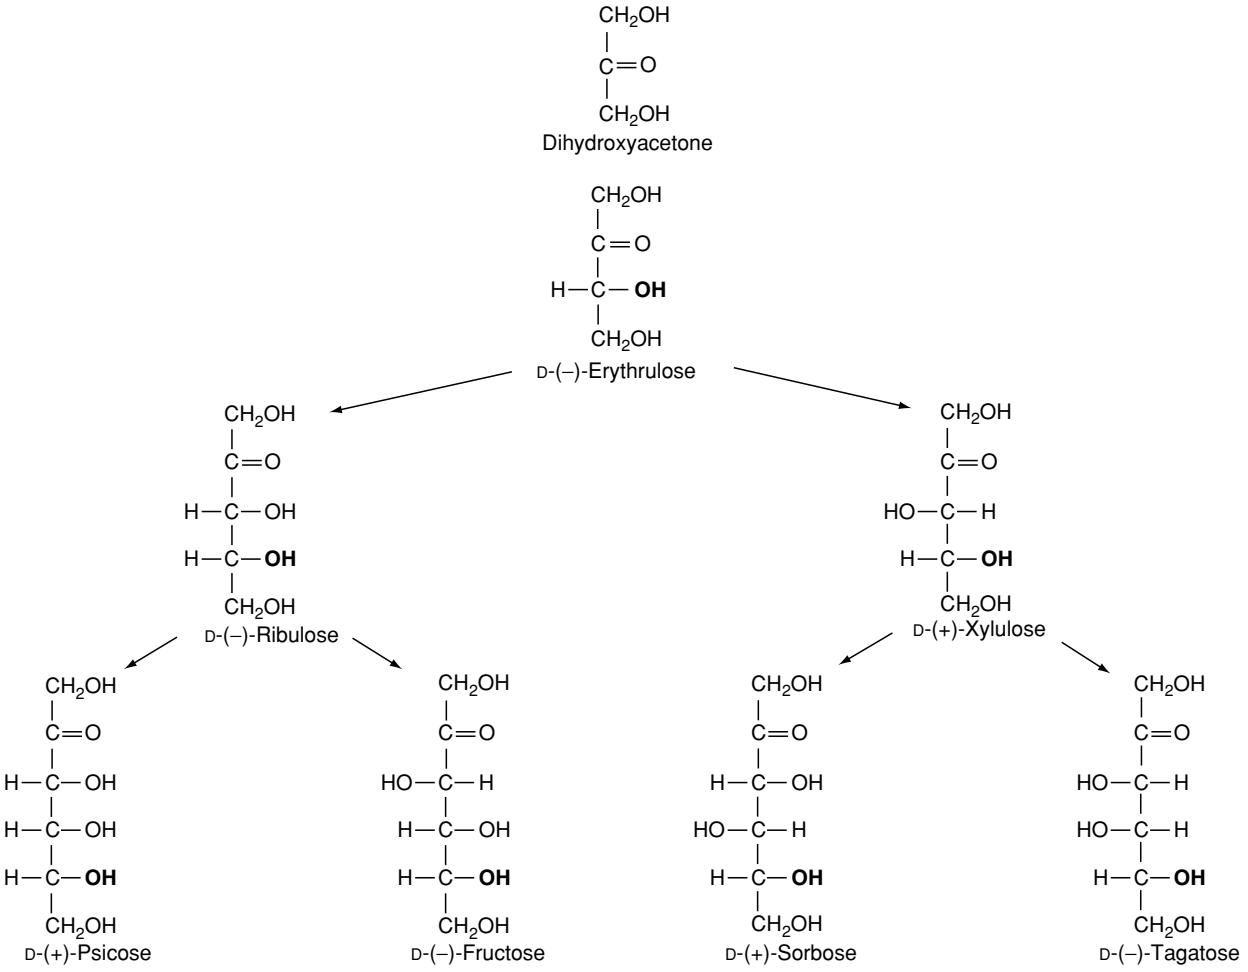

Figure 4 The D-series of ketoses derived from dihydroxyacetone. Sugars containing four, five, and six carbon atoms are known as ketotetroses, ketopentoses, and ketohexoses, respectively. These Fischer projection formulae have the penultimate OH group (bold characters) attached to the highest numbered chiral center, on the right-hand side of the projection formula.

There is confusion in the old literature with regard to the use of the letters D- and L- and also d- and l-. Both the upper-case and lower-case letters were used in the past to describe the configuration as well as the direction of optical rotation. The latter has also been denoted less ambiguously as (*dextro*-) and (*levo*-). The conventional notation currently in use is D- and L- for configuration and (+) and (−) for optical rotation.

Isomerism of Monosaccharides

Isomers are substances that have identical molecular formulas but differ in the way in which the atoms are bonded to each other. Stereoisomers differ only in the way the atoms are arranged in space as already explained. The number of stereoisomers for any monosaccharide is 2^n, where n is the number of chiral centers. Aldohexoses have four chiral centers and, therefore, $2^4 = 16$ isomers (Figure 3). There will be eight D-isomers and eight L-isomers. Therefore, the number of enantiomer pairs is 8 (2^{n-1}). Ketohexoses have only three chiral centers and thus eight isomers and four enantiomer pairs (Figure 4). It should be noted that the specific rotation of a pair of enantiomers has the same numerical value and differs only in sign. For example, the enantiomer of a D-(+)-glucose ($[\alpha]^{20} = +52.5°$) is L-(−)-glucose ($[\alpha]^{20} = -52.5°$). Biological systems can utilize either D- or L-molecules, but not both. The human body utilizes only D-glucose. By contrast, amino acids in the human diet belong to the L-series, and their D-form is not metabolized. However, L-arabinose, L-fucose, and L-rhamnose occur in plants, whereas their D-counterparts do not.

Epimers

Two sugars differing in configuration at a single asymmetric carbon atom are known as epimers. Glucose and mannose are C2 epimers, ribose and xylose

are C3 epimers, and gulose and galactose are also C3 epimers (Figure 3). D-Arabinose and L-xylose are C4 epimers, and so are D-glucose and D-galactose. In all cases (and there are several more), changing the position of H and OH on the same carbon atom (epimeric) of one sugar gives rise to the other sugar, i.e., its epimer. Epimers are also diastereoisomers, i.e., they have a similar structure but are not enantiomers (chiral or mirror images).

Mutarotation and Cyclic Hemiacetals

Glucose crystallized from methanol has a melting point of 147 °C. When dissolved in water, it has an initial specific rotation of +113°, which falls after several hours to +52.5°. Glucose crystallized from water at a high temperature (> 50 °C) has a melting point of 150 °C. Its initial specific rotation is +19° and rises gradually to the value of +52.5°. The change in optical rotation on standing is called mutarotation. This is explained by the fact that glucose gives rise to a cyclic 'internal' hemiacetal with the formation of a bond between carbon atom 5 (carrying an OH group) and carbon atom 1 (the aldehyde carbonyl group), as shown in Figure 5.

During ring closure, a new chiral center is formed (carbon atom 1), and the hydroxyl group will assume either the α- or the β-configuration (right or left respectively of the projection formula). The new chiral center is known as the anomeric carbon, and the resulting two structures as the α- and β-anomers. Anomers are not enantiomers and have different specific rotations. The planar ring structures, termed Haworth projections, are perpendicular to the plane of the paper with the thick lines directed towards the observer. The cyclic structures are then described as pyranoses (and their derivatives as pyranosides) and furanoses (or furanosides) by reference to the heterocyclic compounds pyran and furan. In aqueous solution, a dynamic equilibrium is established between the α- and β-glucopyranose structures. The equilibrium mixture of glucose at room temperature consists of about 36% of the α-anomer and 64% of the β-anomer. There is only a negligible amount of the open chain form. There is also a very small proportion (< 0.5%) of the α- and β-anomers of glucofuranose rings. In general, equilibrated solutions of most sugars contain different proportions of the two furanose and the two pyranose structures.

Fructose undergoes a similar rearrangement. Crystalline β-D-fructopyranose has an initial specific rotation of −133.5° and undergoes rapid mutarotation to − 92°. The equilibrated solution contains about 20% of the fructofuranose form. The four ring forms of fructose are shown in Figure 6.

Ring Conformations

So far, we have dealt with the spatial arrangement of atoms in various forms of monosaccharides. This is known as the configuration of molecules and involves the breaking of chemical bonds when converting, for example, from the D- to the L-form or from the α- to the β-anomeric form. Although the Haworth ring structure of sugars gives an exact view of the spatial arrangement of the hydroxyl groups of a particular sugar, it is misleading, because there is now ample

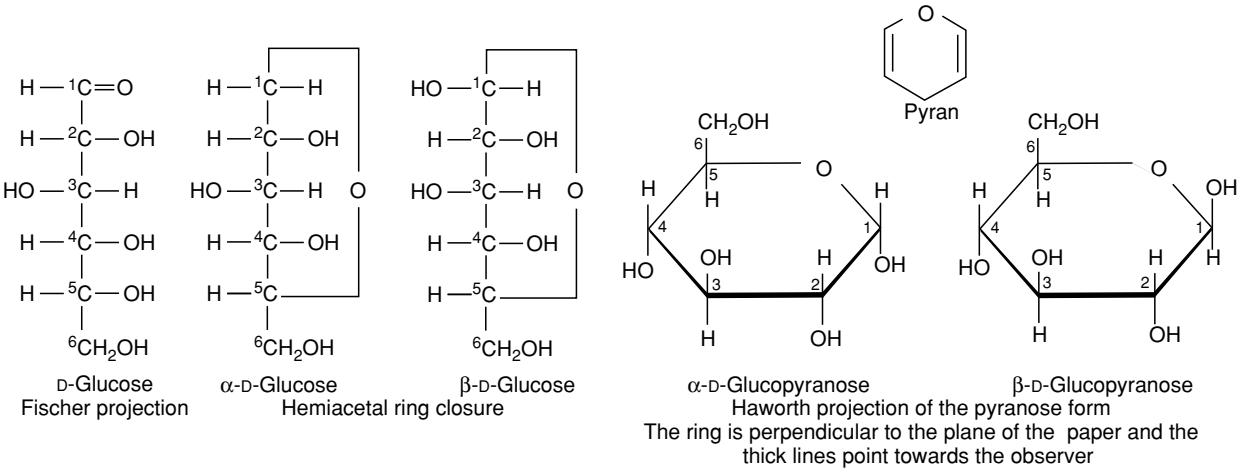

Figure 5 Cyclic hemiacetal formation between carbon 5 and carbon 1 of glucose. The anomeric carbon 1 is chiral, and two positions are possible for the OH group, which can be below (α-form) or above (β-form) the pyranose ring, or right and left, respectively, on the projection formula. The two forms are in equilibrium in aqueous solution. There is a small proportion (< 0.5%) of each of the two furanose forms and an almost negligible amount (0.003%) of the open-chain form.

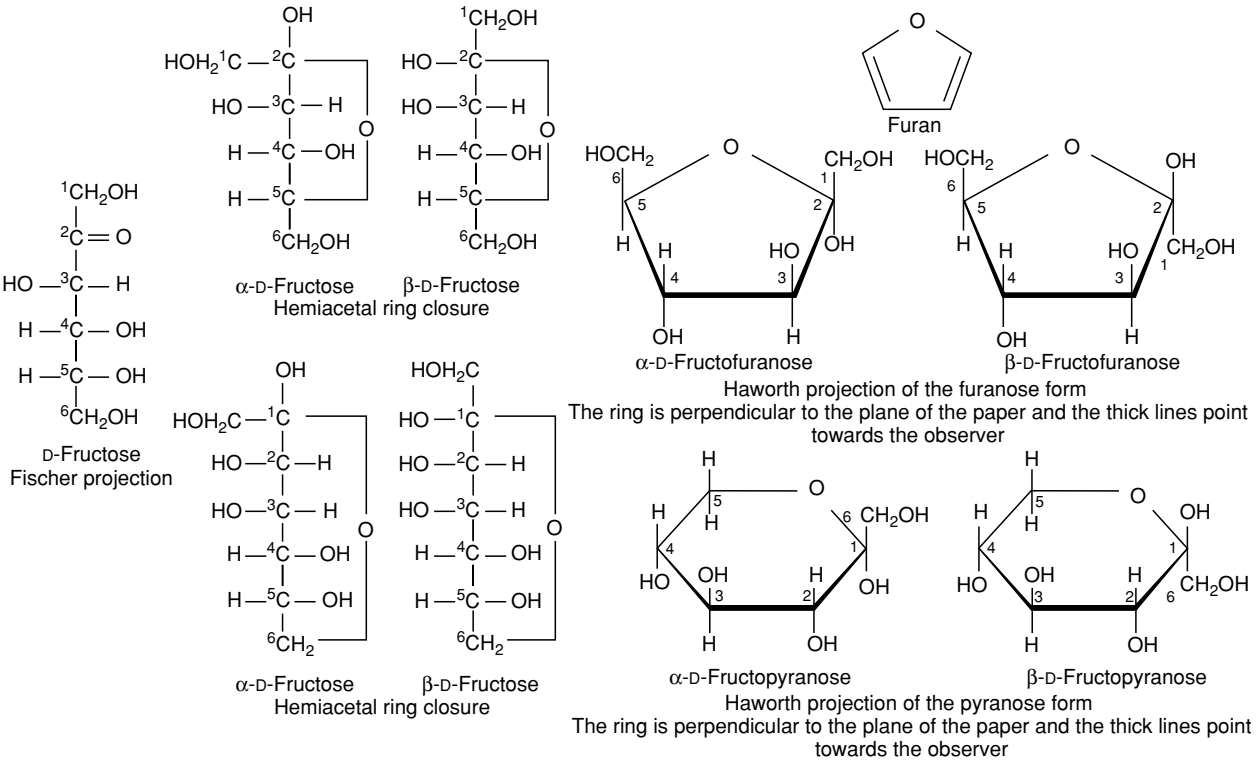

Figure 6 Cyclic hemiacetal (hemiketal) formation between carbon 5 and carbon 2 of fructose leads to the furanose structure. Hemiacetal formation between carbons 6 and 1 leads to the pyranose structure. The anomeric carbon atoms 2 and 1 are chiral, and two configurations are possible for the OH group. There are about 76% of the β-pyranose form, 20% of the β-furanose form, about 4% of the α-furanose form, and a negligible amount of the open-chain form.

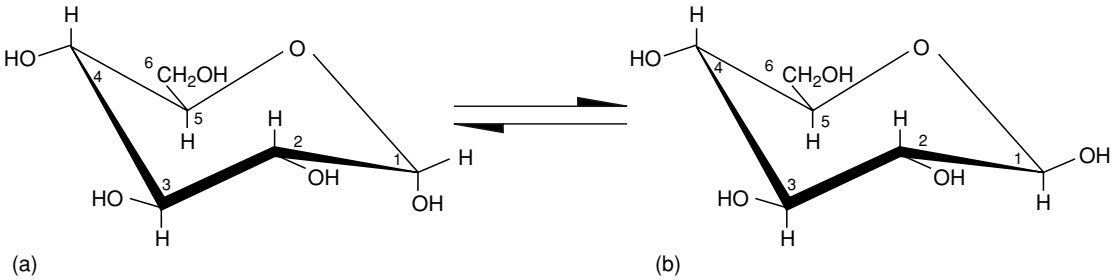

Figure 7 Cyclic hemiacetal form of glucose anomers. Chair [4C1] conformation of (a) α-D-Glucopyranose and (b) β-D-Glucopyranose. Note that all OH groups are equatorial, with the exception of OH on the anomeric carbon atom 1 in (a). In aqueous solution anomer (b) is more abundant (64%) than (a) (36%), because the all-equatorial conformation is thermodynamically favoured. The two forms are in equilibrium; there is a negligible fraction of the acyclic (open chain) form in solution.

evidence that the ring is not planar. The bonds in a planar ring are under considerable strain, which could be relieved if the ring adopted a nonplanar conformation to comply with the tetrahedral direction of valences. A change in the conformation of the ring structure of a sugar does not involve the breaking of bonds. It affects only bond angles and leads to an energetically favorable arrangement of atoms. Theoretical and experimental investigations have thrown considerable light on the conformation of the furanose ring in particular, both in the solid state and in solution. Complex formation, nuclear magnetic resonance spectroscopy and X-ray crystallography are the most useful techniques. Various theoretical schemes and energy minimization studies have also been useful in elucidating the conformation of carbohydrates. The preferred conformation for glucose is the so-called 'chair form' (Figure 7).

Glycosides

When an aldehyde or a ketone reacts with an alcohol in the presence of acid, a hemiacetal is formed first, and then an acetal with the addition of a second molecule of alcohol. The reaction is shown in Figure 8.

We have already seen that the cyclic forms of monosaccharides are hemiacetals. The hydroxyl group attached to the anomeric carbon atom can react with an alcohol (or the OH of another sugar). The resulting product is known as a 'glycoside' (from Greek *glykys* = sweet; gluco- is used specifically for glucose). For example, glucose (α-pyranose form) reacts with ethanol and gives rise to ethyl α-D-glucopyranoside, where the ethyl part of the molecule is known as the aglycone (see Figure 9).

There are many naturally occurring glycosides. Salicin is an example where the aglycone is *o*-(hydroxymethyl) phenol. Amygralin is another glycoside, which occurs in the kernels of bitter almonds, peaches, and apricots. Its composition is [(6-*O*-β-D-glucopyranosyl-β-D-glucopyranosyl)oxy]benzeneacetonitrile. It is hydrolyzed by β-glucosidase (the enzyme emulsin). Glycosides linked in the α-position are hydrolyzed by α-glucosidase, of which yeast is a principal source. Anthocyanins, the coloring matter of flowers and fruits, occur in nature as glycosides, which are hydrolyzed by acid to yield anthocyanidins and a number of sugars. Of course, oligo- and polysaccharides are all glycosides where the aglycone is any other sugar.

Representative Monosaccharides

Both glucose (*See* **Glucose**: Properties and Analysis) and fructose (*See* **Fructose**) occur widely in plants, particularly in fruits. They are also found in honey (*See* **Honey**). Glucose is an important item of commerce as crystalline dextrose monohydrate ($C_6H_{12}O_6.H_2O$), or as a component of glucose syrup and high fructose syrup (*See* **Syrups**). Other monosaccharides occur as components of polysaccharides rather than as free sugars (see below). The pentoses D-ribose and D-2-deoxyribose are components of nucleotides.

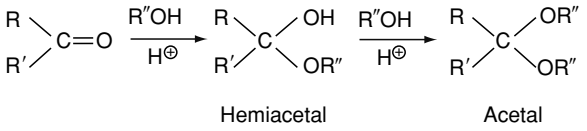

Figure 8 Addition of an alcohol to an aldehyde gives rise to a hemiacetal. Addition of a second molecule of alcohol gives an acetal (with the elimination of water).

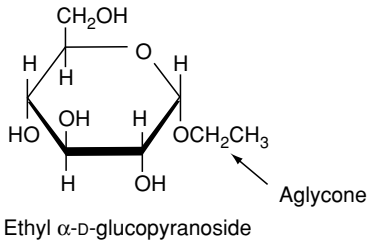

Figure 9 Formation of a 'glycoside' by the addition of ethanol and elimination of water.

Disaccharides

Nomenclature

Disaccharides can be reducing (having a free carbonyl group) or nonreducing. In the latter case, the two component monosaccharides are linked at their respective anomeric centers, and therefore, the carbonyl group is not available for reaction. Disaccharides are named as glycosides where the aglycone is another monosaccharide. Reducing disaccharides are named as substituted monosaccharides (Figure 10).

Sucrose (saccharose) is by far the most important disaccharide (*See* **Sucrose**: Properties and Determination; Dietary Importance; **Sugar**: Sugarcane; Sugarbeet; Palms and Maples; Refining of Sugarbeet and Sugarcane). Lactose (*See* **Lactose**) occurs in the milk of mammals but very rarely in the plant kingdom. Trehalose (α-D-glucopyranosyl α-D-glucopyranoside) (nonreducing) occurs in mushrooms and other fungi. Maltose is formed during the mashing of malt (*See* **Malt**: Malt Types and Products; Chemistry of Malting) in brewing and serves as a substrate for yeast in alcoholic fermentation. It is also a component of high-maltose syrup. Cellobiose (β-D-glucopyranosyl-(1→4)-D-glucose) (reducing) is formed by the enzymatic hydrolysis of cellulose.

Oligosaccharides

The so-called raffinose family of oligosaccharides comprises raffinose (trisaccharide), stachyose (tetrasaccharide), and verbascose (pentasaccharide), all of which occur in the seeds of legumes, as well as in different parts of plants. Verbascose (Figure 11) has three molecules of α-D-galactose attached to sucrose; stachyose has two, and raffinose one. They are all nonreducing. Invertase releases the fructose moiety and gives rise to reducing saccharides. Treatment of raffinose with invertase (β-fructosidase) gives fructose and melibiose, whereas α-galactosidase (from green coffee beans) gives sucrose and galactose. Lactase (β-galactosidase) has no effect.

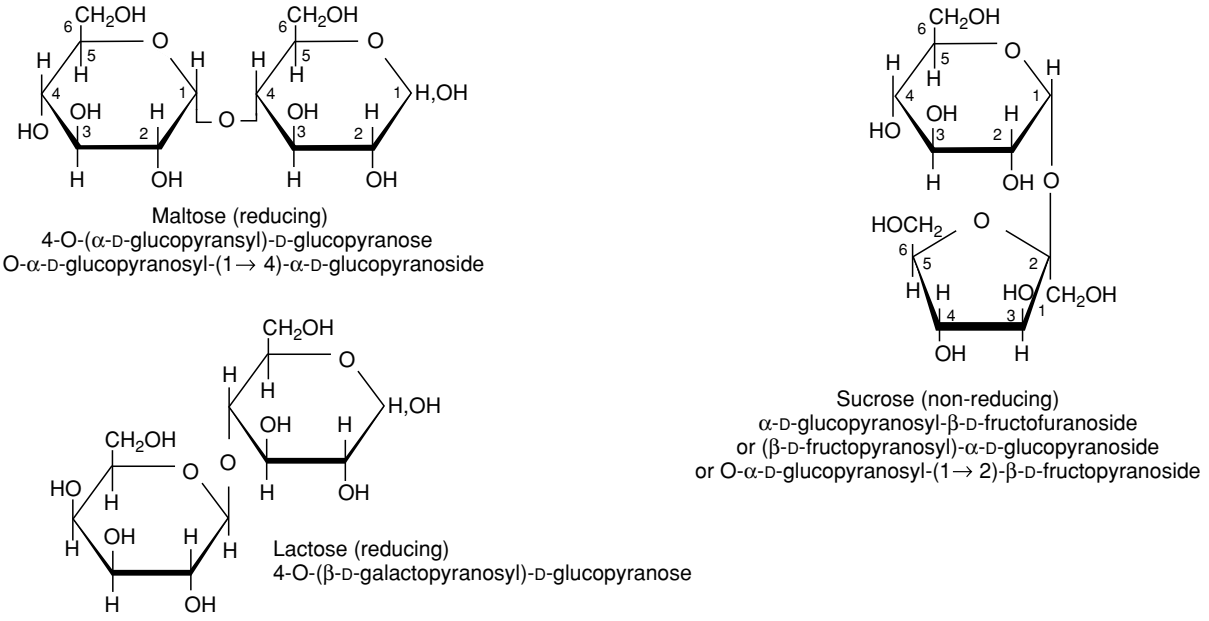

Figure 10 Formulae and nomenclature of three common disaccharides. Sucrose does not have a free carbonyl group. The OH group on the anomeric carbon atom of maltose and lactose can acquire either the α- or the β-configuration. Both sugars mutarotate when dissolved in water, and equilibrium is established after several hours. A few drops of ammonia accelerate the rate of mutarotation, and a constant specific rotation is rapidly attained.

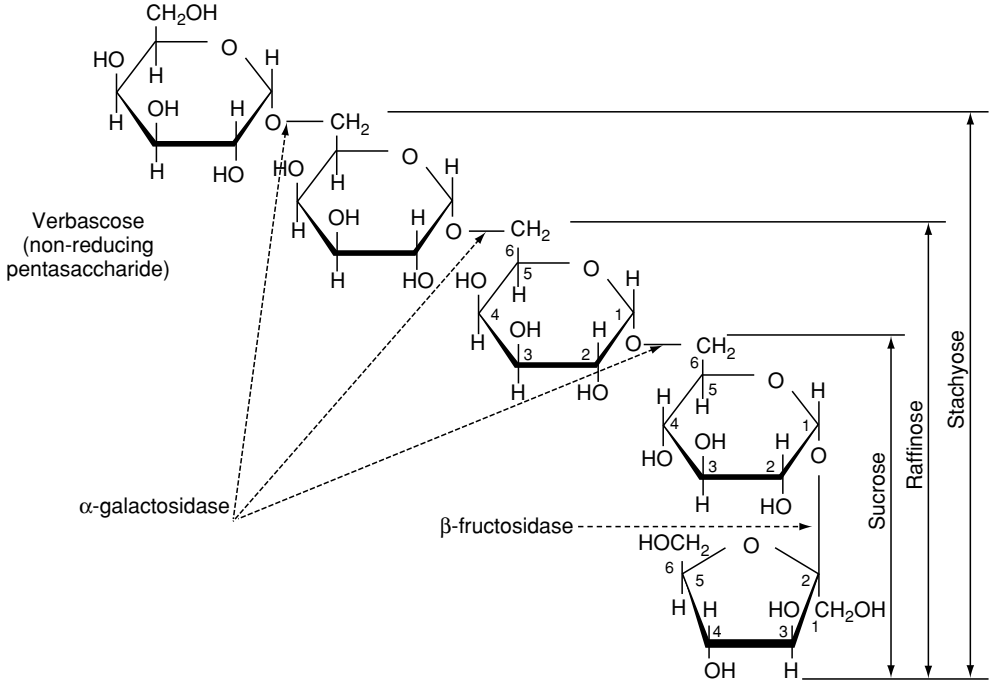

Figure 11 *O*-α-D-Galactopyranosyl-(1→6)-[*O*-α-D-galactopyranosyl-(1→6)]$_2$-*O*-α-D-glucopyranosyl-(1→2) β-D-frutofuranoside. Arrows indicate the points of hydrolysis by enzymes.

Polysaccharides

Nomenclature

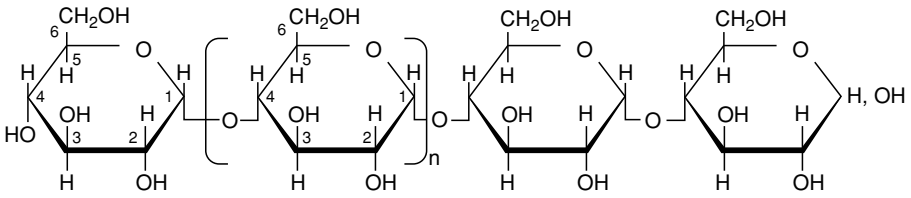
Polysaccharides are also known as 'glycans.' Depending on the monomeric sugar, they are described as glucans, fructans, galactans, mannans, xylans, etc., where the first four letters refer to glucose, fructose, galactose, mannose, and xylose, respectively. Polysaccharides consisting of a single type of monomer are known as 'homopolysaccharides.' When two or more types of sugar monomers are involved, they are known as 'heteropolysaccharides.' The properties of polysaccharides are discussed in **Carbohydrates**: Interactions with Other Food Components.

Representative Polysaccharides

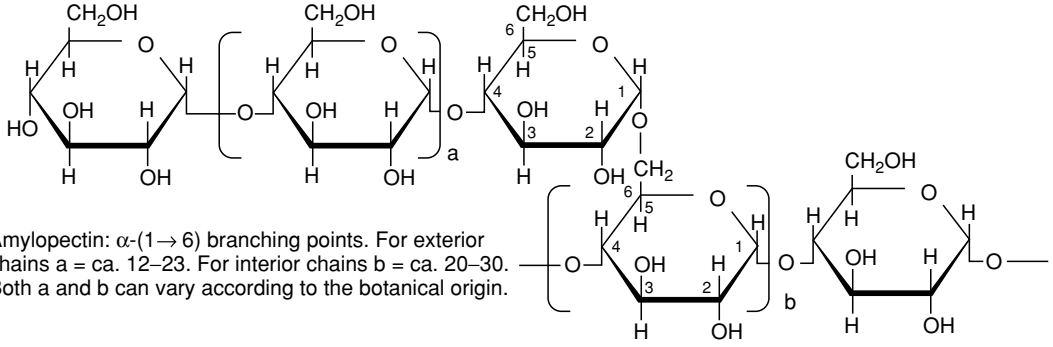
Cellulose (*See* **Cereals**: Contribution to the Diet) is the most abundant polysaccharide in nature. It consists of β-linked glucose units in the form of long chains, which associate parallel to each other by hydrogen bonding to form fibers, which are insoluble in water. Cellulose is a component of plant cell walls and occurs also in leaves and stems, often associated with lignin and xylans. The textural characteristics of leafy vegetables depend, in part, on cellulose. The related β-glucans (water-soluble) of malted barley cause filtration problems in brewing.

Starch (*See* **Starch**: Structure, Properties, and Determination; Sources and Processing; Functional Properties; Modified Starches; Resistant Starch) is the energy reserve polysaccharide of plants. It occurs in the form of microscopic granules (about 5–50 nm in diameter) in cereal grains, in roots, tubers, stems, and, to a lesser extent, in some fruit and leaves. The granules are insoluble in water at ambient temperature but absorb water and swell when heated to their gelatinization temperature (*c*. 50–70 °C depending on the origin). Starch consists of two polymers: essentially linear amylose with an average degree of polymerization (DP) of *c*. 1000, and branched amylopectin as shown in Figure 12. Amylopectin consists of α-(1 → 4)-linked glucose units (95%) and α-(1 → 6)-linked branched points (5%). The DP is 10^4–10^5. Glycogen (*See* **Glycogen**) is the reserve carbohydrate of the animal kingdom. It resembles amylopectin in structure but has more extensive multiple branching.

Dextran (*See* **Dextran**) is a polymer of dextrose synthesized from sucrose by *Leuconostoc dextranicum* or *L. mesenteroides*. It consists mainly of α-D-(1 → 6) linked glucose units to which are attached α-(1 → 3) and some α-(1 → 2) glucan branches. Low-molecular-weight products are water-soluble, whereas high-molecular-weight products are insoluble. Dextrins (*See* **Dextrins**) are products of partial acid hydrolysis of starch (very low acid at



Amylose: α-(1→ 4)-glucan: average n = ca. 1000. The linear molecule may carry a few occasional moderately long chains linked α-(1→ 60).



Amylopectin: α-(1→ 6) branching points. For exterior chains a = ca. 12–23. For interior chains b = ca. 20–30. Both a and b can vary according to the botanical origin.

Figure 12 Basic structure of amylose and amylopectin.

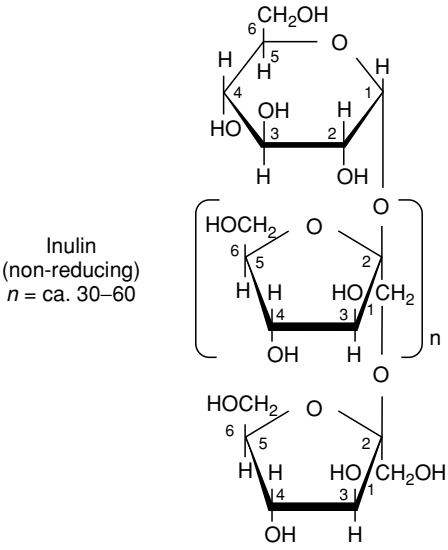


Figure 13 Structure of inulin. This polysaccharide is soluble in water and is not hydrolyzed by β-fructosidase.

high temperature). They are water-soluble and available in several grades. They are used mainly as adhesives, although food-grade dextrins are also known. Nonstarch, noncellulosic polysaccharides (formerly known as hemicelluloses) occur in cereals, roots, fruits, leaves, and stems of plants. They are the main components of dietary fiber (*See* **Dietary Fiber**: Properties and Sources; Determination; Physiological Effects; Effects of Fiber on Absorption; Bran and may consist of pentosans (composite polymers of pentoses), β-glucans, and pectic substances. Some are insoluble, whereas some are soluble in water. Rhamnogalacturonans, arabinogalactans, glucuronoxylans, and xyloglucans occur mainly in fruits and vegetables, whereas glucuronoarabinoxylans occur in cereals. Inulin (Figure 13) is a polymer of fructose, having one molecule of glucose at the start of the chain. It is soluble in water and is not hydrolyzed by invertase. Polysaccharides from various sources used as food additives are discussed in **Carbohydrates**: Interactions with Other Food Components.

Glycoproteins and Glycolipids

Some proteins may contain small amounts of carbohydrates. Casein contains 1% galactose, 1.2% galactosamine, and 2.4% acetyl neuramic acid. Egg white contains considerable amounts of carbohydrate (2–30% in the various fractions), the main sugars being galactose, mannose, and glucosamine. Glycolipids are found in various membranes in both plants and animals. The carbohydrate content is relatively minor.

Physical Properties

Most sugars are soluble in water and form syrups at high concentrations. Crystallization (*See* **Crystallization**: Basic Principles) occurs in saturated solutions. They are mainly used for their sweetness. Sucrose and fructose at a concentration of > 65% (w/w) have a preservative effect because of high osmotic pressure (*See* **Water Activity**: Principles and Measurement; Effect on Food Stability) that prevents the proliferation of microbes (*See* **Carbohydrates**: Interactions with Other Food Components). They also impart desirable textural characteristics to a wide range of foods like cakes, biscuits, and confectionery products. Polysaccharides are mostly used in foods to impart viscosity and induce gel formation (*See* **Carbohydrates**: Interactions with Other Food Components). Table 1 lists some of the properties of sugars.

Chemical Properties

Sugars undergo a variety of reactions and give rise to many derivatives. These are not all of immediate interest to the food scientist. Relevant interactions are discussed in **Carbohydrates**: Interactions with Other Food Components.

Reduction

Monosaccharides are easily reduced to alditols (known also as 'polyols') by sodium borohydride ($NaBH_4$) in weak alkaline solution. Large-scale reduction is carried out by catalytic hydrogenation. Alditols are linear molecules, do not form rings, and do not exist as anomeric forms. These are important properties used advantageously in sugar analysis by gas chromatography, since each alditol gives rise to a single peak on a chromatogram. Tetritols, pentitols, and hexitols have 2, 3, and 4 chiral centers, respectively. In general, they have a low specific rotation, and some are optically inactive (*meso*-forms); the latter are also known as internally compensated molecules, because they have a plane of symmetry (Figure 14).

It is noteworthy that when D-glucitol is rotated 180°, it is identical to D-gulitol, which is also identical to L-glucitol, the latter being the enantiomer (mirror image) of D-glucitol. L-Glucitol does not occur in nature, but D-glucitol (sorbitol) is fairly common (plums, berries). On hydrogenation of fructose, a new chiral center is created, and thus two alditols are produced, namely D-glucitol (75%) and D-mannitol (25%) (epimers). Galactose gives rise to D-galactitol (dulcitol) and maltose to maltitol. Lactitol is obtained by the hydrogenation of lactose. The free carbonyl end of oligo- and

polysaccharides can be reduced to -OH (alditol), as in hydrogenated glucose syrup, which is claimed to be less harmful to teeth and does not participate in the Maillard reaction. Xylitol and sorbitol are also considered as noncariogenic. They all taste sweet. Sorbitol, mannitol, and xylitol are absorbed by passive diffusion in the digestive system and subsequently metabolized. However, large doses have a laxative effect.

Oxidation

The aldehyde group of monosaccharides is easily oxidized (Figure 15) and gives aldonic acids. This occurs when the familiar Fehling's reagent is used for the detection of reducing sugars, whereby blue cupric ions in solution are reduced to insoluble red cuprous oxide. Strong oxidizing agents (e.g., nitric acid) oxidize both ends of the alsose molecule and give rise to aldaric acid. For example, glucose is oxidized by bromine water to gluconic acid, which is isolated as the δ-lactone. Nitric acid gives rise to glucaric (saccharic) acid, which forms a dilactone. A third type of acid is obtained when the aldehyde group is protected prior to oxidation. The OH group of carbon atom 6 is oxidized to give uronic acid. Uronic acids (*See* **Uronic Acids**) frequently occur in natural polymers (*See* **Pectin**: Properties and Determination; Food Use), and are discussed **Carbohydrates**: Interactions with Other Food Components.

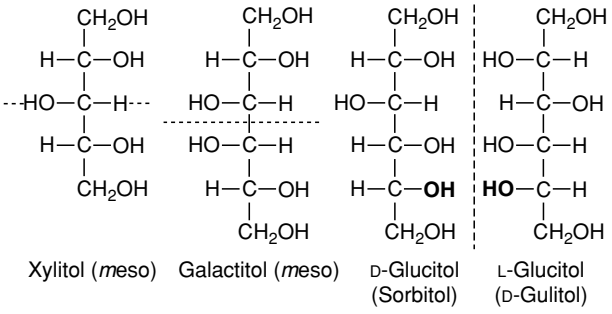

Figure 14 Some alditols and their stereochemical relationships.

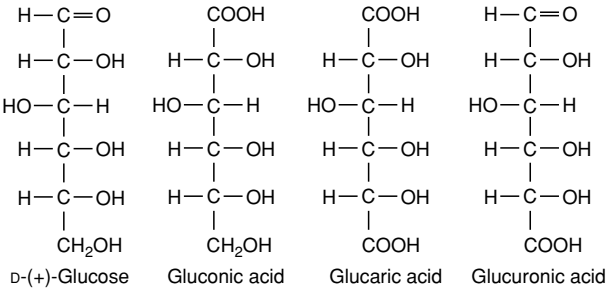

Figure 15 Glucose can be oxidized to give three different acids. The enzyme glucose oxidase gives rise to gluconic acid and H_2O_2. Cupric ions and ferricyanide ions also oxidize glucose to gluconic acid. Glucuronic acid is the monomeric component of pectin and occurs mostly as the methyl ester (methylated pectin).

Esterification

The hydroxyl groups of sugars are relatively easily esterified by anhydrides of organic acids. In sugar analysis, monosaccharides are firstly reduced to alditols and subsequently fully esterified with acetic anhydride; the resulting alditol acetates are then identified and quantified by gas chromatography. In biological systems, D-ribose esterified with phosphoric acid is the carbohydrate moiety of ribonucleotides and deoxyribose in deoxyribonucleotides.

Alkaline Rearrangement

In the presence of alkali, the sugars glucose, mannose, and fructose are interconvertible. This is known as the 'Lobry de Bruyn–Alberda van Ekenstein rearrangement.' The transformation is believed to occur by a 1,2-enolization reaction. However, prolonged contact with alkali leads to degradation of sugars.

Reaction with Amino Acids, Peptides, and Proteins

Reducing sugars readily interact with amino acids and give rise to Maillard reaction products, which lead to progressive browning and aroma formation. The color and aroma of dark beer, baked goods, toasted bread, and grilled foods are, at least in part, due to this reaction, which is initiated when the carbonyl group of a sugar reacts with an amino group (*See* **Browning**: Nonenzymatic). The initial products of the reaction are *N*-glycosylamines or *N*-fructosylamines, which give rise to intermediate products and final heterocyclization and polymerization.

Interactions with Other Food Components

R F Tester and J Karkalas, Glasgow Caledonian University, Glasgow, UK

Carbohydrate Interactions

Carbohydrates include simple sugars, oligosaccharides, and polysaccharides (*See* **Carbohydrates**: Classification and Properties). They can interact with themselves, or with noncarbohydrate substances. These interactions may be (1) physical (e.g., altered rheological properties, lowering of water activity), (2) ionic, (3) stable associations involving hydrogen bonds and van der Walls interactions in the form of helices, and (4) chemically bonded structures (covalent bonds) resulting from reactions of carbohydrates with other molecules. In addition, carbohydrates can be decomposed and oxidized at high temperatures. These interactions provide structure (e.g., gel formation), limit digestibility (e.g., with amylases), and may restrict bioavailability of trace elements. Sometimes, these interactions are deliberately created during food processing (e.g., generation of color or aroma), whereas at other times, they may be undesirable (e.g., browning of dehydrated foods, loss of nutrients), and steps are taken to prevent their occurrence.

Physical Associations and Interactions

Sugars

Sugars are generally very soluble in water. The saturation concentration of sucrose in water at 20 °C is 66.6% (by weight) or 1.994 kg in 1 l of water. Fructose is very soluble (> 70%), but glucose has limited solubility (about 48% by weight) at 20 °C. The viscosity of these sugars increases with increasing concentration, e.g., in cordials, golden syrup (a mixture of sucrose and invert sugar), and honey. The high solubility of sugars is due to the affinity of hydroxyl groups for water. Crystallization of sugars occurs when the solubility limit is exceeded. Sugar crystals, in common with all crystalline substances, have a highly ordered structure built from unit cells of the constituent molecules.

Fondant is a suspension of a very large number of minute sucrose crystals (< 20 μm particle diameter) in a saturated solution of sucrose. The creamy texture of this product is due to the very fine crystals of sucrose that are not detected on the palate. By contrast, crystallization of sucrose is prevented by the addition of glucose syrup or by partial inversion of the sucrose as in candies (hard-boiled sweets and fruit drops). (*See* **Sweets and Candies**: Sugar Confectionery.)

Lactose (milk sugar) has rather limited solubility (21.6% by weight at 25 °C) and crystallizes readily as the monohydrate ($C_{24}H_{22}O_{11}.H_2O$). This sugar forms gritty particles in sweetened condensed milk, because its solubility limit is exceeded during evaporation. By the judicious addition of a small quantity of exceedingly fine lactose crystals to the milk and sucrose mixture during evaporation, lactose is induced to crystallize as very fine crystals (< 30 μm diameter) that are not perceptible in the mouth.

Partially purified sucrose crystals (e.g., soft sugar, brown sugar, Demerara sugar, and Muscovado sugar) are coated with a thin film of molasses, which imparts a brown color and a characteristic flavor. These products are often considered nutritionally superior to white sugar. This is an erroneous assumption, because the protein and mineral contents are usually less than 1%. The 'unrefined' sugars contain only traces of vitamins. The cohesive nature of these products is due to a small quantity of inverted sugar and accompanying moisture (*c.* 1–5%), both of which originate from the molasses.

Apart from their widespread use as sweeteners, simple sugars have a preservative effect in concentrated solution. A 65% (by weight) solution of sucrose lowers the water activity (a_w) (*See* **Water Activity**: Principles and Measurement; Effect on

Food Stability) to about 0.8, and the product resists microbial growth because of the prevailing high osmotic pressure. Jams and preserves owe their stability at ambient temperature to this effect. The long shelf-life of intermediate-moisture foods (e.g., fruitcake) depends on the same principle. Glucose is not useful in this respect, because of its relatively low solubility. Conversely, invert sugar causes a considerable reduction in water activity as in honey, for example ($a_w = 0.75$). 'Set honey' is saturated with respect to glucose, which remains suspended as very small crystals in a viscous, almost solid, medium. Unlike sugars, polysaccharides do not cause any significant lowering of water activity, because they have a large molecular weight and because they are used at a very low concentration (normally < 5%).

Apart from sugar–sugar and sugar–water interactions as discussed above, sugars may interact chemically and form more extensive bonding (covalent bonds) with themselves and other molecules (below). However, certain sugars (like glucose) are also valuable in food systems because of their inherent reducing properties. These interactions may stabilize ionic groups in solutions and facilitate their absorption when ingested (e.g., maintenance of the ferrous form of iron and conversion from the ferric form).

Polysaccharides

Polysaccharides are macromolecules, many of which can adopt organized structures in foods. Most are polyhydric alcohols, acids and/or esters, which, depending on the monomeric sugar composition, are likely to interact with themselves, other polysaccharides, or other molecules. Polysaccharides may be insoluble in water, dissolve, and form true solutions, colloidal dispersions, and/or gels. In mixed polysaccharide systems, the polymers may intersperse and form a number of interactive states. These interactions may be described as:

1. *Additive*, where the measured property is the sum of the property of the individual polymers.
2. *Complementary*, where polymer one provides a characteristic that polymer two (or more) lacks.
3. *Synergistic*, where the effect of the combined polymer population is greater than the additive effect.
4. *Antagonistic* with respect to a ternary system, where there is phase separation as a consequence of solvent incompatibility. The phase separation process (coacervation) results in one phase being rich in one of the two solutes and the other phase being rich in the other solute. This process is utilized in, for example, encapsulation of flavors.

When polysaccharides are added to foods to stabilize structural form, they are described as 'stabilizers' (*See* **Stabilizers**: Types and Function; Applications) or 'gums' (*See* **Gums**: Properties of Individual Gums). Stabilization reflects thickening rather than emulsification in the true sense, although stabilizers are used in foods to prevent separation of emulsions and sedimentation of suspended solids. In many products (e.g., instant soups), they impart a desirable 'mouth feel.' Some act as gelling agents, which again impart desirable physical properties. With the exception of gelatine (a protein), all stabilizers are polysaccharides whose main function is to increase the viscosity of aqueous systems. Most of the polysaccharides listed in Table 1 are used as stabilizers in a wide range of manufactured foods. Nonmodified (native) starch is exceptional, because it is primarily a very important nutrient (together with sugars, it provides about 50% of food energy in the UK), which also happens to be a good stabilizer and texture modifier. According to Stokes' law, the velocity of sedimentation of particles is inversely proportional to the viscosity of the medium in which the particles are suspended.

Polysaccharides consist of chains of varying length, which generally occur as random coils in dilute aqueous systems. The chains can be branched or linear. They are surrounded by a cloud of water molecules, and this gives rise to internal friction and hence viscosity. They behave as imaginary spheres whose 'effective volume' or 'hydrodynamic volume' is related to the 'radius of gyration' of the polysaccharide chain. Branched polysaccharides have a lower viscosity than their linear counterparts of the same molecular weight because their hydrodynamic volume is smaller. Polysaccharides give rise to a substantial increase in viscosity, even at a very low concentration (< 1%). As the concentration increases, the random coils begin to overlap and a considerable increase in viscosity is observed as the chains interact with each other. Many polysaccharides, but not all, give rise to gels at a higher concentration (1–4%). The gel-forming properties of polysaccharides may be due to weak Van der Waals interactions, ionic interactions, hydrogen bonding, or helix formation. As a consequence, junction zones are established, which stabilize the three-dimensional structure that leads to self-supporting gels.

With the exception of starch, polysaccharides are not digested by the endogenous enzymes of the human digestive tract and are considered as dietary fiber. Nutritionally speaking, however, there may be a drawback, in so far as charged polysaccharides may bind minerals (cations) and make them less available to the human body.

Table 1 Polysaccharides used in foods

Polysaccharide	*Origin*	*Monomeric sugars*	*E-number*
Starch	Cereals, tubers, roots	α-(1→ 4)-D-Glucose [amylose] and α-(1 → 6)-D-glucose branches [amylopectin]	
Cellulose	Cell walls, wood, cotton	β-(1 → 4)-D-Glucose	E 460
Tree exudates			
Gum acacia (Arabic)	*Acacia senegal*	β-(1 → 3)-D-Galactose backbone with L-rhamnose, D-glucuronic acid, D-galactose, L-arabinose side-chains	E 414
Gum karaya (sterculia)	*Sterculia urens*	D-galacturonic acid, D-galactose, L-rhamnose, D-glucuronic acid in three-dimensional arrangement	E 416
Gum tragacanth	*Astragalus gummifer*	α-(1 → 4)-D-Galacturonic acid backbone with D-galactose -β-(1 → 2)-D-xylose, L-fucose-β-(1 → 2)-D-xylose and D-xylose-β-(1 → 3) side-chains	E 413
Seed gums			
Locust bean (carob) gum	*Ceratonia siliqua*	β-(1 → 4)-D-Mannose with α-(1 → 6)-D-galactose side-chains (Man:Gal = 4:1)	E 410
Guar gum	*Cyamopsis tetragonoloba*	β-(1 → 4)-D-Mannose with α-(1 → 6)-D-galactose side-chains (Man:Gal = 2:1)	E 412
Algal products			
Agar	*Gelidium* spp.	β-D-Galactose and 3,6-anhydro-D-galactose. Low esterification with sulfate groups	E 406
Alginic acid	*Ascophyllum nodosum, Laminaria hyperborea, Macrocystis pyrifera*	β-(1 → 4)-Mannuronic acid chains and α-(1 → 4)-guluronic acid chains, with alternating mannuronic–guluronic acid chains	E 400
Carrageenan	*Gigartina stallata*, *Chondrus crispus*, etc.	Galactose-sulfate, galactose disulfate and anhydogalactose chains; occurs in different forms: τ-, κ-, λ-, μ- and ν-carrageenan	E 407
Fruit products			
Pectin	Apple pomace, citrus peal	α-(1 → 4)-Galacturonic acid, largely esterified with methanol; some rhamnose and xylose may be present	E 440
Microbial products			
Curdlan	*Alcaligenes faecalis* var. *myxogenes*	β-(1 → 3)-D-Glucose	
Gellan	*Pseudomonas elodea*	β-(1 → 4)-D-Glucose-β-(1 → 4)-glucuronic acid-β-(1 → 4)-glucose-α-rhamnose-tetrameric repeat unit	E 418
Xanthan	*Xanthomonas campestris*	α-(1 → 4)-glucose backbone with mannose–glucuronic acid–mannose side-chains with terminal carboxyl groups	E 415
Root polysaccharides			
Inulin	*Helianthus tuberosus* (Jerusalem artichoke) and *Cichorium intybus* (chicory root)	β-(1 → 2)-D-Fructose	
Konjac	*Amorphophallus konjac*	β-(1 → 4)-D-Mannose, β-(1 → 4)-D-glucose	E 425

Homopolysaccharides

Homopolysaccharides (homoglycans) consist of a single type of monomer. Cellulose and starch are the best-known examples. However, they have very different properties. Cellulose (*See* **Cereals: Contribution to the Diet**) consists of β-(1 → 4)-linked glucose units arranged in a ribbon-type conformation in a zigzag pattern. Parallel chains fit closely to each other and associate with multiple hydrogen bonds to give rise to long fibers, which are totally insoluble in water and relatively inert. Although subject to some swelling in water, cellulose is completely unaffected by boiling in water. Natural cellulose (cellulose I) has considerable crystallinity (60–80%), as revealed by X-ray diffraction. Starch consists of two components, *viz*. amylose (essentially linear) and amylopectin (branched).

The α-(1 → 4)-linked glucose molecules in amylose allow considerable conformational freedom. In freshly prepared dilute solution, amylose is in the form of a random coil. On standing at ambient temperature, it 'retrogrades' (see below), i.e., the random coils form double helical associations, which are

insoluble and sediment as a white precipitate. At a high concentration, free settling is prevented, and gels are formed as the randomly oriented chains approach each other at several junction zones. Double helices are formed at the junctions, which do not extend the full length of the molecule. The net result is a three-dimensional structure, whose rigidity depends on the concentration of amylose and hence the number of junction zones per unit volume. Amylose gels are translucent to almost opaque, owing to light scattering. Double helices of retrograded amylose are dissociated at a temperature of about 160 °C.

Amylopectin consists of α-(1 → 4)-linked glucose units (95%) and α-(1 → 6)-linked branched points (5%) and is fairly soluble in water. The outer chains of amylopectin, consisting of about 15–25 glucose units, because of their close proximity readily form short double helices during starch biosynthesis and within food systems upon storage. Amylopectin is fairly stable in solution and forms soft gels at a high concentration. Waxy maize starch consists almost entirely of amylopectin and gives clear or slightly translucent weak gels.

When native starches (*See* **Starch**: Structure, Properties, and Determination; Sources and Processing; Functional Properties) are heated in excess water, the double helices progressively dissociate, water is imbibed, and the granules swell. This process of gelatinization is characteristic of the botanical origin. Typically, it occurs at around 65 °C and is irreversible, forming a solution, a colloid, or a gel, depending on the origin of starch and its concentration. Once gelatinized, double helices may reform in food systems (below).

Fructans are polymers of fructose linked by β-(1 → 2) bonds. The best-known example is inulin with 3–60 fructose units per chain. This forms clear viscous solutions in water. Inulin is not digested by the endogenous enzymes of the human digestive system. It is considered as dietary fiber and is used in some functional foods (*See* **Functional Foods**).

Curdlan is a microbial homopolysaccharide that is insoluble in water at ambient temperature. It forms a gel > 54 °C with an almost constant strength between 60–80 °C and increases up to, and beyond, 100 °C. It is an approved food additive in the USA.

Heteropolysaccharides

Heteropolysaccharides (heteroglycans) consist of more than one type of monomeric sugar. Indeed, the majority of polysaccharides used as food additives are heteropolysaccharides (Table 1).

Single Polymer Systems

Heteropolysaccharides can associate in a number of ways in food and nonfood systems forming solutions, colloids, gels, and sometimes associated helices. The physical properties are critical in terms of texturization in food systems and must be optimized for a given application. These structures are dependent on the nature of the polysaccharide and its concentration; agar, for example, can form relatively strong gels at the level of 1%, whereas starch concentrations of > 4% are required for gelling. Some, like carrageenan [β-(1 → 4)-linked galactose and galactose sulfate residues], form hydrogen-bonded 'junction zones' between two polymer chains that stabilize the gels. In agar [also β-(1 → 4)-linked galactose and galactose sulfate residues] and carrageenan, the polysaccharide chains form double helices, which associate further to form more complex junction structures. Pectin forms strong gels (e.g., jam-making) by a different mechanism. In pectin, the highly esterified polymers (methylated polygalacturonic acid) are heated in acid solution (pH about 3.5) in the presence of a high proportion (> 50%) of sucrose. The low pH suppresses ionization of the nonesterified galacturonic acid units, whereas the high degree of methylation favors the formation of junction zones by hydrophobic interactions. The sucrose further competes for water allowing junction zones to form without separation from water. However, when the gel is mechanically disturbed (broken), liquid is released as a result of shrinkage (syneresis).

Alkali metal salts of alginates are soluble in water, although the free acids are insoluble. These polymers are composed of mannuronic (M) and guluronic (G) acids. Three major arrangements of the sugars occur, namely linear regions consisting of M or G (M_n and G_n are known as periodically arranged monosaccharides) interspersed with regions of alternating M and G (MG_n, aperiodic segments). In the presence of divalent cations (especially calcium), the carboxylic groups of adjacent chains are linked to form the so-called 'egg-box' structure. The final three-dimensional structures give exceptionally rigid and stable gels. Addition of sodium phosphate or of sodium ethylenediaminetetraacetate destroys the gel structure by removing calcium ions.

Mixed Polymer Systems – Synergistic and Nonsynergistic Interactions

It is known that the viscosity of binary mixtures of some polysaccharides can be higher than the viscosity of the individual components measured at the same concentration. This synergistic interaction is particularly pronounced in mixtures of guar

(galactomannan) and xanthan gums. This interaction can be interpreted by the Flory and Huggins theory.

Three types of polymeric interactive behavior have been identified and characterized:

1. *Incompatibility*, where there is phase separation.
2. *Compatibility*, where a uniform homogeneous phase is created.
3. *Polymer associations*, where solid coacervates or gels are formed. Most mixed polymer systems are incompatible (especially above solution concentrations of 1–2%). If one of the polymers is charged, miscibility is promoted, but if both species are charged, immiscibility results.

In terms of strength of interactions, agarose–galactomannan and κ-carrageenan–galactomannan interactions are reduced as the galactose content of the galactomannan increases. This is because linear mannan regions form tight associations with double helices (below) of the other polymers. All these interactions can be very important in polysaccharide blends used in food systems.

Electrostatic Interactions

Polysaccharides carrying acidic groups have a strong tendency to bind cations. Neutral polysaccharides do not bind cations, whereas polycarboxylates like demethylated pectin, alginic acid, and xanthan readily bind divalent cations. Similarly, sulfated polysaccharides like κ-carrageenan also bind cations. Certain polysaccharides contain primary amine groups (like chitin and chitosan) and form associations with transition metals.

Polysaccharide–cation interactions lead to two transitions: sol–gel and phase separation. Where sol–gel transitions occur, viscous solutions are present below the transition concentration and above the transition temperature. Above the sol–gel transition concentration and below the sol–gel transition temperature, gels exist that exhibit viscoelasticity. High cation concentrations generally lead to phase separation in the form of precipitation of the polysaccharide.

There is a real nutritional concern (although there is some controversy regarding its significance) that minerals may be lost from the human body owing to polysaccharide–mineral interactions. Acidic conditions in the stomach will tend to discharge the minerals and make them potentially more easily absorbed lower in the intestine. In the almost neutral pH of the small intestine where the minerals would primarily be absorbed, however, re-association of cations with charged polymers will occur. The stability of these associations in this region of the gastrointestinal tract is uncertain as well as the restrictions imposed upon absorption. Additionally, the polysaccharides may be fermented in the large intestine, releasing the minerals for absorption in this region (assuming that there is little or no competition from the microflora, which will also tend to absorb the minerals).

Helical Structures

Polysaccharides can, as discussed above, assume a helical conformation. The helices may be single (one chain) where stabilization is achieved by the presence of a guest molecule (ligand) in the lumen of the helix. These structures are commonly referred to as 'inclusion complexes.' Starch polymers (amylose and amylopectin) are highly effective in forming inclusion complexes; especially amylose with its long linear α-(1 → 4) bonded chains. The formation of a blue color when iodine solution is added to starch is a familiar example, and it has been shown to be due to the formation of a helical complex. The starch–iodine reaction is used as a quantitative tool for the determination of amylose by colorimetry where a blue color is generated with a λ_{max} at 635 nm. This color is a function of the chain length. Amylopectin, with its shorter unit chain, gives rise to a red color with iodine and absorbs light in the region 570–580 nm.

Starch (particularly amylose) can also form inclusion complexes with organic guest molecules. Free fatty acids and their alkali metal salts, acyl monoglycerides of fatty acids, fatty alcohols, and surfactants containing linear acyl groups give rise to amylose–lipid complexes that are insoluble in water at pH < 7. These interactions occur during food processing and are common in extruded foods. Acyl monoglycerides are added to instant mash potato granules to prevent stickiness, and acetylated tartaric acid esters of acyl monoglycerides are added to bread to retard staling. Sodium and potassium salts of fatty acids are permitted additives in Dutch type rusks. Complexes are also possible with many other guest molecules, including flavoring agents, aldehydes, ketones, alcohols, vitamins, and dyes. However, many of these so-called 'complexes' have not been structurally characterized as being true inclusion complexes rather than unidentified associations.

It should be emphasized that amylose in solution occurs as a random coil, and not as a preformed helix. It assumes a helical conformation (left-handed helix) only in the presence of a hydrophobic guest (e.g., palmitic acid), because the interior of the helix is essentially hydrophobic with an affinity for the hydrocarbon chain of the ligand. Inclusion complexes (V-type helices) containing 6, 7, or 8 glucose residues per helical turn can be formed, depending on the

cross-sectional dimensions of the guest molecule. Adjacent helical turns (pitch 0.8 nm) are held together by hydrogen bonding, which is the main stabilizing force of the complexes. It has been shown that a stoichiometric relationship exists between the amylose and the guest molecules when the helix is completely saturated with the ligand. For instance, lauric acid (1.73 nm chain length, C12:0) is completely surrounded by 2.16 helical turns corresponding to about 13 anhydroglucose residues. Arachidic acid (2.74 nm chain length, C20:0) is surrounded by 3.42 helical turns corresponding to 20.5 anhydroglucose units. The long complexed helices fold upon themselves to form three-dimensional structures, which give characteristic X-ray diffraction patterns (amylose V-pattern), owing to the ordered packing of the helices. Complexes are also characterized by their distinct dissociation temperatures, which are mainly functions of the chain length of the ligand and the temperature at which the complexes are formed. The dissociation energy of the complexes is a measure of the energy required to disrupt intrahelical hydrogen bonds. Thermal properties of complexes are studied by differential scanning calorimetry.

Apart from single helices, which form around guest molecules, double helices may be formed from polysaccharide chains. Furthermore, these double helices may form ordered (registered) arrays and consequently generate crystalline regions (see below), as found in native starch granules. Double helices are stabilized by interchain hydrogen bonding and in this form are essentially insoluble.

Crystallinity and Retrogradation

Although helices or similar structures of polysaccharides may be formed from solutions/food systems, these structures need not necessarily be crystalline. For crystallinity to be present (as determined by X-ray diffraction, for example), the helical structures must be associated in ordered/registered structures. The ordered structures have unit cell repeats, which create characteristic diffraction patterns. Many polysaccharides associate to form true crystalline structures, although these are often 'contrived' by making specific derivatives of the polymers.

In food systems, polysaccharides would generally find it difficult to crystallize, because of interference from other molecular species. However, starch polymers (especially amylose) do crystallize relatively quickly in/from solutions and in highly hydrated systems like baked goods (bread, cakes, etc.). The consequence in terms of product texture is apparent to anyone who has eaten stale bread. This contains appreciable quantities of recrystallized or retrograded starch, which, being a form of 'resistant starch' (*See* **Starch**: Resistant Starch), imparts an unpleasant texture and potentially restricts amylase hydrolysis. In some products, there is a relatively high resistant starch content owing to retrogradation, and this is sometimes promoted as a positive dietary feature. Probably, the best-known example is corn flakes.

Formation of Covalent Bonds

Some carbohydrate interactions with other carbohydrates or other types of molecules incorporate true covalent bonding, as described below.

Caramelization

The process of caramelization (*See* **Caramel**: Properties and Analysis; Methods of Manufacture; **Carbohydrates**: Classification and Properties) involves the formation of brown-colored and odorous products from melted sugars. Many confectionery products incorporate steps that cause caramelization (e.g., toffee-making), although commercially available caramel is also added to products to impart a desirable color (e.g., colas and whisky). Hexoses are converted by heat to dicarbonyl compounds via an enediol intermediate. Loss of water leads to 5-hydroxymethylfurfural and related chemical species, which are very reactive. Pentoses give furfural. Maltol and isomaltol are also produced, both of which have a characteristic odor.

Nonenzymic (Maillard) Browning

Nonenzymic browning, as the name indicates, does not depend on the action of enzymes. The NH_2-groups of amino acids (especially the ε-amino group of lysine) in alkaline or neutral pH react with the aldehyde groups of sugars to form brown pigments. The N-substituted 1-amino-1-deoxy-ketoses (Amadori compounds) lead to the formation of a range of dicarbonyl compounds. These compounds may react further with amino acids (Strecker degradation) to form pyrazines, for example. Polymerization of the products of the amino acid sugar reactions causes the formation of very complex polymers (melanoidins), which impart color to foods. Flavor compounds are also generated as a consequence of these processes. Hence, in food systems, these browning reactions generate products with desirable sensory characteristics. However, there is a loss of nutritional quality as the amino acid availability progressively declines. This can be particularly undesirable in low-protein diets, where amino acids (especially essential) are made unavailable. The Maillard reaction can be minimized by lowering the pH, avoiding high temperatures and long storage times, and maintaining a low

water activity. The reaction is inhibited by SO_2 or busulfite salts and can be avoided in some foods by the use of nonreducing sugars.

Other Interactions

Sucrose is readily hydrolyzed to glucose and fructose (invert sugar) either by acids or by the enzyme β-fructosidase (invertase). In soft drinks containing acid (e.g., citric or phosphoric), gradual inversion of sucrose takes place, even at ambient temperature.

Digestion, Absorption, and Metabolism

D H Alpers, Washington University School of Medicine, Washington, USA

Introduction

The assimilation of dietary carbohydrate into the body is a complex process involving secretion (salivary glands, stomach, and pancreas), hydrolysis (stomach, small intestine, and colon), and absorption (small intestine and colon; **Figure 1**). Abnormalities in each of these organs or processes can lead to diminished assimilation of carbohydrates.

Digestion

Dietary Carbohydrates

Western diets contain on average 200–300 g of carbohydrates day^{-1}, accounting for 40–50% of total food sources of energy but only 22% of total daily calories. The sources of this carbohydrate include complex polymers (e.g., starch), and simple sugars, including the disaccharides lactose and sucrose, and the monosaccharides glucose and fructose. Nearly all of these carbohydrates, except for lactose in milk and some muscle glycogen, are found in plants. Dietary fiber is the term used to describe polymeric substances (nearly all carbohydrate) that are not digested and absorbed in the small intestine. In addition to dietary

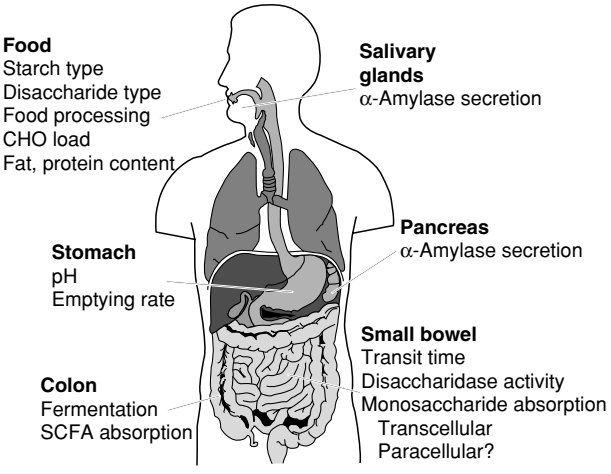

Figure 1 Factors affecting carbohydrate (CHO) assimilation. SCFA, short chain fatty acid. Reproduced from Carbohydrates: Digestion, Absorption and Metabolism. *Encyclopaedia of Food Science and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

fiber, plants contain oligosaccharides (3–8 sugars) mainly as α-galactosides in legumes (e.g., raffinose, stachyose) and as fructans (e.g., fructooligosaccharides) found in onions and other vegetables. Some of the undigested fiber and oligosaccharides (or disaccharides) can be hydrolyzed by colonic bacteria and their products absorbed.

Starch is the major storage form of polysaccharides in plants, along with cellulose (a β1–4 linked glucopolymer), hemicelluloses (e.g., galactans, arabinans), pectins, and gums. Starch is composed of polymers of glucose joined in straight-chain α1–4 linkages without (amylose) or with α1–6 branched chains (amylopectin). Even the starch is not completely digested, and some of the dietary fiber represents 'resistant starch.' Although the assay of 'resistant starch' is not well standardized, its presence is probably proportional to the amount of dietary fiber. The plant content of starch depends upon the type, part, and age of the plant. The efficiency of digestion of plant starch is inconsistent, as plant starches are enclosed in granules that are incompletely and variably disrupted during cooking or processing. Thus, actual dietary starch content may vary significantly from that contained in published tables.

The percentage of carbohydrate ingested as simple sugars has been increasing in recent decades. Sucrose is found in most fruits and vegetables and (in purified form) as table sugar and a sweetener for many foods. Sucrose accounts for about $40\,g\,day^{-1}$ (30% of carbohydrate intake, 9% of calories), two-thirds in the form of sweetener. Lactose is the major sugar in milk and processed foods, and can account for as much as 10% of total carbohydrate calories in non-lactase-deficient persons. Glucose and fructose are also found in fruits and vegetables, but most fructose is ingested as the sweetener, high-fructose corn syrup. Estimated intake for glucose is $20\,g\,day^{-1}$, but may be as high as $150\,g\,day^{-1}$ for fructose. The sugar alcohol D-glucitol (sorbitol), found in many fruits, especially prunes, pears, plums, and cherries, is slowly absorbed. It may cause diarrhea when it is added to foods as a noncaloric sweetener, if consumed in excessive amounts. Another sugar alcohol, xylitol, is tolerated somewhat more effectively by the digestive tract.

Starches and disaccharides are digested by secreted and by mucosal enzymes, respectively, in the mouth, stomach, and small intestine. The resistant portion of starch, undigested or malabsorbed disaccharides and monosaccharides, and the dietary fiber components are digested by bacteria in the lumen of the nonruminant colon. In the ruminant this digestion occurs in the forestomach.

Salivary and Gastric Digestion

Salivary amylase is probably important in initiating starch digestion, depending upon the time spent chewing. Human salivary amylase is 94% identical with pancreatic amylase, but is inactivated in the acid pH of the gastric lumen. Starch supplements are better tolerated in breast-fed than bottle-fed infants, because of the presence of human milk amylase. In humans before 1 year of age, α-amylase activity in the duodenum is fairly low, due to delay in development of full secretory capacity. Presence of starch or its hydrolytic products can protect the enzyme from acid denaturation, and in this way some salivary or milk amylase reaches the more neutral pH of the duodenal lumen.

Gastric juice contains no other carbohydrases than α-amylase. Acid nonenzymic hydrolysis of some carbohydrates can occur, presumably in the stomach, although the extent of this process *in vivo* is probably small. The rate of gastric emptying is inversely related to caloric load, limiting the delivery of undigested food to the duodenum so as not to exceed hydrolytic capacity.

Pancreatic Digestion

Although lipid and protein substrates are hydrolyzed by more than one gastric and pancreatic enzyme, duodenal fluid contains only α-amylase, derived largely from pancreatic secretion. Starch hydrolysis begins with random cleavage of internal α1–4 glucose bonds, proceeding to smaller fragments until only small linear glucopolymers (2–8 residues) or small α-limit dextrins (containing α1–6 branch chains) are left. These compounds require brush border disaccharidases for digestion.

There are many factors that affect the completeness of starch digestion in addition to the physical form and processing of the starch in foods. Meal composition may affect variation in transit time from meal to meal, and intestinal transit time is slowed by nutrient-triggered inhibitory feedback. This feedback is initiated in part by lipids, and mediated by peptide YY. Starch feeding can increase amylase secretion in animals and in newborn humans. Fat and protein may also increase the secretion of pancreatic amylase via release of cholecystokinin. These nutrients also delay gastric emptying, preventing too rapid delivery of starch into the duodenum. Amylase activity can be inhibited by proteins found in certain plants, although their role in normal assimilation of carbohydrates is unclear.

The release of glucose from maltose, resulting from starch digestion, elicits a rise in blood glucose. The amount of this rise (glycemic response) varies

depending upon the form and processing of the food starch, the presence of other nutrients in the meal, and the degree of secretion of the fat-responsive gastric-inhibitory polypeptide (GIP) that mediates the enhancement of the glucose-stimulated insulin release. Because of the variety of factors affecting the glycemic response to food carbohydrates, it is not surprising that this response is variable and often unpredictable.

Intestinal (Brush Border) Digestion

All the hydrolytic products of starch digestion, as well as ingested disaccharides, are hydrolyzed by the brush border carbohydrases, sucrase-isomaltase, lactase, maltase-glucoamylase, and trehalase (Table 1). These enzymes are all α-hydrolases, except for lactase, which cleaves β-bonds. The result of this digestion is monosaccharides that can be absorbed across the apical membrane of the enterocyte by specific transporters. These proteins are ectoenzymes present either as heterodimers (sucrase) or as single subunits (lactase, maltase, trehalase). They are synthesized as single peptide chains and modified by glycosylation with or without subsequent cleavage.

Only monosaccharides can be absorbed readily from the human intestine. Disaccharide absorption is very low, but does increase slightly relative to monosaccharides in conditions such as celiac sprue that produce mucosal damage. The disaccharidase activity is rate-limiting for absorption of glucose and galactose from lactose, and of glucose from hydrolysis of glucose oligomers when α-amylase activity is scarce (e.g., in the newborn child). The distribution of disaccharidases along the length of the gut is designed for efficient digestion, as digestion is nearly complete by mid-jejunum, and the enzyme content peaks in the jejunum. Expression along the vertical axis of the villi is also appropriate for hydrolysis of luminal contents. The enzymes are transcribed maximally in the lower and mid-villus, decreasing to the villus tip, and the enzyme content follows this pattern. Lactase mRNA in adults is more restricted to the lower villus, in contrast to its appearance in all villus cells before birth, but the protein persists in all villus enterocytes. The lower levels of enzymes near the villus tip may be related to their release from the membrane by pancreatic proteases.

The products of amylase digestion (maltotriose, maltose, and α-limit dextrins) cannot be absorbed without further digestion. Two of the disaccharidases, maltase-glucoamylase and sucrase-isomaltase, act sequentially to complete the hydrolysis of starch begun by α-amylase. Maltase-glucoamylase has maximal activity against linear polymers of 5–9 glucose residues, and cleaves all maltotriose, and a small amount of maltose and α-limit dextrins. Sucrase-isomaltase hydrolyzes most of the α-limit dextrins and maltose, providing the monosaccharides that can be efficiently absorbed.

Sucrase-isomaltase is anchored to the membrane by a transmembrane N-terminal fragment, and cleavage into sucrase and isomaltase subunits is mediated by trypsin on the external surface of the enterocyte. Sucrase-isomaltase is expressed in the colon from 12–28 weeks of gestation, but disappears at birth, along with the villus/crypt structure seen in small intestine. At birth in humans there is high sucrase activity in the small intestine that persists into adulthood. In rodents born with immature intestines, sucrase is hardly detectable at birth, and rises to adult levels after weaning. In rats, the high fasting levels of sucrase-isomaltase decline after eating, because of

rapid enzyme turnover mediated by pancreatic proteases. Starvation decreases sucrase activity, and refeeding restores it. Sucrose and fructose more than starch induce sucrase and maltase activities. Sucrase deficiency in humans results from a number of different defects in glycosylation, intracellular transport, and possibly in altered catalytic activity.

The digestion and absorption of lactose, the major carbohydrate in milk, are often variable, and are related to lactase-phlorizin hydrolase levels that are rate-limiting for absorption, as well as the rate of gastric emptying, small intestinal transit rate, and the degree of colonic digestion and salvage. Lactase is anchored by a COOH-terminal sequence and then undergoes SH-sensitive intramolecular folding in the endoplasmic reticulum. Prior to arrival at the apical membrane, the 225-kDa lactase precursor undergoes cleavage to a 160-kDa intermediate form. On the apical cell surface final cleavage to the 145-kDa active enzyme occurs by the action of trypsin. Unlike the human, the rat lactase undergoes a several-step cleavage on the apical surface. Lactase activity is high at birth in most mammals, and declines in the human during childhood or adolescence, reaching levels about 5–10% those at birth. Initiation of this process is 'hard-wired,' but can be modified by hormones and nutrients, at least in animals. The age at which the fall in activity occurs varies according to the genetic background of the individual. Inherited lactase deficiency in humans involves transcriptional and posttranscriptional mechanisms. The phenotype in many Caucasians for persistence of lactase is inherited as an autosomal recessive trait. In all other mammals, lactase activity falls after weaning. Lactose feeding in humans does not increase lactase activity, and the absence of dietary lactose, in diets used for patients with galactosemia, does not cause a fall in activity. Lactase activity falls during malnutrition in children, but not in adults. A variety of infectious and inflammatory processes decrease lactase activity more than that of other disaccharidases. Activity may be slow to recover after an acute infectious process, and remains low in chronic inflammatory conditions, such as Crohn's disease and human immunodeficiency virus (HIV-1) infection. Table 2 summarizes the factors altering carbohydrase activity.

Maltase-glucoamylase accounts for about 2% of the brush border protein, and cleaves small glucose polymers and α-limit dextrins produced by α-amylase activity. Unlike sucrase and maltase in humans, the protein is inserted into the brush border membrane without any intra- or extracellular cleavage. In the pig and rat surface cleavage by pancreatic enzymes occurs. As all forms are enzymatically active; the significance of these structural differences is unknown. Also, unlike sucrase and lactase there is relatively little change in maltase levels at the time of birth, either in human or animal intestines.

Colonic (Bacterial) Digestion

Up to 70 g of carbohydrate (including the components of dietary fiber and other dietary carbohydrates that escape small bowel digestion) may reach the colon each day in humans. This carbohydrate is fermented by colonic bacteria to short-chain fatty acids (largely acetate, propionate, and butyrate), hydrogen gas, and methane. The overall fermentation reaction can be estimated thus:

$$34.5\ C_6H_2O_6 \rightarrow 48\ CH_3\,COOH + CH_3\,CH_2\,COOH + 5\ CH_3(CH_2)_2\,COOH + 23.75\ CH_4 + 34.25\ CO_2 + 10.5\ H_2O$$

In ruminants these fatty acids are produced in the forestomach, and in other mammals in the cecum and colon. Butyrate and caproate can be released by

Table 2 Factors affecting carbohydrase activity

Enzyme	*Factor*	*Enzyme content*	*Mechanism*
α-Amylase	Starch feeding	↑	↑d mRNA content
	Hydrolytic products	↑	Degradation inhibited
	Prenatal development	↑	↑d mRNA content

t/2, half life.

gastric lipase action on milk triacylglycerols, and may be nutritionally important in infants. The carbohydrate moieties of mucins and other glycoproteins are also used to support bacterial growth. Thus, endogenous carbohydrates are important in perpetuating colonic bacterial cultures, which in turn are responsible for salvaging much of the nutrient value of undigested dietary carbohydrate.

Absorption and Metabolism

General Characteristics of the Mucosal Barrier

The only carbohydrates absorbed to any extent across the intestinal mucosa are monosaccharides. The mechanism for absorption involves the use of either Na^+-coupled or non-Na^+ transporters (Table 3). The GLUT transporters mediate a facilitated diffusion process, whereas SGLT1-associated transport is an active process, involving the Na^+/K^+-ATPase located in the basolateral membrane of the enterocyte. This protein uses adenosine triphosphate (ATP) to maintain a low intracellular Na^+ concentration, providing a chemical gradient for Na^+ (and coupled glucose) from the lumen to the cell. The delivery of the solute to the cell surface is a function of the efficiency of stirring of the luminal contents. Although the thickness of this unstirred water layer in humans has been thought to be large, in the dog, where stirring can be vigorously conducted, the unstirred water layer is only 40 μm. Metabolism of disaccharides proceeds in two steps, with surface digestion by disaccharidases preceding absorption of the sugar. Thus, the delay in traversing this barrier should be brief, and the rate-limiting step for absorption is most likely due to the apical sugar transporters.

Water absorption is coupled with that of the monosaccharide and Na^+. The mechanism whereby this occurs is not well defined. In some epithelial cells, such as renal collecting ducts, there are specialized water transporters called aquaporins. Expression of these proteins in the intestinal mucosa is either nonexistent or sufficiently low to be functionally insignificant. A unique hypothesis suggests that SGLT is able to account for the water absorption, as about 260 water molecules are cotransported *in vitro* for every 2 Na^+ and every one sugar molecule. This capacity should be large enough to account for about 5 l of waterday^{-1} for a human ingesting a diet of average carbohydrate content. This hypothesis has yet to be tested *in vivo* in humans.

Another hypothesis suggested from data in small rodents that water movement in the intestine is paracellular, via the tight junctions. This route might also account for absorption of ions and other solutes for which there are no specific apical transporters. Moreover, the tight junctions are subject to regulation of their cross-sectional area, and could serve as a size-selective filter mechanism. Calculations have suggested that the rates of glucose absorption in humans ($> 200\,mmol\,h^{-1}$) exceed by an estimated 2–10-fold the predicted capacity for active sugar absorption. However, L-glucose, a driver for paracellular movement potentially equivalent to D-glucose, does not produce significant water absorption in either dog or rat intestines. Thus, there are insufficient data to suggest that paracellular movement of sugar or its coupled water is important in mammals.

Glucose and Galactose Absorption

Active hexose transport is driven by an electrogenic sodium gradient. The stoichiometry for Na^+-coupled glucose transport is 2:1. In intact brush border vesicles, both high- and low-affinity glucose uptake has been found, depending on the species. The low-affinity uptake would be suitable for the high intraluminal postprandial concentrations. These 'systems' vary independently depending on the developmental or fed status of the animal form which the membranes were made.

Despite these data suggesting more than one active hexose transport system in intestinal brush border membranes, only one Na^+-coupled transporter has

Table 3 Major cellular monosaccharide transporters

Transporter	*Na^+-coupled*	*Organ expression*	*Transport function*
GLUT1	No	Many tissues, especially RBC, blood–brain barrier	Glucose, across blood–tissue barriers
GLUT2	No	Liver, kidney, small bowel, pancreatic β-cells	Low-affinity, across basolateral membranes
GLUT3	No	Many tissues, especially brain	Glucose across basolateral membranes
GLUT4	No	Skeletal and cardiac muscle, adipose tissue	Insulin-dependent uptake
GLUT5	No	Small bowel, kidney, testis, adipose tissue, muscle	Fructose ≫ glucose across apical ≫ basolateral membranes
SGLT1	Yes	Intestine, kidney	High-affinity glu > gal, apical transport
SGLT2	Yes	Kidney	Low-affinity glu > gal apical transport

RBC, red blood cells.

been found in intestine, SGLT1. In humans the activity and expression of this transporter are maintained by the presence of luminal nutrients, as suggested by the brush border experiments in fed and fasted animals. The low-affinity SGLT2 is only found in kidney, and its kinetics can be explained by reducing the Na^+/glucose coupling from 2:1 to 1:1. SGLT1 is a glycoprotein of 75 kDa with 14 membrane-spanning regions, existing as a homotetramer in the membrane. The single *N*-linked carbohydrate side chain is not required for function. The relative specificity of the transporter is the same as that previously characterized for the active membrane transport system, i.e., D-glucose>α-methyl-D-glucose>D-galactose>3-*O*-methyl-D-glucopyranose>>>L-glucose. It is clear that SGLT1 accounts for all of the active glucose transport, because mutations in this protein account for the entire phenotype in patients with hereditary glucose-galactose malabsorption.

Glucose absorbed into the enterocyte is transported across the basolateral membrane by facilitated diffusion mediated by GLUT2. This high-capacity transporter has 12 membrane-spanning regions, and can transport fructose as well as glucose. Although glucose is metabolized by the enterocyte, the preferred energy substrates for this cell are amino acids, preferentially glutamate, glutamine, and aspartate. In the presence of amino acids, intestinal metabolism of glucose is decreased. After exit from the cell, glucose enters the portal vein, and is delivered to the liver and peripheral tissues (mostly muscle), in which tissues the glucose is extensively metabolized.

Fructose Absorption

Fructose transport occurs by an Na^+-independent, saturable system of lower capacity than that for glucose or galactose. The capacity for fructose absorption in humans is limited, although theoretical estimates of absorption capacity are relatively high. GLUT5 mediates all or most of fructose transport across the apical membrane of enterocytes. Human GLUT5 transports fructose alone, but the rat homolog recognizes both glucose and fructose. However, absorption of fructose in humans can be inhibited by the presence of glucose. Thus, it is possible that a second apical fructose transporter exists. Unlike the relatively wide tissue distribution in humans (Table 3), rat GLUT5 is expressed largely in the small bowel, kidney, and brain. Fructose is poorly metabolized in the enterocyte, and is transported from the cell by basolateral GLUT2, and in humans by basolateral GLUT5 as well. Expression of GLUT5 is increased in animals fed fructose. This adaptation accompanies the increase in sucrase-isomaltase found after fructose or sucrose feeding.

Short-chain Fatty Acid Absorption

Short-chain fatty acids are the major nutrients produced by bacterial fermentation. The usual starting substrates are carbohydrates. In humans the fermentation products are produced and absorbed in the colon. Both small bowel and colonic mucosa readily absorb unionized short-chain fatty acids. The transporter responsible for this uptake is most likely a member of the monocarboxylate-type transport proteins, perhaps by the anion exchanger AE2 found in apical membranes of intestinal mucosal cells. The anion gradient across the apical membrane is butyrate>bicarbonate>propionate>chloride. The capacity of this transporter is much lower than that for SGLT1, but is still sufficient to achieve some salvage of malabsorbed carbohydrate.

Unlike hexoses in the small intestine, short-chain fatty acids are partly metabolized in the colonic cells, and appear to be a major nutrient source. Most of the fatty acids are metabolized intracellularly to CO_2. Estimates of the contribution of short-chain fatty acid metabolism to the basal metabolic requirement vary from low (1–2% in the pig and 6–9% in humans) to high (30–40% in the rabbit). The importance of this pathway in humans increases in patients with sugar malabsorption, when delivery of nonabsorbed sugar is increased to the colonic lumen.

Requirements and Dietary Importance

I Macdonald, University of London, London, UK

Introduction

Dietary carbohydrates are the cheapest source of energy for metabolism by the body. They are cheap because they are produced by plants for energy metabolism and storage and consequently can be harvested in most temperate and humid climates. To produce a million calories for human consumption requires 0.08 ha for sucrose, 0.16 ha for potatoes, 0.4 ha for wheat and 6.88 ha for cattle. Thus a very important factor when considering requirement of dietary carbohydrate lies largely in economic necessity. Carbohydrates have long been the mainstay in world dietaries, with sucrose and starches being the major sources for human consumption. In regions where per capita incomes are low and the balance between food production and demand is close, consumption of carbohydrates as cereals or starchy root vegetables largely meets the need for energy intake. In some underdeveloped countries carbohydrates supply up to 90% of the dietary energy consumed and, of course, consumption at this level gives rise to concern about deficiencies of the other nutrients such as proteins, minerals, and vitamins. In industrial countries dietary carbohydrates provide about half the daily energy intake.

Although the total carbohydrate intake may be similar between some developing and developed countries, the nature of the carbohydrates eaten and the proportion they contribute to the energy intake may not be similar. Carbohydrates from staple foods such as cereals and roots are composed mainly of starch and may represent 85% of the carbohydrate intake in developing countries but only 62% in affluent ones. The difference is largely made up by carbohydrates from fruit, sucrose, corn syrups (mainly in North America) and, to a lesser extent, lactose.

Surveys in the 1980s have shown that the consumption of sucrose is changing, tending to fall in the more developed countries while rising in the other countries, and it has been suggested that the saturation point occurs at about $160\,g\,day^{-1}$ per person. In developing regions, starch consumption from cereals and roots seems to be related to income, rising when personal income rises. In developed regions, cereal consumption, and therefore starch intake, has fallen, especially in Japan and Eastern Europe, with little change in North America and Australia. These changes might also reflect income, for at higher income levels food choice is not limited to purchasing power and as income rises the proportion of energy derived from carbohydrate tends to fall.

Complex carbohydrates, like other insoluble components of the diet, have no taste, only 'mouth feel,' but carbohydrates with a comparatively smaller molecular weight are soluble and stimulate the taste buds for sweetness. This property of sugars, and especially sucrose, makes them an organoleptic requirement for many, especially the young. It has been suggested that this property of the simple carbohydrates is useful in making palatable those foods which are nutritionally desirable but may not be so pleasant to consume. (*See* **Cereals**: Contribution to the Diet; **Sucrose**: Dietary Importance.)

Metabolic Importance of Dietary Carbohydrate

The major carbohydrates that are found in the body tissues in humans are glycogen, glucose, fructose, galactose, and lactose (in lactation).

Glycogen, the storage form of carbohydrate, is found in the liver and muscle. Before being released into the blood for transport to other regions of the body, it has to be hydrolyzed to the monosaccharide, glucose. (*See* **Glycogen**.)

Glucose is the common metabolic currency of carbohydrate in the body and all cells are able to metabolize glucose to carbon dioxide and water with the consequent release of energy. However, glucose is not only used as a readily available source of energy but it can also be converted to glycogen or, if consumed in excess, to fat for storage. Although glucose can be utilized by all cells, it is only in a few organs that glucose is essential, and these include the brain and red cells of the blood. During pregnancy and growth, glucose is essential for the formation of cell constituents. (*See* **Glucose**: Function and Metabolism.)

Fructose, which largely comes from the sucrose in the diet and also from honey, does not seem to have a specific role in the body and the only site of production of fructose in humans seems to be in the seminal vesicles, where it is made from glucose.

Galactose is, along with glucose, one of the monosaccharides in lactose; practically the only dietary source of galactose is milk. Galactose is synthesized from glucose in the lactating mammary gland. (*See* **Galactose**.)

Metabolic Sources of Carbohydrate other than Dietary Carbohydrate

As glucose is essential to the biochemistry of the body it is not surprising that there are sources of glucose other than those in the diet. One of these is liver or muscle glycogen but these stores of 'animal starch' are very limited. After 24 h or so of complete starvation the stores are empty; yet, as long as water is supplied, a normal-weight person can survive complete starvation for 50–60 days, so alternative sources of glucose must exist.

Another source of glucose in the body is from the glycerol moiety of triglyceride. This part of the triglyceride molecule forms about 10% of its molecular weight, and when triglycerides are hydrolyzed the released glycerol can be converted to glucose. Another source of glucose within the body is from the so-called glucogenic amino acids, which can be metabolized to glucose. (*See* **Triglycerides**: Structures and Properties.)

Although dietary carbohydrates can be converted to fat in the body, fat cannot be converted to carbohydrate.

Metabolic Requirements for Dietary Carbohydrate

Apart from the fact that a diet with little or no carbohydrate would be most unpalatable, there is a metabolic need for dietary carbohydrate. Total deprivation of energy intake has been used in the treatment of obesity and this has provided the opportunity to study the effects of a zero intake of dietary carbohydrate. The effects of diets which are high in protein and fat and very low in carbohydrate have also been studied and the striking consequence of a low or zero carbohydrate intake is that the breakdown of fat in the body cannot go to completion. The final end product of fat metabolism is then a two-carbon chain remnant, existing in the blood as acetoacetic acid or β-hydroxy butyrate. The classical breath odor in this condition, known as ketosis, is due to acetone excretion by the lungs. Clinically, ketosis occurs in uncontrolled diabetes mellitus and after 24 h or more of dietary carbohydrate deprivation in otherwise healthy individuals. Thus carbohydrate is needed in order that the catabolism of fat can be completed to carbon dioxide and water. (*See* **Fats**: Digestion, Absorption, and Transport.)

There are two disadvantages of the ketotic state in an individual: (1) the judgment of such a person may be impaired and it could therefore be unwise to handle potentially dangerous machinery (e.g., a car) while ketotic; (2) the ketone bodies excreted in the breath and urine contain utilizable energy and thus represent an energy loss to the body and diminishing body stores. Production of ketone bodies in large quantities, as in uncontrolled diabetes mellitus, can lead to coma and death. Thus there is a need in all individuals for a minimal daily intake of carbohydrate that can supply the amount of glucose necessary to complete the breakdown of depot fat.

What is the minimum desirable intake of glucose or its equivalent? Under normal circumstances the adult brain needs about 140 g of glucose per day and the red blood cells need another 40 g day^{-1}. If diet contains no sugars or starch, about 130 g of glucose can be provided endogenously from the catabolism of protein and from the glycerol moiety of depot fat, thus leaving a shortfall of approximately 50 g day^{-1} to be obtained from the diet. It is therefore possible to state a minimum desirable intake of glucose or its equivalent for adults. After several days in the ketotic state the brain, a major consumer of glucose, adapts and can use, to some extent, the energy present in the ketone bodies, thus lessening the minimal daily requirement for dietary carbohydrate.

Metabolic Knock-on Effects of Dietary Carbohydrate

All dietary carbohydrates have to be broken down to their constituent monosaccharides (glucose, fructose, or galactose) before they can be absorbed from the intestine but only glucose stimulates the release of insulin, a hormone which not only accelerates the cellular uptake of glucose but also facilitates the uptake of amino acids. Insulin is, in general, an anabolic hormone, so that the glucose provided by the carbohydrate in the diet can have far-reaching effects on the metabolism of other dietary constituents, through its ability to bring about the release of insulin.

The amount of energy stored in the body as carbohydrate is minute when compared with that stored as fat or protein. The total quantity of carbohydrate in liver, muscle, kidney, and other tissues, plus the glucose that circulates in the blood, amounts to about 1800 kcal (7.56 MJ). However, it has been found that the carbohydrate stored in the skeletal muscle can be increased considerably by reducing the proportion of fat in the diet and replacing it with carbohydrate. This is of importance to those who compete in endurance sports and has led to the expression 'carbohydrate loading.'

Finally, there is what used to be called the protein-sparing effect of dietary carbohydrate. When the energy intake in the diet is below requirement, administration of carbohydrate (which raises insulin levels) reduces the breakdown of body protein, whereas dietary fat under comparable circumstances has a negligible effect on reducing protein breakdown. (*See* **Protein:** Interactions and Reactions Involved in Food Processing.)

Metabolism of Sugars

I Macdonald, University of London, London, UK

Background

There are only three sugars that are normally present within the body, and these are the monosaccharides, glucose, fructose, and galactose. Glucose is the prime carbohydrate in the body; fructose is consumed mainly with glucose as the disaccharide sucrose and plays a relatively minor role; galactose is associated with lactation and milk ingestion, and is, along with glucose, one of the monosaccharides of the lactose molecule. (*See* **Fructose; Galactose; Glucose:** Function and Metabolism.)

Glucose

To produce energy, the glucose molecule must enter a cell from the blood and there be converted to glucose 6-phosphate in the cytoplasm. This compound can then be metabolized in a number of ways, depending on the needs and versatility of the cell. It can (1) be broken down to pyruvic acid/lactic acid, (2) go down the pentose phosphate pathway, or (3) form glycogen (**Figure 1**).

1. The most important way by which energy is released from the glucose molecule is by the splitting of the molecule to form two molecules of pyruvic acid (glycolysis). This end product of glycolysis may then enter the tricarboxylic acid cycle inside the mitochondria of the cell and be broken down completely to carbon dioxide and water with the release of energy.

   When quantities of pyruvic acid and hydrogen atoms become excessive, as in severe exercise, these two products inhibit glycolysis and react with each other to form lactic acid.
2. The pentose phosphate pathway accounts for as much as 30% of the glucose metabolism in the liver and more than this in the fat cells. This pathway supplies reducing power for fat synthesis from carbohydrate sources. Most enzymes involved in carbohydrate metabolism require vitamin B metabolites as essential co-factors.
3. When glucose is not immediately required for energy, the extra glucose that continually enters the cells is stored as glycogen or converted to fat. Glucose is preferentially stored as glycogen, and only when the cell approaches saturation with glycogen is the additional glucose then converted to fat. (*See* **Glycogen.**)

Fructose

Fructose in the bloodstream is utilized about twice as fast as blood glucose; the liver and, to a lesser extent, the kidney and small intestine are the main sites of

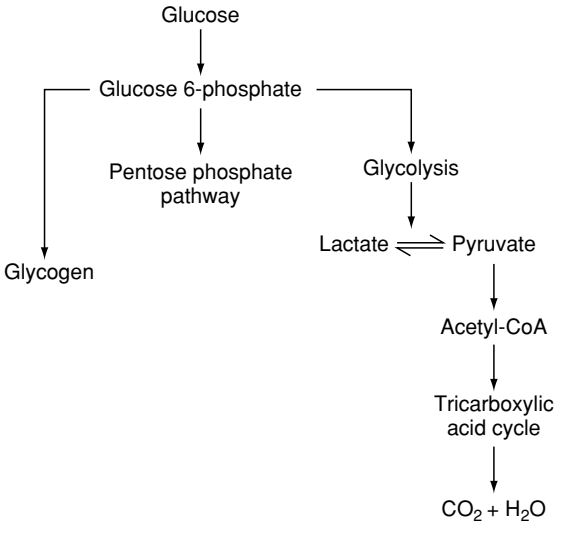

Figure 1 Metabolic options for glucose metabolism. Reproduced from Carbohydrates: Metabolism of Sugars, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

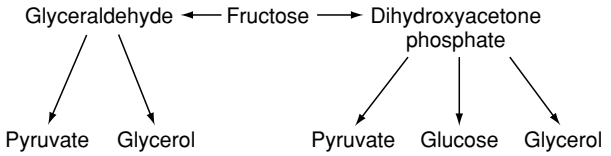

Figure 2 Metabolism of fructose. Reproduced from Carbohydrates: Metabolism of Sugars, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

fructose metabolism. The utilization of fructose by other peripheral tissues seems to be negligible. The first step in the metabolism of fructose is the formation of fructose 1-phosphate, which then splits to form two 3-carbon molecules, namely glyceraldehyde and dihydroxyacetone phosphate. As shown in Figure 2, these trioses can form pyruvate, glycerol, and, in the case of dihydroxyacetone phosphate, glucose.

Fructose is mainly converted to glucose and lactic acid, with perhaps up to 3% of the fructose being converted to triglycerides; ketone bodies; glycerol and sorbitol are minor end products.

Metabolism of Sugars in the Liver

Glucose

In the liver, glucose has no difficulty in crossing the cell wall; the main factors influencing the rate of entry are the concentration of glucose in the blood and the ability of the enzymes in the cell to dispose of the glucose. Much of the glucose that is absorbed from the intestine never reaches the peripheral circulation, as it is taken up in the first pass through the liver.

The liver is also capable of releasing glucose into the blood, either as a result of the breakdown of glycogen or protein, or as a result of synthesis from glycerol. The balance of input and output of glucose by the liver is entirely controlled by hormones, acting via the enzymes within cells:

1. Insulin, which is produced by the β cells of the pancreas, accelerates glycogen formation. In other cells in the body, insulin is solely concerned with the transfer of glucose into the cell, but in the liver, insulin influences the synthesis of enzymes.
2. Glucagon is produced by the α cells of the pancreas, and causes a rapid breakdown of liver glycogen.
3. Adrenaline, like glucagon, stimulates the breakdown of glycogen, but, unlike glucagon, it is able to do this in muscles as well; it does not stimulate insulin release.
4. Glucocorticoids are produced by the adrenal gland. These hormones maintain and aid the formation of glycogen. (*See* **Hormones**: Adrenal Hormones.)

Fructose

In man, most of the fructose absorbed from the intestine is taken up by the liver, hence the low blood levels of fructose after its ingestion. Compared with glucose, fructose has a greater ability to form lactate, but, unlike glucose, fructose administration leads to an increase in blood uric acid levels and, for this reason, has been used as a screening test for gout. Also in the liver, fructose is converted to the lipid triglyceride to a greater extent than is glucose; again, unlike glucose, whether given orally or intravenously, fructose speeds up the metabolism of ethanol by the liver.

Sugars and Muscle

The muscle mass, because of its size and sheer need, plays a principal role in carbohydrate metabolism. The uptake of glucose by muscle cells is insulin-sensitive, but the metabolism of fructose in the cell is probably minimal, and only the pyruvate and lactate formed from fructose in the liver would be of any support to the muscle cell.

Sugars and Depot Fat

It has been known since 1852 that dietary carbohydrate can be converted to depot fat, and this would appear to be in conflict (bearing in mind the current obesity epidemic) with the current dietary advice from several international authorities to reduce the fat intake and replace it by carbohydrate. However, when energy balance is in equilibrium, high-carbohydrate/low-fat diets do not result in appreciable *de novo* lipogenesis.

However, a high-carbohydrate diet can alter the blood lipid pattern in a direction that may be considered undesirable in terms of cardiovascular disease, but this change may be offset by the weight loss that usually occurs on switching to a high-carbohydrate diet.

There is no metabolic reason why sugars should be different in their ability to be converted to depot fat. The FAO/WHO 1998 consultation on Dietary Guidelines proposes no specific limit for sugar consumption, since any putative relationship of sugar consumption to obesity is offset by the inverse relationship between sugar and fat intake.

Fructose can enter the adipocyte, but its rate of transport is slow, and only at high concentrations of fructose do significant amounts enter the adipocyte.

Sugars and the Brain

The brain seems to be entirely dependent on glucose and oxygen, and a reduction in the supply of either will soon lead to irreversible damage. The brain

removes a fixed amount of glucose per unit time, irrespective of the blood concentration of glucose, and its uptake is not dependent on insulin. There has been a suggestion that the insulin release following glucose ingestion increases the level of serotonin in the cerebral tissue and that this compound diminishes the sensation of pain and produces a feeling of well-being.

Sugars and the Metabolic Rate

The increase in metabolic rate after the ingestion of various sugars is greater after sucrose or a mixture of fructose and glucose than after glucose alone, suggesting that the body 'handles' fructose more efficiently than glucose.

Sugars and the Fetus and Neonate

As lipid does not cross the placenta to any great extent, the fat present in the infant at birth must have been synthesized in the fetus from glucose or amino acid. Changes in the maternal blood glucose level are quickly reflected in the fetal blood.

In contrast to glucose, fructose cannot cross the placenta, although some animal species (not humans) can transform glucose to fructose in the placenta.

In the neonate, the sole dietary source of carbohydrate is the lactose in milk, but no specific role for lactose has been identified.

Factors Affecting the Metabolic Response to Dietary Sugars

Sex of the Consumer

The increase in blood triglycerides seen in men after a diet high in fructose is not seen in young women but is found in postmenopausal women. Although both sexes increase hepatic lipogenesis after fructose ingestion, it is possible that premenopausal women are able to remove the blood triglycerides more rapidly.

Type of Fat Accompanying the Carbohydrate

A synergistic effect of sucrose and animal fat on blood triglycerides has been shown, and the raised levels found after a diet high in sucrose are considerably reduced by polyunsaturated fat accompanying the sucrose.

Dietary Protein

The recovery of serum albumin after protein deficiency seems to be slower with sucrose in the diet than with starch, and the interplay of the metabolism of sugars and protein becomes more interesting when it is appreciated that the amino acids arginine and leucine stimulate the release of insulin. (*See* **Protein**: Interactions and Reactions Involved in Food Processing.)

'Sensitivity' of the Consumer

The extent to which sugars are converted to lipids, especially triglycerides, seems to vary between individuals. Those persons whose level of triglycerides in fasted blood is high, and who may be more prone to coronary heart disease, have a greater increase in these triglycerides after consuming carbohydrates than persons with normal lipid levels.

Species

There are not only within-species differences in metabolic responses to sugars but also more marked differences between the species. For example, rats can absorb fructose from the intestine very rapidly, and this will affect the metabolic handling of fructose when compared with humans.

Determination

D A T Southgate, Norwich, Norfolk, UK

Introduction

The carbohydrates in foods are a heterogeneous group of substances ranging from monosaccharides, such as glucose and fructose, through to the complex polysaccharides found in the matrix of the plant cell walls in foods. In many cases the carbohydrate species may be limited and typical of the food or group of foods, such as lactose in milk and milk products, but

many foods contain complex mixtures which present many problems for the analyst.

As in so many aspects of food analysis, the choice of method is very much decided by the purpose of the analysis and the uses for which the analytical information is required. Thus, for quality control purposes a relatively simple empirical method may be adequate, whereas for nutritional research purposes the current trend is a requirement for relatively complete and chemically specific data.

The food matrix itself is frequently a deciding factor in the choice of method, as this will determine the extraction procedures required and the procedures needed to free the extracts of interfering materials. Thus many analytical procedures have been devised that are specific for a particular group of foods and the carbohydrates they contain.

The Carbohydrates in Foods

It is possible to classify the carbohydrates in foods according to a number of different principles. Table 1 illustrates a classification based primarily on structural terms which is linked to the physiological behavior of the carbohydrates once consumed: this is the most useful classification nutritionally.

Nutritionally it is convenient to consider the carbohydrates in foods as falling into three major groups:

1. Sugars, including mono- and disaccharides.
2. Oligosaccharides with three to nine monosaccharide units.
3. Polysaccharides with 10 or more monosaccharide units.

Oligosaccharides with three to nine monosaccharide units fall into two subgroups: the malto series, which are hydrolyzed by the brush border α-glucosidases, and the raffino and fructo series, which are poorly absorbed in the small intestine but are used as substrates by the microflora of the large intestine. The term short-chain polysaccharides has been suggested for this group because analytically it is difficult to separate some lower polysaccharides from conventional oligosaccharides.

Polysaccharides with 10 or more (usually very many more) monosaccharide units also fall into two subgroups: first, the α-glucans principally, the starches, but also including glycogen, and second, the nonstarch polysaccharides (NSP), which include a wide range of structural types of polysaccharides derived from plant cell wall materials in foods and a range of polysaccharide food additives.

Table 1 The major carbohydrates in foods

Number of monosaccharide units	*Class*	*Major examples*	*Physiological characteristics*
1	Monosaccharides	Glucose Fructose	Absorbed directly in the small intestine
2	Disaccharides	Sucrose Lactose Maltose	Hydrolyzed in the brush border by specific disaccharidases
3–9	Oligosaccharides	Malto- Fructo- Raffinose Stachyose Verbascose	Hydrolyzed in the brush border Poorly absorbed from the small intestine Fermented by the microflora in the large intestine
< 9	Polysaccharides		
	Starches		Hydrolyzed by gastric and pancreatic amylases and by brush border enzymes
		Amylose Amylopectin	
	Nonstarch polysaccharides		Not hydrolyzed in small intestine, fermented by the microflora in the large intestine
	Cell wall components	Cellulose Noncellulosic polysaccharides	
	Polysaccharide food additives	Gums Mucilages Algal Polysaccharides Modified starches, pectins, etc.	

Table 1 also illustrates the task facing the analyst asked to measure all the carbohydrates in foods, even where polysaccharides are grouped as suggested above. It also demonstrates the need for the analyst to consider the food matrix under examination because this will often simplify the procedures needed.

During the 19th century, food chemistry was in the early stages of development and the inadequacy of understanding carbohydrate chemistry led to the adoption of the so-called proximate method of food analysis. In this method, carbohydrates were determined by difference. Moisture, protein (from total nitrogen content), fat (by simple lipid solvent extraction) and ash (by incineration) were measured directly and deducted from 100% to give a value for carbohydrate. Although this method has effectively been superseded by the growth in knowledge and the developments in analytical chemistry, it is still in wide use and much food composition data are still based on this type of analysis.

Analytical Characteristics of Carbohydrates

The carbohydrates as a class, despite the wide range of species occurring in foods, present the analyst with a limited range of reactions that can be used analytically. As a class they are all polyhydric alcohols which undergo substitution reactions. These are very valuable in structural analysis but less useful analytically.

Physical Methods

These were developed within the sugar-processing industry, where analysts were primarily concerned with the analysis of solutions of sucrose and the products of its hydrolysis, glucose and fructose. The simplest methods were based on the very high solubility of sucrose in water and involved the measurement of specific gravity or refractive indices of the solutions which are very nearly linearly related to sucrose concentration. These methods are still in use for the analysis of syrups. The second method made use of the optical activity of the sugars: polarimetry provides a quick and reliable index of the proportions of sucrose and glucose and fructose in an aqueous solution.

Chemical Methods

The monosaccharides have aldehyde or keto functional groups which have powerful reducing properties by virtue of their ability to form enediol arrangements. These form the basis of a series of reductiometric procedures which are widely used. The Munson-Walker and Lane and Eynon procedures have formed the basic techniques for analysis in the sugar industry. These reductiometric techniques are highly empirical and require close attention to analytical protocols for consistent and accurate performance. Reduction of ferricyanide has also provided the basis for colorimetric procedures using this type of technique.

Nonreducing disaccharides such as sucrose require hydrolysis before the reducing sugar methods can be used and polysaccharides such as starch have also been measured as monosaccharides after hydrolysis. Each monosaccharide has, however, slightly different reducing strengths and the analyst concerned with mixtures of reducing sugars has to make adjustments for the composition of the mixture.

The polyhydric structure of the carbohydrate also renders them susceptible to dehydration and the formation of furan structures in strong acids, and these react with a number of chromogenic phenolic substances to form colors which are suitable for colorimetric measurement. These reactions tend to be relatively unspecific and careful control of conditions is required for satisfactory measurements.

Biochemical Methods

The sugars (monosaccharides and disaccharides) are involved in a series of biochemical reactions with highly specific enzyme systems. Most of these enzymes are available in a highly purified state and can be coupled with NADH or NADPH to provide a very specific and highly sensitive method for the measurement of specific sugars in complex mixtures. The clinical measurement of glucose uses an enzymatic method coupled with a colorimetric method. However, in many situations the development of chromatographic procedures has displaced these elegant methods.

Chromatographic Methods

The difficulty of precisely quantifying mixtures of sugars provided a major stimulus to the search of separation procedures. Paper chromatography and later thin-layer chromatography provided the first effective qualitative and semiquantitative analytical methods. Conventional ion-exchange techniques were difficult to apply, although some success was achieved in separating the weak borate complexes. The nonvolatile nature of sugars slowed the application of gas liquid chromatography until trimethyl silyl derivatives were developed which gave good separations. At present most analyses are based on the use of alditol acetate derivatives where sugars are reduced to alditols with borohydride and then acetylated.

Gas liquid chromatographic techniques are widely used, particularly in analysis of polysaccharides in plant cell walls and in the measurement of NSP. The derivatization stages are time-consuming and not

completely specific because fructose gives the same alditol as glucose (and partially as mannose).

High-performance liquid chromatography (HPLC) removes the need for the preparation of derivatives and provides separation of all the monosaccharides, disaccharides, and oligosaccharides. Initially the carbohydrate columns were rather erratic in performance but now consistent separations are usual. Detection systems initially used the refractive index but these were not very sensitive and pulsed amperometric systems have been introduced which have overcome this limitation.

Extraction and Clean-up

As can be seen from the above, a selection of methods for the end analyses of carbohydrates are used, most of which are designed to measure monosaccharides. Virtually all analytical methods for carbohydrate involve the preparation of an extract free from interfering substances.

The extraction and clean-up procedures are usually food-specific because this simplifies the procedure that needs to be used. This is especially important when the analysis is being carried out for quality control purposes, but applies across the whole range of purposes for which carbohydrates are measured.

Thus, in the sugar-processing industry the samples are often in aqueous solution and the interfering substances can be removed using precipitation with metal salts. Analogously, milks and many milk products only require the removal of proteins to provide a suitable extract for sugar analysis.

Foods which contain more complex mixtures of carbohydrates or when analyses of the various carbohydrate species are required need more detailed extraction and fractionation schemes. A large number of schemes have been, and are being, used, especially where the individual polysaccharides are being separated and measured but this article will focus on the principles of the most widely used approaches.

The major stages are illustrated in Figure 1.

Sample preparation As with all analyses, this is a critical stage. Sugars are sensitive to heat and polymers containing furanoside linkages are susceptible to acid hydrolysis under mild conditions. This means that the preparation of samples needs to minimize any possible changes due to heat and acid. Very acid samples should be neutralized before drying or extraction; freeze-drying is a suitably mild drying procedure. The sample also needs to be finely divided and care must be taken to prevent fractionation of the sample into different sizes of particles.

High-fat (>10%) foods need to be extracted with a lipid solvent to assist in later extraction procedures.

Extraction with Aqueous Alcohol The most common extractant is hot 80%v/v ethanol, but isopropanol has also been used, as has 85%v/v methanol. This provides a very good separation of polysaccharides from the other groups, but some lower polysaccharides such as inulin are incompletely precipitated by ethanol of this strength and some arabinans are also partially soluble.

Use of Supernatant This is usually suitable for many analytical procedures after dilution or removal of the ethanol by rotary evaporation. Reductiometric methods may call for clean-up with metal salts and colorimetric methods may require removal of strongly colored pigments using similar procedures. Dilution prior to chromatographic separation using HPLC is the preferred method for analyzing mixture of sugars and oligosaccharides. Table 2 presents the range of major options, which depend on the required objectives of the analysis.

Analysis of Total Carbohydrate and Sugars The colorimetric reactions with phenol/sulfuric and anthrone/sulfuric are general-purpose methods which give reasonable estimates of total sugars present and which, with suitable standard mixtures, can give acceptable accuracy.

Many of the classical reductiometric techniques depend for their accuracy on the existence of standard tables giving the reduction equivalents for a wide range of mixtures of glucose and fructose and of invert sugar and sucrose.

The specific enzyme procedures are based around reactions of the type illustrated below:

$$\text{Glucose} + \text{ATP} \xrightarrow{\text{Hexokinase}} \text{Glucose-6-phosphate} + \text{ADP}$$

$$\text{Glucose-6-phosphate} + \text{NADP} \xrightarrow{\text{Glucose-6-phosphate dehydrogenase}} \text{6-phosphogluconate} + \text{NADPH}$$

The amount of NADPH formed is proportional to the glucose present and can be measured by measuring in the ultraviolet range at 340 and 360 nm. Any fructose-6-phosphate produced by the hexokinase is converted to glucose-6-phosphate with phosphoglucose isomerase, which leads to formation of more NADPH, permitting the analysis of a mixture. Table 3 lists the enzymes used for the different carbohydrate species.

Oligosaccharides The ethanolic extracts contain the oligosaccharides and some polysaccharides with lower degrees of polymerization such as inulin. These will measure as total sugars with the colorimetric reactions in strong acid but the choice of another

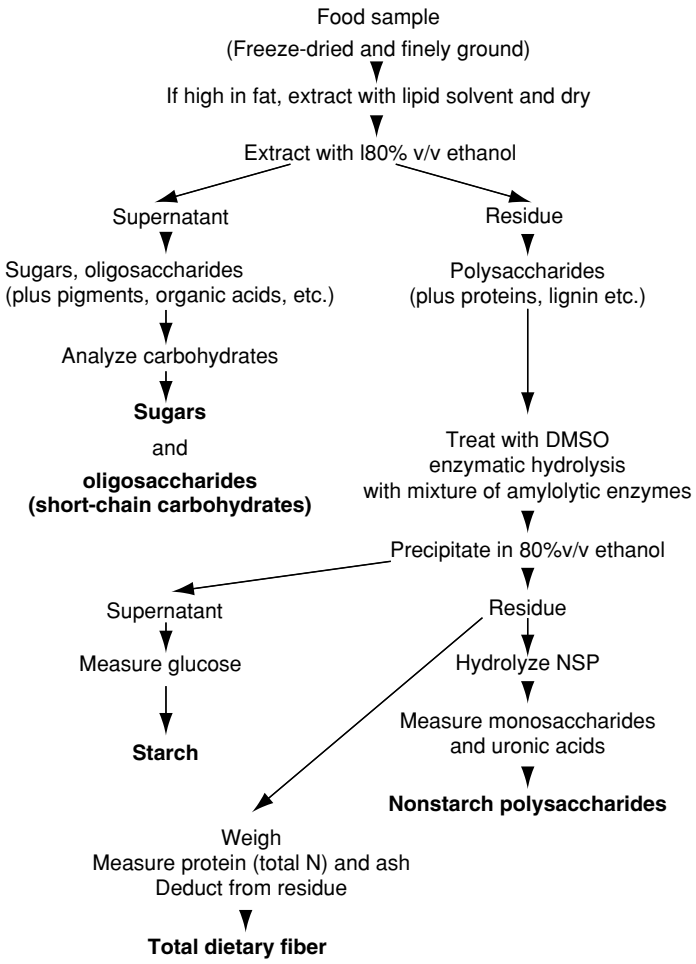

Figure 1 Typical scheme of fractionation used in the analysis of the major carbohydrates in foods. DMSO, dimethyl sulfoxide; NSP, nonstarch polysaccharides.

Table 2 Options for the analysis of the ethanolic extract[a]

Analytical objective	*Type of method*	*Choice of method*	*Limitations*
Total sugars	Colorimetric	Phenol//sulfuric	Color yield depends on sugars present
Total sugars	Reductiometric/colorimetric	Ferricyanide	Color yield depends on sugars present
Hexoses	Colorimetric	Anthrone	Color yield depends on sugars present
Reducing sugars	Reductiometric/volumetric	Lane and Eynon; Munson-Walker Copper salts in alkaline solution	Reduction depends on ratios of sugars present
Sucrose in invert sugar solutions	Reductiometric before and after inversion	Copper salts in alkaline solution	Reduction depends on ratio of invert sugar to sucrose
Individual sugars in mixture	Specific enzymatic procedures	Specific enzymes coupled with NADH and ultraviolet measurements	Availability of enzymes
Individual sugars in mixture	HPLC	Using either refractive index or pulsed amperometric detectors	Capital cost of equipment

[a]In most cases, removal of ethanol before analysis is necessary.
HPLC, high-performance liquid chromatography.

Table 3 Enzymes used in carbohydrate analyses

Enzyme class	*Substrate*	*EC number*	*Source*
Oxidoreductases			
Lactate dehydrogenase	Lactic acid	1.1.1.27	Pig muscle

Modified from Determination. In: Chaplin MF (1998) Encyclopedia of Food Science and Nutrition. 1st edition, pp. 684–691.

Table 4 Major carbohydrates in the nonstarch polysaccharides

Major group	*Components*	*Structural features*	*Distribution in foods*
Plant cell wall			
Cellulosic	Cellulose	Linear β-glucans	All cell walls
Noncellulosic			
	Pectic substances	Rhamnogalacturonans	Mainly in fruits and vegetables
		Arabinogalactans	Fruits and vegetables
	Hemicelluloses	Arabinoxylans	Cereals
		Glucuronoarabinoxylans	Cereals
		Glucuronoxylans	Fruits and vegetables
		Xyloglucans	Fruits and vegetables
		β-Glucans	Cereals

method must be based on the types present. The malto series will usually be hydrolyzed by the combination of amylase enzymes used to hydrolyze starch and, if no other oligosaccharides are present, may be hydrolyzed with dilute acid and the free sugars measured. Acid hydrolysis cannot be used if fructose-containing polymers are present because fructose is destroyed by acid; fructanase enzymes are available for selective hydrolysis. HPLC is the preferred method for the separation and analysis of oligosaccharides.

Treatment of the Residue: Hydrolysis of Starch The residue in most foods is a mixture of starch, NSP, proteins, the noncarbohydrate lignin, heat artifacts formed during the heat processing of foods and some inorganic matter.

Treatment with dimethyl sulfoxide (DMSO) renders any retrograded amylose soluble, and the starch can be completely hydrolyzed using a mixture of amylases. A heat-labile amylase is frequently used to give rapid solubilization of the starch followed by a mixture of pullulanase and amyloglucosidase or α-amylase to hydrolyze starch to glucose which can then be measured after precipitating the unchanged NSP with 80% v/v ethanol. The use of a glucose-specific method such as the colorimetric glucose oxidase method is preferred for analysis of glucose released by starch hydrolysis, but in practice any approach can be adopted.

Analysis of Nonstarch Polysaccharides NSPs form a complex mixture (Tables 4 and 5) and separation of the various types of polysaccharide is usually only carried out by those concerned with the study of the structure of the plant cell wall. A typical fractionation and analysis scheme is illustrated in outline in Figure 2.

Table 5 Polysaccharide food ingredients in nonstarch polysaccharides

Major group	*Components*	*Structural features*	*Use in foods*
Gums	Gum arabic	Arabinogalactans	Confectionery
	Guar, locust bean	Galactomannans	Soups as thickeners
Algal polysaccharides			
	Agar	Galactoanhydrogalactans	Powerful gelling agent
	Alginates	Guluronomannuronans	Powerful gelling agents
	Carageenans	Several different sulfated galactoanhydrogalactans	Interact with proteins to control physical properties
Modified starches		Phosphated and cross-linked, esters and ethers	Used to control starch retrogradation and as gelling agents
Cell wall extracts	Pectins		Gelling agent in jams
	Modified pectins (amidated)		Gelling agent
	Cellulose, esters, and ethers		

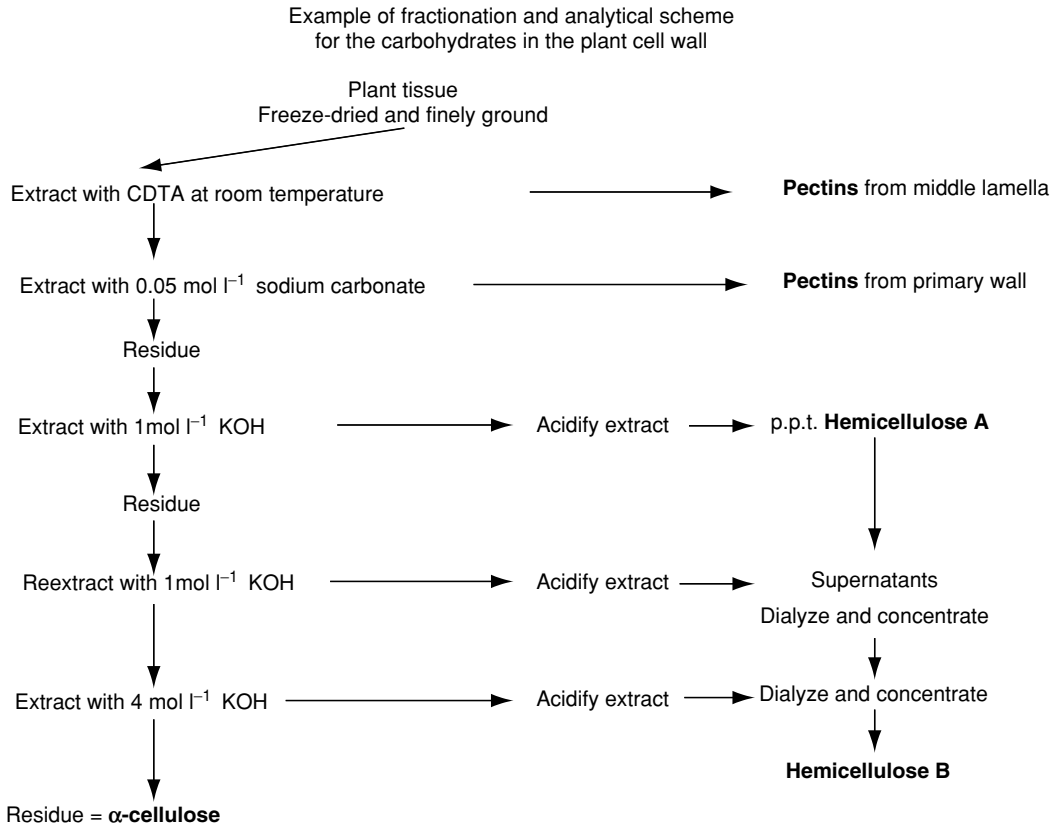

Figure 2 Typical scheme for fractionating and analyzing the carbohydrates in the plant cell wall. CDTA, cyclohexane diamine tetraacetate.

The polysaccharides in the extracts are concentrated and cleaned up by extensive dialysis and may occasionally be measured after freeze-drying the extract. More commonly, the extracts are further fractionated by size exclusion chromatography to separate the noncellulosic polysaccharides (pectins and hemicelluloses) into fractions based on molecular size. They may then be further characterized by methylation and hydrolysis for structural studies using chromatographic systems linked to mass spectrography. Monosaccharide composition is measured as described for the less detailed NSP analyses described below.

Most food analyses are restricted to the analysis of total NSP, although measurement of the cellulosic and noncellulosic fraction is often of value

nutritionally. Some procedures include treatment with a protease alongside the removal of starch, to reduce protein contamination before precipitating the NSP. This provides a procedure for measuring nonstarch components gravimetrically, and forms the basis of the official method of the Association of Official Analytical Chemists (AOAC) for measuring total dietary fiber. The residue contains the noncarbohydrate lignin and any heat-induced artifacts in processed foods. There is also some residual protein and inorganic matter and in the official method these are measured and deducted from the residue weight.

Measurement of the insoluble and soluble NSP fractions was until recently seen to be of nutritional value but this division is not now considered useful. This is because solubility is highly method-dependent in the choice of aqueous buffer used and the conditions under which it is measured and these have yet to be related to solubility under physiological conditions.

Hydrolysis of NSP Complete hydrolysis to the component monosaccharides is achieved using initially solubilization in $12\,\text{mol}\,l^{-1}$ H_2SO_4 followed by dilution to $2\,\text{mol}\,l^{-1}$ and heating to 100 °C for 1 h. The conditions do not release uronic acids which require enzymatic hydrolysis of the polysaccharides. In the Englyst method the uronic acids were measured colorimetrically and the monosaccharides by gas liquid chromatography (or HPLC). The noncellulosic polysaccharides are hydrolyzed in $2\,\text{mol}\,l^{-1}$ H_2SO_4 by heating at 100 °C for 1 h.

The monosaccharide constituents in both types of hydrolysates are measured after neutralization. For gas liquid chromatography the monosaccharides are reduced with sodium borohydride and then acetylated. It is necessary to use an internal standard such as allose to control these stages. Gas liquid chromatography is performed on a wide-bore capillary column with a flame ionization detector.

HPLC is controlled with an internal standard using a pulsed amperometric detector. Standard mixtures of the monosaccharides are analyzed in the same way and used to derive correction factors. Colorimetric procedures using the ferricyanide reaction may also be used to measure the total monosaccharides released by the $12\,\text{mol}\,l^{-1}$ H_2SO_4 hydrolysis. The standard mixture should reflect the ratios of the components in the samples under analysis to allow for differences in reduction equivalents.

Polyuronans which form part of the NSP are not completely hydrolyzed under these conditions and for this reason the uronic acids are measured separately colorimetrically in the $12\,\text{mol}\,l^{-1}$ hydrolysates using dimethyl phenol in $2\,\text{mol}\,l^{-1}$ H_2SO_4.

Modes of Expression

The carbohydrates in foods may be expressed in a number of ways. Total carbohydrate is often expressed as the value obtained by difference. This mode of expression is still widely used in food labeling. In the USA and the European Union (EU) this excludes dietary fiber. In the USA this implies total dietary fiber, as measured by the official AOAC method. In the EU, agreement on the procedure for dietary fiber has been slow to be reached and may be the AOAC value or a NSP value.

Total carbohydrate may also be expressed as the sum of the directly measured carbohydrates as they are present in the food, i.e., starch as starch or sucrose as sucrose. Once again, dietary fiber values are excluded. In the UK and some other nutritional databases, the carbohydrates are expressed as the monosaccharides. This can cause confusion if the mode of expression is not recognized because 100 g starch gives 110 g glucose and 100 g of disaccharide give 105 g monosaccharides.

Current international opinion on the measurement of carbohydrates in foods is that, wherever possible, direct and specific analytical methods should be preferred.

Sensory Properties

C S Setser, Kansas State University, Manhattan, KS, USA
G D Brannan, Customized Sensory Services, Wyoming, OH, USA

Background

The first sensory response expected of low-molecular-weight carbohydrates is sweetness. More than 100 substances are sweet and chemically identified as sugars, or nutritive carbohydrate sweeteners. Many other unrelated substances of diverse molecular geometry elicit the sweet taste, including some aliphatic and aromatic organic compounds, amino acids, and certain inorganic salts. However, not all sugars are equally sweet, and, moreover, the sensory properties of foods that are influenced by carbohydrates extend beyond sweetness. Flavors, in addition to the sweet taste, develop from browning reaction products. Color is another sensory property developed with browning reactions. Textural attributes are influenced in numerous ways: the low-molecular-weight carbohydrates contribute body and viscosity or interact with other components, including water and the high-molecular-weight carbohydrates, to influence sensory properties of food products; and the starches and gums contribute thickening and gel structure alone and by interactions with each other to alter other mechanical and geometrical texture characteristics.

Sweetness of Sugars

Stereochemical Similarities of Sweet Compounds

The common structural feature associated with all compounds possessing the sweet taste is a glycophore capable of concerted hydrogen bonding. A proton-donating group, often called the AH group, and a B group serve as a proton or hydrogen bond acceptor, respectively. The primary AH,B system of the common sugars is the α-glycol grouping, the portion farthest from the reactive, anomeric center; for example, the 3,4 α-glycol system of glucopyranose structures is responsible for its sweet taste. High-potency sweetness and bitterness can occur if a third component (X, or γ) functions as a 'dispersion' or hydrophobic site, and the electron-withdrawing group enhances the activity of the AH,B dipole. The sweet glycophores have AH–B distances of approximately 2.6 angstroms (Å), AH–X distances of 3.5 Å, and B–X distances of 5.5 Å.

A criticism of the AH,B system is that not all compounds that possess the AH,B system taste sweet, and some are actually bitter or tasteless. Symmetry principles help resolve this criticism. The charge on the dipole of the sweet substance must be bilaterally symmetrical, i.e., of opposite sign but nearly equal, for sweetness to be perceived.

Another issue is related to the enantiomers. Initially, the belief was that the D-sugars (and amino acids, for that matter) tasted sweet, but L-antipods did not. If the AH,B system were correct, both D- and L-sugars would be sweet. Later, it was learned that some L-sugars do taste sweet. The AH,B system of a stimulating compound would combine reversibly by intermolecular, antiparallel hydrogen bonding with a commensurate AH,B system on a proteinaceous receptor molecule of the tongue (Figure 1). The tripartite two-dimensional attributes of the faces of tastants determine the tastes of enantiomers. Such a fixed AH, B system would approach the receptor from only one direction, and L-forms of amino acids could be sterically restricted by side-chains from interaction with the receptor. This issue has not yet been resolved.

The AH,B model for the stimulus structure of sweet compounds suggests that only one receptor for sweetness is critical. However, current theories of sweet taste perception make it unlikely that a single receptor molecule can accommodate all sweet stimuli. Responses vary among species, individuals, and cells. Receptor sites for sugars also are not identical from one taste bud to the next.

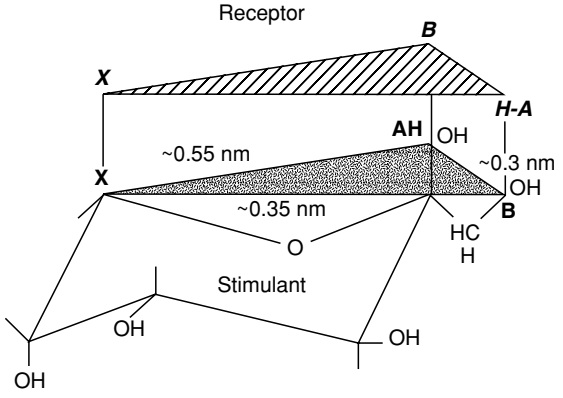

Figure 1 Representation of sweetness stimulant–receptor interaction for the AH-B-X theory using D-glucose as an example. The location of the AH-B-X units on the D-glucose template is shown in relation to a corresponding receptor site. Reproduced from Carbohydrates: Sensory Properties, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Sweet Taste Transduction

Perception begins with the contact of the sweet stimulus and a surface receptor molecule on the taste cell that leads to cellular changes via secondary messengers, which are translated into ion-channel events. Subsequently, the modified ion channels cause changes in cell polarization, resulting in the release of neurotransmitters to adjacent neurons and eventually an action potential. The theory of taste transduction, the process of translating sensory information into a signal useful to the nervous system indicates that high-intensity sweeteners, especially polyols, react with a seven-transmembrane receptor protein that is associated with a G-protein inside the cell. Several mechanisms on multiple receptor sites are possible; some, for example, use cyclic adenosine monophosphate (cAMP) as a second messenger, and others use inositol triphosphate (IP3). High-potency compounds apparently disrupt the transduction process at the G-protein. The number of sites involved and the effectiveness of the interaction have been related to the potency. Both sweet and bitter receptors share some of the same transduction components, such as IP3. These theories could help explain the close association between sweet and bitter tastes of some substances.

Sweeteners in Products

Sweetener synergy is critically important to the food processor. Synergistic effects are inferred if the sweetness of the mixture is greater than the sum of sweetness of the individual components. Synergism might result from solute–solute, solute–water, and solute–receptor interactions. The effects with any given sugar are not universal. Fructose, for example, shares a synergistic relationship with glucose and with saccharin, but not with other carbohydrate sweeteners. Recent evidence suggests that synergy depends on the compatibility of component hydration and the influence on water's structure. If components with identical types of hydration are mixed, increased water mobility in the proximity of the sweetener and a reduction in volume of the hydrated solute molecule result in synergy. Reduced water mobility in the medium has been observed with sweetness suppression of mixtures (sucrose–aspartame), and an increased water mobility led to enhancement (synergism) of sweet taste (sucrose–cyclamate and maltitol–acesulfame K mixtures), but no effect on water mobility and no appreciable synergy has been observed with alitame plus either sucrose or maltitol or with acesulfame K with sucrose.

Intensity of Sweetness

Sweetness generally decreases with the molecular weight of the sugar, although the reason is unknown. Perhaps, only one sugar residue in each oligosaccharide binds to the taste cell receptors. Lack of sweetness in some compounds is caused by steric interference of one or both of the axial hydroxyl groups, thus preventing binding to the taste cell receptor.

Food processors are interested in relative sweetness scores. Such numerical values attempt to relate overall sweetness of one substance to that of another substance. The value is defined as the 'ratio of concentration of substances matching in sweetness,' and sucrose is used as the reference (Table 1). The relative sweetness score has limited use, because it fails to recognize different solution properties of dissimilar substances and quality differences that occur because of a sweetener's multidimensional nature (onset, duration, intensity) is integrated into a single value. If the sweetener is in solution or in its crystalline form, the age of the test medium and the degree to which the sugar has mutarotated are further factors influencing relative sweetness.

Table 1 Relative sweetness of carbohydrate sweeteners

Sweetener	*Approximate sweetness*[a]
Bulk solids	
Fructose	1.2–1.7
Glucose	0.7–0.8
Invert sugar	1.0
Isomalt (Palatnit)	0.5–0.6
Lactitol	0.3
Lactose	0.2–0.4
Maltose	0.4–0.5
Mannitol	0.4–0.7
Mannose	0.6
Sorbitol	0.5–0.6
Xylitol	0.9–1.2
Xylose	0.7
Bulk syrups	
Corn syrup, unmixed, acid-converted	
30 DE[b]	0.3–0.35
36 DE	0.35–0.4
42 DE	0.45–0.5
54 DE	0.5–0.55
62 DE	0.6–0.7
High-fructose corn syrup	
42%	0.9–1.0
55%	1.0–1.1
90%	1.2–1.6
Hydrogenated glucose syrup (Lycasin)	0.4–0.75
Chloroderivatives of sucrose (Sucralose)	5–2000
Stevioside	300

[a]Sucrose = 1.0. Sweetness is a relative measurement dependent upon many external factors including concentration, temperature, pH, structural configuration, and degree of hydrolysis.
[b]DE, dextrose equivalent.

Concentration effects between 2 and 16% are approximately linear for sugars and sugar alcohols relative to sucrose standards. However, the psychophysical laws that govern responses indicate that increasingly larger stimulus increments are required with high concentrations to elicit measurable differences. An additional factor operating with concentration increases its adaptation. If a person is exposed repeatedly to a stimulus, the perceived intensity is reduced. The relative sweetness of sucralose, a potent sweetener, decreases with increases in the concentration at high concentrations. For most high-potency, noncarbohydrate sweeteners, the concentration response plots are hyperbolic. Concentration increases can negate or alter intensity differences or induce unpleasantness. The different behavior of polyols from high-potency sweeteners supports the tentative conclusion that at least two routes to receptor-cell activation exist.

Temporal effects and the sweetness response Onset time and duration of sweetness influence the acceptability of a sweetener. Consumers detect sucrose sweetness within 1 s, and that sweetness lasts about 30 s. Any sweetening agent that has a delayed initial sweetness or a sharp or prolonged sweetness sensation will taste unusual to many persons. A localized concentration of stimulus molecules at receptor sites is believed to govern the persistence or duration of sweetness. The lipophilic site could be responsible for directing potent sweeteners into localized concentrations at a nonspecific area of the cell membrane and account for persistence of sweetness. Thus, the physical length of the queue could determine the duration of sweetness by the length of time the receptor is supplied with stimuli.

Temperature effects and the sweetness response Temperature influences the sweet response, and not all sweeteners respond to temperature similarly. Heat can break intramolecular bonds of sweeteners, which could free more hydroxyl groups to participate in the AH,B system. Changes in structural form with bond breaking can result in isomers that do not have a sweetness equal to the original sweetener. An increase in temperature results in increased sucrose intensity, but decreased persistence. Temperature is believed by some to affect the approach of the stimulus molecules to the receptor site prior to the transduction process. However, others believe that the optimum temperature for detection of sweetness is near the temperature of the tongue, which is explained by maximal electrophysical responses at that point.

Synergism of Sugars with Other Food Components

Interactions of Components and Effects on Sweetness

The presence and concentration of other tastes, sweeteners, and flavors; the structural matrix, whether a solid, liquid, or gas; viscosity and solvent polarity of the medium; extreme temperatures of processing, storage, and preparation; and the microbes and enzymes present all influence and modify perception of sweetness from the sugars. Typically, sweet compounds are embedded in a complex matrix with bitter, sweet, sour, and salty tastes, and the flavor nuances of other ingredients. The 'taste modifiers' alter sweetness quality, increase or reduce intensity, or mask aftertaste probably by exerting a physical or chemical effect on the stimulus rather than the taste receptor. Sensory acuity to carbohydrate sweetness diminishes in the presence of other tastes, but the degree of suppression depends on the nature of the secondary agent, the concentration, and the intensity of taste.

Sweetness seems to be enhanced at low (< 0.4%) sodium chloride (NaCl) concentrations, but perceived sweetness declines if the concentration of NaCl is high. Sweetness of sucrose, fructose, and glucose is affected differently by various acids and the relative concentrations of each of the components. Sweetener–acid interactions, as well as interactions with fruit flavors, are important in the formulation of several beverages. Fruit flavorings alter the sweetness perception of aqueous systems, generally enhancing the sweetness of the carbohydrate sweetener. The sugars decrease the perception of bitterness in foods and beverages.

The relative initial and maximum sweetness of sugars is different in food products than in model systems. The texture and physical properties of a food affect its taste, because texture partially controls the amount and the rate which tastants reach the taste buds. The thresholds for the four basic tastes are higher in food products than in aqueous solutions. Sweetness is maximal when little or no interference from physical behavior of the taste medium exists. Viscous and oil solvents exhibit an interfering behavior that can raise the threshold and decrease the perceived sweetness intensity.

Sugar–Protein Interactions

Flavors and colors of foods are altered by the nonenzymatic browning of carbohydrates. Thermal decomposition of simple and complex carbohydrates usually occurs in combination with inorganic or

organic catalysts and results in caramelization, the key pathway for the formation of flavors associated with molasses, maple syrup, and caramel flavorings and colorings. The carbonyl-amine reaction involves a thermally induced interaction between an amino acid and a reducing sugar. Many pathways and reaction schemes follow ring opening and enolization of the sugars and their interactions with nitrogenous amino groups. The unique color and flavor compounds produced in roasted coffee, nuts, meats, chocolate, maple syrup, and bakery products result, in large part, from the carbonyl-amine reaction. Products of the carbonyl-amine reaction and interactions of the caramelization and carbonyl-amine reactions include pyrroles, pyridines, imidazoles, pyrazines, furfurals, furanones, oxazoles, and thiazoles, and they can form numerous brown to black polymers. Maltol and isomaltol, with their fragrant, caramel-like aromas, enhance both the flavor and sweetness of many foods. In micowaved and extruded foods, the time–temperature–moisture conditions result in a lack of flavor and color, because only low levels of the browning reaction products are formed. Strecker degradation and the fragmentation of carbonyl–amines are well-defined pathways that also can result in many off-flavor compounds in foods. During the final steps of the Strecker degradation reaction, formaldehydes and pyrazines evolve from amino ketone fragments of the reducing sugar. Food processors should optimize desirable caramel-type aromas but must minimize the burnt, bitter, and acrid notes that can be produced.

Sugar Interactions and Textural Changes in Foods

Carbohydrate sweeteners' colligative properties, which depend on the concentration of the solute, influence the body/viscosity of liquid and solid foods, and alter the texture of other foods by the effects on freezing point, boiling point, osmotic pressure, and vapor pressure. Increasing the number of sweetener molecules increases the boiling point and osmotic pressure, and decreases the freezing point and vapor pressure.

In addition to solute concentration, the viscosity of carbohydrate-sweetened solutions is governed by the temperature. With an increased temperature, molecular motion is increased, reducing the friction among the molecules and resulting in a decreased resistance to flow. The viscosities of most carbohydrate-sweeteners in solution are similar with equivalent molar weights except for glucose syrups. A large percentage of high-molecular-weight polysaccharides increase the relative viscosity of glucose syrups. Consequently, these syrups impart more cohesiveness, body, and adhesiveness to a food system than other types of sweeteners. The viscosity of carbohydrate sweetened solutions also is governed by solute concentration and temperature. With an increased temperature, molecular motion is increased, reducing the friction among the molecules and resulting in a decreased resistance to flow.

Low-dextrose equivalent syrups are viscous and increase the chewiness of products such as caramels and cookies more than an equal concentration of a higher-conversion, lower-viscosity syrup. The low-viscosity syrups decrease the viscosity of a candy mass of a given sucrose composition by decreasing air retention. The candy is brittle, and good flavor release in the mouth is promoted. The texture of confections is dependent upon dissolution and recrystallization of the sugar. If a sugar solution cools slowly and is not disturbed, large crystals are formed, as in rock candy. Rapid cooling with agitation results in fine crystals, as in creams.

The sharp, crystalline edges of sugars contribute to the aerated nature of chemically leavened bakery products by helping disperse the lipid portion of a batter in the initial creaming stages of multistage mixed batters and doughs. The creaming of the shortening allows the formation of many air cells, thus increasing the volume and tenderness. Sugars, particularly glucose, are efficient fermentation media, providing aeration in some bakery products. Sugars further tenderize bakery products by controlling starch hydration and by dispersing protein and starch molecules. Starch and protein molecules are separated by the sugars, as well as by lipids, and are prevented from forming a continuous mass. The structure remains flexible and pliable enough to allow for maximum expansion during leavening and before thermal setting. Excessive sugar can increase the fluidity of the batter, increase the coagulation temperature of the egg proteins, and increase the temperature at which starch gelatinization occurs to the extent that the structure is too weak to support its weight. The batter structure rises before it is thermal set, but then it collapses.

Regulating the amount and type of sugar controls cookie spread and surface cracking. Increasing the amount of sugar with a given amount of water generates more solution than is available with water alone. Small crystals increase cookie spread, because fine crystals dissolve more readily, generating more solution at a given time and temperature than do the coarser particles. Consequently, gelatinization and thermal set times are delayed, the dough is more fluid, the cookie spreads farther before the structure sets, and it is crisper. When cookies contain high levels of sucrose, a hard, sweet cookie with 'snap,' or a crispness and crunchiness, and surface cracks

results, because, after cooling, the sugar syrup recrystallizes to form an amorphous glass. Molasses, honey, glucose syrups, and high-fructose corn syrup inhibit crystallization and result in softer cookies that are chewy, rather than crisp.

Properties of Polysaccharides in Relation to Food Product Structure

Polysaccharides affect the sensory properties, particularly the texture, of food products by retarding the flow as well as by modifying the gelling characteristics. Nonstructured, amorphous regions of polysaccharides are highly hydratable and bind large quantities of water. In contrast, areas that contain a large portion of straight-chained, crystalline regions, such as retrograded starch gels, exclude water. Most natural and synthetic hydrocolloids, or gums, display pseudoplastic flow properties, that is the viscosity of the solution decreases as the shear rate increases. With high shear rates, viscosity decreases because the particles are oriented parallel to the shear field. In general terms, viscosity also decreases as the temperature increases.

Sensory Properties and Rheological Character

The predominant sensory property of many gum solutions is slimy characterized by a thick mouth coating and by being difficult to swallow material. Dispersions that approach Newtonian flow behavior are associated with a high degree of sliminess, and gums in solution that depart considerably from Newtonian flow and have a high degree of shear-thinning are less slimy in the mouth. Other sensory attributes used to describe gum solutions are adhesive, starchy, gummy, astringent, slippery, and oily. 'Starchy' is a flavor related to an undercooked product, but the other parameters are related to mouth feel and mechanical textural properties. Normally, blandness is the desired flavor quality for carbohydrate thickeners in food products.

Pseudoplastic behavior is associated with a less slimy mouth feel because the viscosity of the fluid decreases at the shear rate encountered in the mouth (approximately $50\,s^{-1}$). High-viscosity seed and exudate gums – guar, tragacanth, and locust bean – are more pseudoplastic than alginates and cellulose ethers, whereas gum arabic has a low viscosity and almost Newtonian flow properties up to a concentration of at least 40%. Dispersions of microcrystalline cellulose, a synthetic gum, show both thixotropic and plastic behavior. The behavior that dominates depends upon the concentration and shear history. Starches can be modified to alter the consistency; cross-linking contributes short, stringless consistency in waxy and tapioca starches. The unmodified starch dispersions will have a stringy, cohesive consistency. High levels of highly cross-linked waxy corn starch will increase the chewiness in a product.

Gel Properties

Several polysaccharides provide partial gel structure in some food products and total structure in others. High-methoxyl pectins in fruit jams and jellies; low-methoxyl pectins for dietetic gels; starches in puddings, agar in meat products; carrageenan for kosher fruit gels and milk puddings; and alginate in pie fillings, reformed vegetables, fruits, and meat chunks are all examples.

Gels can be brittle, rigid, springy, firm, soft, spreadable, cutable, rubbery, smooth, or grainy, depending upon the concentration and the degree of interactions of the polymers. Gelation balances polymer–polymer and polymer–solvent interactions to form a tertiary network or matrix; a gel is an intermediate state between a solution and a precipitate. Enhanced interactions among polymer molecules result as their solubility decreases and generally lead to firm, rubbery, springy, rigid gels. Gels tend to become more brittle as the concentration increases, but also faster rates of setting and decreased uniformity of matrices result in increased brittleness. A crisp or crunchy mouth feel for snack foods is obtained with high levels of amylose of slightly degraded waxy starch pregels that expand to tender structures with heating and drying. Rubbery structures are obtained with thin boiling corn starch in the presence of high concentrations of sugars. In other instances, substances influence the rigidity or strength by (1) competing with water for the binding loci, such as sugar-softening a starch gel, (2) competing with the solid phase for the liquid, as sugar does in high methoxyl pectin gels, (3) altering the pH, as acids do in pectin systems, (4) interacting chemically with either or both phases, as calcium ions forming cross-bridges with alginates or low-methoxyl pectins, and (5) altering the charge distribution on the polymer molecules.

Relationships of gel strength to interactive forces

The type and strength of the crystalline junction zones in polysaccharide gel networks govern the strength, elasticity, and flow behavior of the gel. If the junction zone is short, and chains are not held together strongly, the polysaccharide molecules will separate under physical pressure or with slight increases in temperature. One or more polysaccharides can be involved in the junction zone; the zones can involve multiple helices or aggregates of ordered ribbons. Agar forms one of the strongest gels known via bundles of associated double helices, and the gels

remain stable at temperatures from 30 to 85 °C. Helical junction zones also are involved in carrageenan and furcelleran gels. Low-methoxyl pectins, with less than 50% esterification, can form stable gels using divalent ions, such as calcium, to form cross-links. Alginate gelation occurs at room temperature in the presence of calcium or other di- or trivalent ions, or in the absence of ions at pH 3 or less. Gellan, in the presence of ions, gels similarly to alginate but it gives a similar brittleness, elasticity, and cohesiveness to agar gels, except that the gellan gels are more firm. In the case of carrageenans, ions are immobilized at the junction zones, although the primary gelation mechanism is believed to be hydrogen bonding. Kappa carrageenans form firm gels with potassium, but not with sodium ions, and iota carrageenan is calcium-sensitive. Kappa and iota carrageenan form a gel; however, lambda fractions are strongly anionic, do not complex readily with cations, and do not gel.

Polysaccharides with carbonyl groups also do not gel easily because of electrical repulsion between approaching chain segments. High methoxyl pectin (55–80% esterification) forms strong gels only if (1) the pH is adjusted to 2.0–3.5 to prevent charge repulsion and ionization of the carbohydrate groups and (2) a dehydrating material is used to increase the intermolecular interactions by hydrogen bonding among the polymers. A synergism between alginates and pectins for gel formation occurs if the system is first acidified to reduce electrostatic repulsion and permit molecular association.

Molecular configuration and gel character Branched molecules do not form strong junction zones, thus they do not form strong, elastic gels. Studies on cross-linking mechanisms of mixed gels suggest an ordered binding between extended ribbon conformations of smooth, unbranched areas on galactomannan chains and double helices of agarose or carrageenan. The smooth, unstructured regions of the mannan and xanthan gum are involved in thermally reversible gels.

Concentration effects Gel strength in simple alginate and pectin gels and in the more complex starch gel is strongly concentration-dependent. A critical concentration, specific for any given polymer–solvent pair, is required. Firm gels can be prepared from a few types of gums, such as pectins, at levels of 1% or less. Other colloidal gelling agents require up to 10%. The higher polymer concentrations necessary in some systems likely allow aggregate formation at low temperatures. The overall strength of starch gels depends upon the residual swollen granules to reinforce the strength of the amylose gel matrix. Soft gums can be obtained with high-amylose starches. Retrogradation of amylose is controlled to give textures ranging from a short, clean bite to a long, somewhat chewy bite in products such as gum drops, orange slices, and gummy bears. Thin boiling starches obtained by acid treatment to produce short chains in the amylopectin portion are used with high concentrations of starch and sugar for the manufacture of firm, rubbery gum candies.

Crystalline junction zones can occur to such a degree in polysaccharide gels that retrogradation and syneresis occur. Increased polyguluronate junction zones in alginate gels result in rigid, brittle gels with high syneresis, whereas few junction zones produce an elastic gel with less tendency to synerese. Generally, syneresis resulting from compression gives a feeling of juiciness in the mouth.

Synergism of Polysaccharides with other Food Components

Gel structures Mixed gels and filled or composite gels are utilized to obtain specific textural properties in food products. The texture is dependent upon the relative proportions of each component and the overall concentration. Locust bean gum with kappa-carrageenan forms brittle, elastic gels, but xanthan gum with kappa-carrageenan or low-methoxyl pectin with iota carrageenan forms soft, cohesive gels. Low levels of gellan gum can give similar gel characteristics to high levels of κ-carrageenan with locust bean gum. Myoglobin and bovine serum albumin are proteins that promote low-methoxyl pectin gelation, but they inhibit the formation of gels using alginate. Each gelling agent can contribute to the gel formation in mixed gels, or one of the gelling agents can be nonactive, modifying the characteristics but not interacting to form the gel network. For example, agar forms microgels in the gelatin matrix of an agar–gelatin mixed gel.

Flavor carriers and encapsulation Carbohydrates can enrobe, absorb, and retain flavor volatiles during processing, which has important implications in food systems. Gum arabic, guar gum, modified starches, and maltodextrins as well as sucrose and lactose are used for encapsulation by spray-drying or extrusion processes. Inclusion complexing is used for encapsulation by the β-cyclodextrins.

Glossary

Enantiomers – D and L forms of molecules;
Encapsulation – packaging of solids, liquids or gaseous materials in miniature, sealed capsules; that can

release the contents at controlled rates under specific conditions

Newtonian – fluid with a rate of deformation directly proportional to stress;

Pseudoplastic – fluid that undergoes thinning with increasing rates of shear;

Pyschophysical – study of the relationship between sensory stimuli and human responses;

Stereochemical – referring to spatial arrangement of atoms and groups in molecules;

Synergism – action of two or more substances to achieve effect of which each individually is incapable;

Syneresis – leakage of liquid from a gel;

Transduction – translating sensory stimuli information into signals useful to the nervous system

Carcinogenic Substances in Food: Mechanisms

R Mehta and T J Schrader, Sir Frederick Banting Research Centre, Ottawa, Ontario, Canada

Background

Cancer is a major disease resulting in more than 7 million deaths per year worldwide. The risk of cancer varies from region to region, suggesting a role for geographic, environmental, and cultural factors in cancer causation. Current figures suggest that although about 37% of cancers deaths in the USA are caused by cigarette smoking, diet is also a significant risk factor, estimated to be associated with about 35% of cancer deaths.

The human diet, whether derived from an animal or a plant source, is an extremely complex and a variable mixture of macro- and micronutrients, and naturally occurring and synthetic substances. Studies in experimental animals and human epidemiology have shown that cancer development is a multistep process consisting of three main stages: initiation, promotion, and progression (Figure 1). Each stage further involves numerous events, many of which have as yet not been defined precisely. Generally, during the initiation stage, normal cells are exposed to chemical, viral, or physical carcinogens. Such exposure may cause change(s) in the genome, providing a selective growth advantage to the altered cells. Promotion involves selective growth of these genetically altered cells leading to precancerous lesions and eventually tumors. In the progression stage, the tumor undergoes additional genetic and morphological changes, making it malignant with the ability to invade and spread (or metastasize) to other sites in the body. Natural or synthetic carcinogens in food may contribute to cancer development during either the initiation or promotion stage, depending on the type of reactivity with the genetic material.

Naturally Occurring Carcinogens in Food

Environmental exposures to naturally occurring chemicals result principally from the food we consume ($1.5\,kg\,day^{-1}$). Although air and water frequently contain at least trace levels of man-made contaminants, they are seldom a source of naturally occurring carcinogens. The numbers and amounts of naturally occurring substances in a food far exceed the synthetic compounds, and include macronutrients (fat, carbohydrates, and proteins), micronutrients (vitamins and minerals), and nonnutrient constituents.

Both macro- and micronutrients have been shown to modify cancer incidence in experimental animals. In man, the modulation of cancer by macro- and micronutrients is less definitive, though there is some evidence that breast cancer rates are associated with the amount and type of fat as well as with a high proportion of calories as fat. In experimental models, total caloric intake, as opposed to a single macronutrient, is also known to have an impact on age-related changes in tumor incidence. For example, decreasing calorie intake results in a reduction in cancer incidence.

The naturally occurring chemical nonnutrients, also termed natural food contaminants, may originate in the food supply as a result of (1) physiological and biochemical processes inherent in the food organisms themselves; (2) byproducts formed during stress, storage, processing, and preparation of food; (3) infection or spoilage during storage by bacteria or fungi; (4) materials introduced into the food product through the dietary source consumed by the animal destined for food; and (5) naturally occurring substances isolated from raw plants or animal sources and intentionally added back to the food, for example, as a flavor or color enhancer. Examples of carcinogens naturally occurring in normal human diet under each of these categories are shown in Table 1.

Synthetic Carcinogens in Food

Synthetic chemicals in foods occur as (1) direct or intentional additives where synthetic chemicals are added deliberately to enhance the appearance, nutri-

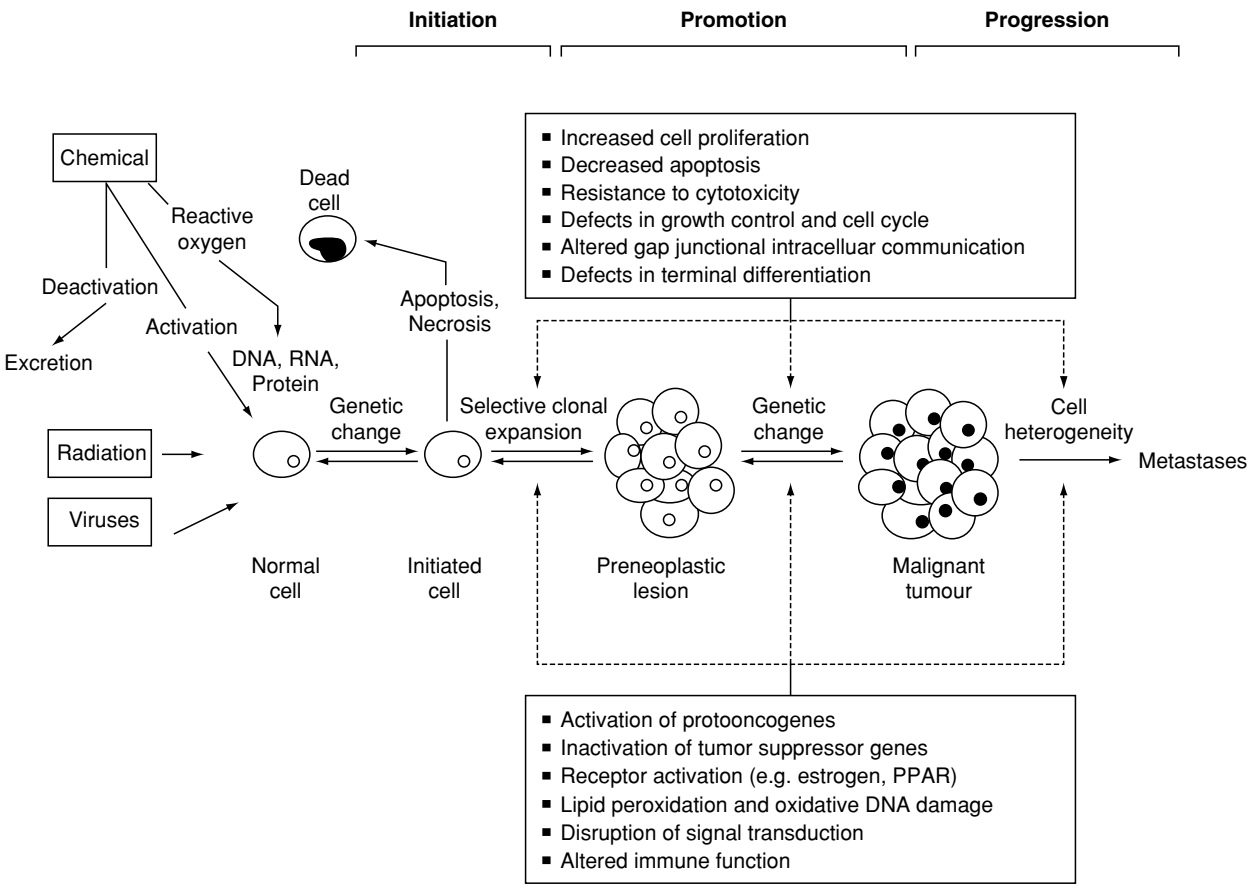

Figure 1 General scheme for sequential steps in multistage carcinogenesis.

Table 1 Naturally occurring substances that may be present in US diets

Origin of natural substance in food	*Examples (partial list)*
(1) Physiologically/biochemically produced through processes inherent in the food organism	Acetaldehyde, caffeic acid, estrone, estradiol, projestrone, safrole, styrene, testosterone, 8-methoxypsoralen (with UV light exposure)
(2) Byproducts formed during stress, storage, food processing, and preparation.	Polycyclic hydrocarbons (benzo[a]pyrene), nitrosoamines (*N*-nitrosodimethylamine), heterocyclic aromatic amines (PhIP, MeIQx, IQ, glu-P-1), methylmercury compounds
(3) Infection or spoilage during storage by bacteria or fungi	Aflatoxins, ochratoxin A, fumonisins, sterigmatocystin
(4) Introduction into food through dietary source consumed by the organism destined for food	Arsenic, cadmium, benz[a]anthracene, benzo[a]pyrene, seafood toxins, indeno(1,2,3)pyrene, toxol in snakeroot, aflatoxin from cows' milk
(5) Natural substances isolated from raw plants or animal sources and intentionally added back to the food	Sucrose, glucose, isolated soy protein flavors extracted or distilled from spices, gums, corn, or tapioca starches

tional quality, or shelf-life of a food product by, for example, adding color, a nutritional supplement, or a preservative; and (2) indirect additives where synthetic chemicals are present as a result of the use of, for example, pesticides, packaging materials, antibiotics, or growth-promoting substances during food production, processing, or storage. Indirect additives may also be termed synthetic food contaminants. Table 2 lists examples of carcinogens under these categories.

Exposure and Risk Evaluation

Origin of synthetic substance in food	*Examples (partial list)*
(1) Directly or intentionally added	*Appearance modifiers*: Glazes, waxes, colors (tartrazine, sunset yellow), surface finishing agents (polyvinyl-pyrrolidone)
	Curing and pickling agents: Sodium nitrite, ascorbic acid, sodium tripolyphosphate
	Nutrient replacements/supplements: Sucrose polyesters, all essential vitamins, minerals and fatty acids
	Sweeteners: Saccharin, aspartame, sucrose, glucose
	Product stability aids: Antioxidants (butylated hydroxyanisole), antimicrobials (sodium benzoate, potassium sorbate)
	Flavoring agents: Triethyl citrate, monosodium glutamate, ethyl maltol
(2) Indirectly or unintentionally added	*Pesticides*: Toxaphene, chlordane, organotins, triazines, dinitranilines, arsenicals and fluorides, DDT, chlordecone
	Growth promoters: Estradiol, progesterone, reserpine, testosterone
	Antibiotics: Sodium *o*-phenyphenate
	Packaging materials: Acrylamide, di-2-ethylhexylphthalate, carbon tetrachloride, chloroform, styrene, styrene oxide, dimethylformamide

food are complicated by (1) the large variety of such materials that are present in the human diet and (2) the ability of such substances to manifest both carcinogenic and anticarcinogenic properties with different mechanisms of action.

When comparing possible carcinogenic risks of natural relative to synthetic substances, it is therefore necessary to take into account (1) their relative exposure through food and (2) any theoretical differences in chemical and biological properties of both types of chemicals. Traditional foods (e.g., grains, fruits, vegetables, and meat) comprise the bulk of the diet. Items such as sugar and salt, generally recognized as safe, are the most highly used direct food additives. Other direct additivies such as artificial sweeteners, colors, preservatives, spices, and flavors are used in much smaller amounts. In contrast, indirect food additives, such as pesticides and substances from packaging materials, represent over 2000 chemicals, many of which may be present in food below the level of detection.

In terms of possible differences in chemical properties, one commercially desirable property for a synthetic food substance is chemical stability, which is often achieved by adding a chlorine group to the synthetic chemical. This may then give rise to persistence of such chemicals in the environment, and accumulation in the plant and animal food chains.

An excellent example of such persistent indirect food additives is pesticides, which, among the general public and regulatory agencies, have raised the most concern compared to other indirect food additives. Pesticides in food may originate from any of the following sources: agricultural residues persisting on the foodstuffs or in the environment, chemicals used during storage, or water used in food preparation. While animal studies provide evidence for the carcinogenicity of many pesticides, most of the data for an association between pesticides and human cancer have been obtained from occupational exposure studies in farmers. The findings of residues of pesticides and their metabolites in blood, urine, breast milk, and adipose tissues of individuals in the general population, however, have sparked concerns over health effects of pesticides. Certain subpopulations, in particular, may be susceptible to higher than normal rates of exposure through the food supply. For example, children are one vulnerable subpopulation that may be exposed to significantly greater amounts of pesticide residues through placental transfer and breast milk. Another subpopulation of current concern is that of the Arctic whose marine food chain has accumulated persistent residues of organochlorine pesticides that were heavily used in southern parts of the North American continent until the 1980s. Such migration of persistent, indirect food additives across continents may result in adverse health consequences for the Arctic indigenous populations that consume marine mammals as part of their traditional diet.

An example of a group of naturally occurring carcinogens in food that have been most studied and regulated include the mycotoxins such as aflatoxins, ochratoxins, and fumonisins. Aflatoxins, produced primarily by strains of *Aspergillus flavus*, have been found as fungal contaminants in peanuts, corn, wheat, rice, and foods made from these commodities. An association between dietary aflatoxin exposure and high incidence of liver cancer has been observed in a number of African and South-east Asian countries. Of all the aflatoxins, aflatoxin B_1 is the most potent liver carcinogen. Recent studies have shown that other factors such as hepatitis B viral (HBV) infection, alcohol consumption, smoking, and other

environmental variables also play a role in liver cancer induction by aflatoxin B_1. In Western countries, human exposure to aflatoxin B_1 is mainly from nuts and nut products, and for children from peanut butter, estimated to be 1–2 ng per kilogram body weight (bw) per day according to Canadian estimates (1985–1987). This intake level is about 10-fold higher than the Canadian set tolerable daily intake (TDI) of 0.11–0.19 ng per kilogram bw per day. This TDI was based on a carcinogenic risk level of 1:100 000, as estimated from epidemiological data obtained from Asian and African populations. However, such an exposure level is not considered a health risk for Canadians because HBV infection, another associated factor in liver cancer development by aflatoxin B_1, is not endemic in Canada, unlike the Asian and African countries.

Another mycotoxin, ochratoxin A, produced by *Aspergillus ochraceus* and related species, has been found to occur in foods of plant origin such as wheat, barley, oats, corn, dry beans, and animal-derived food products. It has also been detected in human blood, milk, and tissues from European and Canadian populations, suggesting widespread human exposure. However, various Western countries have regulations to ensure that levels in food are controlled at levels below the estimated TDI of 1.5–5.7 ng per kilogram bw per day, which is based on a National Toxicology Program carcinogenicity study. Ochratoxin A has been implicated in endemic nephropathies in European populations as well as livestock, and has been shown to cause renal cancer in two rodent species.

Fumonisins, produced by *Fusarium moniliforme* and *F. proliferatum*, are fungal contaminants primarily found in corn and corn-based food products. Six fumonisins have been isolated and characterized from *F. moniliforme*, and are designated as fumonisin B_1, B_2, B_3, B_4, A_1, and A_2. Only fumonisin B_1 and B_2 have been studied to a significant extent. The consumption of corn contaminated with fumonisins has been associated with a high incidence of esophageal cancer in human populations in the Transkei region of South Africa and Henan Province of Northern China. Fumonisin B_1 has also been shown to cause liver cancer in rats and female mice, and renal tubule neoplasms in rats. Levels of fumonisin B_1 vary from year to year, based on fungal growth conditions (e.g., moisture during the growing season), but are consistently in the 0.5–2 p.p.m. range in US cornmeal and have been reported to be as high as 150 p.p.m. in corn for human consumption in South Africa. The levels of this mycotoxin in some foods also change as a result of the cooking process through hydrolysis of the tricarballylic acid groups, or by reacting with reducing sugars producing (carboxymethyl)-fumonisin B_1. Overall, it has been difficult to determine the accurate average daily consumption of fumonisin B_1 in the USA because this will depend on the level of contamination, the diet portion that is corn or corn-based foods, and the cooking habits. In terms of risk management, the TDI for these group of mycotoxins has not been established owing to a lack of sufficient toxicity data, although Switzerland has a regulatory limit of 1 p.p.m. in human food.

Examples of naturally occurring carcinogens that may originate in the food supply as byproducts during food processing and preparation include the nitrosamines, polycyclic aromatic hydrocarbons (PAHs), heterocyclic amines (HCAs), and lipid oxidation products. These compounds are present in some cooked foods, particularly fried, grilled, or barbecued meat and fish products. Exposure to these products can also arise from food processing: curing, drying, smoking, roasting, refining, and fermentation. The most commonly detected PAHs are benzo[a]pyrene, benzo[a]anthracene and dibenzo[a,h]anthracene, of which benzo[a]pyrene is the most carcinogenic. The intake of PAHs in Europe, the USA, and Japan has been estimated to be around 1 mg per person per year, and for benzo[a]pyrene, the values range from 0.01 to 0.61 mg per person per year. Of this, only about 25–30% of the PAHs originates from food, with the majority coming from air pollution and smoking. PAHs have been considered probable human carcinogens based on animal and *in-vitro* mutagenicity data. There is no definitive evidence for a possible relationship between ingestion of PAH-contaminated food and human cancer.

The main forms of *N*-nitroso compounds in food are nonvolatile, including a large number of compounds that could be potentially formed, e.g., proteins containing *N*-nitrosated peptide linkages, such as *N*-nitrosoproline. Although nonvolatile *N*-nitroso compounds have not been shown to be carcinogenic or mutagenic, they could be precursors to the volatile carcinogenic nitrosamines. For example, during food processing, preparation, or preservation, added nitrite and/or nitrate, naturally occurring nitrite, or nitrogen oxides resulting from heating or drying of foods with combustion gases can react with amino compounds to produce *N*-nitroso compounds. Examples of the volatile carcinogenic nitrosamines that occur in food include *N*-nitrosodimethylamine, (NDMA), *N*-nitrosodiethylamine, *N*-nitrosopyrrolidine, and *N*-nitrosopiperidine. The evidence that some *N*-nitroso compound are carcinogenic is overwhelming from animal studies. In epidemiological studies, positive correlations have been observed between the high intake of nitrosamines, and incidences of esophageal and nasal cavity cancers in

China, stomach cancer in Japan and Norway, and colorectal cancer in Finland.

A variety of HCAs are produced as pyrolysis products of sugars, amino acids, creatinine, and other constituents when fish and meat products are subjected to high temperatures during normal cooking processes. The extent of HCA exposure (estimated at nanogram to microgram levels per day per person) is influenced by factors such as type of fish or meat ingested, frequency of consumption, portion size, method of cooking, cooking temperature and duration, and the amounts of the pan residues and gravy ingested. The different groups of HCAs identified include pyrido-imidazoles or indoles (Trp-P-1, Trp-P-2, AαC, MeAαC); derivatives of imidazoquinolines or IQ compounds (IQ, MeIQ); imidazoquinoxalines (Iqx, MeIQx, DiMeIQx); and the imidazopyridines (PhIP). Among the various HCA contained in cooked meat, the content of PhIP is highest, followed by MeIQx in the Western diet. In urine samples from Japanese volunteers, however, the levels of MeIQx are higher than those of PhIP. Long-term animal studies have shown multisite carcinogenic effects with major target organs being the liver, colon, and mammary gland in mice and rats for MeIQx and PhIP, respectively, and liver for IQ in cynomolgus monkeys. Epidemiological studies have focused on meat consumption and several types of human cancer, but a major challenge has been to differentiate the effects of HCAs from that of meat by itself and other confounding factors. DNA adducts in human tissues have also been detected.

Lipid oxidation products, particularly cholesterol oxide products, are common in foods exposed to severe cooking conditions such as deep-fat frying and pan frying following long-term storage in a freezer or in dehydrated form. The formation of cholesterol oxide products is greatly accelerated by autooxidation of coexisting unsaturated triacyglycerols, resulting in oxidized forms or epoxides of cholesterol. Several studies, for example, have reported high levels (6.8–58.8 p.p.m.) of cholesterol oxide products in french fries cooked in animal fats or mixtures of vegetable oils and animal fats. In terms of risk, the relationship between long-term consumption of lipid oxidation products and human health is not clear. Data from animal studies are not reliable, because high levels (10–15% of diet) of lipid oxidation products are required in the diet of the laboratory animal to produce an effect.

Following a number of evaluations, the International Agency for Research on Cancer has concluded that several of the nitrosamines, PAHs, and HCAs are probable or possible human carcinogens based on both long-term animal studies and *in vitro* mutagenicity tests. However, in the absence of sufficient evidence that these mutagens really cause human cancer, no limits have been set for their presence in foods. The regulatory agencies in most developed countries recommend minimizing their occurrence in foods by changing cooking practices.

In the USA, UK, Canada, and many other countries, food-safety legislation is based on traditional food, added substances, and unintended added substances. It would seem, therefore, that food additives and pesticides do not pose a major cancer threat in view of their rigorous regulation, and hence, only limited exposure is expected from below 'tolerance level' quantities being permitted in foods. In the USA, the Food Additive Amendment in 1958 contained the 'Delaney Clause', which states that no natural of synthetic additive be allowed in food in any amount if it has been shown to produce cancer in animal studies or other appropriate tests. There is no legislation, however, to regulate naturally occurring carcinogens from plants or cooking practices, or the macrocomponents of the diet which with improved analytical techniques have been shown in recent years to be a cancer risk, either directly or by modulating the disease process. Attempts to estimate cancer risks from naturally occurring carcinogens are further complicated because of the difficulties in differentiating between the effects of these substances from those of other confounding factors such as individual differences within human populations with respect to rates of exposure, the ability to activate and detoxify these substances, the presence of other protective mechanisms, and lifestyle. An in-depth understanding of the biological mechanisms by which these diverse carcinogens exert their action is therefore necessary for the development of methods and biological markers that allow (1) reliable extrapolation of biological mechanism-related data from appropriate experimental models to humans; (2) accurate biomonitoring in human populations for exposure to specific food borne carcinogens and their health effects; and (3) estimations of cancer susceptibility to specific foodborne substances in individuals and subpopulations. Such measures would then provide essential data for assessment of potential human cancer risk as well as perhaps avenues for legislative control of these substances.

Mechanisms of Carcinogenesis

Although the detailed molecular mechanisms of cancer induction by carcinogens in food remain to be discovered, several factors required for the multistep process have been identified: two or more genetic events, either inherited or resulting from point

mutations, chromosomal rearrangements, insertions or deletions of genes, and gene amplification; cell replication to incorporate the altered DNA into the genome; cell proliferation to selectively expand the altered cell population into a benign tumor; and additional genetic events leading to a malignant tumor with the ability to invade and metastasize to other sites in the body. Some of the genetic events at various stages during cancer development include overexpression and/or activation of cellular protooncogenes, and deletion or inactivation of tumor suppressor genes (Figure 1). Such alterations in the expression of protooncogenes and tumor suppressor genes may then cause the dysregulation of the cell cycle either directly or indirectly. The cell cycle is a complex process involved in the growth and proliferation of cells, and involves numerous regulatory proteins that direct the cell through a specific sequence of events concluding with mitosis and the production of two progeny cells. Many of the protooncogenes and tumor-suppressor genes also play a key role in the regulation of natural cell death or apoptosis. Over the past decade, it has become increasingly clear that cancer is the disease not only of increased cell replication but also of inhibition of apoptosis. The relationship between cell replication and normal cell death (or loss) determines the rate of tumor growth. In addition, the immune system is known to play a role in recognition of cancer cells and may contribute to cancer prevention by killing cancer cells. Therefore, any inhibition of the immune surveillance mechanism may compromise its protective capacity and thus result in tumor development.

Natural or synthetic carcinogens in food can generally be divided into those that directly affect DNA (genotoxic) and those that do not (nongenotoxic), and may be classified according to their role in triggering events during one or more of the stages of cancer induction (Table 3). Genotoxic substances chemically react with DNA and are usually implicated during the initiation stage of carcinogenesis. Nongenotoxic carcinogens, which do not have the capacity to react with the DNA directly, may alter DNA through indirect or epigenetic mechanisms and are, therefore, expected to contribute during the promotion or progression stages. Some chemicals cause indirect DNA damage and genomic alteration through oxygen radical generation in a variety of ways. Certain nongenotoxic carcinogens, such as peroxisome proliferators and estrogens, interact with specific receptor proteins to produce protein–ligand complexes, which then interact with, and

Table 3 Possible mechanisms of carcinogenicity by foodborne substances

Carcinogen classification according to cancer stage of most likely activity	*Capacity to*	*Possible mechanism(s) of action*	*Selected examples*
Initiating agent	Initiate cells only	Electrophile generation through spontaneous breakdown or metabolic activation of chemical with resultant DNA damage and two or more genomic mutations	Mycotoxins (aflatoxin B_1) Nitrosamines (NDMA) Heterocyclic amines (PhIP, IQx) Pesticides (toxaphene)

Promoting agent	Selectively expand the initiated cell population
	Convert an initiated cell or a promoted cell to a malignant cell
		One or more of:
		• enhanced cell proliferation
		• decreased apoptosis
		• epigenetic effects via:
		  • lipid peroxidation and oxidative DNA damage
		  • receptor protein interaction–peroxisome proliferation, hormonal action
		  • altered signal transduction pathways
		  • compromised immune function
			Mycotoxins (fumonisin B_1)[a]
			Pesticides (chlordane, organochlorines, chlorophenols)
			Packaging materials (di-(2-ethylhexyl)phthalate)

Complete carcinogen	Induce cancer from normal cells usually exhibiting the properties of initiating, and promoting agents	Electrophile generation, DNA damage, genomic mutations, and any or all of the above tumor-promoting mechanisms	Mycotoxins (aflatoxin B_1, fumonisin B_1)[a] Nitrosamines Heterocyclic amines Pesticides

[a]Some promoting agents may also exhibit weak initiating capacity with sufficient promoting ability to produce tumors, in which case, they may also be classified as complete carcinogens, e.g., Fumonisin B_1.

modify, the expression of critical regions of genomic DNA. Other substances do not appear to exert any of the above effects, yet greatly enhance cell proliferation, and are usually active during the promotion stage (Table 3).

Metabolic Activation and Electrophile Generation

Many of the genotoxic foodborne carcinogens described above undergo metabolic activation and transformation in the body. Through oxidative metabolism primarily by the cytochrome P450 family of mixed-function oxidase enzymes, highly reactive electron-deficient species can be produced, which can then depurinate or deaminate DNA, or form covalent adducts with cellular macromolecules, including DNA. Electrophiles may also be produced through flavine-dependent enzymes, the prostaglandin endoperoxide synthetase system, and other peroxidases. These electrophiles may be further metabolized by reaction with sulfate, glutathione, or glucuronic acid (phase II reactions), resulting in detoxification and excretion. In some cases, phase II reactions may also lead to carcinogenic metabolites. Therefore, the overall dose of the carcinogen that interacts with DNA (biologically effective dose) is often dependent on the presence of a number of competing metabolic pathways in any given organ or animal species. The following examples illustrate the diversity in organ specificity and mechanisms of metabolic activation leading to DNA interaction among naturally occurring carcinogens originating from fungal contamination and cooking processes.

Mycotoxins Aflatoxin B_1, a liver carcinogen, is metabolized via the cytochrome P450-catalyzed oxidation to various hydroxylated derivatives, and two unstable, highly reactive epoxide isomers. The epoxide, aflatoxin B_1-8,9-oxide is considered to be the active metabolite, which covalently binds to guanine in the DNA to form the major adduct 8,9-dihydro-8-(N^7-guanyl)-9-hydroxyaflatoxin B_1 (AFB_1-N^7-GUA) (Figure 2).

This epoxide can also react with RNA, histones, and albumin. The balance between the various primary steps, the relative rates of detoxification of the hydroxylated metabolites via glutathione or glucuronic acid conjugation, and the extent of formation and repair of the DNA adducts determine the carcinogenicity of aflatoxin B_1 in different species. The AFB_1-N^7-GUA formed may lead to persistence of repair-resistant adducts and depurination or error-prone DNA repair, which then result in single-strand breaks, base-pair substitution, or frameshift mutations. Mispairing of the adduct induces both transversion and transition mutations. Such interactions may also result in the activation of oncogenes and/or inactivation of tumor suppressor genes. Thus, recent human and experimental studies have indicated a high frequency of $G \rightarrow T$ transversions, and the prevalence of the codon 249 mutation in the tumor suppressor p53 gene in liver tumors obtained from populations where aflatoxin B_1 is the causative agent.

Ochratoxin A, a renal carcinogen, contains an isocoumarin moiety linked by a peptide bond to phenylalanine and can be hydroxylated via P450 or degraded by peptidase, as indicated in Figure 3.

Recent studies have provided clear evidence of renal carcinogenicity of ochratoxin A in two rodent species, and ochratoxin A–DNA adducts have been detected in kidney, liver, and spleen of mice exposed to the mycotoxin. Ochratoxin A was initially found not to be mutagenic in various microbial and mammalian gene mutation assays, although weak genotoxic activity was observed to mammalian cells. While the mechanism of carcinogenesis is unknown, one toxic mechanism is the inhibition of protein synthesis by competition with phenylalanine in the phenylalanyl-tRNA synthetase-catalyzed reaction, and inhibition of other enzymes that use phenylalanine as a substrate such as phenylalanine hydroxylase. The effect of ochratoxin A on protein synthesis is followed by an inhibition of RNA synthesis. Ochratoxin A has also been found to enhance lipid peroxidation both *in vitro* and *in vivo*.

Nitrosamines Through mechanistic studies, it is evident that nitrosamines are the most potent initiating carcinogens as well as complete carcinogens. This is because nitrosamines, through metabolic activation, have the capacity to cause point mutations leading to protooncogene activation by alkylation and base substitution of critical sites in DNA. As an example, the metabolic activation of NDMA is illustrated (Figure 4).

N-Nitrosodimethylamine is oxidized by the cytochrome P450 monooxygenase enzymes to hydroxymethyl-methylnitrosamine, which is unstable and further decomposes to formaldehyde and nitrosomethylamine. The latter then gives rise to nitrogen-separated ion pairs and the unstable intermediate methyldiazoniumhydroxide. The proximate species that alkylate sites in protein, RNA, and DNA are produced either directly (methyl cabonium ion) or after loss of water (diazomethane) from methyldiazoniumhydroxide. More than 15 different sites susceptible to alkylation of bases in DNA have been identified. Alkylation at different sites appears to have variable probabilities of generating specific genotoxic events. For example, the miscoding O^6-alkylguanines are likely the predominant sources

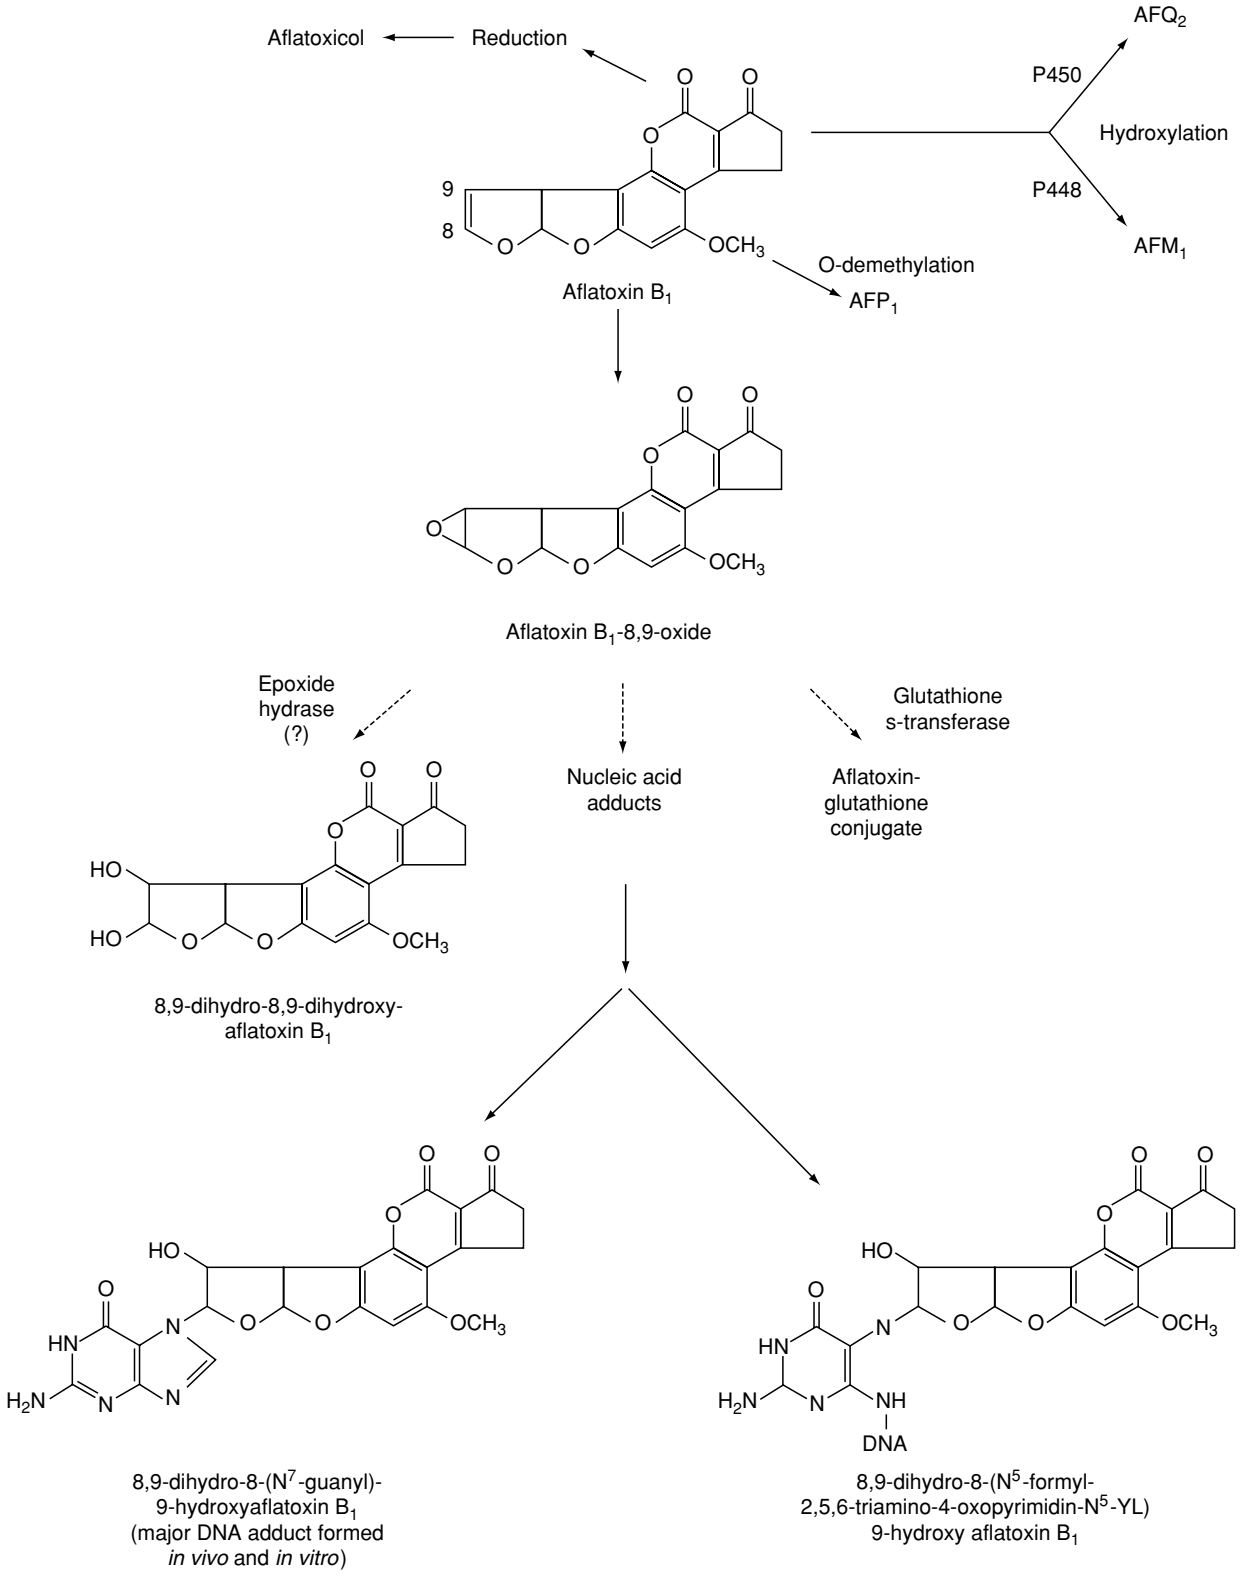

Figure 2 Metabolic activation of aflatoxin B_1.

for mutations leading to activated oncogenes. However, other adducts may also contribute at a lower frequency or may enhance the effects of the O^6-alkylguanine adducts through DNA repair processes that lead to incorporation of incorrect bases.

Heterocyclic amines Studies in rodents and nonhuman primates indicate that HCAs are rapidly absorbed, widely distributed across tissues, extensively metabolized and excreted via urine or feces. The principal sites of HCA metabolism are shown in Figure 5 with MeIQx as an example. These compounds can be metabolized by cytochrome P450-mediated ring oxidation or direct phase II conjugation reactions leading to detoxification. The cytochrome P450-mediated N-oxidation of the exocyclic amine nitrogen produces reactive metabolites that bind to DNA, RNA, and protein in almost all tissues studied. Figure 6 illustrates the structures of MeIQx adducts with guanine in the DNA. Further activation of the *N*-hydroxy HCA metabolites may occur by phase II enzymes to reactive ester derivatives, which are not stable and spontaneously rearrange into electrophilic arylnitrenium ion intermediates that react with DNA, RNA, or protein, and are mutagenic in *in vitro* assays.

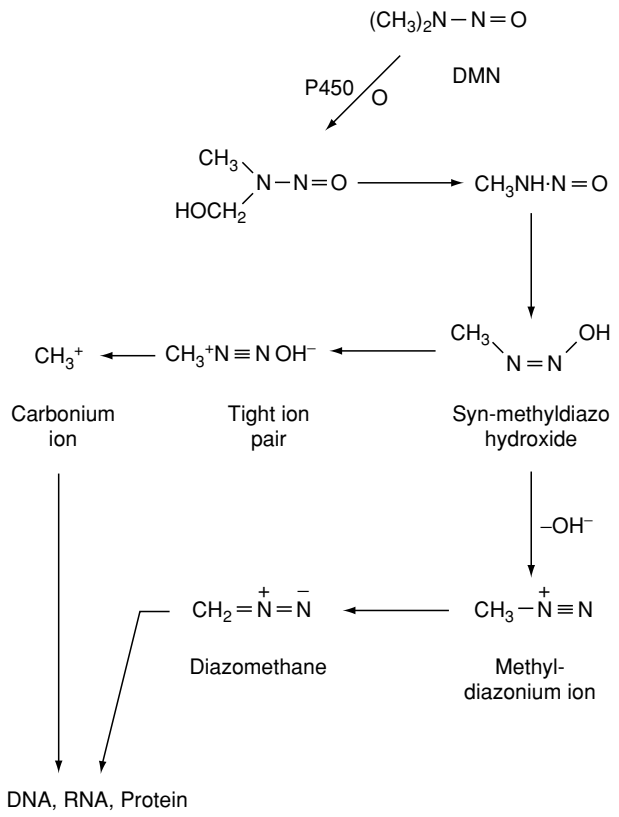

Figure 4 *In vivo* conversion of dimethylnitrosamine.

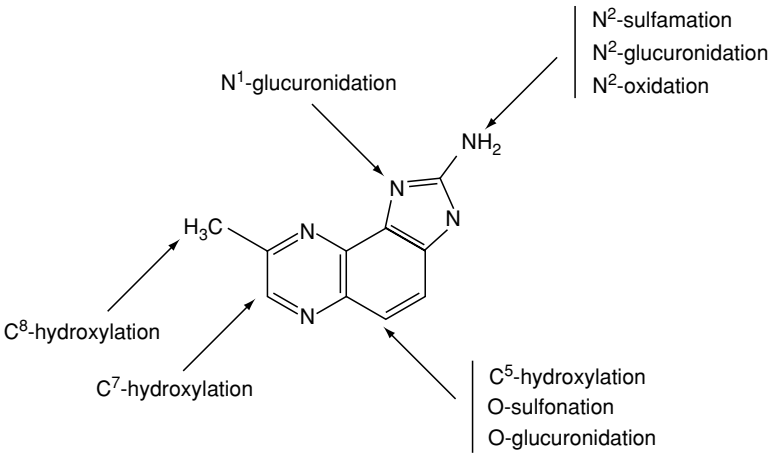

Figure 5 Sites of heterocyclic amine metabolism (MeIQx is shown as an example) by cytochrome P450 and phase II enzymes. The *N*-hydroxy HCA derivatives may undergo further activation by phase II enzymes.

The mutagenicity of HCAs has also been attributed to the DNA adducts formed from the arylnitrenium ion intermediates. Interspecies, interindividual, and tissue-specific differences in the expression of various enymatic pathways influence DNA adduct formation by HCAs. The levels of DNA adduct formation do not always correlate with target organ specificity, suggesting that, as with other genotoxic carcinogens, other factors are necessary for tumor induction by HCAs. These substances generally enhance cell proliferation in their target organs: for example, PhIP, a colon carcinogen in colon, but not liver or kidney; and MeIQx, a hepatocarcinogen, in liver but not colon or kidney. Inhibition of apoptosis, and

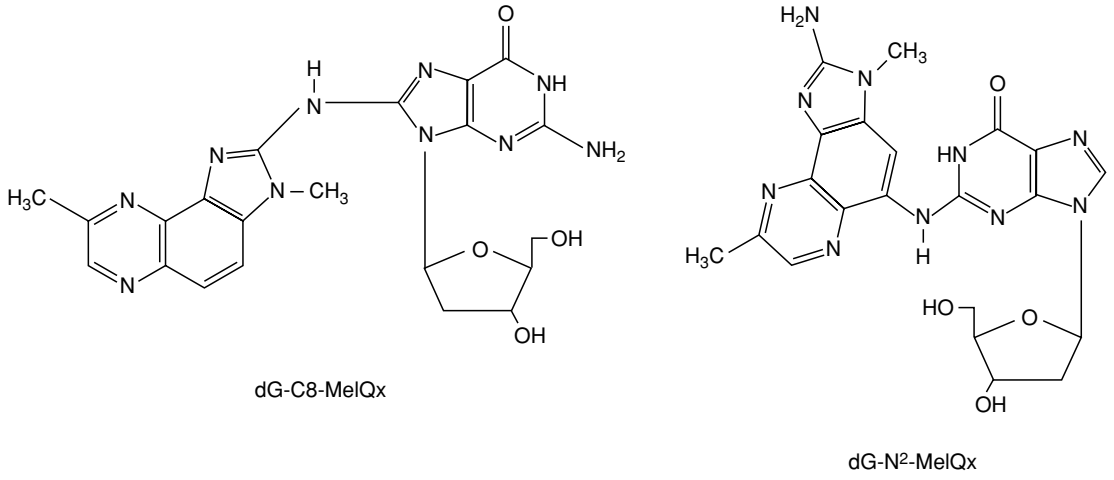

Figure 6 Chemical structures of IQ and MeIQx-DNA adducts formed at the C8 and N^2 atoms of guanine.

mutations in oncogenes and tumor suppressor genes have been reported in various types of HCA-induced tumors. Recent evidence in animal models suggests that spontaneously or artificially induced inherited mutations in cancer-related genes and certain dietary factors increase the susceptibility to cancer induction by HCAs.

Nongenotoxic Carcinogens and Epigenetic Mechanisms

The diversity of epigenetic mechanisms that may contribute to cancer causation by nongenotoxic foodborne carcinogens can be illustrated with various pesticides, and the mycotoxin, fumonisin B_1, as examples (Table 3). The carcinogenic pesticides can be found amongst each category of pesticide, that is, herbicides, insecticides, or fungicides, and belong to several chemical classes such as triazines, organophosphates, and organochlorines. Animal studies indicate that some pesticides are classic genotoxic agents that are metabolically activated to react with DNA and cause mutations or other DNA alterations, as shown above for other groups of foodborne carcinogens. Other pesticides are largely nongenotoxic and function as tumor promoters through the differing mechanisms described below. With more available evidence, it is being realized that, although these diverse epigenetic mechanisms may be implicated only during the promotion or progression stages, this does not necessarily preclude their role(s) during the initiation stage or throughout the carcinogenesis process as well.

Enhanced cellular proliferation and inhibition of apoptosis Some substances have been classified as tumor promoters because they greatly increase cell proliferation in one or more tissues without necessarily exerting any other effects at a significant rate. Studies in rodent liver carcinogenesis models have shown that cell proliferation in response to a chemical carcinogen may be classified as cytotoxic or mitogenic. Cytotoxic carcinogens induce cell death, which is then followed by cell proliferation to replace lost cells. A continued cell proliferation can result in an increase in levels of mutations through DNA replication errors. Mitogenic chemicals in the rodent liver have been observed to produce a sustained increase in organ weight during exposure to the mitogen. However, cell proliferation rates return to normal once the organ has reached its new size. Mitogenic agents provide a selective growth advantage to initiated cells by decreasing apoptosis, inhibiting normal liver cell proliferation or increasing cell proliferation in precancerous cells. Hence, depending on the type of carcinogen and the cell population involved, cell proliferation may affect the initiation of a tumor, whereas proliferative changes in initiated cell populations may influence tumor development and progression.

Similarly, in recent years, it has become known that programmed cell death or apoptosis contributes during multiple stages of cancer development. The number of DNA-damaged cells may be increased by mitosis or lost through apoptosis. Thus, chemicals that decrease the rates of apoptosis may favor initiation, in addition to tumor promotion and progression, or vice versa. For example, agents such as peroxisome proliferators, which induce a transient mitogenic activity, also inhibit apoptosis. Tumor promoters such as *2,3,7,8*-tetrachloro-dibenzo-*p*-dioxin may promote initiated cell growth by inhibiting apoptosis in the initiated cell populations. Current data suggest that responses of cells to proliferation and apoptosis signals may change throughout cancer

development and that, at each stage, a delicate balance between cell proliferation and apoptosis is necessary to prevent cancer induction.

Oxidative DNA damage Recent evidence implicates oxidative DNA damage as having similar consequences for the genome as electrophiles generated through metabolic activation. Fat metabolism, for example, produces a number of reactive oxygen species of which the hydroperoxide radicals ($RO^{\bullet}$ and $ROO^{\bullet}$) are stable and reactive enough to interact with DNA. About 20 different DNA lesions caused by these radicals have been described, including single- and double DNA strand breaks, and the formation of mono- or dihydroxylated derivatives of the DNA bases. Of the adducts, the most studied to date is the 8-hydroxy-2′-deoxyguanosine, which can lead to base mispairing at the same site or at an adjacent base in the DNA. Nitrogen radical-induced damage has also been reported but less frequently than oxygen radical damage. Even though carcinogens producing oxidative DNA damage are similar to the electrophile-generating substances in causing mutations, these chemicals cannot be identified as genotoxic by the current battery of genotoxicity tests, because they do not contain the necessary enzyme functions necessary to permit their detection. Among the foodborne carcinogens, the peroxisome proliferator class of pesticides (chlorophenols and di(2-ethylhexyl)phthalate) and the mycotoxin fumonisin B_1 are likely to generate lipid peroxidation and oxygen radicals, and therefore may be expected to operate through the oxidative DNA damage pathway. Much work is required before this can be confirmed.

Gap junctional intracellular communication Some tumor-promoting organochlorines perhaps operate through mechanisms such as inhibition of gap junctional intercellular communication (GJIC). Gap junctions are clusters of intercellular aqueous channels that allow communications between adjoining cells. They are formed by two semichannels, called connexons, each coming from two adjacent cells. Each connexon consists of six identical or similar transmembrane protein molecules called connexins, which are oligomerized within a plasma membrane. Gap junctions are the only means by which cells in organized tissue can share different messengers of low molecular weight and therefore maintain tissue homeostasis. The nature of these messengers can range from ions, nutrients, nucleotides and metabolites, either of endogenous or exogenous origin. During cancer induction, it has been found that certain tumor cells show high levels of communication with each other but not with surrounding normal cells, thus facilitating rapid selective clonal expansion and malignant transformation of abnormal cells. Two basic mechanisms of altered connexin functions may contribute to carcinogenesis at the genetic and functional levels. Genetic alteration of GJIC may occur at either initiation stage when genotoxic carcinogens induce mutations in connexin or other GJIC-related genes, or at later stages of tumor progression as a result of cumulative genetic alterations due to widespread genetic instability. Findings in cell cultures suggest that GJIC can affect cell-cycle-related gene expression supporting the earliest hypothesis that the role of GJIC may be to provide a channel for distribution of an intracellular factor to control cell growth.

Hormonal mimicry Other pesticides act by mimicking hormones, leading to disruption in endocrine responsive organs such as mammary gland, testis, prostrate, and uterus. For example, the nongenotoxic herbicide atrazine is associated with an increased incidence of mammary tumors and uterine adenocarcinomas in animals This is probably related to atrazine's ability to lengthen the estrous cycle, thus prolonging exposure to endogenous estrogens. Several organochlorines, including chlordecone and DDT, also have demonstrated estrogenic activity. A receptor-mediated mechanism has been suggested to explain the role of hormonal effects in cancer induction. Estrogens stimulate DNA replication and increase the mitotic rate of target cells. This is achieved through interaction of estrogens or estrogen-mimetic substances with the estrogen receptor protein, which may then react with the target cell DNA to modify the expression of genes involved in cell growth and differentiation. Sustained occupation of the estrogen receptors by estrogenic compounds is necessary for alteration of the genome leading to enhanced cell proliferation. Progestins oppose this effect by decreasing the concentration of the estrogen receptors. There is evidence that estrogenic substances may further generate oxidative DNA damage and lipid peroxidation.

Peroxisome proliferation Peroxisome proliferation is another nongenotoxic, receptor-mediated mechanism whereby some pesticides (e.g., chlorophenols and phenoxyacetic acid herbicides) and a packaging material residue (e.g., di(2-ethylhexyl)phthalate) have been shown to induce cancer in rodents. Peroxisomes are subcellular organelles responsible for fat metabolism in various tissues. For the peroxisome proliferator class of compounds, the primary target organ is liver where they cause proliferation of

peroxisomes, induce hypertrophy and hyperplasia of liver, stimulate growth factors, activate oncogenes, and increase the activity of the enzymes catalase, cytochrome P450 monooxygenases, epoxide hydrase, glucuronyl transferase, and those involved in fatty acid β-oxidation. While the precise mechanism of cancer induction by these chemicals is unknown, the pleitropic response appears to be related to activation of a novel steroid hormone receptor, the peroxisome proliferator-activated receptor (PPAR). In addition, two more theories of cancer induction have been proposed. First, induction of fatty acid β-oxidation enzymes by the peroxisome proliferators results in the generation of hydrogen peroxide and reactive oxygen species that interact with DNA to form an oxidative DNA damage-related adduct. In support of this theory, increases in levels of 8-hydroxy-2′-deoxyguanosine have been detected in peroxisome proliferator treated rats. The second theory relates to an increase in liver size and weight that follows peroxisome proliferator administration. This effect has been demonstrated to be due to both enhanced cell replication and a decrease in apoptosis. The possibility then exists that the process of DNA replication itself causes mutations. However, peroxisome proliferators may promote the growth of cells that are already initiated either spontaneously or by other environmental stimuli. Operationally, it is likely that some or all of these mechanisms play a role in cancer induction by peroxisome proliferators. The role of peroxisome proliferators in human cancer is not clear, since peroxisome proliferation does not occur in humans, although they respond to these agents in hyperlipidemia, for example. Preliminary data suggest that PPARs are expressed at low, variable levels in human liver and may also be polymorphic.

Disruption of the sphingolipid pathway The mycotoxin, fumonisin B_1, unlike aflatoxin B_1 and ochratoxin A, does not undergo extensive metabolism. In orally treated rats, the majority of fumonisin B_1 is excreted in the feces in unmetabolized form. In female vervet monkeys, products of hydrolysis of the tricarballylic acid groups of fumonisin B_1 have been observed in feces, suggesting that the only metabolism of fumonisin B_1 is by ester hydrolysis to the less polar aminopentol. Fumonisin B_1 persists in livers and kidneys of rats longer than any other tissues, and this is consistent with the observed toxicity and carcinogenic effects of this mycotoxin in these organs. Although fumonisin B_1 is a liver carcinogen, it lacks mutagenic activity in the Ames assays, and genotoxic effects in *in vivo* and *in vitro* DNA repair assays. This mycotoxin is a weak initiator, as demonstrated in *in vivo* initiation-promotion assays, but has effects

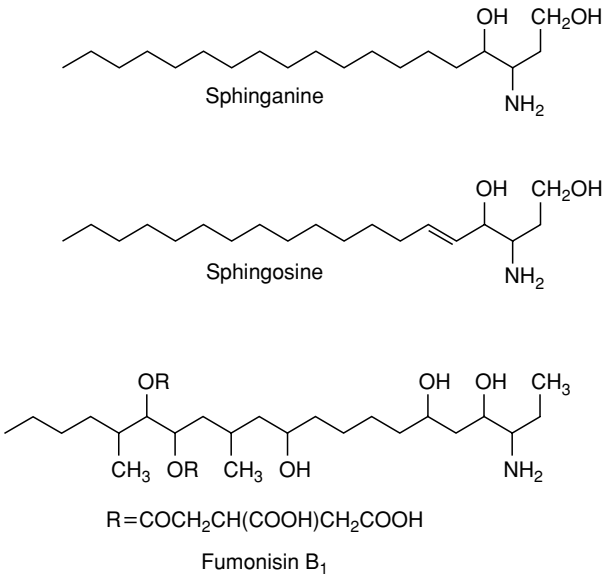

Figure 7 Structures of sphinganine, sphingosine, and fumonisin B_1.

on tumor promotion and selection of initiated cells. Lipid peroxidation and oxidative damage may be involved in the genesis of fumonisin B_1-induced initiated cells. While the molecular mechanism of action of fumonisins is not completely known, the chemical structural similarity of these compounds to sphingosine and sphinganine (Figure 7) has suggested the following mechanism. Sphingolipids are believed to be involved in the regulation of cell growth, differentiation, and cell transformation through effects on cell–cell communication, cell-membrane interactions, cell receptors, and signaling systems (Figure 8).

It has been postulated that fumonisins may exert their effects by disrupting sphingosine metabolism, and current data support this hypothesis. The main target for fumonisins is the inhibition of the enzyme sphinganine (sphingosine) *N*-acyltransferase (or ceramide synthase), resulting in the accumulation of free sphingoid bases in serum, and in the target tissues, which in the rat are the liver and kidney. The exact mechanistic role of the sphingolipid pathway in liver-cancer induction in rats remains to be elucidated.

Altered immune function Alteration of immune function is a known cause of many human cancers. Many pesticides and other foodborne carcinogens are also known to disrupt immune function, which may additionally contribute to their carcinogenic potency. For example, the insecticide, DDT, causes thymus atrophy, and 2,4-dichlorophenoxyacetic acid enhances the T- and B-cell immune response in the mouse and reduces lymphocyte subsets and natural

killer cells in farmers. Organophosphates may play a role in cancer induction through inhibition of serine esterases, which are critical components for the cytolytic activities of T-lymphocytes and natural killer cells. Ochratoxin A, *N*-nitrosodimethylamine, 7,12-dimethylbenz[a]anthracene, benzo[a]pyrene and the antioxidant butylated hydroxytoluene have also been observed as immunosuppressants in animal studies.

Future Considerations

It is clear that the majority of evidence for the types of specific mechanisms in cancer induction is from animal studies. Evidence to date suggests that the most identified genotoxic human carcinogens react with DNA through electrophile generation, but for nongenotoxic carcinogens, the mechanisms are unclear. Much research is required (1) to understand the precise role(s) of the currently known mechanisms, and (2) to discover any new mechanistic pathways that may contribute to human cancer induction by foodborne carcinogens. In addition, there is a need to define the relationship to cancer induction by factors that may interact with carcinogenic substances in food such as macro- and micronutrient levels in the diet, concurrent environmental exposure to multiple chemicals, and genetic differences in responses to these substances.

Carcinogenicity Tests

T J Schrader, Sir Frederick Banting Research Centre, Ottawa, Ontario, Canada

Introduction

Carcinogens may be present in foodstuffs as: (1) natural components; (2) byproducts of cooking, heating, or processing; (3) food additives (preservatives, colors, flavors); (4) leachates from packaging materials; and (5) pesticides. The testing of new foods and food-associated chemicals for carcinogenicity is an important aspect of an overall toxicological assessment for determining product safety and allowable exposure limits. Government regulatory decisions on existing products can also be revisited and modified to include new knowledge gained in the understanding of carcinogenic processes and the results of new testing methods.

In excess of 200 assays have been developed to screen substances for carcinogenic potency and to characterize their modes of action. However, many of the processes involved in carcinogenesis remain poorly understood and a perfect assay for the identification of human carcinogens remains elusive. Confounding factors include: (1) the long latency period (frequently decades) required for metastatic tumor development in humans; (2) the number and types of molecular mechanisms governing the many cellular changes involved in carcinogenesis; (3) the mechanisms involved in tissue-specific susceptibilities, often showing species differences; (4) variations in genetic make-up and metabolic capabilities between individuals in a population not reflected within inbred strains of animals or tissue culture cell lines; (5) the effects of different exposure routes and timing of exposure; and (6) the contribution of coexposure to other chemicals in mixtures or other agents which could modify the carcinogenicity of a test chemical.

A tiered approach can be used to screen chemicals for carcinogenic activity and obtain supportive evidence. The first clues may arise from an examination of the test chemical for structural features which are

common with known carcinogens. Other evidence may arise from epidemiological studies relating human cancer incidence with chemical exposure. Experimental evidence may be gained from a variety of short-term chemical and cell-based (*in vitro*) assays used for screening test chemicals for DNA damage and repair, mutagenesis, chromosomal aberrations, and morphological transformation. However, while these assays can be important in identifying chemicals positive for their respective endpoints and for providing important mechanistic data, they are not representative of the entire carcinogenic process and may lack important endpoints or metabolic processes. Therefore, testing may proceed to mutagenesis and chromosomal aberration assays in animal (*in vivo*) models. Ultimately, the most validated and reliable assay for the evaluation of human carcinogens is the long-term rodent carcinogenicity assay, in which animals are exposed to the test chemical over a large part of their lifespan (generally 18 months for mice and 2 years for rats). Even so, the rodent carcinogenicity assay suffers some major drawbacks which could lead to the misinterpretation of results: (1) species differences in chemical metabolism which could cause the chemical to act in a way not possible in humans; (2) difficulties in determining the human risk of chemicals which affect the formation of tumors which otherwise occur spontaneously with age in some rodent species; and (3) errors which are introduced in extrapolating or estimating the risk to humans at normal exposure limits when chemicals are tested at far higher levels. Therefore, data from the rodent carcinogenicity assay are usually combined with that from some complementary shorter-term tests to confirm the classification of a test chemical. A number of testing procedures can also be used on human blood and urine samples to monitor if exposure to certain classes of carcinogens has occurred. Of course, this tiered approach may also work in the opposite direction, where a chemical found positive *in vivo* is then subjected to a number of *in vitro* tests to obtain information on its mechanism of action.

DNA Damage and Repair Assays

Many assays have been developed to characterize the DNA damage induced by carcinogen exposure as well as the induction of DNA repair and changes in cellular gene expression. With slight modifications, most of the assays can be used for samples arising from both *in vitro* and *in vivo* studies.

Strand Breakage Assays

Comet assay The comet assay has become one of the most convenient and widespread assays for DNA strand breakage. Cells exposed to test agent are embedded in agarose which is spread over a microscope slide to form a thin gel. The cells are then lysed and the DNA electrophoresed under either neutral conditions to detect double strand breaks or alkaline conditions to detect single and double strand breaks as well as apurinic/apyrimidinic sites. When subsequently visualized by staining with a fluorescent dye, the DNA appears as a 'comet' with a compact 'head' of larger-molecular-weight DNA and a 'tail' of smaller fragments, the size of which depends upon the amount of strand breakage present. Various imaging and software packages are available to quantitate the distribution of DNA in the images. The assay can be extended to detect specific DNA adducts and specific forms of oxidative damage by using damage-specific DNA endonucleases to cleave the DNA at the damage sites, thus creating strand breaks.

Other assays for strand breakage include: alkaline gel electrophoresis in which fragmented genomic DNA separates as a smear instead of the discrete band of high-molecular-weight material observed with intact DNA; alkaline elution, in which the time taken for alkaline solutions of DNA to pass through filters is related to the extent of fragmentation; and alkaline unwinding techniques, in which the fluorescent dye ethidium bromide is used to intercalate into the DNA, causing it to unwind. The unwinding in turn causes a decrease in fluorescence intensity which can be related to DNA fragmentation. As well, the induction of strand breakage in compact supercoiled plasmids causes a conformational change to an open circular form, which can be detected as a molecule with slower mobility by agarose gel electrophoresis.

Adduct Assays

^{32}P-Postlabeling The ^{32}P-postlabeling method is extremely sensitive for detecting chemical adducts and is theoretically sensitive to any DNA-damaging agent. Isolated DNA is first broken down into normal and damaged 3′ monophosphate deoxynucleosides. A 5′ radioactive phosphate residue is then added by the enzyme T4 polynucleotide kinase to allow detection of the deoxynucleosides. The radioactive products are separated by multidirectional anion exchange thin-layer chromatography and the presence of adducts detected and quantitated.

Chemical adducts in DNA can also be detected by a variety of other assays. If the chemical is available as a radioisotope, the presence of adducts may be detected as radioactivity copurifying with DNA from treated cells. The adducts may then be isolated and characterized using the radioactive signal as a tracer. As well, particular types of DNA damage can be recognized by damage-specific antibodies which

can be used to quantitate the amount of damage or isolate the damaged sites for further study. Some adducts can be identified by their altered fluorescent properties or mobilities when separated by high-pressure liquid chromatography or gas chromatography. Further chemical identification may also be made by mass spectrometry.

Unscheduled DNA Synthesis or Repair Replication

Unscheduled DNA synthesis refers to the DNA synthesis which occurs in mammalian cells during the repair of DNA damage by the excision repair pathway. During excision repair, damage is removed in the form of an oligonucleotide which must be replaced by a 'repair patch' synthesized using the opposite undamaged strand as a template. This form of repair can be followed in treated cell cultures by including a labeled nucleotide precursor, such as tritiated thymidine or bromodeoxyuridine, in the culture medium. Tritiated thymidine incorporation can be followed by autoradiography of the labeled nuclei or by liquid scintillation counting while bromodeoxyuridine incorporation can be quantitated by immunostaining with antibromodeoxyuridine antibodies.

The repair of DNA damage can be followed in specific genes and comparisons made in transcribed and nontranscribed strands using a variety of molecular biological techniques. Damage-specific endonucleases can be used to cleave the site of damage which can be detected by its increased mobility during gel electrophoresis and different hybridization patterns. Other techniques including strand-specific quantitative polymerase chain reaction (PCR) in which the amount of product is proportional to the undamaged template and strand-specific ligation PCR which allows sites of damage to be identified with DNA sequencing gels.

Gene Expression Assays

Assays which measure carcinogen-induced changes in gene expression are becoming an increasingly important method for characterizing test chemical effects and a variety of assays have been developed. DNA arrays are available which make the analysis of gene expression changes in hundreds or thousands of genes possible by using gene-specific complementary oligonucleotides arranged on either nylon membranes or glass slides. Several reporter gene vectors have been developed in which the expression of a variety of genes coding for easily measured products (such as firefly luciferase, or green fluorescent protein) is controlled by the promoter sequences of genes important for the control of carcinogenesis. A chemical-induced change in the expression of the reporter gene then indicates possible carcinogenic activity. Nuclease protection assays can also be used to quantitate changes in the expression of specific genes involved in carcinogenesis.

Mutagenicity Assays

In vivo Mutagenesis Assays

The mouse specific locus test The mouse specific locus test is used to detect and quantitate mutations in the germ line of a mammalian species. Animals are chosen for mating which differ at certain easily assayed genetic loci such that mutations will produce an offspring which differs from that expected. Males are usually exposed to the test chemical. Three variations of the method have been used for detecting the induction of point mutations in mouse germ cells: (1) a visible specific locus test examining either five or seven loci; (2) a biochemical specific locus test surveying up to 20 enzymes; and (3) a test for histocompatibility loci mutations.

Transgenic mouse mutagenesis assays Transgenic mouse strains have been developed which have had several copies of either *LacI* or *LacZ* gene sequences from *Escherichia coli* incorporated into their genomes, either as part of a shuttle vector or recombinant λ-phage backbone. Animals are exposed to the test chemical and the DNA isolated from tissues. For shuttle vector-based systems, the shuttle vector DNA is excised, recovered, religated, and introduced into the proper *E. coli* host which are then plated on selective medium allowing growth of mutant colonies. Reconstitution of the λ-based systems is somewhat simpler and more efficient, where the λ-DNA can be cleaved and repackaged into phage using commercially available extracts. The phage are used to infect the proper *E. coli* host, which are then plated in the presence of a selective agent. In a positive selection version of the *LacZ* system, only mutant plaques will grow while mutant plaques in the *LacI* system are identified by a blue/colorless selection procedure. Mutation frequencies can be examined in all somatic tissues as well as germline tissues using these transgenic systems and the defined sequences provide a well-characterized target for sequence analysis of the mutations.

Assays in Bacteria

Ames *Salmonella* test The Ames *Salmonella* test remains the most validated mutagenesis assay for reasons of speed, economy, and dependability. A series of *Salmonella* strains have been developed which possess different mutations in the operon
