Presence of *C. botulinum* in the Environment

Spores of *C. botulinum* are commonly present in soils and sediments, but their numbers and types vary, depending on the location (**Table 1**). The possibility of contamination of food with *C. botulinum* depends on the distribution and incidence of spores in the environment where the agricultural products are grown.

C. botulinum spores are widely distributed in North America, but the spore load varies considerably, as does the predominating type. Soils in the USA east of the rise of the Rocky Mountains usually contain type B spores, while type A spores predominate in the western USA. Most US type B strains are proteolytic. Type C spores are localized in soils along the Gulf of Mexico coast. Overall, type E is found infrequently, and only in damp to wet locations. However, in the region around the Great Lakes, and particularly around Green Bay of Lake Michigan, high numbers of type E are found in shoreline and sediment samples. *C. botulinum* type E is also found in the coastal areas of the states of Washington and Alaska, and along the

Pacific, Arctic and Atlantic coastlines of Canada. The distribution of types on the Pacific coast changes with latitude; south of 36 °N, the prevalent types shift from E to A and B.

Type B predominates in the terrestrial environments of the UK, Ireland, Iceland, Denmark, and Switzerland. It is associated with most botulism outbreaks in Spain, Portugal, Italy, France, Belgium, Germany, Poland, the former Czechoslovakia, Hungary, and the former Yugoslavia, indicating wide distribution of this type in the European environment. Type B also predominates in the aquatic environments of the UK. Most European type B strains are nonproteolytic. The predominant serotype from other aquatic environments is E. The highest numbers of type E spores are found in Scandinavian waters, particularly in the Sound and Kattegat, between Denmark and Sweden. The highest overall spore concentrations detected in Europe were reported in The Netherlands, where a mixture of types was found.

Type E spores also predominate in most parts of the former Soviet Union, except for the central portion, where type B spores predominate. In general, surveys of Asia report lower numbers, with the exceptions of a high incidence of type E spores around the Caspian Sea, and a high incidence of all types in the Sinkiang district of China.

Fewer surveys have been carried out in the southern hemisphere. Spores of all types have been detected in South America; type E has been found in fish, oyster, and shrimp samples taken off the Brazilian coast. Type A spores predominate in Brazilian and Argentine soils. In the tropical regions of Asia, types C and D replace type E as the predominant type in aquatic environments.

The distribution of spore types in fish and shellfish is similar to that in the sediments from their respective areas. Because the methods of sampling fish and shellfish differ widely, it is difficult to compare numbers.

In summary, type A spores predominate in soils in the western USA, China, Brazil, and Argentina, and type B spores in the eastern USA, the UK, and much of continental Europe. However, most US type B strains are proteolytic, while most European strains are nonproteolytic. Type E is the predominant type in northern regions, and in most temperate aquatic regions and their surroundings. Types C and D are found more frequently in warmer environments. The reasons for this distribution pattern are not well understood. Type A appears to favor neutral to alkaline soils with low organic content, consistent with its virtual absence in the highly cultivated soils of the eastern USA and Europe. Type E is psychrotolerant, which undoubtedly plays a role in its prevalence in the north and in many aquatic environments. Similarly, the higher optimum growth temperature for types C and D is consistent with their presence in warmer environments.

Presence of *C. botulinum* in Foods

The sequence of events resulting in foodborne botulism begins when *C. botulinum* contaminates a food. This often occurs during growth or harvesting, and is most likely to occur when a product originates in an environment with a high incidence of spores. However, contamination can also occur during or after processing. There have been considerably fewer surveys of foods for contamination with *C. botulinum* than environmental surveys, and they have focused primarily on fish, meats, and infant foods, particularly honey.

Fish may become contaminated with spores of *C. botulinum* in their environment, or during processing and handling. The presence of *C. botulinum*, mostly type E, in fish is readily demonstrated, although the incidence is lower than in environmental surveys. The average level of contamination of prepared fish in the USA appears to be higher than in Europe and Asia. The highest contamination level reported was in salted fish from the Caspian Sea.

The level of contamination of meats is generally low. It appears lower in North America, where the average most probable number (MPN) is about 0.1 spore kg^{-1}, than in Europe, where the average MPN is about 2.5 spores kg^{-1}. The types most often associated with meats are A or B.

C. botulinum is common in soil and organic fertilizers. *C. botulinum* types A or B may be present on fruits and vegetables, particularly those in close contact with the soil. One product of particular concern is cultivated mushrooms, in which up to 2.1×10^3 type B spores kg^{-1} have been detected.

Spores in honey and other infant foods pose a unique hazard because, in some infants, the spores are able to colonize the intestines, produce toxin, and cause infant botulism. By 1984, honey had been implicated as the likely source of botulinum spores in 20 cases of infant botulism in California. Surveys for the presence of *C. botulinum* spores in honey

[a]Most probable number (MPN) calculated using the Halvorson-Zeigler equation $\log_e (n/q)$, where n = the total number of samples analyzed and q = the number of nontoxic samples.

[b]As percentage of the types identified.

Adapted from Hauschild AHW (1989) *Clostridium botulinum*. In: Doyle MP (ed.) *Foodborne Bacterial Pathogens*, pp. 111–184. New York: Marcel Dekker.

suggest that the botulinum spore level in random samples of honey is in the order of 1–10 spores kg^{-1}. However, in honey samples associated with infant botulism the level is approximately 10^4 spores kg^{-1}. Other infant foods have also been examined. While *C. botulinum* has been detected in samples of corn syrup and rice cereal, exposure of infants to botulinum spores via these foods seems to be minimal as the spore levels are low, and spores are unlikely to multiply during manufacture and storage.

Other foods examined, including dairy products, vacuum-packed products, and convenience foods, show a very low incidence of *C. botulinum* spores.

Factors Affecting Growth and Toxin Production in Foods

The main factors affecting growth of *C. botulinum* in foods are temperature, pH, water activity (a_w), redox potential, added preservatives, and other microorganisms. The growth of types A, B, E, and F, of groups I and II, has been intensively studied. Traditionally, food microbiologists have established maximum and/or minimum limits for these parameters which would permit growth of *C. botulinum* (Table 2), and these limits have often been used in the control of *C. botulinum*. However, these factors seldom function independently; usually, they act in concert, often having synergistic or additive effects. Models incorporating pH, a_w, and temperature are available to predict the growth of *C. botulinum* under various combinations of conditions.

Temperature

Because foods are generally stored at low temperatures, studies have focused on determining the minimum temperatures permitting growth. The established lower limits are 10 °C for group I and 3.0 °C for group II. However, these limits apply to relatively few strains and depend on otherwise optimum growth conditions. Production of toxin generally requires several weeks at the lower temperature limits.

Table 2 Properties of group I and II *Clostridium botulinum*

Property	*Group I*	*Group II*
Toxin types	A, B, F	B, E, F
Minimum temperature for growth (°C)	10	3
Maximum temperature for growth (°C)	48	45
Minimum pH for growth	4.6	5
Inhibitory (NaCl) (%)	10	5
Minimum a_w for growth	0.94	0.97
$D_{100\,°C}$ of spores (min)	25	< 0.1
$D_{121\,°C}$ of spores (min)	0.1–0.2	< 0.1

The optimum growth temperature is in the range 35–40 °C for group I organisms, and in the range 25–30 °C for those of group II. The upper temperature limits for group I and group II organisms are approximately 45–50 °C and 40–45 °C, respectively.

pH

It is generally accepted that the minimum pH permitting growth of *C. botulinum* group I is 4.6, and many regulations worldwide use this limit. For group II, the limit is about pH 5.0. The upper pH limits for growth are in the pH range 8–9, but are of little practical consequence. Many fruits and vegetables are sufficiently acidic to inhibit *C. botulinum* by their pH alone, while other products, such as marinated vegetables, are preserved by added acidulants. Several factors influence the acid tolerance of *C. botulinum*, including strain, substrate, temperature, nature of the acidulant, the presence of preservatives, a_w, and redox potential. The growth of acid-tolerant microorganisms such as yeasts and molds may raise the pH in their immediate vicinity to a level that permits growth of *C. botulinum*. *C. botulinum* can also grow in some acidified foods if excessively slow pH equilibration occurs. While high concentrations of proteins in laboratory media appear to protect *C. botulinum* and permit growth at pH levels below 4.6, this does not occur in foods preserved by acidity. Current regulations stipulating a minimal acidity of pH 4.6 for the control of *C. botulinum* are therefore valid.

Salt and a_w

Salt (NaCl) is one of the most important factors controlling *C. botulinum* in foods. Its inhibitory effect is primarily due to the depression of a_w and consequently to its concentration in the aqueous phase, also called the brine concentration (%brine = $NaCl \times 100/(\%H_2O + \%NaCl)$). Under otherwise optimal conditions, the growth-limiting brine concentrations are about 10% for strains of group I and 5% for strains of group II. These concentrations correspond well to the limiting a_w of 0.94 for group I and 0.97 for group II in foods where NaCl is the main a_w-depressant. The type of solute used to control a_w may influence these limits. Generally, NaCl, potassium chloride, glucose, and sucrose show similar patterns, while the use of glycerol reduces the growth-limiting a_w level by up to 0.03 units. The limiting a_w may be raised significantly by other factors, such as increased acidity or preservatives.

Redox Potential

C. botulinum grows optimally at an oxidation–reduction potential (E_h) of −350 mV, but growth

initiation may occur in the E_h range of +30 to +250 mV. The presence of other inhibitory factors lowers this upper limit. Once growth is initiated, the E_h declines rapidly.

Modified atmosphere packaging is being used increasingly to extend the shelf-life and improve the quality of foods. Depending on the atmosphere and the food, growth of *C. botulinum* may be inhibited or stimulated. Many studies have shown that *C. botulinum* will grow as well in foods packed in air as in vacuum-packed foods; the oxygen in the package head space can be rapidly depleted by respiration of background microorganisms or, in the case of modified-atmosphere packaging vegetables, by the plant tissue itself. The safety of different atmospheres with respect to *C. botulinum* should be carefully investigated before use.

Preservatives

Nitrite is important in producing the characteristic color and flavor of cured food products, but its most important role is the inhibition of *C. botulinum*. It is more effective with decreasing pH, increasing NaCl content, and addition of ascorbate or isoascorbate to the food product. Nitrite reacts with many cellular constituents and appears to inhibit *C. botulinum* by more than one mechanism, one of which is probably its reaction with essential iron-sulfur proteins to inhibit the phosphoroclastic system which supplies the cell with energy. The reactions of nitrite, or nitric oxide, with secondary amines in meats to produce nitrosamines, some of which are carcinogenic, has led to regulations limiting the amount of nitrite used.

Other compounds which are active against *C. botulinum* include sorbates, parabens, nisin and other bacteriocins, phenolic antioxidants, polyphosphates, ascorbates, ethylenediaminetetraacetic acid (EDTA), metabisulfite, *n*-monoalkyl maleates and fumarates, and lactate salts. Extracts of certain foods, including mace, bay leaf, and nutmeg extracts, oils from garlic, onion, black pepper, clove, cinnamon, and origanum have all been shown to inhibit the growth of *C. botulinum*. The use of natural or liquid smoke has a significant inhibitory effect against *C. botulinum* in hot smoked fish, reducing the inhibitory water-phase NaCl concentration from 3.7% to 2.9–3.0%.

Other Microorganisms

Other microorganisms have a significant role in the control of *C. botulinum* in foods. Acid-tolerant yeasts and molds may make the environment more favorable for growth of *C. botulinum*. Other microorganisms may inhibit *C. botulinum*, either by changing the environment, or by producing specific inhibitory substances, or both. Lactic acid bacteria, including *Lactobacillus, Pediococcus*, and *Streptococcus* spp., can inhibit growth of *C. botulinum* in meat products, largely by reducing the pH, perhaps also by the production of bacteriocins. Growth of *Bacillus* spp. that produce antimicrobials has been shown to inhibit growth of group II *C. botulinum* in foods. The use of lactic acid bacteria and a fermentable carbohydrate, the 'Wisconsin process,' has been permitted for producing bacon with a decreased level of nitrite in the USA. The growth of other microorganisms may also protect the consumer by causing spoilage that would make a toxic product less likely to be consumed.

Thermal Inactivation

C. botulinum spores of group I are very heat-resistant. *D* values (the time required to inactivate 90% of the population at a given temperature) vary considerably among *C. botulinum* strains and depend on how the spores are produced and treated, the heating environment, and the recovery system. Spores of types A and B are the most heat-resistant, having $D_{121\,^\circ C}$ values in the range 0.1–0.2 min. These spores are of particular concern in the sterilization of canned low-acid foods, and the canning industry has adopted a *D* value of 0.2 min at 121 °C as a standard for calculating thermal processes. The *z* value is defined as the temperature change necessary to bring about a 10-fold change in the *D* value. For the most resistant strains, *z* values are approximately 10 °C, which has also been adopted as a standard. Actual *z* values may vary by several degrees. Despite the variations in *D* and *z* values, the adoption of a 12*D* process ('botulinum cook') as the minimum thermoprocess applied to commercial canned low-acid foods by the canning industry has insured the production of safe products. The botulinum cook will produce a product that is safe but not always sterile, depending upon the presence and levels of other, more heat-resistant, spores. The thermal process of commercially canned foods usually uses the more heat-resistant organisms, such as *Bacillus stearothermophilus*, as target organisms for the process.

Although strains of group 2 are considerably less heat-resistant ($D_{100\,^\circ C} < 0.1$ min) than those of group 1, their survival in pasteurized, refrigerated products is of concern because of their ability to grow at refrigeration temperatures. $D_{82\,^\circ C}$ values of type E in neutral phosphate buffer are generally in the 0.2–1.0 min range. While the *D* values are often higher in foods, the *z* values are essentially the same.

Inactivation by Irradiation

C. botulinum spores are probably the most radiation-resistant spores of public health concern. *D* values (irradiation dose required to inactivate 90% of the population) of group 1 strains at −50 to −10 °C are in the range 2.0–4.5 kGy in neutral buffers and in foods. Spores of type E are only marginally more sensitive, having *D* values in the range 1–2 kGy. The goal of radappertization is to reduce the number of viable spores of the most radiation-resistant *C. botulinum* by 12 $\log_{10}$ cycles. *D* values are affected by any pretreatment of spores, the presence of oxygen, irradiation temperature, and irradiation and recovery environments. Generally, spores are more sensitive in the presence of oxygen or preservatives and at temperatures above 20 °C.

Detection of *C. botulinum* and its Toxins in Foods

It is not necessary to isolate *C. botulinum* in pure culture from foods in order to demonstrate its presence. Usually, the sample is inoculated into a non-selective enrichment medium. If the neurotoxin is present in the culture after incubation, the toxin-producing organism must have been present originally.

Botulinum neurotoxins are recognized by their lethal action in mice and neutralization with specific antisera. While several *in vitro* tests have been developed, they are generally less sensitive and less specific than the mouse bioassay which remains the standard. The sample, or an extract prepared by homogenizing it in a slightly acidic buffer, is clarified by centrifugation and normally filter-sterilized. Trypsin treatment may be required to activate low levels of toxin from nonproteolytic strains. The prepared sample is injected intraperitoneally into mice with and without neutralization with antitoxin. Typical signs of botulism are ruffled fur, pinched waist, laboured breathing, limb paresis, and general paralysis before death. Definitive results are obtained if mice injected with untreated sample display symptoms and die within 72 h, while mice injected with neutralized sample do not display symptoms and survive.

Common enrichment media for detecting viable *C. botulinum* are cooked meat medium (CMM), CMM glucose, chopped meat glucose starch (CMGS) medium, and trypsin–peptone–glucose–yeast extract (TPGY) broth, to which trypsin may be added (TPGYT). Trypsin is necessary to activate the toxin produced by group II organisms, and may also inactivate potential inhibitors of *C. botulinum* such as bacteriocins in mixed cultures. While foods may be inoculated directly, the sediments of centrifuged samples are preferred because potential growth inhibitors are removed. At least two tubes of media are inoculated. One is heated at 75–80 °C or 60 °C, depending on whether the suspected type belongs to group I or II, to select for spores. Alternatively, spores of group II may be selected by holding samples in 50% alcohol for 1 h before inoculation. The other tube is incubated without any heating to allow development of vegetative *C. botulinum* cells in case few or no spores are present. Adding lysozyme to the medium may increase recovery of heat-injured spores. *C. botulinum* is identified after incubation of the enrichment medium by toxin analysis of the supernatant fluid, as outlined above.

Botulism

J W Austin, Bureau of Microbial Hazards, Ottawa, Canada

Introduction

Botulism is a neuroparalytic disease resulting from neurotoxin-mediated inhibition of acetylcholine release from peripheral nerve synapses, including neuromuscular junctions. This results in a descending symmetrical flaccid paralysis beginning with the cranial nerves. Death may result from asphyxiation caused by paralysis of the diaphragm. Botulinum neurotoxin is produced by *Clostridium botulinum* and, rarely, by *C. butyricum* or *C. barati*. Human botulism is classified into four categories. Foodborne botulism, the most common form worldwide, is caused by ingestion of food contaminated with preformed botulinum neurotoxin, usually type A, B, or E. Infant botulism, first recognized in 1976 and now the most common form of botulism in the USA, is caused by ingestion of viable spores which colonize the intestinal tract of infants less than 1 year of age and produce toxin locally. The environment appears to be the most common source of spores for infant botulism, and honey is the only food which has been associated with infant botulism. Would botulism is due to infection of a wound with spores of *C. botulinum* which grow and produce toxin *in situ*. Wound botulism associated with injection drug use has increased dramatically since 1994. Most cases of wound botulism occur among heroin users in California who inject black tar heroin subcutaneously. The fourth category, adult infectious botulism, includes adult cases with intestinal colonization and toxemia, and resembles infant botulism. This entry will discuss the epidemiology, clinical aspects, and prevention of foodborne botulism, and give a brief overview of the structure and mode of action of the neurotoxin.

Epidemiology

Since epidemiological data depend upon the reporting systems, and the thoroughness of these systems varies between countries, these data are scarce in large areas of the world. **Table 1** shows the data for countries with frequent outbreaks. Unrecognized and misdiagnosed cases of botulism do occur, as shown by a 1985 outbreak in Vancouver, Canada, where the initial diagnoses for 28 patients included psychiatric illness, viral syndrome, laryngeal trauma, and overexertion.

Incidence in North America

In Canada, since 1985, 4.4 outbreaks of foodborne botulism occur annually, with an average of 2.75 cases per outbreak. Most botulism outbreaks in Canada have occurred in northern and west-coast native communities. The foods involved were mainly raw meats from marine mammals, fermented meats such as muktuk (meat, blubber, and skin of the beluga whale), raw fish, or fermented salmon eggs. Type E was implicated in almost every case. Toxin production in raw meats can occur because the meats are often held at ambient temperature for some time. The problem with so-called fermented products is that the level of fermentable carbohydrates is too low to ensure a sufficiently rapid pH reduction to prevent growth of *C. botulinum*. Commercial products have been implicated in four incidents in Canada since 1971: bottled marinated mushrooms imported from the USA; bottled garlic in oil, also imported from the USA but temperature-abused locally; inhouse bottled mushrooms; and temperature-abused pâté produced in Quebec.

In the USA, 9.4 outbreaks of botulism occur annually, with an average of 2.5 cases per outbreak. Alaska accounts for 16.2% of all the outbreaks in the USA occurring from 1950 to 1996. All of the Alaskan outbreaks have involved native Alaskans; they

Table 1 Recorded outbreaks of foodborne botulism

NA, not available.

involved raw or fermented native foods, and type E was usually implicated. In continental USA, the situation is quite different. Most of the implicated foods were home-preserved vegetables. The relative prevalence of type A and type B outbreaks was about equal in the east, but type A outbreaks were much more prevalent in the west, where type A spores predominate in the environment. Most botulism outbreaks in the USA are caused by home-processed foods. Commercially processed foods account for only 7% of the botulism cases occurring in the USA since 1970. Temperature abuse of either food ingredients or the final product was often the problem.

Incidence in Europe

Poland reported by far the highest number of cases annually. This probably reflects both a high local incidence of botulism and a very thorough surveillance system. In Poland and several other European countries, including Italy, France, Spain, Germany, Hungary, Portugal, Czechoslovakia, and Belgium, the predominant type involved was B (Table 1). In Poland, the use of weck jars (weckglas) to seal cooked meats (mostly pork) hermetically under a vacuum led to a significant number of botulism cases. Other common vehicles of botulism in Poland include sausages, ham, headcheese (brawn), liver sausage, and bacon. The incidence of botulism was highest in Poland during the period of social change in the 1980s, reaching a peak of 738 cases in 1982. The number of botulism cases in Poland is seasonal, with the greatest incidences in May to August and in December. This may correspond to increased slaughtering of pigs in private farms and increased preparation of home-preserved 'wecked' products. Commercial foods, usually canned meat and fish, were responsible for 26% of cases in Poland.

The foods most frequently implicated, except in Italy and Spain, were home-preserved meats such as ham, fermented sausages, or canned products. Of the implicated foods in France, 12% were of commercial origin, but the manufacturers were generally small local establishments. In Italy and Spain, the most commonly implicated foods were home-preserved vegetables, most of which in Italy had been preserved in oil or water; in Spain, all of the incriminated vegetables had been canned. Commercial products were implicated in several outbreaks in Italy and included canned tuna fish in oil, dairy products (mascarpone cheese), low-acid canned vegetables, and pasteurized eggplant in oil. Scandinavian countries recorded fewer outbreaks, and these were mainly associated with fish and type E. Type E botulism has been reported in Greenland after consumption of raw seal meat and raw seal intestines. An outbreak of type B botulism, involving 12 cases, caused by commercial salted raw pork occurred in Switzerland between 31 December 1993 and 12 January 1994. Botulism outbreaks have been rare in the UK; however, a major outbreak in 1989 involved 27 cases, with one death. Type B toxin had been produced in a hazelnut purée which was then used to flavor a yogurt produced by a local dairy. Other European countries reported either few or no botulism outbreaks.

Incidence in the Russian Federation

The Russian Federation recorded 1327 outbreaks of botulism, involving 2300 cases and 182 deaths from 1988 to 1992. Most of these outbreaks were caused by type B, and most outbreaks were caused by

home-preserved mushrooms. Other foods commonly involved in botulism outbreaks include fish and pork. During this period, commercial foods, usually canned meats and vegetables, were implicated in one to five outbreaks annually. Incidents associated with fish occurred mainly in regions around the Black Sea, the Sea of Azov, the Caspian Sea, and Lake Baikal.

Incidence in Asia

Only a few countries in Asia reported outbreaks of foodborne botulism. Israel reported an outbreak in 1987 which affected eight people, with one fatality. The incriminated food was kapchunka (salted, uneviscerated whitefish) contaminated with type E toxin. All the kapchunka consumed by the patients had been purchased in New York City. While the high salt concentration of the kapchunka would have prevented growth of *C. botulinum* in the flesh of the fish, *C. botulinum* likely grew in the intestines of the fish and neurotoxin may have diffused into the flesh.

Iran reported a high incidence of botulism. Of the 314 cases recorded between 1972 and 1974, 170, comprising 63 outbreaks, were investigated. The majority of outbreaks (97%) were associated with type E and with fish or fish products. However, fleshy portions of fish were responsible for only 10% of the outbreaks; the other 90% were caused by fish eggs. These eggs (ashbal) are salt-cured for several months and then eaten without further treatment. A large outbreak, caused by locally made cheese stored under oil and involving 27 cases with one fatality, occurred in a northern district of Iran in 1997.

China has recorded 745 botulism outbreaks from 1958 to 1989. Most were associated with type A, followed by types B and E. The north-western province of Xinjiang recorded the majority of outbreaks, which were usually type A. Typically, the incriminated food was fermented bean curd. In the northern provinces of Ningxia and Hebei, outbreaks associated with type B predominated. Type E predominated in Xizang province. Neurotoxigenic *C. butyricum* was the cause of an outbreak of foodborne type E botulism in Guanyun, Jiangsu province, China, in January 1994. Six cases of clinically diagnosed botulism were reported after consumption of salted and fermented paste made of soybeans and wax gourds. Type E toxin was detected in the implicated food and *C. butyricum*, but not *C. botulinum*, was isolated. Subsequently, type E neurotoxin-producing *C. butyricum* was isolated from soil from four sites in an area near to the sites where the type E outbreak occurred. *C. butyricum* has also been isolated from sevu (crisp made of gram flour) implicated in a 34-case outbreak of botulism in India in September 1996.

The majority of Japanese outbreaks occurred in northern areas and were associated with type E and fish or fish products. Izushi was the food most often implicated. To prepare izushi, fleshy pieces of fish are soaked in water for a few days, and then packed tightly into a tub with cooked rice, vegetables, salt, vinegar, and spices and left to ferment, often for 3 weeks or longer. Izushi is eaten without further cooking. Two outbreaks in Japan were associated with commercial food. A type A outbreak was caused by vacuum-packaged, stuffed lotus rhizome and involved 36 cases with 11 deaths. An outbreak caused by imported bottled caviar with 21 cases and three deaths was due to type B toxin. Taiwan has also reported a few botulism outbreaks, but reports from other Asian countries are rare.

Incidence in Other Areas

Argentina is the only country in the southern hemisphere which reported a substantial number of botulism outbreaks. These occurred mostly in the provinces of Mendoza and Buenos Aires, and at a latitude between 30° and 40° S. Most outbreaks were associated with type A and the implicated foods were usually vegetables. A recent outbreak of type A botulism among bus drivers in Buenos Aires was caused by consumption of matambre, a meat roll containing vegetables and eggs. The matambre was wrapped in a heat-shrunk plastic wrap and stored with inadequate refrigeration. Mexico, Guatemala, Venezuela, Peru, Brazil, and Chile have all reported few outbreaks.

Chad, Egypt, Kenya, Madagascar, and Zimbabwe are the only African countries with confirmed outbreaks. In April 1991, an outbreak with 91 reported cases of type E botulism and 18 reported deaths occurred in Egypt. The food implicated in this outbreak was faseikh (uneviscerated, salted mullet fish) originating from a single shop in Cairo. In Kenya, two outbreaks were caused by native foods: one by sour milk prepared in a gourd, and one by consumption of raw termites. One of the two outbreaks reported from Madagascar was unusual; the numbers involved were high, and type E toxin was associated with a meat product. About 60 people were involved, with 30 deaths, and locally manufactured bologna was the vehicle.

Since 1942, Australia has recorded only six outbreaks of foodborne botulism, and none since 1991. One outbreak of type A botulism was recorded in New Zealand, caused by home-bottled fermented mussels and watercress, a traditional Maori dish.

Unconfirmed Outbreaks

Several outbreaks of foodborne botulism have been reported in the media and distributed over the

internet by ProMED-mail, the Program for Monitoring Emerging Diseases. ProMED-mail is a program of the International Society for Infectious Diseases (ISID) and acts as a global electronic reporting system for outbreaks of emerging infectious diseases. These outbreaks are all unconfirmed and the only source for these outbreaks is media reports.

Two large unconfirmed botulism outbreaks have been reported in the north African countries Algeria and Morocco. Algerian state-run radio was cited as reporting that an outbreak of botulism killed 17 people in July 1988 in eastern Algeria. One of the foods suspected in this outbreak was a processed meat known as kashir. Another unconfirmed outbreak was reported by Associated Press, stating that mortadella sausage was responsible for a suspected botulism outbreak in Morocco during September 1999 with at least 10 deaths.

Reuters news agency had reported an unconfirmed botulism outbreak involving 90 cases with four deaths from consumption of fish at a wedding reception in the former Soviet republic of Azerbaijan. The Russian news agency Itar-Tass has reported an outbreak of botulism in southern Siberian Buryat, with 48 cases and four deaths after consumption of fish from Lake Baikal. More than 70 cases of botulism, including eight deaths, had been reported in Buryatia in 1999.

Conclusions Regarding Epidemiology

Most botulism outbreaks have occurred in the northern hemisphere, particularly in countries north of the Tropic of Cancer. Argentina is the only country in the southern hemisphere which has reported several outbreaks. Seasonal trends in outbreak frequencies are apparent in some areas. In Canada, Alaska, and Poland most outbreaks occur from May until October, whereas in China most outbreaks occur in the late winter and spring. There is a strong association between the prevalent outbreak type and the prevalent environmental type, as well as the implicated food. In colder regions, Canada, Alaska, Greenland, Scandinavia, parts of Russia, Iran, and northern Japan, type E causes most botulism outbreaks and is the prevalent environmental type. The implicated foods are usually fish or marine mammals. In central Europe, type B causes most outbreaks and is the prevalent environmental type. Meats, particularly home-cured smoked ham, are the major cause of botulism. In the western USA, Argentina, and China, type A causes the majority of outbreaks and is the prevalent environmental isolate. In these areas, the most frequently implicated foods are vegetables.

Clinical Aspects

Symptoms

The disease may vary from a mild illness which may be overlooked or misdiagnosed to a serious disease which may be fatal within 24 h. The onset of symptoms typically occurs 12–36 h after ingestion of toxin, with a range from a few hours to 14 days. Usually, the earlier symptoms appear, the more serious the disease. The first symptoms are generally nausea and vomiting. Mainly neurological signs and symptoms appear next, including visual impairments (blurred or double vision, ptosis, fixed and dilated pupils), loss of normal mouth and throat functions (difficulty in speaking and swallowing, dry mouth, throat and tongue, a sore throat), general fatigue and lack of muscle coordination, and respiratory impairment. Other gastrointestinal symptoms include abdominal pain, diarrhea, and constipation. Diarrhea occurs relatively early in the course of the disease, whereas constipation persists in the advanced stages. Respiratory failure and airway obstruction are the main causes of death. Fatality rates in the first half of the century were about 60%, but with the availability today of antisera and modern respiratory support systems, they have decreased to about 10%.

Treatment

Initially, treatment of botulism is directed toward removing or inactivating the toxin by (1) neutralizing circulating toxin with antiserum; (2) enema or treatment with cathartics to remove residual toxin from the bowel; and (3) in the absence of vomiting, gastric lavage or treatment with emetics. Induced emesis or gastric lavage is recommended if exposure has occurred within several hours. Treatment with antiserum is most effective in the early stages of the illness. The impact of antiserum is obvious from the Chinese data; before the availability of antisera in 1960, the death rate in China was approximately 50%, but it was only 8% in the nearly 4000 patients who received antitoxin. Subsequent treatment is mainly to counteract the paralysis of the respiratory muscles by artificial ventilation.

Diagnosis

The initial diagnosis of foodborne botulism is based on the patient's signs and symptoms, and perhaps food history. It must be confirmed by detecting toxin or viable *C. botulinum* in a suspect food or clinical sample, or by epidemiological association with a laboratory-confirmed case. Serum, feces, enema fluid, stomach contents, and autopsy sections of the small and large intestines, and of the liver, are

suitable specimens for neurotoxin detection. Except for serum, these specimens are also suitable for detecting viable *C. botulinum*. The methods for detecting the neurotoxin and *C. botulinum* are given in the previous article ***Clostridium***: Occurrence of *Clostridium botulinum*. Other than neutralizing any acidic samples, little special treatment is required. Occasionally, extracts prepared from feces cannot be filter-sterilized. In that case, tetracycline should be added to 200 p.p.m. to control infection of the mouse.

Case History

One of the most severe, nonfatal cases of botulism was documented in a patient in the UK. Within approximately 10 h of eating the suspect food, he had blurred and double vision followed by nausea and vomiting, difficulty in swallowing and talking, dryness of the mouth, and arm weakness. He suffered a respiratory arrest on arrival at the hospital and was intubated. A progressive flaccid paralysis ensued. He was given polyvalent antitoxin, a tracheostomy was done and total parenteral nutrition (TPN) was started. There was little change in his condition for 100 days. His ptosis did not resolve until 46 days after onset of symptoms. TPN was stopped on day 158, and respiratory support was withdrawn after 173 days. He was not discharged until after 237 days.

Prevention

Usually, the preservation of high-moisture foods is geared toward control of *C. botulinum*, which usually involves inhibition rather than destruction. Such control generally also insures control of other foodborne pathogens and of many spoilage microorganisms. The effects of different factors on the growth of *C. botulinum* in foods are described in the previous entry ***Clostridium***: Occurrence of *Clostridium botulinum*. Control of *C. botulinum* in commercial foods is generally achieved by one of the following methods:

1. Low-acid shelf-stable canned foods are preserved by a full thermal process.
2. Shelf-stable canned cured meats are preserved by a combination of thermal processing and addition of salt and nitrite.
3. Canned acid foods are preserved by a pasteurizing thermal process and acidity.
4. Products such as dry fermented sausages are preserved by reduced water activity (a_w) and pH, and added nitrite.
5. Packaged raw or cooked meats or fish and shellfish are preserved by refrigeration alone < 3°C.
6. Many meat and fish products are preserved by a combination of added salt and refrigeration.
7. Many cured meat products are preserved by a combination of added salt and nitrite, and refrigeration.
8. Vacuum-packaged smoked fish are preserved by a combination of thermal processing, added salt, smoking, and refrigeration.

Foodborne botulism, caused by home-prepared foods, can be prevented by strict adherence to proper home-canning instructions. The type of container, levels of acidity, and salt and heat treatments are especially important for home-canning. All home-canned foods should be brought to a boil before they are eaten. An effective botulinal toxoid is available from the US Centers for Disease Control for immunization. Immunization of high-risk populations, such as Alaskan and Canadian Inuits, has been repeatedly proposed, but never implemented. At present, only laboratory workers at risk are immunized.

Neurotoxin

As previously stated, seven serologically different neurotoxins are produced by various strains of *C. botulinum*. Some strains of *C. butryricum* produce type E neurotoxin and some strains of *C. barati* can produce type F neurotoxin. In general, the designation of the strain is that of the toxin it produces. Strains of subtypes. AB, AF, BA, and BF are rare and produce, in addition to the first toxin type, lesser amounts of toxin of the second type. Type C and D strains often produce small amounts of D and C toxin, respectively. They may also produce a toxin, C2, which is distinctly different from the neurotoxin and will not be discussed here.

Structure

The neurotoxins are all very similar proteins with a molecular weight of approximately 150 kDa. They are synthesized as a single-chain protein with relatively low toxicity, which is activated when it is 'nicked' by a number of proteases, including proteases of group I C. *botulinum*, into a double-chain molecule which is held together by a disulfide bond. The two components of the nicked toxin, a light (L) and heavy (H) chain, have molecular weights of approximately 50 and 100 kDa, respectively. Individually, the two components are not toxic, but toxicity can be restored by reestablishing the disulfide bond.

The neurotoxins exist as complexes of four molecular sizes: 7S, 12S, 16S, and 19S, designated S (small), M (medium), L (large), and LL (extra large) toxins, respectively. The molecular weights range

from 150 to 900 kDa. The M form is the most common natural form, found in foods and cultures, along with the L form. It is a complex of the S form with an atoxic component. In the L form, a hemagglutinin is also part of the complex. The LL form is only known for type A, and was the first form of the botulinum toxin to be purified and crystallized. It has not been found in cultures and is probably an artificial aggregate. The M and L forms are referred to as progenitor toxins. They dissociate under mild alkaline conditions into the S, or derivative toxin, which is the single-chain protein.

Mode of Action

Botulinum neurotoxins cause paralysis by blocking acetylcholine release at neuromuscular junctions. Cholinergic systems are affected the most, but adrenergic systems may also be affected by high concentrations of toxin. Paralysis appears to be caused by a four-step process. First, the toxin binds to a type-specific receptor on the presynaptic membrane. This step is mediated by the carboxy-terminus of the H chain. Second, the toxin is internalized into the nerve cell by an initial receptor-mediated endocytosis. Acidity in the endosome is believed to induce the amino-terminus of the H chain to form channels in the endosome membrane which permit the L chain to enter the cytoplasm. Finally, the light chain acts as a zinc endopeptidase and hydrolyzes the SNARE proteins responsible for synaptic vesicle fusion: synaptobrevin, syntaxin, or SNAP-25. Cleavage of the SNARE proteins results in inhibition of acetylcholine release, ultimately resulting in flaccid paralysis.

Inactivation

The most effective means of inactivating botulinum toxins in foods is by heat. Heat inactivation curves are biphasic, with an initial steep decline that levels off with time. Foods, especially those high in protein, colloidal components, or ionic strength, have a protective effect. The toxin is most stable between pH 4 and 5. For the safe thermal inactivation of toxin at concentrations up to 10^5 LD_{50} per gram, time/temperature combinations of 20 min at 79 °C or 5 min at 85 °C have been recommended. Other means of toxin inactivation include treatment with chlorine or ozone.

Properties and Determination

M Jägerstad and K Arkbåge, Swedish University of Agricultural Sciences, Uppsala, Sweden

Discovery

The history of cobalamin (vitamin B_{12}) started almost two centuries ago, when a fatal anemia, resulting from some disorder of the digestive and assimilative organs, was described. The symptoms of this anemia, named pernicious anemia, was further outlined during this century, but a successful treatment of this fatal disease was reported first in 1926, when raw liver was introduced as therapy. In 1929, it was shown that the intestinal absorption of the antipernicious anemia principle in liver (extrinsic factor) required prior binding to an 'intrinsic factor' secreted by the stomach. The search for the active principle in liver culminated with the isolation of vitamin B_{12} in 1948 by a team of Merck scientists in the USA, which was confirmed by a British team 3 weeks later. Injections of the isolated vitamin B_{12} into muscular tissues induced a dramatic beneficial response in patients with pernicious anemia. Hodgkin and coworkers elucidated the chemical structure of cyanocobalamin (vitamin B_{12}) by X-ray crystallography in 1964, for which they were rewarded the Nobel Prize in chemistry (the second Nobel Prize designated for this vitamin).

Structure, Nomenclature, and Physical Properties

Cobalamins have a complex chemical structure based on a corrin ring system. Four reduced pyrrole rings are linked together to form a macrocyclic ring designated corrin, which is chelated by the four pyrrole nitrogens. Corrin resembles the heme of hemoglobin, but has one less α-methene bridge and has cobalt (Co) instead of iron at the center. All the compounds containing this ring are designated corrinoids. The fifth co-ordinate covalent bound to cobalt is a nitrogen of a dimethylbenzimidazole moiety. Thus, as with nucleic acids, cobalamins contain a nucleotide, in this case 5,6-dimethylbenzimidazole, rather than various purine or pyrimidine bases. And the sugar, ribose, has an α-glycosidic linkage, unlike the β-linkage in the nucleic acids. The D-1-amino-2-propanol moiety of the molecule is esterified to the nucleotide and joined in amide linkage to the porphyrin-like nucleus. The sixth position of cobalt may be occupied by different anionic ligands, (*R*) according to Figure 1 and Table 1. This ligand can be one of the following types, e.g., –CN(cyanocobalamin), –OH (hydroxocobalamin), $-H_2O$ (aquacobalamin), $-NO_2$ (nitritocobalamin), $-SO_3$ (sulfitocobalamin), $-CH_3$ (methylcobalamin), or –5′-deoxy-5′-adenosyl (adenosylcobalamin). Approximately 20 naturally occurring analogs of cobalamins have been identified. Some of these have no biological activity in mammals, whereas others exhibit at least partial vitamin activity but are often poorly absorbed. Human serum contains not only the active cobalamins (mainly the hydroxo-, methyl-, and adenosyl-cobalamins) but also a variable number of analogs that are biologically inactive noncobalamin corronoids. These vitamin B_{12} analogs have their base of nucleotide, 5,6-dimethylbenzimidazole replaced by other nucleotides, e.g., adenine, guanine, 5-methyl-adenine, or 5-hydroxybenzimidazole.

According to the nomenclature of the corrinoids, a cobalamin is a cobamide in which 5,6-dimethylbenzimidazole is the aglycon attached by a glycosyl link. Consequently, the systemic name of cobalamin given by IUNS (International Union of Nutritional Sciences) and IUPAC (International Union of Pure and Applied Chemistry) is: Coα-[α-(5,6-dimethylbenzimidazolyl)]-Coβ-'*R*' cobamide, where '*R*' denotes 'cyano,' 'aqua,' 'hydroxo,' 'nitrito,' 'adenosyl,' 'methyl,' etc) IUNS and IUPAC state that the term 'vitamin B_{12}' should be used as the generic description for all corrinoids exhibiting qualitatively the biological activity of cyanocobalamin, whereas the term 'corrinoid(s)' should be used as the generic descriptor for all compounds containing the corrin nucleus and thus chemically related to cyanocobalamin. The term 'vitamin B_{12}' has two meanings.

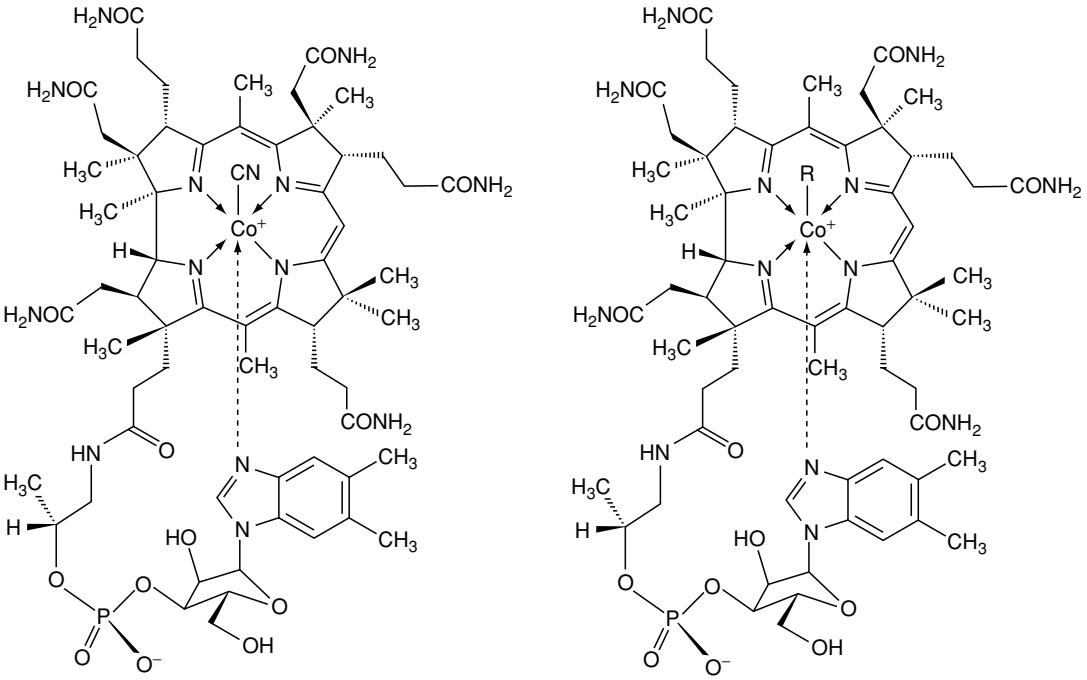

Figure 1 *Left*: Chemical structure of cyanocobalamin; *right*: Coenzyme B_{12}/adenosylcobalamin ($R = 5'$-deoxy-$5'$-adenosyl); methylcobalamin ($R =$ methyl); aquacobalamin ($R = H_2O^+$); hydroxocobalamin ($R =$ OH), with kind permission of Kräutler.

To the chemist, it means only cyanocobalamin, whereas in the nutrition and pharmacology literature, vitamin B_{12} is a generic term for all the cobamides exerting biological activity in humans. So far, all the cobamides found to play a role in human metabolism have been cobalamins. Table 1 summarizes the generic or trivial names for different cobalamins, together with their abbreviations, CAS numbers, and physical properties.

Chemical Properties, and Stability

Cyanocobalamin

Cyanocobalamin, a synthetic form of vitamin B_{12}, is commercially available for medical use, food fortification, and nutrient supplements. The original identification of vitamin B_{12} as cyanocobalamin involved its formation as an artefact of the isolation procedure. Little or no naturally occurring cyanocobalamin exists in foods. Thus, cyanocobalamin is normally not present in humans except in very small amounts in smokers. It is a tasteless, odorless, red crystalline substance with good water solubility. The color of the compound may pose a limitation in the possible addition of cyanocobalamin to certain foods, especially light-colored products (e.g., white bread).

The cyanide group of cyanocobalamin can be replaced by other ions to form hydroxycobalamin, chlorocobalamin, nitritocobalamin, thiocyanatocobalamin, and others; for example, bisulfite ions cause conversion of aquacobalamin to sulfitcobalamin, and similar reactions can occur to form cobalamins substituted with ammonia and nitrite. These reactions have little influence on the net vitamin B_{12} activity of foods, since all the cobalamines are readily reconverted to cyanocobalamin after treatment with cyanide, except methylcobalamin.

Cyanocobalamin appears to be the most stable of the various vitamin B_{12} analogs, being stable in air and in dry form, and is even relatively stable at 100 °C for a few hours. Aqueous solutions at pH 4–7 can be autoclaved at 120 °C. Cyanocobalamin is slowly decomposed by ultraviolet or strong visible light. The cyano group is split off, yielding hydroxocobalamin, which is also a biological active form of vitamin B_{12} (and is available for medical use and used in fortification by the food industry). Prolonged exposure to light, however, causes irreversible decomposition and inactivation.

Mild acid hydrolysis of cyanocobalamin induces the removal of the nucleotide, and additional fragmentation occurs as the severity of the acidic conditions increases. Exposure to alkaline conditions causes hydrolysis of amides, yielding biologically inactive carboxylic acid derivatives of vitamin B_{12}. In solution, thiamin and nicotinamide, or nicotinic acid, destroy cyanocobalamin slowly, whereas the addition of small amounts of iron or thiocyanate appear to protect it. However, the literature is not definitive.

Coenzyme B_{12}

The coenzyme forms of vitamin B_{12} are methylcobalamin and adenosylcobalamin. Methylcobalamin functions coenzymatically in the transfer of a methyl group (from 5-methyltetrahydrofolate to homocysteine) in methionine biosynthesis, whereas 5′-deoxyadenosylcobalamin serves as the coenzyme in an enzymatic rearrangement reaction catalyzed by methylmalonyl-CoA mutase. Both forms of vitamin B_{12} coenzymes are converted to the biological active aquacobalamin upon light exposure. In fact, vitamin B_{12} coenzymes exhibit extreme photosensitivity, which necessitates the use of subdued lighting and low actinic glassware during vitamin B_{12} analyses. The photochemical degradation of vitamin B_{12} coenzymes interferes with experimental studies of vitamin B_{12} metabolism and function, but this conversion has no influence on the total vitamin B_{12} activity of foods, because aquacobalamin retains vitamin B_{12} activity. Surprisingly, methylcobalamin and adenosylcobalamin are relatively stable in neutral aqueous solution in the dark and can be heated for 20 min at 100 °C.

Adenosylcobalamin is unstable under acidic and alkaline conditions, whereas methylcobalamin is stable in the presence of dilute acid or alkali. In general, the natural forms of cobalamins (hydroxo-, aqua-, methyl-, or adenosylcobalamin) are inactivated by severe alkaline conditions, heavy metals, strong oxidizing agents, or strong reducing agents (like ascorbate). A possible interaction with ascorbic acid has been reported to be detrimental to the vitamin, especially under heating conditions. The significance of these observations for the processing of food remains unclear (see further discussion below). The mechanism of vitamin B_{12} degradation has not been fully determined, in part because of the complexity of the molecule and the very low concentration in foods.

Cobalamins in Food

Only microorganisms are able to synthesize cobalamin, and therefore, higher plants are devoid of vitamin B_{12} unless processed microbiologically or contaminated by fecal material, e.g., from fertilizer. Certain legumes have been reported to absorb small amounts of vitamin B_{12} produced by bacteria associated with root nodules, but little enters the seeds. Food from animal origin, especially organs like liver and kidney, contain > 30 μg vitamin B_{12} per 100 g. Other rich sources are meat muscles, fish, dairy products, and eggs. Bovine milk contains about 0.4 μg of vitamin B_{12} per 100 g (range 0.24–0.74 μg per 100 g). Human milk contains only about 15% as much vitamin B_{12} as bovine milk. The predominant source of vitamin B_{12} in bovine milk is biosynthesized by microorganisms in the rumen. Hydroxocobalamin is the predominant form of vitamin B_{12} in bovine milk. There may also be some of the light-sensitive forms of vitamin B_{12}, adenosylcobalamin and methylcobalamin, present. In milk, most of the vitamin B_{12} is protein-bound. The significance of this is still unknown, although a protective effect against microbial breakdown has been suggested. The vitamin B_{12} in most animal tissues consists mainly of the coenzyme forms, methylcobalamin and adenosylcobalamin, in addition to aquacobalamin. Some foods or microorganisms contain other corrinoids, with varying biological activity, some of which may have antivitamin activity. Foods are classified according to their vitamin B_{12} content, as shown in Table 2.

Process and Storage Losses

Under most conditions of food processing and preservation, there is little nutritionally significant loss of vitamin B_{12}. Cyanocobalamin added to breakfast cereal products has been reported to undergo an average loss of 17% during processing, with an additional 17% loss during storage for 12 months at ambient temperature. When milk is pasteurized for 2–3 s, it loses 7% of its available vitamin B_{12}, and boiling for 2–5 min destroys 30%. Sterilization in a bottle for 13 min at 119–120 °C causes a loss of 77%, and rapid sterilization (3–4 s) with superheated steam at 143 °C, i.e., ultrahigh temperature (UHT) destroys about 10% of the vitamin.

There are also processes like fermentation used for manufacture of certain dairy products, e.g., yogurt

Table 2 Grouping of food according to vitamin B_{12} content

Food	*Vitamin B_{12} (μg per 100 g edible weight)*
Very rich sources: organ meats (liver, kidney, heart), bivalves (clams and oysters)	> 10
Moderately rich sources: some fish, crabs, egg yolk	3–10
Moderate sources: muscle meats (beef), some fish, cheese, egg, milk powder	1–3
Good sources: milk, yogurt, muscle meats (pig)	< 1
Poor sources: vegetables, cereals, fruits and berries	n.d.

n.d., not detectable.

and cheeses, which might result in either increased or decreased vitamin B_{12} concentrations depending on the vitamin B_{12}-producing or -consuming microorganisms.

Studies indicate that the storage temperature and time have a significant influence on the rate of breakdown. Thus, if UHT milk is stored at a low temperature (+7 °C), as for pasteurized milk, the losses of vitamin B_{12} are low for up to at least half a year. However, if storage is at ambient temperature, which is a normal condition for an aseptic product such as UHT milk, breakdown of the vitamin may be considerable even within a few weeks. Fermented dairy products might lose or gain vitamin B_{12} during storage for the reason given above.

Like all water-soluble vitamins, vitamin B_{12} is subject to losses through leaching into the cooking water. This indicates the potential for substantial losses of vitamin B_{12} during prolonged heating of foods at or near neutral pH. Typical oven heating of commercially prepared convenience dinners has been shown to yield 79–100% retention of vitamin B_{12}.

Ascorbic acid has long been known to accelerate the degradation of vitamin B_{12}, especially during high-temperature heating, although this may be of little practical significance, because foods containing vitamin B_{12} usually do not contain significant amounts of ascorbic acid. In curing solutions for ham, neither ascorbate nor erythorbate has been found to have any influence on vitamin B_{12} retention, probably since this process does not include high-temperature heating.

Determination of Cobalamins

General

For detection purposes, cobalamins are all UV absorbers. Unfortunately, their absorption spectra vary between different congeners, and detection is complicated by the low concentration at which they occur normally in foods. Available methods for assay of cobalamins developed over the years include both general methods, e.g., polarographic, spectrophotometric, various chromatographic procedures (paper, thin-layer, and open-column chromatography), and more specific and/or sensitive methods, e.g., microbiological, protein-binding, and high-performance liquid chromatography (HPLC) procedures.

Almost all available data on vitamin B_{12} in food have been obtained by microbiological assay (MA) using *Lactobacillus delbrueckii* as the test organism. Still, the microbiological assay is the reference method for assaying cobalamins in foods. For clinical tissues and serum samples, rapid radioprotein-binding assays with ^{57}Co-labeled cyanocobalamin are routine. However, radioassay kits for clinical assay are not reliable for assay of food unless carefully validated for matrix effects. A more recent development of this protein-binding assay is the use of a biosensor technique to quantify cobalamins in food. Although the various forms of vitamin B_{12} can be separated chromatographically, HPLC methods are not readily suitable for food analysis, even if preconcentration steps are used, because of the very low concentrations typically found. Below, only methods currently in use for the assay of naturally occurring cobalamins in foods and/or fortified foods are presented and discussed.

Extraction

All methods for cobalamin analyses of food samples need a preparative step prior to analysis. Since animal products are the sole food sources of vitamin B_{12}, the vitamin must be extracted from protein-rich matrices under conditions that will not lead to its destruction. As a result, extraction procedures often involve digestion with protease followed by extraction in hot (80 °C) ethanol. For quantitation as total vitamin B_{12}, heating in a cyanide- or sulfate-containing buffer has been used to extract the endogenous vitamin B_{12} forms, thereby converting them to the more stable cyano- or sulfitocobalamin forms. The AOAC official method (952.20) recommends mixing approximately 1 g or 1 ml of the sample in $\geq$25 ml of a freshly prepared solution containing sodium phosphate, citric acid, and metabisulfite. The extraction is completed by homogenizing the sample in the extraction solution, autoclaving the mixture at 121–123 °C for 10 min, adjusting the cooled mixture to pH 6.0, filtering and/or centrifugation, and diluting with water to a vitamin B_{12} concentration of approximately 0.2 ng ml^{-1}. However, most extraction procedures described in the literature add either sodium cyanide (NaCN) or potassium cyanide (KCN) to 0.1 M acetate buffer, pH 4.5–4.7, during homogenization and extraction. The heating time varies between 3 and 30 min, and a heating temperature of either 100 °C (boiling water) or 121 °C (autoclavation) is used. The heat-extraction procedure including centrifugation and/or filtration are enough of sample preparation for microbiological assays and protein-binding assays (immunoassays). In the use of HPLC, further clean-up work might be necessary, e.g., ultracentrifugation, ultrafiltering, affinity chromatography, or adsorption on to charcoal or chromatography on anion exchange resin and/or solid-phase extraction on C_{18} cartridges.

The extraction conditions have been shown to affect significantly the efficiency of the overall extraction

process. It has therefore been suggested that the extraction conditions should be optimized for each type of food sample in order to achieve reproducible and good recoveries of the complete analysis.

Microbiological Assay

Over the years, the growth response of various microorganisms has been used to analyze cobalamins in foods and other biological material. The microorganisms that have been used are *Lactobacillus delbrueckii* (previously, *leichmanni*), *Escherichia coli, Euglena gracilis*, and *Ochromonas malhamensis*. Below, only the AOAC (Association of Official Analytical Chemists) Official method (reference method) based on *Lactobacillus delbrueckii* is presented. The other microorganisms have different disadvantages compared with *Lactobacillus delbrueckii*, i.e., less sensitive and/or specific also towards less active biological analogs. In addition, *Euglena gracilis* and *Ochromonas malhamensis* grow more slowly and are thus more painstaking.

The AOAC Official Method 952.20: *Cobalamin (Vitamin B_{12}-activity) in Vitamin preparations* use a microbiological assay with *Lactobacillus delbrueckii* (ATCC 7830) (45.2.02). This method was originally collaborated for use on vitamin preparations, but the AOAC Task Force on Methods for Nutrition Labeling recommended the procedure for use on all food matrices. The *Lactobacillus delbrueckii* growth response is sufficiently sensitive to quantify cyanocobalamin at concentrations approaching 1.0 pg per milliliter of assay growth medium (corresponding to less than 0.5 μg per 100 g). It has a variable response to various cobalamins. A similar growth response has been reported for cyanocobalamin, hydroxocobalamin, sulfitocobalamin, nitritocobalamin, and dicyanocobalamin. However, adenosylcobalamin produces a greater response, and methylcobalamin a lower growth response. This will generally not cause a problem, since excess of cyanide or sulfite is used during the extraction procedure prior to analysis, thereby converting all different native forms of cobalamins except methylcobalamin into one stable form.

An important aspect in all methods of analysis is their specificity. *Lactobacillus delbrueckii* can utilize vitamin B_{12} analogs, e.g., deoxyribonucleotides and deoxyribonucleosides, in addition to biologically active cobalamins. Older literature suggests that dilution of deoxyriboside levels (e.g., thymidine) to less than 1 μg per milliliter of the assay medium will eliminate the effect.

Radioprotein-Binding Assays

Radioprotein-binding assays have been used routinely for blood and tissue analysis since early work by Rothenberg and several others during the 1960s. The principle of this assay is based on the competition of added isotope-labeled cyanocobalamin (^{57}Co) versus cyanocobalamin from the unknown sample for a limited number of binding sites on cobalamin-binding proteins (often intrinsic factor from hog). The amount of labeled cobalamin bound to the binding protein is quantified in a gamma counter, and the concentration of cobalamin in the unknown sample is inversely proportional to the concentration of labeled cobalamin, and calculated from a calibration curve.

Early types of radioprotein-binding assays for determination of vitamin B_{12} in clinical specimens and foods were often inaccurate because the binding protein could bind to active forms of vitamin B_{12} as well as biologically inactive analogs. The specificity of such assays has been greatly improved through the use of a vitamin B_{12}-binding protein (generally porcine intrinsic factor, IF) that is specific for the biologically active forms of the vitamin. Radioligand binding methods based on monospecific antisera that eliminate any cross-reactions with other cobalamins are now available and should be used routinely in all clinical laboratories.

The relative binding affinities of porcine IF for various cobalamins have also been studied. An equivalent affinity has been found for cyano-, dicyano, nitrito-, and methylcobalamins, whereas significantly different binding affinities have been found for hydroxo-, sulfito, and adenosylcobalamins. Therefore, with cyanocobalamin as the calibration standard, it is necessary to add cyanide to the samples prior to quantification during the extraction procedure to convert all native forms to cyanocobalamins.

Studies by several research groups indicate that radioprotein-binding assays with IF can be used for food analysis. When optimized extraction procedures have been used, radioprotein binding assays and microbiological procedures show agreement for most foods; however, differences have been noted often enough to conclude that the two methods are not universally interchangeable for the assay of all foods. Thus, recent work has shown that the radioprotein binding assay could be reliable for food analysis, providing careful method validation including control of selectivity. One should bear in mind that not only the food matrix itself but also substances used during the extraction procedure, e.g., buffer strength, pH, cyanide concentration, and added enzymes needed to release vitamin B_{12} bound to the food matrix, might cause nonspecific binding and therefore must be accounted for in order to achieve reliable results.

An alternative to the protein-binding assay is an enzyme-linked protein-binding assay that appears to be useful for fortified foods in which cyanocobalamin is the predominant cobalamin. The procedure uses an *R*-protein–enzyme conjugate and microtiter plate techniques for quantitation of cyanocobalamin. Since *R*-proteins bind cobalamins and their analogs, the assay has not been applied to nonfortified foods. Another drawback is that the *R*-protein enzyme conjugate is not commercially available. Applications to

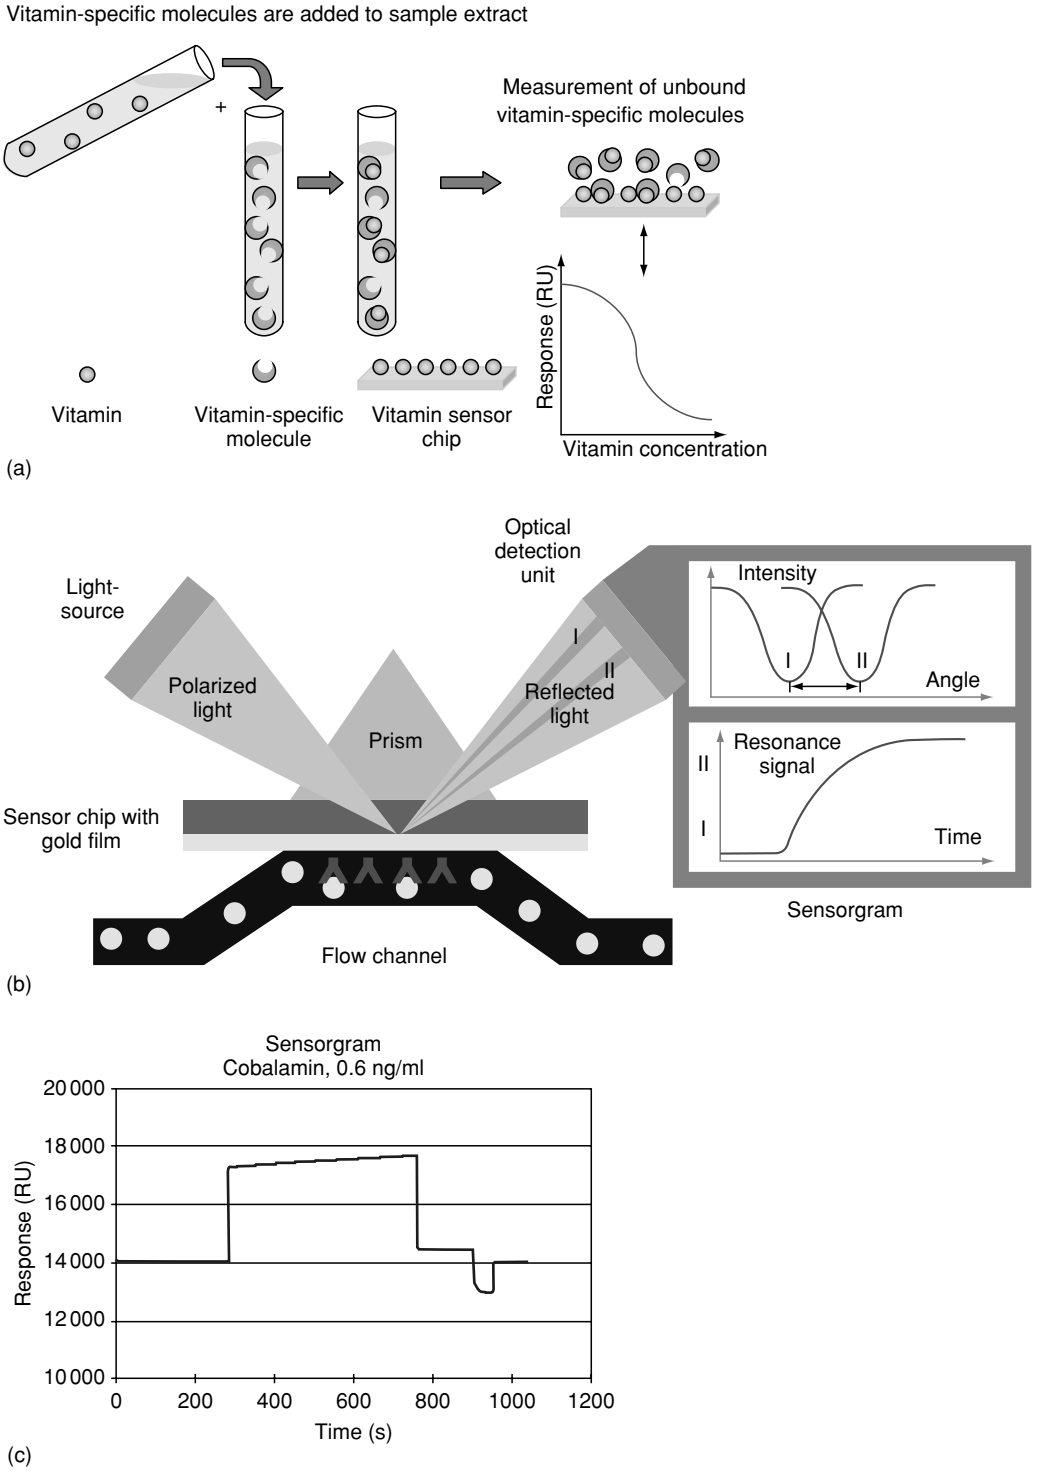

Figure 2 Assay principle for determination of vitamin B_{12} in food using optical biosensor technology (BIACORE).

fortified breakfast cereals have given a limit of detection of 9 pg per well and a quantification limit of 0.09 μg per 100 g.

Optical Biosensor-based Immunoassay

This assay is the latest methodological development for vitamin B_{12} in foods and is based on biospecific recognition of the analyte, cyanocobalamin, by a vitamin B_{12} binding protein. The event of recognition is transduced to a signal by means of an optical sensing mechanism. Real-time biomolecular interaction analysis recently developed by BIACORE is a label-free technology for monitoring biomolecular interaction as they occur. A special kit, Qflex™ Kit Vitamin B_{12}, is commercially available and uses an inhibition assay/indirect assay for the analyses. In an inhibition assay, the analyte or an analog is immobilized onto the surface of a sensor chip. A high-molecular-weight detecting molecule such as a binding protein in a defined concentration is added to the sample. The binding proteins bind to the analyte, but at equilibrium, some binding proteins will remain in solution free to bind to the sensor surface. A standard curve is prepared from solutions with known concentrations. The concentration of analyte in an unknown sample is then derived from a standard curve.

The detection principle relies on surface plasmon resonance (SPR), an electronic charge-density wave phenomenon that arises at the surface of a metallic film, usually based on gold, when light is reflected at the film under specific conditions. The resonance is a result of energy and momentum being transformed from incident photons into surface plasmons and is sensitive to the refractive index of the medium on the opposite side of the film from the reflected light. A scheme of the principle of the optical biosensor technology is shown in Figure 2.

Method validation data using milk-based infant formulas fortified with cyanocobalamin have given the following results; precision (RSD_r): 4.4; recovery: 93–106%; detection limit (LOD $-3 \times$ SD): 0.07 ng ml^{-1} and quantification limit (LOQ $-10 \times$ SD): 0.17 ng ml^{-1}. Samples can be quantified in the range of 0.1–4 ng ml^{-1}, corresponding to an LOQ of $\sim$ 0.5 μg per 100 g, depending on sample preparation.

Samples analyzed by MA and Biacore Q show a good agreement, but the BIACORE method is less sensitive so far. This restricts its use at the moment to fortified foods, e.g., infant milk formulas and gruels, and pharmaceutical vitamin mixtures. The biosensor-based BIA:SPR technique provides a convenient, label-free, and automated quantitative analysis amenable to routine compliance monitoring in the food laboratory. Advantages of this technique include the speed and simplicity of operation for routine compliance analyses and an enhanced precision.

HPLC Methods

Liquid chromatography can be conveniently applied to the assay of vitamin B_{12} in high-concentration supplements and pharmaceutical preparations (usually cyano- or hydroxocobalamin forms). A few such HPLC methods have been published since 1980. It can also effectively resolve natural cobalamins. However, owing to the low levels of analytes, radioligand-binding assays are necessary to quantify eluted cobalamins. For milk, which is a good source of vitamin B_{12} (containing around 4 μg of vitamin B_{12} per liter), an HPLC method based on UV detection (550 nm) and with a detection limit of 0.2 μg of vitamin B_{12} per liter of milk is available. Recently, a novel HPLC method for the determination of vitamin B_{12} (cyanocobalamin) with fluorescence detection has been reported. The method has been used successfully to determine vitamin B_{12} in pharmaceutical preparations, e.g., vitamin B_{12}-containing multivitamin tablets and fermentation medium. The recovery varies from 94 to 102%, and the relative standard deviation is in the range of 1.8–4.1%.

Certified Reference Material

Two Bureau Commission Reference materials, milk powder (CRM 421) and lyophilized pig's liver (CRM 487) are available by the European Commission in Brussel with a certified vitamin B_{12} content analyzed by microbiological assay (*Lactobacillus leichmanni*, ATCC 7830) and radioprotein-binding assay. The two different methods show similar vitamin B_{12} concentrations in these reference materials.

Physiology

C J Bates, MRC Human Nutrition Research, Cambridge, UK

Introduction

The importance of vitamin B_{12} in human nutrition has been dominated by the potentially fatal disease, pernicious anemia, which results from a failure of secretion of the specific cobalamin-binding protein, intrinsic factor, by the parietal cells of the stomach. This protein is essential for the subsequent recognition, binding, and transport of vitamin B_{12} at the ileal wall. Transcobalamin II then carries it to the portal circulation. The treatment of pernicious anemia with massive amounts of dietary liver, followed by the isolation, characterization, and X-ray crystallographic structure determination of vitamin B_{12}, were major achievements of the first half of the 20th century. During the past few years, new evidence has been accumulating to suggest that more subtle, insidious and easily overlooked forms of vitamin B_{12} deficiency may occur in modern-day western society, and that the challenges of their recognition and treatment are by no means entirely solved. The fact that prolonged vitamin B_{12} depletion can lead to irreversible neural damage, coupled with the prediction that defects of absorption can arise slowly and remain entirely unnoticed as people grow older may be of special relevance at a time when the quality of life in old age is becoming a major priority issue. (*See* **Anemia (Anaemia)**: Megaloblastic Anemias.)

Dietary intake by omnivores is much greater than by vegetarians or vegans (who depend to a large extent on contamination sources, unless they deliberately take B_{12} supplements). Some B_{12}-like corrinoids in certain seaweeds have limited B_{12} activity. *In vitro*, vitamin B_{12} may be destroyed by contact with vitamin C (ascorbic acid), but *in vivo* this probably does not occur, which suggests that the catalysis of destruction may depend on free transition metal ions which are not usually present in living tissues. (*See* **Vegetarian Diets**.)

Although B_{12} intakes are much lower in Third World countries than in western countries, severe deficiency is surprisingly rare in the Third World. However, a moderate degree of deficiency has recently been reported from parts of South America, currently attributed to a combination of low intakes and impaired absorption due to gastrointestinal parasites. Fully breast-fed infants of mothers with very low intakes, or of mothers with vitamin-B_{12} malabsorption syndromes (usually pernicious anemia), may develop overt B_{12} deficiency. Older omnivores usually accumulate considerable amounts in their tissues, and in these subjects the effect of a switch to diets with low contents only becomes apparent several decades after the B_{12} supply to the internal milieu has virtually ceased.

There are still some problems with the assay of vitamin B_{12} levels in food, and 5–30% of the reported B_{12} content may be biologically inactive corrinoids. Small amounts of B_{12} arising from bacteria in the ileum can be absorbed, but B_{12} produced by bacteria in the colon is not. An efficient enterohepatic circulation of B_{12} occurs in normal people, and if this cycle is interrupted, as it is in cases of impaired intestinal absorption, this results in an additional source of losses for subjects with impaired B_{12} absorption. (*See* **Microflora of the Intestine**: Role and Effects.)

Large-scale industrial production of vitamin B_{12} makes use of the capacity of organisms such as *Propionibacterium* spp. to synthesize as much as 40 mg B_{12} per liter of growth medium. World consumption was around 5000 kg in the early 1980s.

Absorption and Tests of Status

The key stages in vitamin B_{12} utilization from food sources are depicted in **Table 1**.

Table 1 Stages of normal vitamin B_{12} absorption in humans

- Release from dietary protein by gastric acid and pepsin (this can often become impaired in older people)
- Binding to 'R-binders': glycoproteins secreted by saliva
- Transfer to intrinsic factor (IF) when R-binders are degraded by pancreatic enzymes in the intestine
- Attachment of the B_{12}–IF complex to ileal receptors, followed by endocytotic transfer across the intestinal wall. This has very precise specificity requirements and is the rate-limiting step in absorption. It is most efficient in the range of 1–2 μg B_{12}, whereas passive absorption occurs with only *c.* 1% the efficiency, but over a much wider range of intakes, so that useful amounts are absorbed when intakes are high
- Circulation in the plasma in several forms: transcobalamins (TC) I, II and III, and R-proteins (haptocorrins), of which TC II is the main tissue uptake precursor, with a half-life of only *c.* 6 min
- Storage, mainly in the liver; recycling by enterohepatic circulation; turnover at a rate of *c.* 0.1% of the body pool per day

Table 2 The Schilling test for vitamin B_{12} absorption efficiency

- Measures percentage recovery of an oral dose of labeled vitamin B_{12}, using an intravenous dose to flush the newly absorbed vitamin largely into the urine
- Cobalt-labeled vitamin B_{12} is used, and there are three usable, γ-emitting isotopes: ^{60}Co (half-life 5 years); ^{57}Co (half-life 270 days), and ^{58}Co (half-life 71 days)
- After a parenteral injection of unlabeled B_{12}, normal absorbers excrete *c.* 15% of the labeled dose within 24 h, whereas those with impaired absorption excrete less than 5%
- By using two different isotopes of cobalt simultaneously, it is possible to distinguish the different types of malabsorption, e.g., by comparing free B_{12} against B_{12} bound to intrinsic factor, R-binders, or binding proteins in food

In addition to classical pernicious anemia (lack of secretion of intrinsic factor due to atrophy of gastric mucosa or the production of autoantibodies to intrinsic factor or its intestinal binders), there are several other medical conditions that can result in impaired absorption, as well as a variety of congenital abnormalities of transport of the vitamin, which require both specialized detection procedures and specialized therapeutic measures. These include:

1. surgical procedures such as total gastrectomy, removal of ileum, or presence of blind loops of the small gut with an abnormal bacterial flora
2. the effects of certain parasites, drugs, or substances like nitrous oxide
3. the Imerslund–Gräsbeck syndrome which appears to result from lack of ileal receptors
4. pancreatic insufficiency leading to failure of digestion of R proteins
5. lack of circulating transcobalamin II

The classical procedure for the recognition of impaired absorption, specially designed to detect pernicious anemia, is the urinary excretion (Schilling) test (Table 2). Around 57% of people with pernicious anemia also have circulating antibodies to intrinsic factor in their blood, and their detection can provide further corroborative evidence of the presence and type of pernicious anemia. In conjunction with a macrocytic anemia and a standard assay of circulating plasma vitamin B_{12} or of holo-transcobalamin II, the measurement of these antibodies can be a useful screening procedure to be performed before the more complex Schilling test is undertaken.

Serum vitamin B_{12} levels are usually measured nowadays by radioisotope dilution assay, generally using pure intrinsic factor as the specific binder. Normal levels are above 200 pg ml^{-1}, and levels below 160 pg ml^{-1} (118 pmol l^{-1}) are indicative of deficiency. Many commercial kits are now available for the radioisotope dilution assay. (*See* **Immunoassays:** Radioimmunoassay and Enzyme Immunoassay.)

An older functional test of vitamin B_{12} or folate status is the deoxyuridine suppression test, usually performed *in vitro* on bone marrow aspirates. This looks directly at the cells' ability to synthesize thymidine from deoxyuridine. For B_{12}-deficient cells, B_{12} cofactor is the only addition which will partially overcome the block in conversion. This test has the potential advantage of being a functional test and of probing a specific tissue site, but it is time-consuming, and it is now mainly of research, rather than diagnostic, importance. (*See* **Coenzymes**.)

Another functional test involves the metabolism of an oral load of valine: if B_{12} deficiency is present, then methylmalonyl CoA mutase activity falls (see below) so that methylmalonic acid accumulates, and increased amounts of this byproduct are found in the plasma and excreted in the urine. Moderately raised plasma levels of methylmalonic acid can also arise in subjects with marginal vitamin B_{12} status, even without the loading dose, and this is becoming the basis for a useful diagnostic procedure for marginal status. The most commonly used assay procedure for serum or urinary methyl malonic acid is based on mass spectrometry, although other methods, such

as capillary electrophoresis, are now also becoming available. The assay is still too demanding of skill and expensive equipment for routine clinical chemistry laboratories, but it is becoming the index of choice for the demonstration of mild functional vitamin B_{12} deficiency. Circulating levels of homocysteine can provide further evidence, but since folate and vitamin B_6 status can also affect homocysteine economy, the evidence that it provides is less specific, and requires the investigation of the other vitamins.

Biological Functions of Vitamin B_{12}

Three vitamin B_{12}-dependent enzymes occur in animals. The first, methionine synthase or synthetase, has the Enzyme Commission (EC) official name 5-methyltetrahydrofolate-homocysteine *S*-methyltransferase, EC 2.1.1.13, and requires methylcobalamin as the cofactor or cosubstrate. The other two vitamin B_{12}-dependent enzymes both require adenosyl cobalamin: they are methylmalonyl-coenzyme A (CoA) mutase EC 5.4.99.2, responsible for conversion of methylmalonyl-CoA to succinyl CoA during the oxidation of propionate (see above), and leucine 2,3-aminomutase, EC 5.4.3.7, which converts L-α-leucine to aminoisocaproate as the first step in leucine degradation or synthesis. There is a rare congenital disorder in which the enzyme methylmalonyl-CoA mutase is almost absent, and this is characterized by methylmalonic aciduria, homocysteinuria, muscle cramps, mental retardation, and lethargy. Large parenteral doses of vitamin B_{12} may be helpful.

The most important biochemical reaction catalyzed by vitamin B_{12} in humans and animals is the conversion of homocysteine to methionine. However, the most obvious result of deficiency *in vivo* is a block in DNA synthesis, leading characteristically to megaloblastosis, and macrocytic anemia, which is indistinguishable, at least at the cytological level, from the megaloblastosis and anemia of folate deficiency. A good test for response of a probable case of pernicious anemia, or other B_{12}-deficiency syndrome, is an increase in circulating reticulocyte numbers following B_{12} treatment. (*See* **Amino Acids**: Metabolism; **Anemia (Anaemia)**: Megaloblastic Anemias.)

The most generally accepted explanation for the connection between B_{12} deficiency and the failure of cell division leading to anemia is the 'methylfolate trap hypothesis', in which methylene tetrahydrofolate polyglutamate, the intracellular cofactor for thymidine synthesis, becomes depleted by excessive conversion (i.e., reduction) to methyltetrahydrofolate polyglutamate. The latter is unable to transfer its carbon unit (methyl group) to homocysteine and thus complete the folate cycle back to the methylene form, because of the absence of B_{12} cofactor (methylcobalamin). At the same time, short-chain methylfolate glutamates from the diet are poorly utilized and therefore excreted, so that intracellular folate levels decline. (*See* **Folic Acid**: Physiology.)

An alternative interpretation, the 'formate starvation hypothesis', maintains that because B_{12} deficiency causes a reduction in methionine levels, an important consequence of its deficiency is a reduced conversion of the methyl group of methionine to formyltetrahydrofolate, which is a good precursor of folate polyglutamates and hence of active methylene groups for thymidine synthesis. In the absence of vitamin B_{12}, formate accumulates in blood, liver, and brain, and there is increased formate excretion in the urine. In support of this hypothesis, formylfolate, but not tetrahydrofolate, can correct the functional evidence of B_{12} deficiency, and the organism is still able to oxidize the methyl group of methylfolate to methylene- and formyl-folates. One very useful experimental tool has been the use of nitrous oxide, which can chemically inactivate vitamin B_{12} *in vivo*, e.g., in experimental animals. This procedure has permitted the rapid induction of tissue B_{12} deficiency, without the tedious and protracted use of B_{12}-deficient diets.

An important functional result of vitamin B_{12} deficiency is the failure of maintenance of nerve tissue myelin, which accounts for the irreversible neurological damage seen after prolonged B_{12} deficiency. This lesion may also be connected biochemically with the block in methionine formation (and hence in phospholipid metabolism), but its etiology has not yet been fully elucidated. There may also be other disturbances in lipid metabolism in B_{12}-deficient subjects.

Human Vitamin B_{12} Requirements

In the absence of the metabolic abnormalities that can affect B_{12} absorption and utilization, human dietary requirements for the vitamin are small. A purely nutritional deficiency may, however, occur in strict vegans and lifelong vegetarians such as strict Hindus who have very low intakes because they do not eat any animal products. Studies of the amount of B_{12} needed to cure this, together with studies of populations with low intakes who, nevertheless, do not show deficiency signs, have indicated that the requirement is generally less than $1\,\mu g\,day^{-1}$ for adults, and is probably in the range $0.1–1\,\mu g\,day^{-1}$. There is little firm evidence for a major increase in requirement during pregnancy and lactation, but modest increments in the recommended dietary allowances (RDAs) are usually applied to these physiological

states. The amount secreted in breast milk ranges from 0.1 to 3 μg day^{-1}. Infants who were breast-fed by mothers who were themselves deficient and were secreting milk with a very low content of the vitamin have in several reported instances been diagnosed with B_{12}-responsive megaloblastic anemia. (*See* **Lactation**: Human Milk: Composition and Nutritional Value; Physiology.)

The early recognition of B_{12} deficiency in certain immigrant vegetarian groups, especially Asians, merits attention, especially in western countries where bacterial contamination sources of the vitamin are eliminated more completely than in developing countries.

Typical B_{12} intakes by omnivorous people in western countries are 3–30 μg day^{-1}.

Food table values of B_{12} contents of foods have been obtained mainly by microbiological assays and some further verification is needed. Vitamin B_{12} is stored mainly in the liver (60%) and muscles (30%). Methylcobalamin is the most abundant form in human plasma, whereas in most human tissues, deoxyadenosyl cobalamin is the most abundant, with aquacobalamin coming second.

At high intakes, there is little evidence of toxicity, and injections of as much as 3 mg day^{-1} have been used in an attempt to treat fatigue and neurological disorders. However, there is no evidence that such high doses can have any benefit for normal subjects and they may occasionally result in allergic reactions. Degradation of B_{12} to B_{12} antagonists in multinutrient preparations has been claimed.

The RDAs from the World Health Organization (WHO) currently stand at 1 μg day^{-1} for adults. In the UK the reference nutrient intake for vitamin B_{12} is 1.5 μg day^{-1} for adults, and in the USA, the dietary reference intake is 2.4 μg day^{-1}. Thus there is a rather large variation between the different sources of reference values. Values for pregnancy and lactation are generally slightly higher than for nonpregnant, nonlactating adults. A typical treatment schedule for pernicious anemia would be 500 μg by injections every 2–3 months.

Vitamin B_{12}: Increased Vulnerability in Older People

The aging process is characterized by progressively increasing vulnerability to serious impairment of vitamin B_{12} absorption, and hence the development of functional deficiency. The most widely known example of this is pernicious anemia, often resulting from autoantibodies which interfere with the functions of intrinsic factor, and which can be detected by blood antibody analysis. Another common cause is atrophic gastritis, which reduces gastric acid production and thus interferes with the liberation of the vitamin from the protein binders in food. Several recent studies have highlighted the evidence for a relatively common, mild vitamin B_{12} deficiency in older people living in western countries. There is recent evidence of racial differences in vulnerability to vitamin B_{12} deficiency in older Americans: white and Latin subjects are more vulnerable than black or Asian ones. Raised methylmalonic acid levels and lowered levels of holotranscobalamin II are found. As absorption becomes more severely impaired, the normal B_{12} enterohepatic cycle is also affected, which increases the rate of loss of B_{12} (normally *c.* 0.1% day^{-1}). The longer a deficiency state goes undetected, the greater the danger of permanent neurological damage. In the absence of the highly efficient intrinsic factor-catalyzed absorption pathway, the alternative passive absorption route is only about 1% as efficient; therefore an intake at least 100-fold greater than the normal requirement is needed. At around 100–200 μg day^{-1} this is not available (in the UK) in nonprescribed vitamin supplements; therefore diagnosis and treatment are of critical importance. There is some concern that recent public health interventions designed to increase the level of food fortification with folate may mask the anemia of incipient vitamin B_{12} deficiency, and thus delay diagnosis.

COBALT

A MacPherson and J Dixon, The Scottish Agricultural College, Auchincruive, Ayr, UK

Background

Cobalt was first isolated by a Swedish chemist, Brandt, in 1735 and characterized more fully by Bergman in 1780. However, it had been used as an ore for millennia to give a bright blue color to Egyptian pottery and Iranian glass from 2600 to 2250 BC, respectively. The name is derived from the German word *kobold*, meaning an evil spirit or gnome, as copper miners working in the Harz mountains believed that these spirits delighted in exposing ores that looked like copper but yielded none when smelted.

Cobalt is widely distributed in the earth's crust but it is only 30th in order of abundance and thus less common (at 25 mg kg^{-1}) than all other elements in the first transition series with the exception of scandium (22 mg kg^{-1}). There appears to be some overall loss of cobalt during soil formation as the world mean value is quoted as 12 mg kg^{-1} and Scottish soils at 8 mg kg^{-1}. World consumption of cobalt was 31 400 tonnes in 1997 and is projected to increase by 50–100% by 2012. Asia, including China, is the largest consuming region, and the chemical sector is the largest end user. The use of cobalt in chemicals for rechargeable batteries is having a significant impact on total consumption.

The metal itself is silvery in appearance with a bluish tinge and considerably harder than iron. It has only one naturally occurring isotope, ^{59}Co, but this can be converted to radioactive ^{60}Co by bombardment with thermal neutrons. This has a half-life of 5.271 years and decays to nonradioactive ^{60}Ni. The radioactive isotope ^{60}Co is used medically in cancer therapy, where it can selectively destroy abnormal areas in the brain, such as tumors or arteriovenous malformations, while leaving normal tissue unaffected. This procedure has been termed 'radiosurgery.' Nitrosylcobalamin shows potential as a biologically compatible and selective chemotherapeutic agent as tumor cells have surface receptors for vitamin B_{12}. ^{60}Co also affords a concentrated source of radiation for research purposes. ^{57}Co is used in the assay of vitamin B_{12} by radioisotope dilution.

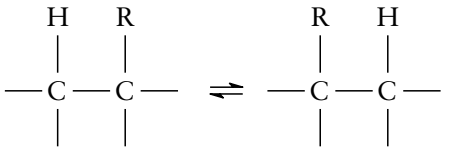
Like iron, cobalt is a ferromagnetic element, but is considerably less chemically reactive. It is stable to oxygen, and the range of oxidation states is considerably fewer than for earlier members of the first transition series. The commonest are $+2$ and $+3$, but, as the latter is a strong oxidizing agent, it decomposes rapidly in aqueous solution with the production of oxygen. As a result, only a few Co^{3+} salts exist, and these tend to be unstable. However, Co^{3+} forms a large number of coordination complexes, particularly with nitrogen donor ligands, and this is important in its biological role as a structural component of vitamin B_{12}. This structure is characterized by a 'corrin' ring, where the cobalt is coordinated to four coplanar nitrogen atoms with another (imidazole) nitrogen in the fifth position. The sixth position, however, makes vitamin B_{12} unique as, here, the cobalt is bonded to carbon, making it to date the only naturally occurring organometallic vitamin.

The incorporation of cobalt into the corrin ring affects its reduction potential and gives it the three consecutive oxidation states shown in eqn (1). The reduced Co^{+} species is a highly reactive compound and can liberate hydrogen from water. Both vitamin B_{12r} and vitamin B_{12s} are very labile in the presence of air and are instantly oxidized to the Co^{3+}

$$\underset{\text{Red}}{\text{Vitamin } B_{12}(Co^{3+})} \underset{O_2}{\overset{NaBH_4,H^+}{\rightleftharpoons}} \underset{\text{Brown}}{\text{Vitamin } B_{12r}(Co^{2+})}$$

$$\underset{O_2}{\overset{NaBH_4,OH^-}{\rightleftharpoons}} \underset{\text{Blue–gray green}}{\text{Vitamin } B_{12s}(Co^{+})} \qquad (1)$$

compound cobalamin. The sixth coordination site is crucial to the biological role of vitamin B_{12}, where it is involved as a hydrogen carrier in substitution reactions of the type shown in eqn (2):



(2)

Occurrence in Soil

This is primarily dependent on the geological nature of the parent material from which the soil is derived. Thus, soils formed from old red sandstone, granitic, and other acid igneous, limestone, and predominantly sandy rocks are liable to be cobalt-deficient.

The availability of soil cobalt and hence its uptake by pasture and crops are affected by the natural drainage conditions of the soil, and so cobalt deficiency is most likely to be found on freely drained soils. Improvement of upland pasture by the removal of heather and the introduction of more productive grass species, raising the soil pH by liming, and improving the drainage tend to lower the availability of soil cobalt and thus induce cobalt deficiency in the grazing animal where none existed previously. Soil maps have been produced based on the cobalt content of the B horizon and these categorize the concentrations (in $mg\,kg^{-1}$) as follows: low <5, medium 5–15 and high >15. Areas falling into the 'low' category have the highest risk of cobalt deficiency. Soils that have a high content of secondary manganese or iron oxides adversely affect cobalt availability, as they strongly absorb native cobalt.

Concentrations in Food and Dietary Intakes

Cobalt, like other trace elements, tends to be concentrated in young actively growing parts of plants, with green leafy material often having the highest concentrations. Concentrations tend to be lower in stems, roots, tubers, and cereal grains and also tend to diminish as maturity is reached. Typical values for some foods are given in Table 1 but are scarce. A dietary and nutritional survey of British adults conducted in 1995 concluded that average dietary intakes of cobalt were lower than those reported previously. The Committee on Toxicology stated that levels of cobalt in the UK diet are not a cause for toxicological concern.

There is, however, a wide margin of safety between the cobalt concentration of ordinary diets and toxic levels, which are around 250–300 $mg\,kg^{-1}$ and thus more than 1000 times normal dietary concentrations. High cobalt levels have, however, been implicated as a triggering factor in cases of severe cardiac failure in heavy beer drinkers (up to 12 l daily). Cobalt had been added as a foaming agent in concentrations of 1.2–1.5 $mg\,l^{-1}$, but high alcohol and cobalt intakes, together with poor-quality diets, combined to produce a distinctive cardiomyopathy, and so this practice has been discontinued. Cardiomyopathy has also been reported in humans following industrial exposure to cobalt. Studies in Germany have suggested that

Table 1 Range of cobalt concentrations in foods

Food	*Co ($mg\,kg^{-1}$)*[a]	*Co ($mg\,kg^{-1}$)*[b]	*Co ($mg\,kg^{-1}$)*[c]
Green leafy vegetables	0.20–0.60	0.009	0.01–0.12
Dairy products	0.01–0.03	0.004	0.0005–0.001
Liver and kidney	0.15–0.25	0.06	0.004–0.47

solutions used for total parenteral nutrition (TPN) are virtually all contaminated with cobalt, but, even so, several preparations include supplemental cobalt in addition. Serum cobalt concentrations in preterm babies on TPN at $1.44 \pm 0.48\,\mathrm{ng\,l^{-1}}$ have been found to be significantly higher than those ($0.67 \pm 0.47\,\mathrm{ng\,l^{-1}}$) of age-matched controls. No toxic consequences have been reported, but any clinical consequences of long-term cobalt surplus have yet to be studied systematically. Most species studied have a high tolerance to cobalt, particularly sheep, but recent evidence suggests that this does not extend to lambs < 6 weeks old. Cattle are more susceptible to toxic effects from excess cobalt intakes.

Cobalt is present in very low concentration in body fluids and tissues, with the total content of an adult human body being < 1.5 mg, with liver, heart, and bone containing the highest concentrations. Reference levels are said to be 0.22, < 0.16, 0.06, 0.11, and < 0.08 mg of cobalt per kilogram (dry matter) in liver, spleen, kidney, heart, and pancreas, respectively. Cobalt deficiency in ruminants has been diagnosed on the basis of liver concentrations of $< 0.06\,\mathrm{mg\,kg^{-1}}$ (dry matter) with values $> 0.1\,\mathrm{mg\,kg^{-1}}$ being regarded as adequate. Deficiency during pregnancy will result, with the offspring being born with inadequate concentrations, and this has an adverse effect on their viability. Supplementation of the dams diet or by direct treatment overcomes this problem.

Cobalt differs from all other essential trace elements in that it is required by the body in a preformed compound, vitamin B_{12}, whereas the other elements are required in ionic form and then converted into their metabolically active species. Animals and humans are unable to synthesize vitamin B_{12}. This ability is found only in some bacteria and algae. Some of these occur in ruminants, so that, provided there is an adequate supply of dietary cobalt salts ($> 0.1\,\mathrm{mg\,kg^{-1}}$, dry matter), vitamin B_{12} is synthesized in the rumen and then absorbed lower down the intestinal tract. Humans derive their essential vitamin B_{12} through the consumption of animal-related foods. It has been thought that animals do not produce or require these cobalt-related compounds, and strict vegetarians and vegans are at risk from pernicious anemia, unless they take synthetic supplements. Recent evidence suggests that this may not be strictly true, but it remains practically so, as the amounts involved would be of little nutritional significance.

The cobalt atom in vitamin B_{12} catalyzes the reactions of two B_{12} coenzymes – adenosyl cobalamin and methyl cobalamin – which are essential cofactors in the activity of methylmalonyl-coenzyme A mutase and methionine synthetase. The unique nature of the cobalt–carbon bond in adenosylcobalamin means that it can undergo reversible homolytic splitting with the production of free radicals, which are stabilized by the cobalt atom. This allows the intramolecular rearrangements of the type referred to earlier to take place. Methylcobalamin has a similar cobalt–carbon bond that is involved in the synthesis of methionine. The mechanism has not yet been fully established, but it is thought that vitamin B_{12s} (in the Co^{+} form) is involved, as it can undergo rapid addition and substitution reactions.

Analytical Methods

Sample Preparation

Since many of the available analytical methods require cobalt to be in solution, solid samples such as foods and clinical and biological materials need to be subjected to a primary dissolution process. Most commonly, this involves either acid digestion or dry-ashing procedures, which mineralize cobalt through destruction of the organic matter present. The most frequently used ashing technique is by muffle furnace at temperatures within the range 450–550 °C. Alternatively, there are low-temperature ashers that operate between 100 and 200 °C under low pressure using a gaseous oxidant, usually oxygen or an oxygen/tetrafluoromethane mixture; the oxidant is activated by a high-frequency electromagnetic field. Dissolution of cobalt from the ashed material is usually achieved using dilute acid.

There are a number of different combinations of acids and oxidizing chemicals that have proved to be effective digestion mixtures, namely nitric acid/perchloric acid, nitric acid/perchloric acid/sulfuric acid, and sulfuric acid/hydrogen peroxide. These operations have been traditionally performed in an open Kjeldahl-type flask; however, much more rapid digestion procedures have recently been developed using Teflon bomb vessels and microwave heating.

Dissolution of cobalt from soils and related materials can be performed using strong acid digestion, normally hydrofluoric acid or a hydrochloric acid/nitric acid mixture (aqua regia), whereas the more readily available fractions of cobalt are extracted with dilute acetic acid. Water samples and biological fluids such as urine and blood plasma can be analyzed directly using one of the more modern sensitive techniques such as electrothermal atomization atomic absorption spectrometry (ETAAAS).

Where limited sample preparation of solid material, other than drying and milling, is required, a solid sample presentation can be made using direct current arc emission spectrometry (DCarcES), direct current

plasma atomic emission spectrometry (DCPAES) and ETAAAS; presentation in slurry form can also be made with the last two techniques. Nondestructive analysis can be performed using X-ray fluorescence (XRF).

Analytical Techniques

Traditional gravimetric and titrimetric methods have much poorer levels of detection for cobalt than modern instrumental techniques and are subject to interferences. Two of the more commonly used precipitating reagents are 1-nitroso-2-naphthol (interference from copper and iron) and anthranilic acid (interference from iron, nickel and zinc). Typical titrants are potassium cyanide (interference from copper, mercury, and zinc), potassium hexacyanoferrate (interference from manganese), and ethylenediaminetetra acetic acid (EDTA) (interferences from nickel, zinc, and copper).

Prior to the rapid expansion of flame atomic absorption spectrometry (FAAS) in the 1960s, the analysis of cobalt at the microgram level was performed routinely by colorimetric techniques using spectrophotometry in the ultraviolet and visible wavelength range (300–700 nm). However, this technique is also subject to chemical interference from a wide range of other elements. These have to be eliminated either by the addition of masking agents or buffers, or by solvent extraction of the cobalt complex. The more widely used complexing agents are ammonium thiocyanate (interferences from iron and copper), nitroso-*R*-salt (interferences from iron, chromium, nickel, vanadium, and copper), 1-nitroso-2-naphthol (interference from copper and iron), and sodium diethyldithiocarbamate (interferences from iron, aluminum, chromium, titanium, manganese, copper, and nickel). By applying modern chemometric procedures to spectrophotometric measurements, cobalt can be determined simultaneously with other trace elements. Flow injection analysis has automated many cobalt colorimetric methods. Recently, sensitive spectrophotometric methods have been developed that depend on the catalytic effect of the cobalt iron on the oxidation reaction between hydrogen peroxide and *o*-dihydroxybenzene derivatives such as tiron (disodium 1,2-dihydroxybenzene-3,6-disulfonate), catechol, quinazarin, and gallocyanine; detection limits at the picogram level are obtainable. A more recent novel utilization of catalysis incorporates chemiluminescence sensors that measure the catalytic activity of cobalt on the reaction between luminol and certain oxidizing agents such as hydrogen peroxide or periodate salts.

The following spectrographic techniques have been used for the analysis of cobalt (approximate detection limits have been quoted to an order of magnitude): FAAS (detection limit, $0.01\,\mu g\,g^{-1}$), ETAAAS (detection limit, $0.0002\,\mu g\,g^{-1}$), inductively coupled plasma atomic emission spectrometry ICPAES, detection limit, $0.01\,\mu g\,g^{-1}$), inductively coupled plasma mass spectrometry (ICPMS, detection limit, 0.0002 $\mu g\,g^{-1}$), DCarcES (detection limit, $0.3\,\mu g\,g^{-1}$), spark source mass spectrometry (SSMS, detection limit, 0.005 $\mu g\,g^{-1}$) and DCPAES (detection limit, $0.01\,\mu g\,g^{-1}$).

FAAS has been the most extensively used technique for the routine determination of cobalt at the microgram level in food, agricultural, and biological materials. The technique is relatively free from chemical and spectral interferences, and a large number of preconcentration chemical procedures have been developed to improve detection levels. Ammonium pyrrolidinedithiocarbamate and sodium diethyldithiocarbamate are the two principal chelating agents that have been used for multitrace element complexation prior to solvent extraction, although a more cobalt-specific chelate is 1-nitroso-2-naphthol. A range of different organic solvents have been used for extraction of the chelated cobalt compounds, the two most common being methyl isobutyl ketone and chloroform. Ion-exchange resins such as chelex-100 or C-18 sorbant materials can be used as a method of on-line preconcentration in FIA systems for FAAS.

ETAAAS has proved to be sufficiently sensitive for the determination of cobalt at the nanogram level in clinical and biochemical samples. The technique is more susceptible to sample matrix interferences than FAAS, but these have been significantly reduced by using FAAS-type preconcentration techniques as separation procedures for the removal of major elements. Alternatively, matrix modifiers such as palladium, magnesium, or certain inorganic salts such as ammonium phosphate or thiocyanate have proved effective. Graphite tubes are normally used for atomization, but more recently, tungsten tubes have been found to be equally effective. Automatic on-line preconcentration systems have been developed that utilize a microcolumn packed with Muromac A-1 chelating resin. Analysis of solid samples is now possible through the incorporation of minature cups that can hold powdered samples. The resonant absorption wavelength for cobalt lies in the ultraviolet region at 240.7 nm. Measurements are therefore subject to background interferences that occur to a greater degree in electrothermal rather than flame atomization. All modern AAS instruments have automatic background correction; there are four different types: Zeeman, deuterium continuum, Smith–Hieftje, and xenon continuum in the simultaneous

multielement atomic absorption continuum instruments. The normal detection limit for cobalt as determined by ETA-AAS has been further improved through the coupling of laser technology with electrothermal atomization. This is either in the form of laser-excited atomicfluorescence spectrometry or with the laser-enhanced ionization technique.

The 1980s saw a rapid growth in the number of commercial ICPAE spectrometers being used for multielement analysis. Since the detection limit for cobalt by ICPAES is similar to that for FAAS, similar preconcentration techniques have been applied. The two most prominent emission lines are almost equal in sensitivity; however, since the line at 238.8 nm is subject to strong spectral interference from iron, the cobalt line at 228.6 nm has been preferentially used, but this suffers from a significant spectral interference from titanium and slight spectral interference from nickel and iron. The exact magnititude of the interfering spectral overlap depends on the spectral resolution of each particular type of spectrometer. Interfering elements that produce strong spectral overlap used to be removed by chemical separation prior to instrumental analysis, whereas those that exhibit a small degree of spectral overlap can be corrected for by appropriate interelement spectral subtraction procedures.

Since the mid 1980s, there has been a steady growth in the application of ICPMS to multielement ultratrace analysis of clinical and biochemical samples. Detection limits are about the same as for ETAAAS, and therefore, cobalt can be determined at the nanogram level. Interferences occur from the production of polyatomic ions within the plasma that have the same atomic mass as ^{59}Co, e.g., calcium–oxygen and argon–sodium. These are corrected for by measuring the background levels of such ions in simulated blank solutions. Automatic on-line preconcentration systems have also been developed for ICPMS.

DCarcES, SSMS, and XRF have mainly been applied to the direct analysis of cobalt in solid samples such as soils and related materials; with these techniques, matrix matching of samples with calibration standards and choice of internal standards are the most critical aspects of the determination. The application of the DCarcES to plant and agricultural materials has been largely superceded by AAS and ICPAES.

Electrochemical techniques have proved to be very effective in the determination of cobalt at the microgram and nanogram levels in food, biological, and environmental samples, being among the most sensitive techniques for the determination of cobalt in natural waters. During the 1980s, the technique of adsorptive stripping voltametry was developed as the most sensitive of the polarographic methods for trace metal analysis. For the determination of cobalt, the square wave stripping is more sensitive than the differential stripping mode. Electrolytic preconcentration of cobalt at the mercury electrode is carried out with chelated cobalt, since the free cobalt ion would be irreversibly adsorbed. The most widely used chelating agent has been dimethyl glyoxime; adsorption of the cobalt dimethyl glyoximate occurs at -0.7 V, and the voltammetric peak at -1.12 V in a cell system using a silver/silver chloride/potassium chloride electrode as the nonworking electrode. Interference from zinc can be masked by the addition of nitrilotriacetic acid or sodium iminodiacetate; nickel interferes if present in great excess, but this is reduced by using alternative chelating agents such as 1,2-cyclohexanedione dioxime or α-furil dioxime for complexing the cobalt. More recently, cathodic stripping voltammetry coupled with FIA has become a successful addition to the range of electrochemical techniques used for cobalt analysis.

High-performance liquid chromatography (HPLC) has been successfully applied to the determination of cobalt and other trace metals in plant materials, natural waters, and environmental samples, and detection levels of nanogram quantities are obtainable. The use of disubstituted dithiocarbamates such as sodium diethyldithiocarbamate, ammonium pyrrolidinedithiocarbamate, and ammonium bis(2-hydroxyethyl)dithiocarbamate has been favored, since they rapidly form stable complexes with a wide range of trace metals. These metal complexes can be separated chromatographically using alkyl-bonded silica columns and quantitatively determined with ultraviolet/visible diode array detectors or electrochemical detectors. Precolumn derivitization can be done off-line using solvent extraction for water-insoluble complexes or in-line using a presentation column loaded with an appropriate ion-pair reagent such as cetyltrimethylammonium bromide-dithiocarbamate. On-column derivatization can be performed by including the dithiocarbamate reagent in the mobile phase, usually a water/methanol mixture; however, this process is less sensitive than precolumn derivatization. Other complexing chelating agents that can be used include EDTA or 4-(2-pyridylazo)resorcinol. Metal ion chromatography can be applied to cobalt analysis using an appropriate complexing chelating agent such as pyridine-2-carboxyaldehyde phenylhydrazone as a stationary phase immobilized on a silica matrix.

HPLC has been successfully interfaced with a wide range of spectroscopic instruments (FAAS, ETAAAS, ICPAES, and ICPMS) to provide powerful techniques

for cobalt speciation analysis. The cyanocobalamin form of cobalt has been measured in blood serum, seminal fluid, and milk serum. Vitamin B_{12} analogs have also been determined in animal carcass tissue. These speciation techniques should see intense development in future.

Neutron activation analysis can be used to determine the amount of cobalt in biological and environmental samples; typical detection levels are $0.03\,\mu g\,g^{-1}$. This technique usually requires a post-irradiation period of around 3 weeks before γ-ray emission from the ^{60}Co isotope can be measured. Radiation flux levels are usually around 10^{12}–10^{13} neutrons $cm^{-2}s^{-1}$. Concentration techniques using dithiocarbamate complexation are usually applied to improve detection levels.

Introduction

The most valuable constituents in cocoa are cocoa butter and flavors. Both are specific for seeds of *Theobroma cacao* L. Whilst the quality of cocoa butter is not changed during processing, the particular flavor of cocoa depends on profound chemical reactions which take place during processing and manufacturing. The unprocessed cocoa seed would not give the characteristic flavor when roasted unless it was first fermented and dried. The sequence of raw cocoa processing in the tropics and then manufacturing is essential since reactions during fermentation depend on water and enzymes of the living seed, whilst manufacturing comprises nonenzymatic reactions in a dry lipid phase. Raw cocoa beans are the link between processing (normally in the tropics) and manufacturing (normally in the consuming

countries). A large number of essential constituents of cocoa flavor are produced during roasting of raw cocoa from flavor precursors formed during tropical processing. Reactions during fermentation and drying resulting in raw cocoa beans and subsequent reactions taking place during manufacturing are described in this first article.

Chemistry of Raw Cocoa Processing

Both the seeds and the pulp are essential components in raw cocoa processing. However, the reactions which are essential for raw cocoa quality take place within the seeds alone and not in the pulp. Enzymes of the seeds are directly involved but microorganisms only indirectly, in that bacteria and fungi are responsible for the degradation of the pulp, and their metabolites, especially acetic acid, which are instrumental in the subsequent changes in the seeds. Organisms participating in the direct attack on the nibs during the late stage of fermentation and overfermentation are also important.

Processing depends on the chemical composition and physiological state of the beans, their enzymes, and their pre- and postmortem subcellular structures. They greatly affect the final product quality.

Biology of the Seed

Two commercially exploited types of the species *T. cacao*, Criollo and Forastero, are distinguished on the basis of fruit morphology and geographic origin. Criollo gives fine-flavor cocoas, although in low yields, while the more vigorous, high-yielding Forastero subtypes and hybrids predominate in plantations worldwide. Cocoa pods contain about 35–45 seeds consisting of the embryo and the shell, which is covered when ripe by a mucilaginous pulp, the endocarp (Figure 1). The main parts of the embryo are two folded cotyledons connected by a small embryonic axis. A rudimentary, skin-like endosperm covers the surface of the embryo. After fermentation the shell, covered with residues of pulp, comprises about 12–16% of the seed dry weight, depending on bean size and pulp degradation during fermentation. The dry weight of a seed varies considerably, but is approximately 1.0–1.2 g. Only the cotyledons are used for cocoa and chocolate manufacturing and in these the leaf mesophyll is the dominating tissue, consisting of two types of cells which differ in composition.

About 80% of the cells store lipid and protein, the major volume of which is occupied by a large number of individual lipid bodies of constant size (about 2 μm) surrounding one or more branched protein storage vacuoles and amyloplasts. The remaining 20% of the cells are polyphenol storage cells. Their lumen is almost entirely occupied by one central vacuole containing all the stored polyphenols and purines.

Figure 1 Unfermented cocoa seeds showing the pulp, the testa and the cotyledons. Reproduced from Cocoa: Chemistry of Processing. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Subcellular structures in the lipid and protein storage cells control pre- and postmortem reactions during fermentation, which are not the same as in cell free systems. On the subcellular level *in vivo*, the situation can roughly be described as a dispersed lipid phase (lipid bodies) in a continuous water phase (cytoplasm; Figure 2). During fermentation, the cells are killed by heat and acetic acid, but postmortem structures are maintained. In the cell lumen, with low concentrations of acetic acid, the lipid bodies fuse *in situ*, and they form, more or less, a continuous lipid phase which separates cytoplasmic inclusions as a hydrophilic dispersed phase. In contrast, in the presence of a high concentration of acetic acid, fusion of the lipid bodies is more extensive, causing complete

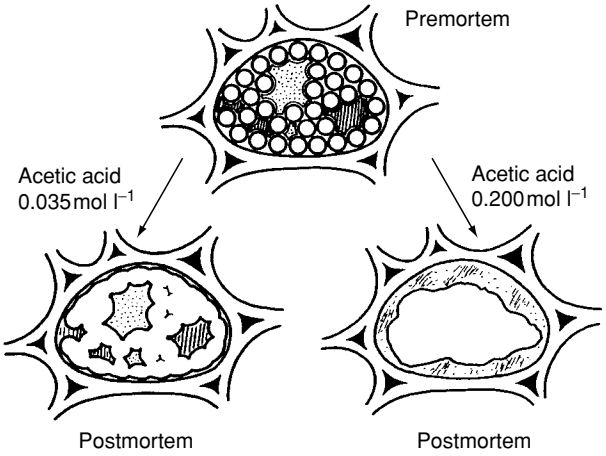

Figure 2 Schematic representation of electron microscopic aspects of postmortem changes in mesophyll cells caused by different concentrations of acetic acid during fermentation-like seed incubation. Spherical lipid globules in the living cell fuse *in situ* (left) or form a central bulk of lipid (right). Hydrophilic compartments are indicated by dots or dashes. Reproduced from Cocoa: Chemistry of Processing. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

segregation of the lipid in the cell center (Figure 2). In the first case, intracellular diffusion of water-soluble compounds is reduced by lipid barriers. In the latter case, diffusion is not restricted. Proteolysis, browning reactions, acid diffusion, and flavor precursor formation mutually depend on these structures.

Composition of Unfermented Cocoa Seeds

The prominent secondary compounds are flavonoids and purines (theobromine and caffeine). The storage reserves include predominantly cocoa butter but also protein and starch. All these compounds are stored in the cotyledons. The composition of ripe seeds is shown in Table 1. Differences of cocoa butter, proteins, and pigments are found between Forastero and Criollo types.

Cocoa Butter

Fat, the main storage component, on average comprises 53–58% of the cotyledon dry weight. It contains about 95% triacylglycerols, 2% diacylglycerols, <1% monoacylglycerols, 1% polar lipids, and 1% free fatty acids (as percentages of lipids). Triacylglycerols consist of about 37% oleic (O), 32% stearic (S), 27% palmitic (P) and 2–5% linoleic (L) acids (as percentages of total fatty acids). Other saturated and monounsaturated fatty acids do not contribute more than about 2% of the fatty acids. These values are typical of fermented beans but do vary between samples, and between genetic and geographic origins. This is also true of the complex fatty acid composition in triacylglycerols. In cocoa butter, the disaturated triacylglycerols, mainly POS, SOS, and POP predominate by far over monosaturated triacylglycerols,

mainly POO and SOO. The melting temperature of cocoa butter at 31–34 °C is an essential characteristic. Differences of fat hardness are reflected in the iodine value of cocoa butter and the ratio of disaturated to monosaturated triacylglycerols (Table 2B, C). South American cocoas are the softest compared with cocoa from Asia and Africa. Storage fat accumulation during seed development undergoes characteristic changes in fatty acid composition (Table 2A). Climate, demonstrably the ambient temperature and stress due to heat or drought, affects biosynthesis and thus the final composition of triacylglycerols, and the melting and crystallization characteristics of cocoa butter. Whilst the amount of fat per seed depends on both, genetics and physiology of pod development, effects due to genetic differences or the process of fermentation on cocoa butter quality are not unequivocal. (*See* **Fatty Acids**: Properties; **Triglycerides**: Structures and Properties.)

Polyphenols

Flavonols are the major components. The order of quantities in Forastero types is (approximate weight percentages of total polyphenols): proanthocyanidins (58–65%), catechins (29–38%), then anthocyanins (1.7–4.0%). Specific compounds detected include: anthocyanins (3-α-L-arabinosidyl cyanidin and 3- β-D-galactosidyl cyanidin); catechins ((−)-epicatechin, (+)-catechin, (+)-gallocatechin, (−)-epigallocatechin). Additionally, several (up to eight) proanthocyanidins (di- and oligomeric) and proanthocyanidinglycosides (predominantly based on (−)epicatechin) have been isolated and identified. Three flavonols have been found as minor constituents: quercitin, quercitin-3-glucoside, and quercitin-3-galactoside. Up to 17 phenolic acids and esters have also been reported. The total amount of seven of them comprise not more than 23 p.p.m. of the seed dry weight (phloroglucinol, protocatechuic acid, vanillic acid, *o*-hydroxyphenylacetic acid, *p*-coumaric acid, caffeic acid, ferulic acid). (*See* **Tannins and Polyphenols**.)

Anthocyanins and their aglyca are lacking in Criollo-type seeds but provide the characteristic color of Forastero seeds. They are also taken as an indicator of the 'degree of fermentation.' Colorless proanthocyanidins and catechins are strongly astringent and are effective tannins. Their enzymatic oxidation and polymerization cause browning reactions after cell wounding and reduction of astringent taste. Cocoa polyphenols are strong antioxidants which are increasingly considered as antioxidative protectors in food. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Anthocyanins and their aglyca are lacking in Criollo-type seeds but provide the characteristic color of Forastero seeds. They are also taken as an indicator of the 'degree of fermentation.' Colorless proanthocyanidins and catechins are strongly astringent and are effective tannins. Their enzymatic oxidation and polymerization cause browning reactions after cell wounding and reduction of astringent taste. Cocoa polyphenols are strong antioxidants which are increasingly considered as antioxidative protectors in food. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Alkaloids

The composition of methylxanthines in cocoa seeds is genetically variable but characteristic of cocoa. Theobromine (1–2%, dry weight) and caffeine (0–2%, dry weight), together with traces of theophylline and 7-methylxanthine, are found. They are not metabolized during fermentation. Theobromine plays a role in the bitter taste of cocoa. Several phenolic amines and alkaloids derived from tyrosine and tryptophan have been detected at very low levels (3–40 $\mu g\,g^{-1}$) in both unroasted and roasted cocoas. (*See* **Alkaloids**: Toxicology.)

Sugars and Acids

Besides a total of around 12% (dry weight) of polysaccharides (Table 1), the free sugar content in cocoa seeds is not more than 2–4% (dry weight). Sucrose is the major component (about 90% of total sugars), followed by fructose plus glucose (about 6%). In addition, galactose, raffinose, melobiose, sorbose, mannotriose, xylose, arabinose, mannitol, and inositol have been detected by several investigators in

minor quantities. (*See* **Carbohydrates**: Classification and Properties.)

Volatile acids are not found in fresh cocoa beans, but nonvolatile acids are found in low concentrations. Phosphoric, malic plus tartaric acids were found to make up 0.32% (dry weight), oxalic acid 0.35%, and citric acid 0.73%. These acids in unfermented seeds are not metabolized during processing nor do they contribute to cocoa quality.

Proteins and Amino Acids

Correct analyses of proteins strictly depend on suitable protection against tanning, especially against protein–quinone reactions. The protein content in the cotyledons of ripe seeds varies between 10 and 16% (dry weight). Criollo cocoa seeds have been reported to contain less protein than Forastero seeds. The proteins of Forastero seeds reveal about 16 peptide bands in sodium dodecyl sulfate–polyacryl amide gel electrophoresis (SDS-PAGE): four of them predominate in amounts. They are subunits of vacuolar storage proteins. One of these polypeptides is an albumin of 21 kDa, characterized as a Kunitz protease inhibitor (52% (w/w) of total protein). Three – the 47-kDa, the 31-kDa, and the 16-kDa polypeptides – make up about 43% (w/w) of total protein. They are subunits of the vicilin-type (7*S*) globulin, a glycoprotein, each of them consisting of multiple pI-forms. The 31-kDa and the 16-kDa subunits are posttranslational processing products of the 47-kDa subunit. The native (7*S*) globulin is a trimer (139-kDa) composed of 47-kDa and (31-kDa7 + 16-kDa) subunits. It is almost unsoluble at pH < 5.0. The amino acid sequences of the major polypeptides (47, 31 and 21 kDa) and their precursors have been derived from the nucleotide sequences of the corresponding cDNAs and genomic clones from immature cocoa beans. The sequence of cocoa (7*S*) globulin is unique but similar to that of cotton seeds and is different from those of other plants. Cocoa seeds do not contain legumin-like (11*S*) globulin.

The fresh cotyledons from ripe seeds contain about 5 mg g^{-1} (dry weight) of free amino acids. Acidic amino acids dominate. (*See* **Amino Acids**: Properties and Occurrence.)

Enzymes

Various enzymes have been identified in cotyledons of fresh, ungerminated cocoa seeds which in part are active during postmortem fermentation or drying, including glycosidases, invertase, proteases, polyphenoloxidase, and peroxidase. Several proteases have been established:

1. An aspartic endoprotease: its activity optimum is at pH 3.5. It consists of two polypeptides, which are obviously derived from a 42-kDa polypeptide by self-digestion. It splits native (7*S*) globulin, and its specific activity is 20–50-fold higher in recalcitrant cocoa seeds compared with that in orthodox seeds of several higher plants.
2. A cysteine endoprotease: its specific activity is considerably lower than that of the aspartic endoprotease. In contrast to an additional cysteine endoprotease which is induced during germination, it does not split the native (7*S*) globulin.
3. A seryl exopeptidase: this carboxypeptidase reveals optimum pH around pH 5.8 and substrate specificity, preferentially liberating hydrophobic amino acids.
4. A leucine-*p*-nitroanilide cleaving seryl exopeptidase displaying maximal activity at pH 6.8. (*See* **Enzymes**: Functions and Characteristics.)

Glycosidases are responsible for hydrolysis of flavonoid glycosides. Their highest activity in cocoa beans was found between pH 3.5 and 4.5. Polyphenoloxidase (*o*-diphenol: O_2 oxidoreductase) in unfermented seeds displays a high activity which is strongly reduced after fermentation. Under a wide range of pH optima reported by several authors, pH 6.0–6.4 is the most probable range of highest activity. In wounded plant tissues it effectively oxidizes polyphenols, and the resulting quinones react spontaneously to give brown polymerization products.

Composition of Pulp

The mucilaginous, sweet pulp firmly adhering to each of the individual seeds is formed during pod development from an endocarp meristem. Pulp from ripe seeds contains high but variable amounts of sugars (Table 3) which impair seed germination. Citric acid is responsible for the low pH value (pH 3.5–3.8). The pulp variably binds a lot of water due to pectins. Additionally hemicelluloses, cellulose, and proteins are constituents which are insoluble in water and which resist hydrolysis in strong mineral acids.

Besides pectins in the pulp, the seed testa also contains mucilage: both swell considerably after removal of acid.

Changes During Fermentation

Changes in the seeds (cf. Figure 3 in **Cocoa**: Production, Products and Uses) start in the organized subcellular structure of the living seed. They proceed to postmortem reactions which are caused by heat and diffusion of acetic acid from the fermenting pulp

Table 3 Analysis of cocoa pulp mucilage

Fraction	*Unit*	*Quantity*

Pulp dry weight	mg seed^{-1}	200–240[a] (120–180)[b]

Unpublished data from Dziggel M and Biehl B (1986).
Pulp of seeds from Amelonado-type and in some cases Malaysian hybrids from [a]ripe pods and in some cases from [b]overripe pods were analyzed giving one example of strongly variable quantities, depending on pod physiology and ripeness. Compare Table 1 in Chapter Cocoa – Production, Products and Uses and see Biehl B, Meyer B, Crone G, and Pollmenn L (1989) *Journal of the Science of Food and Agriculture* 48: 189–208.

(Figure 2). These changes are controlled by the effective concentration of acetic acid and the nib pH value, which drops to pH 5.0–4.0.

Once the plasma membranes and tonoplasts are destroyed, proteins, polyphenols, and other compounds are released from their compartments and come into contact with enzymes. The pH value established in the cells controls the postmortem activity of acidic hydrolases (proteases, glycosidases, invertase) under anaerobic conditions.

As a result of cell destruction, variable amounts of soluble constituents, flavonoids, amino acids, purines, and sugars are lost from the seeds due to exudation. A loss of 10–40% of soluble substances modifies the original composition of cocoa seeds. Reported changes in the content of fat are in accordance with this loss of soluble substances.

Sucrose disappears to a large extent from the seeds during fermentation, due to invertase activity. However, the amount of fructose plus glucose in the fermented beans is not more than 50% of the original amount of sucrose. Since their proportions are variable, they obviously undergo further reactions.

The flavonoid glycosides are hydrolyzed by acidic glycosidases. The violet aglycon cyanidin subsequently undergoes bleaching by nonenzymatic transformation to a colorless pseudobase. Leucocyanidins and proanthocyanidins are transferred nonenzymatically to more complex forms. Although no reactions of the catechins have been established, the loss of 50–75% suggests nonenzymatic oligomerization. These strongly tanning compounds are released from polyphenol storage cells but they do not prevent proteolysis in the absence of oxygen.

Proteolysis in the beans is crucial for the formation of cocoa-specific aroma precursors. It starts after uptake of acetic acid. The extent and type of proteolysis, and thus the resulting aroma potential in fermented beans, strongly depend on the pH value established in the beans during this stage of proteolysis. The significant details have been found by comparing changes during fermentation with aseptic incubations of seeds, acetone dry powder, and of purified cocoa seed proteins and proteases (Figure 3).

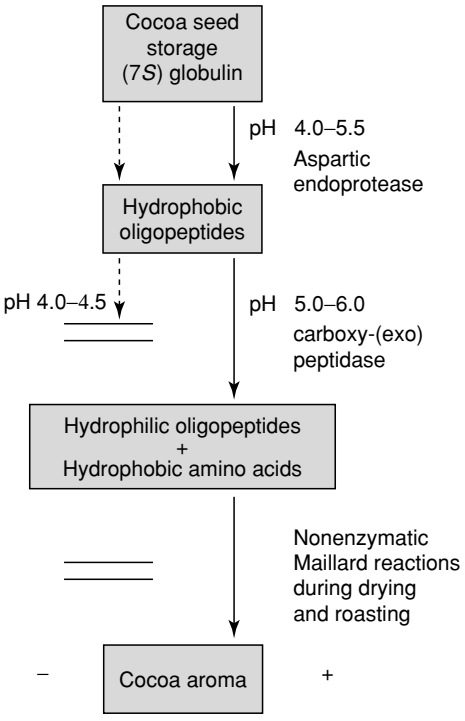

Figure 3 Proteolytic formation of cocoa-specific flavor precursors during fermentation and their transformation during drying and roasting.

All cocoa seed proteins, especially albumin and (7*S*) globulin, are degraded by cocoa aspartic endoprotease after strong acidification (pH ≤ 4.0). However, at higher pH values (pH 5.0–5.5), the (7*S*) globulin is the only protein attacked by the aspartic endoprotease. Cocoa-specific aroma precursors comprise characteristic patterns of hydrophilic oligopeptides and free hydrophobic amino acids resulting from suitable degradation exclusively of cocoa (7*S*) globulin. Neither cocoa albumin nor (7*S*) globulins from other plants (so far as these have been investigated) give the characteristics degradation pattern and cocoa-specific aroma precursors depends on the substrate specificity and the specific cooperation of both the aspartic endoprotease and the carboxyexopeptidase. In the pH range 4.0–5.5, the aspartic endoprotease cleaves (7*S*) globulin at the site of hydrophobic amino acids in its chain, giving a considerable number of hydrophobic oligopeptides. At pH ≥ 5.0, carboxyexopeptidase acts near to its pH optimum and specifically removes hydrophobic amino acids from the hydrophobic oligopeptides. In this way they are further converted to hydrophilic oligopeptides and free hydrophobic amino acids, especially leucine, alanine, phenylalanine, and tyrosine. After incubation or fermentation, their proportions are significantly higher than in the proteins (Table 4).

Consequently, during strongly acidic fermentation (around pH 4.0), almost no hydrophilic oligopeptides and few free amino acids are generated and cocoa aroma potential in fermented beans is low in contrast to moderate nib acidification during fermentation. At pH ≥ 5.0 both enzymes are sufficiently active.

During fermentation, about 2 days after seed death, the rate of proteolysis decreases significantly. This decrease is not due to tanning since it is also found in the absence of polyphenols during acetone-dry powder autolysis.

The liberated amino acids and peptides in the beans do not seem to be metabolized during fermentation unless the seed takes up oxygen during the final stages of fermentation. They may now be exposed to direct aerobic microbial attack, especially during subsequent prolonged (over)fermentation.

Changes in the pulp are considered below in Microbiology of Pulp Fermentation.

Changes During Drying

Reactions during drying are an oxidative continuation of fermentation. They are important for quality. Only about 10–20% of catechins and proanthocyanidins present in unfermented beans are found in raw cocoa after fermentation and drying. Polyphenols are oxidized by molecular oxygen: the resulting quinones undergo polymerization to give brown products. Oxidation is brought about by residual activities of the polyphenoloxidase. However, as it is optimum at pH 6, in acidic beans (pH 4.0–5.0) browning is impaired during drying. At pH > 7.0 polyphenols are oxidized nonenzymatically. Thus, overfermented cocoa easily turns brown, giving an incorrect appearance in the cut test of perfectly fermented cocoa beans. Since

High-performance liquid chromatography was used for estimation of amino acids in polyphenol-free extracts of cotyledons, lyophilized after treatments.[a–d]

enzymatic browning requires high oxygen concentrations, browning does not take place before drying. A consequence of polyphenol oxidation and quinone polymerization is the reduction of the astringent flavor, which is due to the tanning property of catechins and procyanidins, especially the oligomeric forms. Oxidation and polymerization transfer these mono- and oligomeric flavonoids to nonastringent brown polymers. (*See* **Browning**: Enzymatic – Biochemical Aspects.)

Thus, the extent of these polymerizations is controlled by the nib pH, the permeability of the shell to oxygen, and the destruction of subcellular compartmentation. Roughly, the internal color of raw cocoa beans is related to astringency. Slaty beans reveal a strongly astringent taste while entirely brown beans and, especially, overfermented beans give an insipid taste.

The extent of the browning reaction also affects the residual seed proteins. Free amino- and sulfhydryl groups of proteins readily react with quinones and thus participate in the production of brown polymers. Amino acids and oligopeptides are less reactive. However, they participate in the formation of Maillard products during drying. The spontaneous reaction of proteins and quinones is also responsible for the toxic effects of quinones on bacteria and fungi. Therefore, overfermentation is suppressed during browning reactions in the course of drying. However, the resulting polymers are not toxic and would not impair microbial growth on brown raw cocoa beans during storage and on fully brown beans in particular.

Microbiology of Pulp Fermentation

The events taking place during pulp fermentation correspond to a succession of microorganisms metabolizing the pulp. The wide range of organisms in the wild inoculum is similar in different cocoa-growing countries. When starting fermentation, the low pH value and the high sugar content of the pulp allow anaerobic fermentation by yeasts and lactic acid bacteria. Ethanol is produced, and after exhaustion of pulp sugars, acetic acid bacteria predominate. Acetic acid and lactic acid are the most significant metabolites penetrating the beans. Several authors have isolated more than 30 species from 13 genera of yeasts. The size of the population of lactic acid bacteria is subordinate, and is further repressed when acetic acid bacteria subsequently become active after exhaustion of pulp sugars. Several homofermentative and heterofermentative lactobacilli have been isolated. (*See* **Lactic Acid Bacteria**.)

A number of species of the genus *Acetobacter* which have been found in fermented cocoa not only oxidize ethanol to form acetic acid but also oxidize this acid, causing a decrease in acetic acid during late stages of fermentation. Additionally, *Gluconobacter* spp. were found.

The sizes of these populations correlate with the amount of products formed (ethanol, lactic acid, acetic acid). However, there is no information available about the more detailed competition and significance of all these individual species.

More recent experiments have been described studying the effect during usual fermentation of pure cultures of selected microorganisms either in addition to or in the absence of wild inoculum. In total, from different observations with respect to changes in the pulp, temperature increase, acid production, and final bean quality, it can be deduced that a limited number of species, yeasts, lactic acid, and acetic acid bacteria, which are adapted to the conditions in the cocoa pulp, can completely substitute for the numerous organisms in fermenting cocoa.

Besides pulp sugar and acid metabolism, pectinolytic activity is of interest: this assists in drainage of pulp in the early stage of fermentation. *Kluyveromyces marxianus* was found to have highest pectolytic (endopolygalacturonase, EC 3.2.1.15) activity but additionally *Saccharomyces chevalieri, Torulopsis candida, Candida norvegensis*, and *Kluyveromyces fragilis* were reported to reveal significant endopolygalacturonase activity.

The last stage of fermentation is characterized by the development and dominance of aerophilic bacteria, depending on aeration. Up to 14 species of the genus *Bacillus* have been isolated which, in part, are facultative anaerobes. Further species of other genera have been reported. There is no direct evidence as to how they contribute to cocoa fermentation in detail. Most probably they participate by increasing the shell permeability and later on in overfermentation. *Bacillus stearothermophilus, B. subtilis, B. circulans, B. licheniformis* and *Streptococcus thermophilus* have been found as dominating organisms. Species like *B. megaterium, B. subtilis, B. coagulans, B. cereus, B. polymyxa* or *Enterobacter aerogenes* have been isolated, which metabolize carbonic acids, proteins, and amino acids, producing low-molecular-weight fatty acids. Propionic, butyric, and isovaleric acids are increased to 0.1–1.0% of dry weight each in overfermented cocoa beans, compared to 0–0.02% in controls. These findings strongly indicate bacterial degradation of amino acids (and flavor precursors) during overfermentation. (*See* ***Bacillus***: Occurrence.)

A large number of different filamentous fungi develop on the seeds in well-aerated niches, especially when less acidic and strongly aerated during the later stages after a steep pH increase. They may develop

further during drying when the humidity is high. Xerophilic fungi like *Aspergillus fumigatus*, as well as *A. glaucus, Penicillium* spp., *Mucor* sp., *Paecilomyces* sp. and *Geotrichum* sp., which have been found to develop during late stages of fermentation, have also been reported to occur on stored raw cocoa beans.

Flavor Compounds and Flavor Precursors Formed during Fermentation and Drying

Some characteristic flavor compounds in cocoa products are original constituents of the unfermented seeds but they are changed in amount during fermentation and drying: theobromine tastes bitter. Astringency is due to tanning flavonoids, and their oligomeres. Further oligomerization during fermentation increases. Oxidation and polymerization during drying decrease their taste intensity. Acidic taste is due to lactic and acetic acid, which diffuse into the beans during fermentation and persist in variable amounts after drying and roasting. When present in high concentrations, acetic acid may mask the impression of cocoa aroma.

Cocoa flavor precursors comprise compounds in fermented beans which react during drying and manufacturing, especially roasting, to give flavor. Specific cocoa aroma precursors are not original components of the seed but are formed during fermentation and drying: reducing sugars, free amino acids, and oligopeptides result from enzymatic hydrolysis. Their formation and significance is described above, in the section on changes during fermentation. They undergo Maillard reactions during drying and roasting in order to generate cocoa aroma.

After *in vitro* proteolysis under suitable conditions of cocoa (7*S*) globulin in the presence of cocoa seed proteases, the methanol extract of aroma precursors gives a typical cocoa aroma when roasted in the presence of reducing sugars. Synthetic mixtures of amino acids, adapted to the composition of free amino acids in fermented cocoa beans in the presence of reducing sugars but in the absence of the fraction of hydrophilic oligopeptides, do not generate cocoa aroma on roasting.

Intermediate Amadori products and several pyrazines have been found in fermented and dried beans before roasting; pyrazines (mono-, di-, tri-, and tetramethyl-pyrazines) in part are already generated during fermentation. Polyphenols (flavonoids), although important for the final astringent taste, do not contribute to the cocoa aroma. Some authors found that they enhance cocoa aroma.

In addition to cocoa aroma precursors, oligopeptides and theobromine are flavor precursors: during roasting, N-terminal amino acids of several hydrophobic peptides produce diketopiperazines which give the characteristic cocoa bitter principle in a 1:2 complex with theobromine on roasting.

Chemistry of Manufacturing Processes

Cocoa flavor is chemically very complex because it arises from fermentation and roasting and is influenced by further processing steps. The flavor of plain chocolate is modified but chemically very similar to cocoa. The flavor sensations of cocoa products and chocolates are based on a great number of volatile aroma compounds and their interaction with nonvolatile constituents which affect taste and tactile characteristics.

Cocoa Flavor Development

Flavor of unroasted cocoa Raw cocoa has an acid taste and a flat but characteristic aroma. As a result of the fermentation process it contains aroma precursors, mainly free amino acids, monosaccharides, and their first reaction products (Amadori compounds), peptides, monomeric flavonoids, and methylxanthines. The first aroma compounds were developed in an early Maillard reaction during the drying of the fermented seeds or absorbed from the fruit pulp. The major volatiles in the concentration range 0.1–1 mg kg^{-1} are aldehydes (produced via Strecker degradation of amino acids), alcohols, acetates, and acids, which derive from valine, leucine, isoleucine, and phenylalanine (Tables 4 and 5). Tetramethylpyrazine is formed by microorganisms. Special flavor-grade cocoas, mainly harvested in Venezuela, Trinidad, and Ecuador (Arriba), reveal a flowery and tea-like aroma and contain significant concentrations (0.5–2 mg kg^{-1}) of linalool and further terpenoids which contribute to this valuable note. On the other hand, basic cocoas from West Africa, Malaysia, or Brazil (Bahia) carry a fairly strong inherent flavor and have very low concentrations of linalool. The sharp acidity of raw cocoas arises from acetic acid, the astringency and bitterness from soluble polyphenols (mainly epicatechin), tannins, theobromine, and caffeine. A smoky flavor, which is a flavor defect of some cocoas, is produced by the absorption of volatile phenols from the smoke of the firewood used for drying.

Roasting and Aroma Formation Aroma is formed from its precursors in raw cocoa beans. In contrast to amino acids, glucose and fructose are consumed to a large extent during roasting (up to 90%). While the composition of triacylglycerols in cocoa butter remains unchanged during roasting and further

processing steps, the entire cocoa aroma is formed by careful roasting of fermented and dried seeds at temperatures between 120 and 140 °C. Using modern technology, cocoas can be roasted at different particle sizes, such as whole beans, as nibs, which are coarsely ground and broken beans, or as liquid cocoa mass, which is produced by a fine grinding of cocoa and liquefying within its own fat. The roasting of smaller particles has the advantages of better controlled roasting, partial exhaustion of abundant acetic acid, and reduced roasting time (beans about 30 min, nibs 12 min, mass 2 min).

About 600 compounds have been identified in cocoa aroma. In common with all roasting aromas there is a large number of carbonyl and heterocyclic compounds. The main carbonyl groups are acids and esters (each about 50 compounds), alcohols, aldehydes, and ketones (each between 30 and 40 derivatives). The main heterocyclic compounds are pyrazines and chinoxalines (together about 80 compounds), furans, pyrones, and lactones (together 40 compounds), diketopiperazines, phenols, pyrroles, and oxazoles (each group about 10 compounds). Derivatives of phenylalanine are prominent volatiles after roasting. As a result of the Maillard reaction, pyrazines, pyrroles, phenylacetaldehyde, phenylalk-2-enals, pyrones, furanones, and furans increase during cocoa roasting, whereas alcohols, esters, and acids remain more or less unchanged.

Simple aldehydes arise by Strecker degradation of free amino acids. Their immediate flavor characteristics are not very striking, but they act as most important reactants. Some phenylalk-2-enals are generated via the aldol condensation, for example, which carry a typical flowery odor fairly reminiscent of chocolate or cocoa. Many pyrazines with different substitutes and chinoxalines with desirable flavor properties contribute to the roasted note. It was found that methylpyrazines are formed during roasting according to a specific rate depending on substitution. Some pyrones and furanones, as dihydrohydroxymaltol, hydroxymaltol, and furaneol, arise from degradation of monosaccharides and reach remarkable concentrations in roasted cocoas. Characteristic of cocoa aroma are abundant phenyl derivatives which arise from phenylalanine and contribute to the intensive sweet aromatic note. The typical intense bitterness of roasted cocoa is to a great extent induced by adducts of such diketopiperazines with theobromine and caffeine. In the course of roasting, monosaccharides react to the extent of about 60–90%, while free amino acids only react to about 20%. Therefore, in several roasters the unroasted nibs or masses are treated with aqueous sugar solutions to increase the concentration of the carbohydrate precursors and to improve the aroma yield. In addition, during the moist thermal treatment of cocoa, the level of Amadori compounds may be raised and the aroma may be intensified. (*See* **Caffeine**.)

Technologically Influenced Flavor Changes Roasted cocoa nibs and mass are important semimanufactured goods and are used for the production of cocoa powder, cocoa butter, or chocolate mass. The cocoa flavor is modified and improved by the subsequent processing, mainly by alkalization of nibs, degassing of cocoa mass, or conching of chocolate mass.

Conching of chocolate The conversion of the bitter cocoa flavor to the finer chocolate flavor occurs in the conche. There, a mixture of cocoa mass, sugar, cocoa butter, and milk powder (for milk chocolate production), fine ground in rolling mills, is stirred vigorously and treated for about 8–24 h at 50–60 °C. In addition to the aroma improvement, this process gives the desired consistency to the chocolate by covering all the solid particles with fat. Aroma and consistency are important for the flavor of the finished product. There are two main functions of the conche: degassing and mechanical–thermal treatment of the chocolate mass. Low-boiling volatiles are removed, together with steam. Acetic, propionic, isobutyric, and isovaleric acids are reduced by about 30%. About 20–40% of the unspecified aroma compounds,

such as abundant aldehydes and alcohols, as well as of aroma-damaging substances like volatile phenols, are also removed. As a result the typical and slightly volatile aroma becomes more pronounced.

Sorption phenomena of aroma materials at particle surfaces of the heterogeneous chocolate mass of fat and fat-free portions have considerable influence on the flavor.

Thin-layer treatment of cocoa mass During modern chocolate processing the cocoa liquor is degassed before being put into the chocolate recipe. By using special equipment, degassing can be performed more effectively than in the conche. Thin-layer vaporizers are generally used, which may shorten the remaining conching time considerably. The process conditions have to be coordinated with the quality of the cocoa liquor, so that the valuable aroma is not removed together with the more volatile unknown materials, thereby flattening the taste of the product. A reduction of 10–30% of acids and low-boiling compounds seems to be optimal.

Alkalization of cocoa Alkalization ('Dutching') is mainly used to intensify the color, to modify the flavor, and to improve the dispersability of cocoa powder in water or milk. In this process, beans, nibs, or mass are treated with solutions or suspensions of alkali, usually potassium or sodium carbonate, sometimes hydroxides or ammonia. The permitted maximum is generally 2.5–3 parts of potassium carbonate (or equivalent alkali) per 100 parts of cocoa. The pH of a natural cocoa is about 5.5, whereas the pH of commercially available Dutch process cocoas will fall between 6.8 and 8.0.

Color and flavor changes during alkalization are mainly based on modifications of polyphenolic substances. Dutch processing results in a milder and altered flavor, and a darker color. Under alkaline conditions, soluble monomeric flavonoids (mainly epicatechin) are oxidized and condensed to give polymer tannins. Red and brown pigments are developed and the astringency is reduced. Volatile acids are partially neutralized.

Cocoa Aroma Analysis

The cocoa aroma volatiles only occur in milli- or microgram per kilogram quantities. They are dissolved in the fat phase or physically bound to a heterogeneous matrix of constituents of differing polarity. Isolation and enrichment techniques are necessary to obtain the flavor volatiles in sufficiently high concentrations. Distillation methods, headspace techniques, and extractions, or combinations of these techniques are used. The separation of the volatiles is performed by means of capillary gas chromatography (GC) or high-performance liquid chromatography (HPLC). (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography.)

Isolation and Analytical Techniques

Extraction Extraction techniques have several disadvantages (time-consuming and the possibility of introducing artifacts) but have the advantage of quantitatively isolating volatiles independent of their boiling points. Usually, cocoa is defatted with petroleum ether and the residue is extracted with a polar solvent such as water, ethanol, acetonitrile, ethyl ether, or subcritical carbon dioxide. By means of extraction, specific high-boiling compounds have been isolated from cocoa: diketopiperazines, pyrones, amines, amides, aromatic acids and phenols (these compounds are mainly for subsequent GC separation), and theobromine, caffeine, and monomeric flavonoids (for HPLC measurement).

Distillation Most of the known aroma volatiles have been isolated from cocoa by means of distillation (steam distillation, vacuum condensation, simultaneous steam distillation–extraction (SDE), head-space enrichment). Nonvolatile impurities can thus be avoided and a defatting step is not necessary, but high-boiling compounds are partially lost and one has to be aware of possible reactions during the heat treatment.

The aqueous distillates are usually extracted with small portions of ethyl ether for performing GC or may be injected directly into an HPLC system.

Table 6 shows typical volatiles of roasted cocoa. The flavor chromatograms of different cocoas are rather similar, but the quantitative distribution of the single constituents and their total amounts vary distinctly with origin, fermentation, drying, roasting, degassing, alkalization, or conching. Distillates of chocolate contain similar compounds in lower concentration and altered distribution.

Analysis of indicative compounds and key odorants

Objective analytical data are necessary to relieve the industrial quality control of time-consuming sensory tests. For that purpose suitable indicators are needed to evaluate the flavor. Several examples of indicative compounds in cocoa aroma follow, together with methods suitable for their estimation (GC; HPLC; ultraviolet (UV) detector; electrochemical detector (ELCD)): Fermentation degree – epicatechin (HPLC–ELCD), tetramethylpyrazine (GC or HPLC–UV); flavor-grade cocoas linalool (GC); roasting intensity ratios of 2,5-dimethyl- to tetramethylpyrazine

Table 6 Selected aroma compounds identified in extracts of roasted cocoas

Compound	*Concentration range*
3-Methylbutanal	IV
2,3-Butandione	III
3-Methyl-butan-1-oe	IV
Acetone	II

3-Methyl butanoic acid	V
Phenylacetaldehyde	IV
Acetophenone	III
Furfuryl alcohol	I
1-Phenylethanol	I
2-Phenethyl acetate	II
2-Hydroxy-3-methyl-2-cyclo penten-1-one (cyclotene)	II
Guajacol	I
Benzylalcohol	II
2-Phenylethanol	III
2-Phenylbut-2-enal	III
2-Phenethylamine	II
2-Acetylpyrrole	III
4-Methyl-2-phenylpent-2-enal	II
Phenol	I
3-Hydroxy-2-methyl-4-pyron (maltol)	II
4-Hydroxy-2,5-dimethyl-3-(2*H*)-furanone (furanol)	III
5-Methyl-2-phenylhex-2-enal	III
2-Pyrrolecarbaldehyde	II
5-Methyl-2-pyrrolecarbaldehyde	II
2,3-Dihydro-3,5-dihydroxy-6-methyl-4-pyrone (dihydrohydroxymaltol)	IV
3,5-Dihydroxy-6-methyl-4-pyrone (hydroxymaltol)	II
5-(2-Hydroxyethyl)-4 -methylthiazole	III
1,2-Benzenediol	III
Benzoic acid	II
2-Phenylacetic acid	IV
2-Phenylacetamide	IV

Usual concentration range (mg kg^{-1}): I, < 0·1; II, 0·1–0·5, III, 0·5–2; IV, 2–10; V, > 10. Succession of gas chromatographic retention times on a DB-wax capillary column.

or trimethyl- to tetramethylpyrazine (GC or HPLC–UV), ratio of 5-methyl-2-phenyl-hex-2-enal to 2-phenylethanol (GC), dihydrohydroxymaltol (GC or HPLC–ELCD–UV); intensity of degassing of cocoa masses – 3-methylbutanal (head-space GC).

Aroma extract dilution analyses (AEDA) is a potent tool to screen the most odor-active compounds in foods. The application of AEDA on the cocoa volatiles revealed about 40 main odorants in cocoa mass.

Sensory Evaluation

Sensory evaluation is extremely important for cocoa process control and for the quality assurance of cocoa and chocolate products. Based on a tasting panel, which consists of trained and selected members, different sensory tests (flavor profile, difference, and scoring tests) are used and the results are statistically evaluated. (*See* **Sensory Evaluation**: Taste.)

The flavor profile test This test is essential to obtain an assessment of the development of taste and flavor within the mouth as a result of individual sensory perceptions. The varying intensities of the specific characteristics are observed and evaluated. An evaluation plan is used which considers the flavor and texture characteristics and is completed by a numeric scale. Some characteristics of cocoa mass are raw, acid, flavorful, typical cocoa bitterness, burnt/bitter, astringent, off-taste (cooked, moldy, smoky, ham, chemical, etc.). In addition, descriptors for plain chocolate are sweetness, aromatic, cocoa intensity, harmonic, persistent, caramel, vanilla, off-taste (cardboard, metallic, rancid, etc.). Intensities range from 0 to 4: absent, barely perceptible, weak, medium, strong. Texture descriptors are sticky/neat, coarse/smooth, dry/mellow, snappy/soft. (*See* **Sensory Evaluation**: Descriptive Analysis.)

Difference tests These are preference tests to compare a sample against a control: in a simple form it is a paired test or, with one sample duplicated, a triangular test. Preferences and the intensity of deviations are reported. Triangular tests are used to check samples which have slight deviations from the standard.

Scoring test This test is used for production quality control and for assessing chocolate samples after periods of storage under different conditions. Sensory evaluation: 9–7, optimal to good; 6–4, satisfactory to sufficient; 3–1, lacking to unsatisfactory. (*See* **Sensory Evaluation**: Sensory Rating and Scoring Methods.)

Tasting method Solid cocoa masses are chopped and tasted with a spoon. Cocoa powders are

suspended to 10% in warm water, plain chocolates are broken into pieces and tasted.

Introduction

This article describes raw cocoa processing and the nature, the technologies, and the use of cocoa powder and chocolate. These are made from defatted and nondefatted raw cocoa beans, respectively, which come from the fermented seeds of the tropical tree *Theobroma cacao* L. 'Cocoa' here is used as the overall term covering the finished products (cocoa powders and chocolate), the semifinished product (the raw cocoa beans), and the original seeds in the pods on the tree.

Although cocoa products contain valuable nutrients, their special nature lies in the unique flavor which is not obtained from other plants. The unprocessed seeds, however, do not have this desired flavor, but instead an astringent unpleasant taste. Hence the constituents expressed by the unique genetic potential of the cocoa seeds are profoundly changed by processing and production techniques, and these are responsible for realizing or destroying the flavor potential, as described in the previous article.

'Processing' covers all steps from harvesting the pods up to the stage where the raw cocoa beans come to the industrial manufacturer's plant for 'production' of the final goods.

Raw Cocoa Processing

General Outline

Processing usually includes the harvesting and breaking of the pods, extraction of the wet beans, transport

(of pods or wet beans), fermentation in covered heaps or containers for some days, drying of the fermented beans, sorting, grading, sacking, and storage. 'Beans' is a traditional term used commercially for seeds of cocoa at any stage of their processing. Wet beans are the seeds covered by the mucilaginous, sweet and acidic pulp or its remainder during fermentation. Raw cocoa beans are fermented and dried. The term 'fermentation' is used to describe the overall process of heaping wet cocoa beans for several days, microbial pulp degradation, and also endogenous postmortem reactions, both enzymatic and nonenzymatic, that take place in the seeds and which are induced by pulp fermentation.

At the cocoa plantations, fermentation and drying may primarily be looked upon as a curing process in order to stabilize the fresh beans by microbial degradation of the firmly adhering, perishable pulp, and by drying.

From this point of view the resulting qualities, especially the flavor potential, may be subordinate aspects. However, the quality is essential for subsequent manufacture of finished products. Raw cocoa quality may vary considerably depending on the manner of processing. First grades command an extra premium. However, since grading takes into account defects of raw cocoa, but not flavor intensities or flavor notes, there is no way of providing an extra premium for raw cocoa with superior flavor potential. Certain raw cocoa origins are given preference (and a higher price) by the industry and the market in virtue of experienced quality differences compared to less desirable origins.

Origin of Flavor Differences

Some experts assume flavor differences to be due to edaphic, climatic, or plant genetic particularities in the cocoa-growing countries. However, these differences may partially or even predominantly be due to traditional processing practices which are not uniform in the various producing countries.

Soil nutrients and climate generally affect the physiology of plants. Climatic changes have influence on pod growth, seed size, the amount of seed constituents, and thus on the starting material used for cocoa processing. Apart from the variable response of cocoa cultivars to climate, there is inadequate knowledge about the significance of genetic diversity of the planted cocoa trees and harvested seeds with respect to its influence on flavor quality. Criollo (fine) and Forastero (bulk) raw cocoas reveal flavor differences which are attributed to genetic influences. A huge number of different genotypes and hybrids, derived from one or both of these varieties and their forms, are planted. During the last decade genotype-depending flavors in raw cocoa beans have been reported which were harvested from trees of different vegetative clones and which were processed under empirical standard conditions. Unequivocal conclusions are complicated since flavor determinant constituents in raw cocoa (like acids, catechins, and peptides) underwent profound transformations during processing. Physiological effects like variation of the seed's individual pulp layers also interfere. In the case of clonal effects it is likely that flavor differences do not depend on the genetic expression of the cotyledons (nibs), but rather on the genotype of the vegetative tree controlling pod growth and the property of pulp and testa. All vegetative parts of a cloned hybrid represent the same genotype but the generative progeny, the embryos, does not.

Practice of Fermentation

Handling and care during processing significantly affect raw cocoa quality and flavor. To improve raw cocoa quality, repeated attempts have been made to modify the methods. Few met general application. The different methods of cocoa fermentation are mostly developed from local traditions under particular conditions in the various cocoa-growing countries. They will not be described in this article. The reader is referred to earlier reviews cited below for detailed and valuable information. Instead, representative processing methods as practiced in Brazil, Ghana, and Malaysia, variable courses of fermentation, and effective modifications will be described. Most of the common practices correspond to the description given in the following sections. Heap fermentation and box fermentation as the prevailing methods will be described briefly.

In both cases, ripe pods are harvested and the husks are opened by means of a cutlass or wooden billet. The wet seeds are removed from the husk and placenta and are collected for transport. Abnormal, black, infested or clustered beans and foreign matter are removed. The wet cocoa is piled up in heaps or boxes of variable capacity, allowing drainage of sweatings through the bottom. Care is taken that mixing can be carried out by turning the fermenting cocoa upside down and inside out. The wet cocoa is covered with banana leaves or jute bags and is left by itself for 5–7 days, interrupted by one or more turnings after 24, 48, or 72 h. After a given time, or following an assessment of its appearance and odor, the fermented cocoa is transferred to a drier.

Standardized methods, such as the heap and box fermentations, are used at well-established farms or estates but they are not in common use elsewhere. Any kind of box or other receptacle such as troughs, frames, baskets, boats, or bags can be found to serve

for curing widely varying quantities of wet cocoa. Alternatively, the wet cocoa is left on the ground or on a drying platform where a partial fermentation may occur, depending on the depth of the layer, occasional heaping, and weather conditions. These irregular types of curing probably play a subordinate role in most of the raw cocoa-producing countries, but they contribute to the nonuniform low-quality cocoas as they appear on the market. However, some special methods are used to produce high-quality cocoas, as is reported from Ecuador, where in some estates the wet beans are spread at day but heaped overnight. This reminds us that cocoa fermentation is still basically an empirical procedure.

Heap fermentation (Figure 1) The typical succession of microbial pulp degradation occurs whenever wet cocoa is piled up for several days. Heap fermentation is used in West Africa. The heap is prepared outdoors on banana leaves layered on wooden sticks to allow better drainage. The cocoa is covered by the same leaves by folding up the peripheral ends in such a way that rain is kept off. The amount of wet cocoa (80–1000 kg) depends on the harvest. Due to the flat, conical shape of the heap compared to boxes, the bottom layer and the surface layer are large, which promotes not only aeration but also cooling. Thus, at least one turning after 48 h is necessary. The highest temperature may normally be found 5 cm beneath the surface.

Box fermentation (Figure 2) Boxes are placed under roofs and are made from locally indigenous timbers. They are jacked up and their bottom (sometimes also the walls) are perforated to allow drainage. On large plantations the fermentary would consist of batteries of several open boxes ($1.0 \times 1.0 \times 1.0$ m) which facilitate turning from one box to the next. Alternatively, long boxes (e.g., 10 m length) can be divided by partitions. Depending on the harvest, the cocoa is filled up to 100 cm in depth.

Compared to average-sized heaps (about 50–80 cm top height), the deep box (100 cm) depth requires a longer time for fermentation because of reduced aeration (almost exclusively from the top).

In Malaysia, shallow boxes have been introduced to overcome the lack of uniformity (see below and Figure 2). Cascades of shallow boxes are used in large estates, each of which may have a capacity of several tonnes, but a height not exceeding 35 cm.

Revolving barrels which are provided with perforations for aeration and with some device for effective mixing during gentle rotations allow quite uniform fermentations. Aeration, pulp loss, and water evaporation are significantly increased by frequent turnings. Whether this is favorable or not depends on the ripeness and constitution of the pulp.

Standard Course of Fermentation

The progress of fermentation is characterized by visual changes and changes of odor. Most typical are

Figure 1 Preparing a heap fermentation (Cocoa Research Institute of Ghana, Ghana). Reproduced from Cocoa: Production, Products and Uses. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Figure 2 Experimental shallow box fermentation (Malaysian Agricultural Research and Development Institute, Malaysia). color changes and the accumulation of a red sap in the beans penetrating the shell when the beans die. The internal appearance of dried beans taken at regular stages from the fermenter also indicates the progress of fermentation. Seeds appear slatey as long as anthocyanins have not yet been released from their intact storage cells. After seed death they would dry to compact beans, violet in color, with the shells sticking strongly to the nibs. When fermentation is completed the nibs would turn brown and the beans retain a plump, porous structure, with a loosened shell. This is the type of bean required for marketing. For grading on the market, the internal appearance of beans is taken to estimate the so-called 'degree of fermentation' in a cut test. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

After harvested pods have been broken, the wet cocoa is inoculated by spores of an ubiquitous range of airborne microorganisms. The course of fermentation may be subdivided into four stages (I–IV). The succession of events is generally as follows (cf. solid line in Figure 3).

Stage I

Pulp In the mucous, acidic (pH 3.5–4.0) pulp, anaerobic, microbial metabolism of sugar starts immediately, with alcoholic fermentation first dominating over the lactic acid fermentation. Pulp is drained off. Carbon dioxide is produced and this displaces air from the box. The odor changes from sweet fruits to ethanol.

Seeds Most seeds at this stage are still alive (germination test).

Stage II

Pulp As more pulp has been drained off and sugar metabolized, less carbon dioxide is produced. Consequently, more air is taken up by the pulp, giving rise to oxidative formation of acetic acid, an exothermic process heating up the cocoa from the ambient temperature to 45–52 °C. Aeration would now be randomized and accelerated by turning. There is an odor of acetic acid.

Seeds Both the temperature increase to > 45 °C and the uptake of acetic acid kill the seeds. A maximum level of acetic acid produced in the pulp is followed by a maximum amount of acetic acid absorbed in the beans. The average pH value in the nibs drops from 6.4 to 4.0–4.7. Oxygen is quantitatively consumed in the fermenting pulp, keeping the nib under anaerobic conditions and allowing postmortem reactions in the absence of oxygen.

Stage III

Pulp As acetic acid production slows down because of exhaustion of substrate, bacterial oxidation of acetic acid causes a slow increase in pulp pH. The temperature may drop because of lack of substrates and reduced microbial activity in the pulp, which is still acidic (about pH 5.0). Lactic acid formation, which has been suppressed during stage II, may increase once more. The odor is still acidic but changes to a bread-like impression.

Seeds Most of the postmortem enzymatic and nonenzymatic reactions in the seeds are completed by this time.

Stage IV

Pulp Now, after pulp degradation, a buoyant air flow from the bottom to the top of the hot cocoa

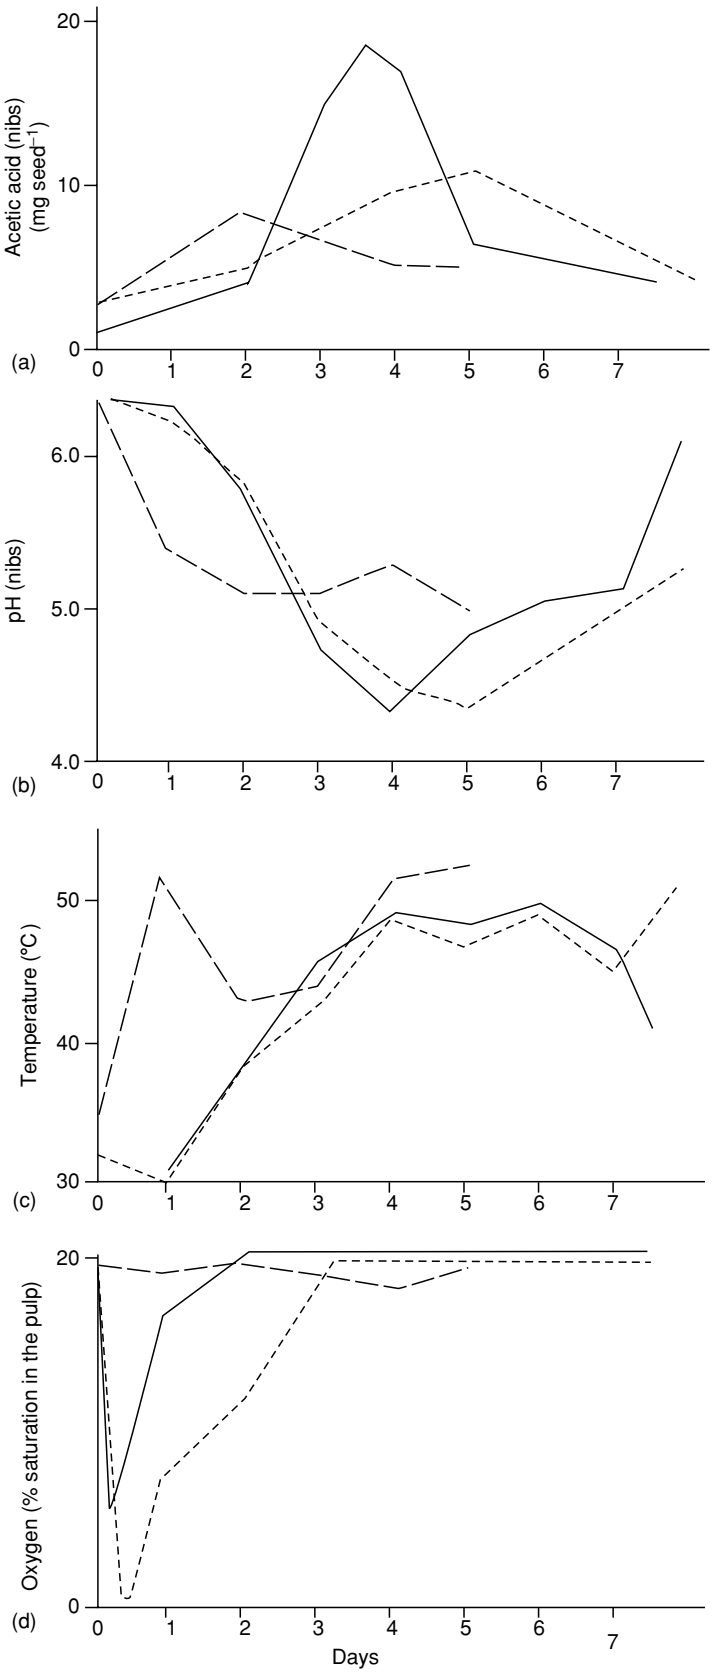

Figure 3 Differences in the course of shallow box fermentations. Solid lines, well-aerated top layer; seeds from unstored ripe pods (up to 8 days of fermentation). Dotted lines, less aerated middle layer; seeds from unstored ripe pods (up to 8 days of fermentation).

provides the beans with access to air. A second temperature increase indicates a new aerobic microbial activity on the shells, which will spread to the nibs if drying is delayed.

Seeds Stage IV seems to be important to insure browning of the beans and to harmonize flavor during subsequent drying. Although no experimental explanation is available, it is probable that developing aerophilic organisms may now help to increase shell permeability. (*See* **Lactic Acid Bacteria**.)

Although this fourth stage cannot clearly be distinguished from the preceding one, it merits special attention for correct termination of fermentation to avoid subsequent overfermentation.

Overfermentation subsequent to stage IV is characterized by a steep increase in pH value, first at the surface of the beans, and later in the nibs. It is accompanied by a pronounced darkening or even blackening of the beans and a characteristic hammy off-flavor which persists in the raw cocoa to an extent which depends on how severely this process took place before drying. Overfermentation may be looked upon as a direct aerophilic microbial attack on the nibs, destroying the cocoa flavor potential. Depending on the bean surface moisture at stage IV, the transition to overfermentation may be slow or very rapid. Wet beans may turn black overnight and may evolve a typical strong hammy off-flavor. It appears that the oxygen concentration in the fermenting mass at this stage is high enough for saturating respiration of aerobes and microaerophilic organisms, but too low for sufficient polyphenoloxidase-triggered browning reactions which would impair microbial growth.

Variables in the Course of Fermentation

Rate of fermentation The above description may give the incorrect impression of a uniform process running on a constant timescale. The stages described in the previous section and illustrated in Figure 3, however, are not bound to a fixed time but may be considerably shorter or longer.

The main reason is aeration: the more the wet cocoa is aerated in stages I and II, the quicker the temperature increases, the quicker the peak of acetic acid appears first and decreases later on (solid and dotted lines in Figure 3). These differences are much more pronounced in deep boxes. The succession of events described is not changed. Wet cocoa containing >1.0 ml of pulp per seed would pass through an ethanol fermentation even under continued aeration during stage I. In contrast, if no aeration is allowed at stage I, the pulp of wet cocoa may appear unchanged for several days. Lactic acid fermentation would slowly acidify the seeds at a low temperature. Later on, forced aeration at stages III or IV causes a quick pH increase in the nibs.

Thus, if fermentations are terminated at a prefixed time, e.g., after 6 days, the cocoa may be at stage III, stage IV, or overfermented, revealing a low or a high pH value in the nibs, respectively. In practice, aeration is intensified by turning, batch size, type of fermenter, and pulp volume per seed: the smaller the batch size, the larger is the specific surface for air uptake. The surface area is also influenced by the type of fermenter. A small conical heap (e.g., 250 kg) is much more aerated than a deep box (100 cm depth). A shallow box (30 cm depth) helps to increase surface aeration.

Nonuniformity in the course of fermentation Not only variation in rates of fermentation but also local differences in the fermenting heaps or boxes are due to inhomogeneous aeration. This applies especially to deep boxes. At stage I, oxygen is only accessible at the surface layer, where the process is accelerated, while the lower layers are still under a carbon dioxide atmosphere. The hot zone of pulp oxidation and acetic acid production slowly moves down to the bottom. If pulp volume is large and the cocoa is not turned, the anaerobic, cold situation (stage I) in the bottom layer may persist during the time the top layer goes through stages I–IV. After drying, the bottom layer would produce slatey or violet beans, whereas the top layer would consist of properly fermented or overfermented brown beans. Turning after 24 and 48 h reduces this inhomogeneity, but not enough to eliminate this effect entirely. As shown in Figure 3, even in shallow boxes acetic acid accumulation and consumption are delayed in a less aerated middle layer compared to a top layer. While this type of nonuniformity is found during fermentation of wet cocoa beans with a fully developed pulp layer, the situation may be different with beans from overripe pods covered by a thin layer of pulp. Too many turnings would reduce the capacity of the pulp to fulfill the entire sequence of stages I–IV and a premature overfermentation would result. Additionally, beans in unturned, aerated niches of

Dashed lines, middle layer; seeds from ripe pods stored for 10 days (up to 5 days of fermentation). Fermentations were performed with wet beans from Malaysian hybrids. Simplified curves: turnings in (a) after 44, 92, and 139 h; (b) and (c) after 67 and 120 h. Data derived from Meyer B, Biehl B, Said M, Samarakoddy RJ (1989) Post harvest pod storage: a method for pulp preconditioning to impair strong nib acidification during cocoa fermentation in Malaysia. *Journal of Science and Food Agriculture* 48: 285–304.

the batches in boxes or heaps may undergo abnormal changes due to heat loss, drying out, or fungal attack.

Effect of harvest and postharvest treatment on fermentation and raw cocoa quality Controlled aeration is helpful in overcoming nonuniformity but does not help in avoiding strong nib acidification (Figure 3). The minimal pH value in the beans during enzymatic reactions at stage II is essential for the formation of flavor precursors rather than the nib pH when terminating fermentation. With a large pulp volume per seed, an excess of aeration during the first stages accelerates acidification, but does neither limit acetic acid production nor decrease of nib pH values to less than pH 4.5 (Figure 3, solid line). However, nib acidification is moderate if the pulp volume per seed is small (Figure 3, dashed line).

The composition and volume of the pulp depend on pod ripeness at harvest and postharvest treatments. Ten days of open-air postharvest pod storage or several hours of bean spreading for pulp drying after breaking the pods were found significantly to reduce pulp volume, pulp water, and pulp sugar per seed (Table 1). These methods are particularly helpful prior to fermentation of small seeds with a strong layer of pulp. Subsequent shallow box fermentation proceeds with well-aerated pulp during stage I. Correspondingly, there is an early steep temperature increase, but the decrease of nib pH value and the formation and accumulation of acetic acid in pulp and nibs is considerably reduced (Figure 3). It is assumed that early aeration of a thin pulp surface layer enhances respiration of sugars by yeasts and reduces alcoholic fermentation beneath the surface, in contrast to a voluminous pulp.

The important pulp/seed relation depends on both genetic and physiological parameters: large seeds bear less pulp per seed surface area than small seeds. However, seed size does not only depend on genetics. Pods and seeds may be considerably smaller than usual when growing under adverse conditions, e.g., during severe drought. Furthermore, the pulp-to-seed ratio is significantly reduced during ripening. Large pulp volumes per seed from unripe seeds cause badly aerated slimy fermentations. In overripe pods the pulp volume is reduced as with stored pods, leading to well-aerated, rapid fermentations. Raw cocoa flavor characteristics with particular origins may depend to a large extent on these physiological stages of wet cocoa due to local traditions in postharvest treatments. In average, bean size and ripeness of pods harvested in Malaysia or in Ghana are quite different.

Seasonal effects on fermentation and raw cocoa quality are often due to these differences in the pulp. In practice, it depends on the circumstances discussed above whether or not pulp preconditioning is advisable.

Finally, if wet cocoa is exposed to rain, subsequent fermentation may lack sugar for heating and acetic acid production, and would proceed in an erratic way.

Drying

Enzyme-controlled browning reactions which do not occur before drying are essential for quality.

For sun-drying, the beans are spread on the ground, on mats or on wooden floors raised from the ground and protected against rain. Care is taken to move the drying cocoa. The layers of cocoa are made shallow or high to regulate the time of drying. Five to seven days are usually necessary to reduce the water content to less than 7.0%, a limit for fungal growth. (*See* **Drying**: Drying Using Natural Radiation.)

For artificial drying, wood fires or oil burners are connected to a flue under a floor of closely spaced slats. There are many devices of this type for passing a stream of hot air, but not of smoke, through the layer of cocoa beans. The industry rejects smoky beans but the smell of smoke may be confused with a hammy off-flavor of overfermented beans. On large estates, different types of industrial driers are used for

Table 1 Changes in the pulp during pod storage and bean spreading

effective, short-time drying. (*See* **Drying**: Theory of Air-drying.)

The first stage of drying should be effective in order to avoid overfermentation or fungal growth on the wet cocoa, if the internal pH value is high. At this stage, there is no danger in using hot air (e.g., 100 °C), although the temperature of the beans should not exceed 40–60 °C. In a shallow layer of cocoa beans, water evaporation will keep the beans cool. However, hot air flow through a deep layer ($\geq$ 10 cm) would heat the beans excessively. After external dryness of the beans has been attained, the second stage of drying can be continued slowly to facilitate enzymatic browning in the nibs and to allow moisture equilibrium in the beans from the wet core to the dry surface. Artificial drying may be interrupted for a while by a resting period. In a third stage, the cocoa should effectively be dried to < 7.5% water (w/w), preferably in a stream of warm (< 60 °C) but not hot air.

Rewetting, polishing, and drying raw cocoa are practiced locally to improve the external appearance, especially of moldy beans, but shell breaking and reinfection of the nibs may result. Rewetting also increases browning of violet beans.

After drying, the raw cocoa is sorted by removing flat, broken, externally moldy beans and foreign matter and by sieving (in the case of nonuniform bean size) to meet the quality standards. Locally, batches from different origins may be blended to reach the maximum percentage of the particular visible bean defects which are allowed in the official grading system.

Storage

Provided there are good storage conditions, properly processed raw cocoa can be stored for years without any unwanted, serious sensory or analytical indication of loss of quality or of spoilage. However, once processed, raw cocoa usually travels a long way from the tropical origin to the final manufacturing plant, being subjected to several risks underway. These risks are primarily water and high air humidity, insect infestation, and consequences of improper processing. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

In addition to general rules for storage in tropical and temperate climates, the hygroscopy of raw cocoa beans must be considered. Dry raw cocoa containing < 7.5% water will not be attacked by fungi. According to moisture absorption isotherms, this bean moisture would not be exceeded at < 80% relative humidity. However, at a high level of air humidity, any reduction in air temperature (e.g., during shipping) would cause damage by water condensation and mold growth. Residual humidity from fast drying must be considered. Repeated moisture determinations are necessary in every lot. Fungal spores are ubiquitous. However, moldy beans resulting from fermentation and drying increase the danger of fungal growth at a critical level of moisture. Thermophilic and xerophilic fungi such as *Aspergillus glaucus, A. fumigatus, Penicillium* spp. and *Mucor* sp. have been found to occur during both processing and storage. Internal mold is further facilitated on broken beans and on injured shells. Brittle shells, particularly from overfermented or rewetted cocoa, not only increase the danger of mold but also increase the amount of broken beans during transport and stacking of bags. (*See* **Spoilage**: Molds in Spoilage.)

Out of nine insect species listed by Rohan, four were mentioned to be important threats to stored raw cocoa in the tropics: *Cadra cautella, Lasioderma serricorne, Araecerus fasciculatus* and *Tribolium castaneum*. *Ephistia elutella*, the cocoa moth, is only found in temperate climates. In tropical countries, insects are controlled by fumigation of raw cocoa using the gases methyl bromide or phosphine applied to stacks of stored cocoa under a gas-proof and waterproof polythene sheet for 1.5 h. The gas is then extracted by fans. The sheets are left to protect the cocoa against uptake of moisture and insects. (*See* **Fumigants**; **Insect Pests**: Problems Caused by Insects and Mites.)

Production of Cocoa Powder and Semifinished Products

Cocoa Products

Two products are derived solely from cocoa beans: chocolate and cocoa powder. These products are interrelated, and two intermediate products play an important role – cocoa mass and cocoa butter. This relationship is made clear in Figure 4. The system

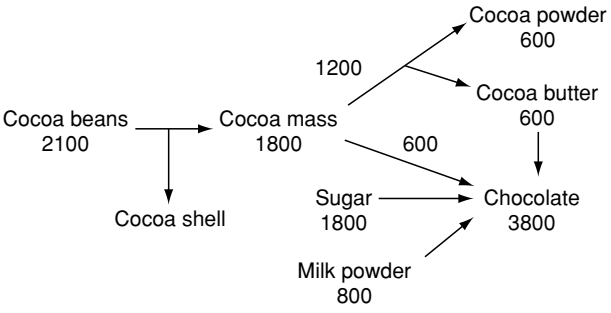

Figure 4 Products derived from cocoa beans. The figures are approximate and in 1000 tonnes. Reproduced from Cocoa: Production, Products and Uses. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

shown in Figure 4 is not fully in balance. The chocolate industry needs a certain quantity of cocoa butter and this implies that a fixed quantity of cocoa powder is also produced. However, the demand for cocoa powder does not always meet this volume. As a result, the price of cocoa butter is usually substantially higher than that of cocoa powder. The relatively high price of cocoa butter has made it attractive to lipid chemists to look for cheaper fats which could replace cocoa butter. This is not easy, as cocoa butter has unique properties, especially hardness and melting behavior. In the course of time, cocoa butter substitutes (CBSs) were developed, mostly based on palm kernel fat. These are used in combination with cocoa powder for manufacturing imitation chocolate, or coatings (for biscuits, cakes, icecream, etc). Recently, ways have been found to separate the desired triacylglycerols from other fats and to put them together in the right proportion, thus obtaining a fat that closely resembles cocoa butter. Such a fat is called a cocoa butter equivalent (CBE) and can replace cocoa butter in chocolate (Figure 5).

Quality Aspects

Cocoa powder is sold in retail packages to consumers. However, most cocoa powder reaches the consumer as a color and flavor in other products, like dessert powders, sterilized chocolate milk, chocolate cake, icecream, etc. Most of the cocoa powder produced is sold as an ingredient to other food manufacturers. Such a product should have the necessary quality aspects to meet the needs of the user, regarding microbiology, consistency, purity, and other factors. In the case of cocoa powder this can only be fulfilled when maintaining strict good manufacturing practices, the reason being that there are a number of problems which put cocoa powder in a high-risk category:

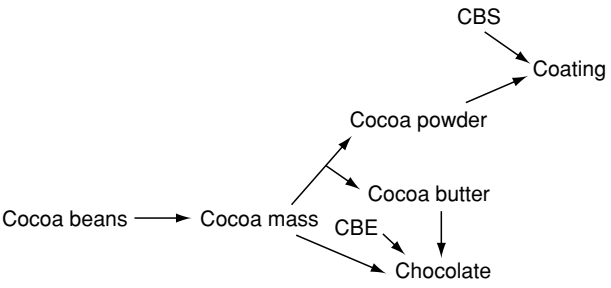

Figure 5 The use of alternative fats to cocoa butter. CBS, cocoa butter substitute; CBE, cocoa butter equivalent. Reproduced from Cocoa: Production, Products and Uses. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

- Cocoa beans undergo a fermentation process, which leaves very high bacteria counts on the bean shell.
- During fermentation the temperature goes up to 50 °C, which leaves thermoresistant spores on the bean. These may interfere with the sterilization process of chocolate milk.
- After fermentation, the cocoa beans are dried in the open air, allowing contamination with bird droppings. *Salmonella* bacteria can thus be found on crude cocoa beans.
- Bacteria which are present in cocoa mass are surrounded by fat during the grinding process. The fat gives them good protection and it has been shown that *Salmonella* can live for months in chocolate. Also, the bacteria will be protected in the stomach against its natural acidity when chocolate is eaten.
- Cocoa powder is used in many different foodstuffs, made with different manufacturing processes, requiring different shelf-lives, and having different moisture contents. As the cocoa manufacturer does not always know how the powder will be used, all the product must meet the strictest hygiene specifications. (*See* **Spoilage**: Bacterial Spoilage.)

Environment

The cocoa-processing industry is not one of the major polluters of the environment. The raw materials and the products are simply too expensive to be discarded. Of course, there are the general problems of each factory, such as noise and high, ugly buildings. How these can be avoided is well known and is taken into consideration when new chocolate factories are built. The main problem comes from the smell of exhaust gases – air blown through the grinding systems and combustion gas from the roasters. These gases also contain dust. To collect the dust, cyclones are used on a large scale in the cocoa industry. Biological filters are being tested for the removal of odors but they have not been completely successful. The present method of solving the problem is to build high chimneys. Cocoa bean-processing gives one waste product – the shell, about 10% of the weight of the beans. This loose material is usually ground to reduce its volume and sold to fertilizer or cattle feed manufacturers. Burning the shell could be worthwhile when energy costs are high, but introduces the problem of removing large quantities of dust from the combustion gas.

Production of Cocoa Mass

All cocoa beans are initially turned into cocoa mass. The necessary processes are illustrated in Figure 6. The word 'nib' is used in all languages to indicate the

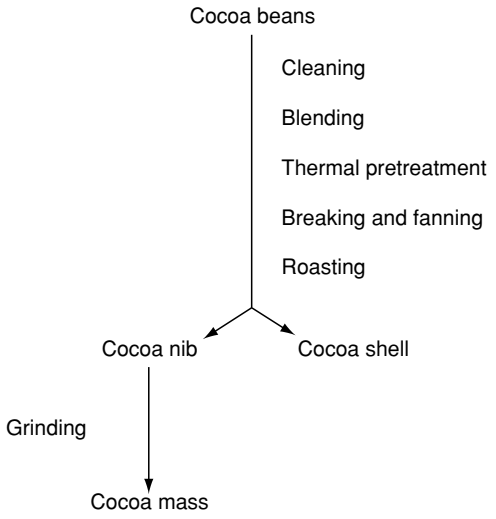

Figure 6 The production of cocoa mass. Reproduced from Cocoa: Production, Products and Uses. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

broken pieces of the kernel of the cocoa bean. Cocoa mass contains approximately 55% cocoa butter. The fat is liquid after the roasting and grinding procedures, which make the whole mass liquid. It can be pumped and transported in tank lorries.

Cleaning Cocoa beans, from silo storage or directly from their burlap bags, first pass through cleaning machines – screens, magnets and controlled air streams. Extraneous materials removed include sticks, stones, string, and metal objects.

Blending Substantial variety in flavor exists among cocoa beans from different countries. It is seldom that one batch of beans will be used exclusively in a formula. One reason is that blending provides the opportunity to obtain a certain flavor. Another reason stems from the inconsistency of cocoa beans in flavor and other quality aspects. Batches of cocoa beans show variations from one locality to another, due to differences in the weather during growth and ripening, from differences in fermentation and other variations in processing conditions. Blending will contribute to uniformity.

Thermal pretreatment An important quality aspect in cocoa bean processing is removal of the cocoa shell. The shell, as the covering of the kernel, is always greatly polluted with sand, high bacteria counts, and pesticide residues. Depending on the fermentation, the shell often sticks to the kernel, which prevents easy removal. Recently machines have been introduced which loosen the shells by means of a thermal shock. This is achieved with hot air, saturated steam, or infrared radiation.

Breaking and fanning To remove the shell, the beans are first broken between adjustable toothed rollers. The broken pieces are subsequently separated in fractions by sieving. Each fraction is treated with a stream of air which carries away the light shell pieces. This breaking and fanning process is often referred to as 'winnowing.'

Roasting The roasting process at 120–140 °C is needed for the development of the typical flavor of cocoa. Using modern technology, cocoas can be roasted at different particle sizes, such as whole beans, or as liquid cocoa mass, which is produced by a fine grinding of cocoa and liquefying within its own fat. The roasting of smaller particles has the advantages of better controlled roasting, partial exhaustion of abundant acetic acid, and reduced roasting time (beans take about 30 min, nibs 12 min, mass 2 min). The type of roasting technique may also influence microbiological aspects. The bacteria present are on the shell and by removing the shell first the material enters the roasting (= sterilization) process with a lower initial bacteria count.

Grinding and refining The next step is grinding of the cocoa nib particles. The nib consists of 55% cocoa butter and 45% solid material coming from the plant cells. The latter must be ground very finely. When eating chocolate or drinking chocolate milk, no grittiness should be felt in the mouth. For both cocoa powder and chocolate it is important that the final particle size distribution is narrow. This facilitates the pressing operation and improves the rheological properties of chocolate. The desired fineness (15–70 μm) and particle size distribution are reached in several successive grinding steps. Pregrinding of the large and hard nib particles is done in disk mills, hammer mills, or pin mills. To reach the ultimate fineness, mass for pressing is refined in modern versions of the triple stone mill, or in vertical ball mills (attrittors). In the chocolate industry, roller mills with five rolls are most commonly used for refining the mass. These are also used to grind the chocolate mass, after adding preground sugar and milk powder. (*See* **Milling**: Characteristics of Milled Products.)

Types Cocoa mass may be used for the production of chocolate, or for pressing, i.e., in the production of cocoa butter and cocoa powder. The difference between these two types of cocoa mass are the bean

blend, fineness, and microbiological condition, among others.

For chocolate, many manufacturers prefer beans from Ghana and Nigeria on account of their desirable flavor attributes. For the highest qualities, South American so-called flavor beans may also be added to the blend.

Although for all purposes mass needs to be completely safe from the bacteriological point of view, cocoa powder requires, moreover, that thermoresistant spores are absent. This condition must already have been reached in the mass, which tolerates higher temperatures than cocoa powder.

Mass for pressing is also already alkalized. This process will be discussed below.

Packaging and shelf-life When cocoa mass has to be stored or transported, it is usually packed into 30-kg cardboard boxes with a plastic liner or bag inside. In Europe and the USA most of the transport takes place in liquid form.

Cocoa mass has a very good shelf-life. The solid particles are protected by a fat with a high degree of saturation. Moreover, cocoa contains powerful natural antioxidants. These conditions also apply to cocoa beans. If the moisture content of the beans is well under control, their shelf-life will be several years. (*See* **Antioxidants**: Natural Antioxidants.)

Production of cocoa butter Cocoa mass contains 55% cocoa butter. Part of this can be extracted by mechanical pressing. The solids which stay in the press contain 22% fat, or even as low as 10%. These press cakes are ground to cocoa powder. The cocoa butter is filtered and part of it is deodorized. The production process is illustrated in Figure 7.

Pressing The cocoa mass is pumped to horizontal hydraulic presses, with pots lined up face to face, each equipped with very fine mesh metal filter screens. When all the pots are filled with mass at a temperature of 90 °C, the hydraulic ram is set in motion and the cocoa butter begins to flow through the screens on both sides of each pot. The pressure then increases to 400 bars. The hard cocoa cakes remaining are then discharged from the press. The cocoa butter collected from the press is not 'clean,' having carried with it a small amount of tiny nonfat particles. It is therefore filtered through filter paper.

Deodorization and blending Crude cocoa butter has a strong flavor. This is desirable in dark chocolate. However, in milk chocolate much more cocoa butter is used and the cocoa flavor would become too strong, suppressing the milk flavor. Thus, buyers are stipulating a cocoa butter with a weak flavor, or no flavor at all. This is reached by steam deodorization of the cocoa butter and blending crude and deodorized butter to the desired flavor. This is controlled by sensory testing, or a chemical method, the determination of the flavor profile. Crude cocoa butter, being a natural product, has a rather inconsistent flavor strength. Even if crude cocoa butter is asked for, some blending with deodorized butter is performed

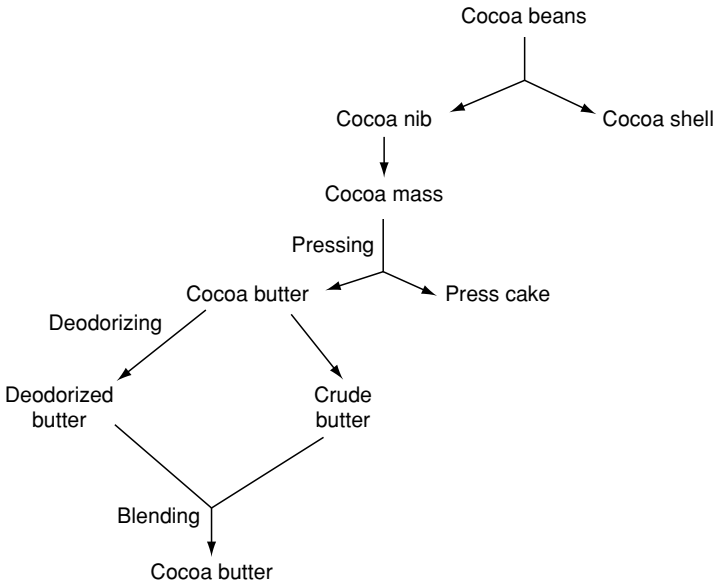

Figure 7 The production of cocoa butter. Reproduced from Cocoa: Production, Products and Uses. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

to standardize the flavor. (*See* **Sensory Evaluation**: Taste.)

Properties Cocoa butter is one of the most expensive natural fats. This is due to its unique melting behavior. Cocoa butter has a much narrower melting range than any other fat. This quality is fundamental to chocolate. Chocolate should be hard – even in hot weather – and it should not stick to the fingers. At room temperature, about 70% of the triacylglycerols in cocoa butter are solid. On eating, the cocoa butter in the chocolate should melt completely in the mouth and cause a pleasant taste sensation due to the consumed melting enthalpy. The relatively narrow melting range of cocoa butter is important in the production of chocolate. When the chocolate is cooled and the fat solidifies, a considerable decrease in volume takes place. This contraction makes it easy to release chocolate articles from their molds.

Types The above discussion has been restricted to the processing of sound cocoa beans, from which the shell has been properly removed. The fat derived from this raw material is called prime pure pressed cocoa butter. In practice, not all cocoa beans that are harvested are of a good quality. Even if the beans are unripe, moldy, or smoky, they contain a fat that can be made fully fit for human consumption by refining. When processing subgrade cocoa beans, it is difficult to remove their shells. Such beans are processed whole in continuous expeller presses. The resulting press cake still holds another 10% of fat, which can be obtained by solvent extraction. The remaining solids are, of course, not edible and are best put back on the land as a fertilizer. Although the fat will be edible after refining, the quality is inferior to the prime pure pressed butter. It is less hard and shows a smaller volume contraction. The following types of subgrade cocoa fat are recognized by the Codex Alimentarius:

1. Expeller cocoa butter: the fat extracted by means of mechanical pressing from material which has approximately the composition of whole cocoa beans.
2. Solvent-extracted cocoa butter: the fat obtained from cocoa beans or cocoa waste materials by means of extraction with permitted solvents.
3. Refined cocoa butter: any of the fats obtained in the ways mentioned above and afterwards fully refined according to the standard processing techniques for edible oils and fats.
4. Cocoa fat: fat extracted from waste materials and having a quality below certain standards.

The above processing options are summarized in Figure 8.

Packaging, transport, and shelf-life Much like cocoa mass, cocoa butter is packed in 30-kg slabs or transported and stored in a liquid form. The shelf-life

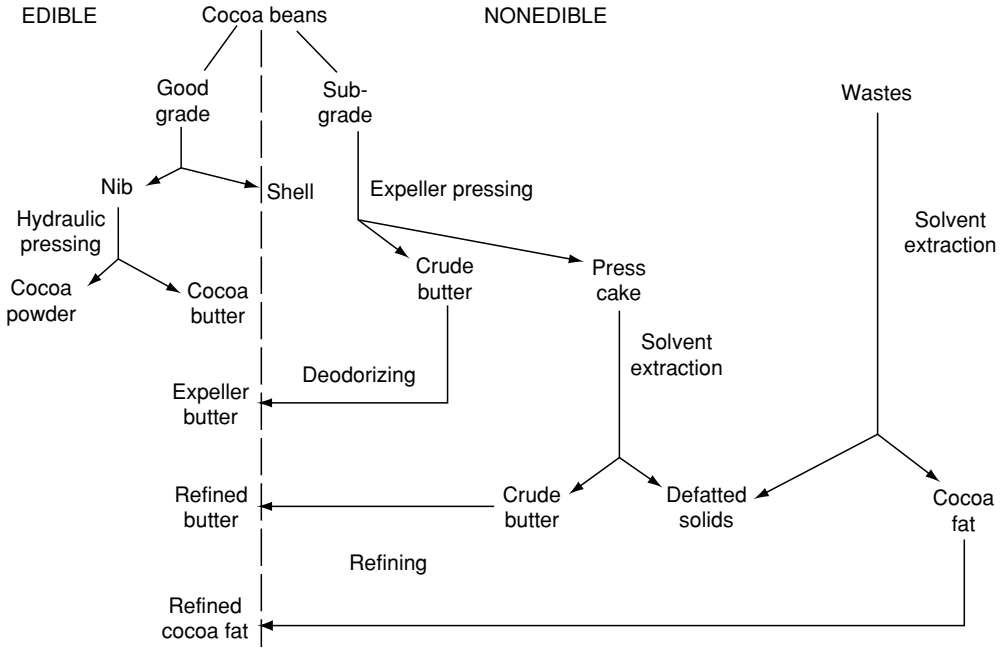

Figure 8 Types of cocoa butter. Reproduced from Cocoa: Production, Products and Uses. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

of cocoa butter is good, due to its high degree of saturation, and the shelf-life of solid cocoa butter is several months to a year, if properly packed and stored.

Production of Cocoa Powder

The press cakes are ground to powder, which is packed after complete cooling. The alkalizing process can be used to create many types of cocoa powder with differing colors. The production of cocoa powder is shown in Figure 9.

Alkalizing The alkalizing process was invented in the first half of the 19th century in the Netherlands. It improves the quality of cocoa powder in two ways:

1. It takes away the slightly acid taste of cocoa.
2. It makes the color darker. This is due to condensation reactions forming high-molecular-weight colored products. Careful control of the reactions can lead to different shades of color: orange, red, brown, and even black is possible.

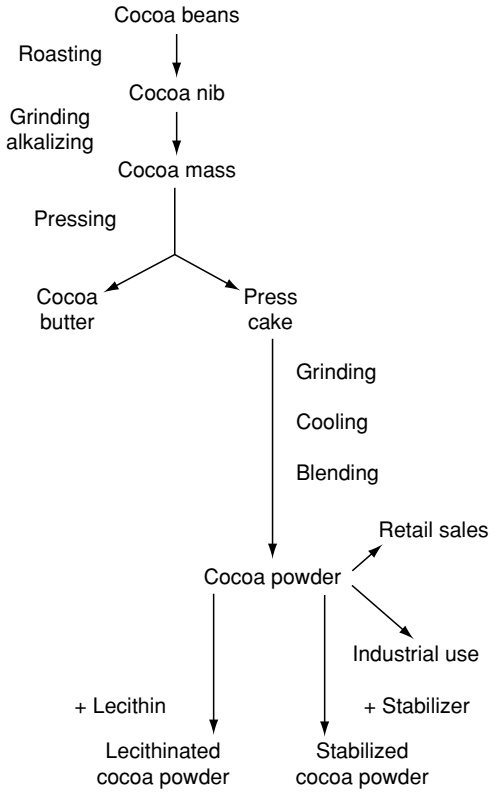

Figure 9 The production of cocoa powder. Reproduced from Cocoa: Production, Products and Uses. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Alkalizing consists of treating the cocoa with a solution of an alkali, mostly potash. Legally, the maximum amount of potash which may be used is 3%, calculated on the nib. The treatment can be performed with the nib, mass, press cake, or powder. The specific color is reached by choice of the reaction conditions: temperature, time, amount and concentration of the alkaline solution, and other factors.

Grinding, cooling, and blending of cocoa cake The press cakes are broken and then ground to powder in pin or other mills. The cocoa powder leaves the mill hot. It should be completely cooled before packing, otherwise the setting fat will turn it into hard lumps inside the package.

Blending of pieces of broken cake before grinding allows standardization of the color, or the preparation of blends with intermediate colors.

Types Variations in the two main processes lead to the formation of hundreds of different types of cocoa powder. The pressing can be performed to a fat content in the cake of 20% (giving cocoa powder) or to 10% (giving low-fat cocoa powder), while the alkalizing process creates many different colors. Cocoa powder with 20% fat is the common household type. The food industry uses mostly low-fat cocoa powder (10%), in many different colors.

For use in certain cocoa-flavored products, some special types of cocoa powder have been developed. Lecithinated cocoa powder contains 5% of soya lecithin. Owing to its fat content, cocoa powder is difficult to wet and to disperse in water. Even in hot water or milk, lumps will be formed easily. Lecithin can improve these properties by its action as a wetting agent. Five percent of soya lecithin is intensively mixed with cocoa powder and the resulting lecithinated powder is agglomerated with sugar. This gives so-called instant cocoa, which can be put directly into cold milk. (*See* **Emulsifiers**: Organic Emulsifiers.)

Stabilized cocoa powder contains about 2% carrageenan. This is a polysaccharide derived from seaweed. It prevents the cocoa powder from settling in sterilized chocolate milk. (*See* **Stabilizers**: Types and Function.)

Packaging, transport, and shelf-life Paper or tin retail packaging is well known. For bulk deliveries, 25-kg (or 50-lb) multiple paper bags are commonly used. Loose bulk delivery or storage of cocoa powder is difficult. The fat-containing fine powder tends to stick and to block pipelines for pneumatic transport. Only large users, in cooperation with large suppliers, have developed workable bulk systems. The shelf-life of cocoa powder is excellent. Even after 10 years the

flavor is good when packed in air- and moisture-proof containers. Only some fading of the color may be noticed, comparable with fat bloom on chocolate. This disappears when the cocoa is used in milk.

Production of Chocolate

The major ingredient of chocolate is cocoa mass, which is mixed with sugar and, in the case of milk chocolate, also with milk powder. The conching process then follows, which is very important for the development of the full chocolate flavor. Melted cocoa butter is added, the chocolate mass becomes liquid, and is cooled, tempered, and poured into molds to form chocolate products (Figure 10).

Mixing of ingredients and refining Sugar, cocoa mass, and milk powder are intensively mixed, forming a dry powder. This powder is preground in various types of mills and then finely ground in a five-roll roller refiner. Small operators also use vertical ball mills. The sizes of particles in chocolate are between 15 and 70 μm.

Conching The flavor which has been formed during roasting is rounded off into the typical chocolate flavor by the conching process. This process also contributes to the physical properties of the chocolate, and hence its eating characteristics. Conching is a mechanical treatment of the chocolate mass in large containers fitted with rollers, paddles, or a variety of other devices. Chemical and physical changes take place under the influence of air which is brought into the mass, at a temperature of about 60 °C, and of rubbing and shearing forces. The result is the formation or liberation of flavor components which give the delicate chocolate note. The chemistry of this process is largely unknown. Physically the dry, crumbled mass is converted into a flowable liquid suspension. The sharp edges of the sugar particles are rounded off, which will give the chocolate a smooth feeling in the mouth.

Three phases can be distinguished in conching:

1. Dry phase: the powdered chocolate mass loses moisture and less desirable volatile flavor components like acetic acid.
2. Pasty phase: during dry conching the mass becomes pasty. Flavor development takes place under the influence of shearing forces.
3. Liquid phase: the last component, cocoa butter, is added. The chocolate mass becomes liquid. Homogenizing takes place under the influence of intensive stirring and shearing.

The final degree of viscosity is very important: the melted chocolate must be sufficiently thin to fill all cavities of the molds. The melted cocoa butter is the liquid phase. However, this is the most expensive component of chocolate. A substantial saving of butter can be obtained by using an emulsifier. Soya lecithin (0.3%) is the most commonly used emulsifier which is added during the third conching phase.

A special way to produce milk chocolate is from crumb. The sugar and cocoa mass are brought into liquid milk and the whole is dried. During the lengthy drying a caramel flavor is developed. Dry milk chocolate crumb has a good shelf-life, due to the natural antioxidants of cocoa. To make chocolate, only cocoa butter has to be added. Crumb is much used in the UK.

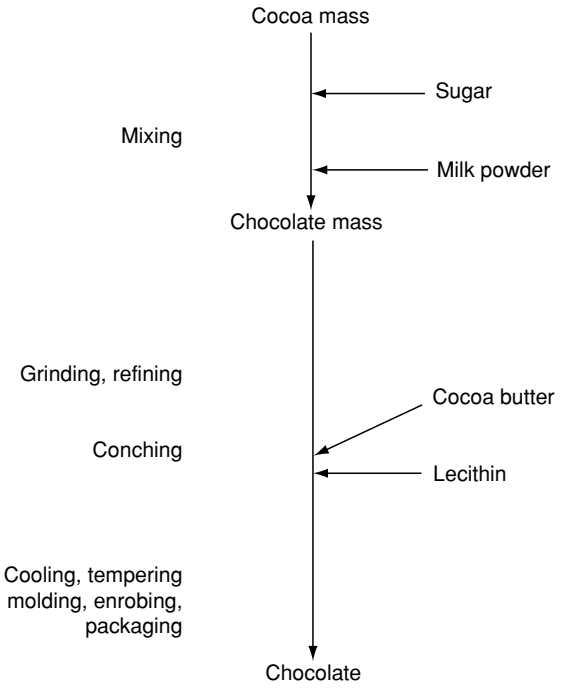

Figure 10 The production of chocolate. Reproduced from Cocoa: Production, Product and Uses. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Cooling and Tempering

Critical to the appearance, gloss, shelf-life, and mouth feel of chocolate is the way it is cooled before solidifying in molds. Cocoa butter triacylglycerides can set in several polymorphic forms. Some are unstable and recrystallization into the stable form will occur after some hours or days. This will result in a loss of gloss and the formation of white fat crystals on the surface of the chocolate – the so-called 'fat bloom.' To obtain stable crystals, stable seed crystals must be formed first. This is done in a process called

tempering. The liquid chocolate at a temperature of 45–50 °C is cooled to 32 °C, then to 27–27.5 °C and treated by special shear elements. Shear forces enhance the nucleation of stable cocoa butter crystals. The temperature is now raised to 29–31 °C, causing any crystals of unstable form to melt. The exact temperatures required for this process depend on the type of chocolate. After tempering, the chocolate is ready to be poured into the molds. It is still liquid but contains 0.1–1% of crystallized fat as seeding material.

Molding and Enrobing

Chocolate articles are made in two distinct ways.

In molding, the chocolate is poured into a mold, which then moves on a belt through a cooling tunnel. After setting, the mold is turned upside down and as a result of the volume contraction of cocoa butter, the article will easily fall out of the mold. Solid bars are then ready for packaging. It is also possible partly to fill the mold. After filling, the mold is immediately emptied, and a thin layer remains on the bottom and wall of the mold. The mold is then cooled, and a filling is poured in. After cooling, a further chocolate layer is put on the filling: this becomes the bottom of the candy when the mold is turned. Large filled bars are made this way, as also is smaller confectionery.

To make Easter eggs and other hollow products, a small quantity of chocolate is poured into a split mold. The mold is then closed and put in a shaking machine to cool. The chocolate sets against the inner wall.

In enrobing, the liquid chocolate is poured over a solid center. Many different products are made this way, like candy bars, biscuits, cakes, and icecream. The viscosity of the chocolate determines the thickness of the layer. This can be controlled with the fat content of the chocolate, which is usually slightly higher than that of molding chocolate (Table 2).

Packaging, Storage, and Shelf-life

Packaging should protect chocolate products against moisture and against odors, which can easily be picked up by the chocolate fat. Furthermore, of course, the outside of the packaging must radiate the delicacy and luxury which is the image of chocolate. Up to now these requirements have resulted in multiple packages: aluminum foil first, paper or heat-sealed foil, finally a cardboard box. Often, the combination of materials prevents reuse and it is foreseeable that less complicated packaging will be developed in the near future.

Chocolate, with its very low moisture content (below 1%) and natural antioxidants, has a very good shelf-life. However, rats, insects, and molds like it just as much as humans. Thus, proper storage is important. Another danger arises from high and irregular storage temperatures. The latter causes the formation of fat bloom. Although the white color of the fat resembles mold growing on the product, the phenomenon is completely harmless.

Food Uses of Cocoa Products

Uses of Cocoa Powder

Cocoa powder is used as a natural color and flavor in a wide variety of sweet foodstuffs. These may be solid, semisolid, or liquid, and consumed frozen or hot. These products can be grouped in the following way:

1. Aqueous systems, consumed frozen. This is the category to which icecream belongs. The cocoa powder used is mostly low-fat (10%). A great variety of colors is used to attain effects resembling dark or milk chocolate.
2. Aqueous systems, consumed at room temperature. Examples are milk products like chocolate milk drinks and desserts. Lightly alkalized cocoa with 10% fat is mostly used.
3. Aqueous systems, consumed hot. Hot chocolate is the product in which lightly alkalized cocoa powder with 20% fat is used most frequently.
4. Fat systems. These are coatings based on cocoa butter substitutes, made with 10% fat cocoa and often not alkalized (real chocolate is also not alkalized). Cocoa butter substitutes may be used for the sake of economy and, indeed, their use may be unavoidable for technical reasons. This is the case with coatings on icecream. At the low temperature of icecream, chocolate becomes too brittle and softer fats are needed.

Table 2 Indicative composition of some types of chocolate

	Cocoa mass (%)	*Cocoa butter (%)*	*Milk powder (%)*	*Sugar (%)*
Dark chocolate	40	10	—	50
Milk chocolate	10	20	15	55
Enrobing chocolate	40	15	—	45
White chocolate	—	25	25	50

Uses of Chocolate

Chocolate can be consumed as such, but it is also much used as an ingredient on or in other foodstuffs. Enrobing of biscuits and other items has already been mentioned. Chocolate drops go into biscuits, and chocolate is used in between wafers. The latter is an example of the possible use of chocolate in tropical or subtropical countries. Even if the chocolate melts, it does not spoil the outside appearance of the product, nor does it stick to the fingers.

Legislation of Cocoa Products

General directives, serving as a guideline for national food laws, are laid down by the Codex Alimentarius. Based on this, the European Union has developed harmonized directives for its member countries. The Food, Drug, and Cosmetics Act in the USA gives similar rules. In most of these countries the name 'chocolate' may only be used if no other fat is present but cocoa butter. CBE fats, up to 5% of the total chocolate content, may be used in the European Union. In Japan three types of chocolate are distinguished: pure chocolate, chocolate, and semichocolate. Only the first of these may not contain fats other than cocoa butter. *See* **Legislation**: International Standards.

COCONUT PALM

J J Lal and C V Sreeranjit Kumar, Centre for Development of Science and Technology, Thrissur, Kerala, India
M Indira, University of Kerala, Thiruvananthapuram, Kariavattom, India

Background

This is a graceful palm, 20–30 m in height, and native to the tropical regions of the world. Its requirement of high humidity, abundant rainfall (60 cm) and mean annual temperature of about 33 °F makes the sea coast its usual habitat. Characterized by tall slender and uniformly thick stem and massive crown with a large number of paripinnate leaves bearing bunches of nuts in their axils, the palm enhances the natural panoramic beauty of countries where it is extensively cultivated. It is a long-lived plant that may live as long as 100 years (Figure 1).

The fact that the coconut palm could be found throughout the tropics, even before the advent of European explorers, renders the tracing of its origin quite difficult. Coconut was first mentioned by an Egyptian monk, Cosmos Indicopleustes in 'Topographia Christiana' in AD 545. The most important regions of coconut production are the Philippine islands, Malaysia, India, Indonesia, and Sri Lanka.

There are several different varieties of coconut palms, including tall and dwarf. The common tall varieties are Ceylon tall, Indian tall, Jamaica tall, Malayan tall, Java tall, and Laguna. Malayan dwarf, Dwarf green, Dwarf orange, and Dwarf Fijian are some of the dwarf varieties. Tall varieties are commonly cultivated for commercial purpose. Tall varieties are slow to mature and produce the first flowers 6–10 years after planting. The life span of tall varieties is about 60–100 years. Dwarf varieties may grow to a height of 7.5–9 m, produce the first flowers after 3 years, and have a life span of about 30 years. Dwarf varieties are thought to have originated as a result of a mutation of tall types. D × T (dwarf × tall) and T × D (tall × dwarf) hybrids are early bearers and are found to be superior to their parents in terms of yield under favorable conditions. There are also several unusual types of coconut palms in different parts of the world. *Lodoicea maldivica*, a palm very closely related to coconut is known as double coconut or Maldive nut. Its nut is considered to be the largest plant seed in the world and looks like two coconuts joined together side by side. Macapuno is a Philippine variety of the coconut palm that does not have any water inside the coconut shell. Its 'meat' is a soft jelly-like substance that is used in popular Filipino sweets.

Coconut palm adapts to almost all types of well-drained tropical soils like coastal sand, red loam, laterite, alluvial, and the reclaimed soil of the marshy low land. A water table that is too high and remains static for long periods is harmful, but the palm can tolerate salinity and a wide range of pHs from 5.0 to 8.0.

Coconut palm is propagated with the help of seeds. Seeds are selected from healthy, high-yielding, and regularly bearing palms. One-year-old healthy seedlings with a minimum of six leaves are selected for planting. Nine-month-old seedlings with a minimum of four leaves can also be used for planting. The square system of planting, with a spacing of 7.5–9 m accommodates, 124–177 palms per hectare. The

Figure 1 (see color plate 37) Coconut palm.

triangular method with a spacing of 7.6 m accomodates 198 palms per hectare. In the hedge system of planting, larger number of plants can be planted in a unit area, ensuring sufficient light on each palm.

Calopagonium muconoides, *Mimosa invisa*, *Stylosanthes gracilis*, etc. are cultivated as cover crops in coconut gardens. *Crotalaria juncea*, *Tephrosia purpurea*, *Indigofera hirsuta*, etc. are grown as green manure crops in coconut gardens. Under rain-fed conditions, tuber crops (tapioca, yams, ginger, turmeric, etc.), banana, pineapple, and pulses can be grown as intercrops in adult coconut plantations without affecting the fertility of the soil and productivity of the palms. Under irrigated conditions, plants like cocoa form crop combinations with coconut. Pepper, cinnamon, clove, nutmeg, etc. are ideal for mixed cropping with coconut. Mixed farming, including the rearing of cattle on fodder grasses and legumes raised as intercrops with coconut gardens, in turn yield dung, and urine is a very remunerative form of mixed husbandry suited to farmers with small coconut holdings. It increases the fertility of the soil by recycling organic wastes, enhances the yield of palms, and generates additional income and job opportunities for the farmers.

Once the palm has attained the normal bearing stage, it continues to bear a bunch of nuts in every leaf axil at monthly intervals throughout its life extending over 50–60 years. The nuts mature 1 year after fertilization. Harvesting is done once every 45 or 60 days. Tender nuts are harvested at the age of 6–7 months for delicious soft drinks. Nuts for culinary purposes and copra are harvested at 11 months. The average yield per hectare varies from 10 000 to 14 000 nuts per annum. In Asia, experienced harvesters often pick the nuts from the tree after observing the color of the nuts, position of the bunch, quantity of water inside the nut, and texture of the husk. But in certain regions of the world, the ripe nuts are collected only after they have fallen from the tree. Coconut harvesting after picking from tall trees is a tedious operation, so various techniques such as coconut-climbing machines have been adopted in different regions.

Harvesting of immature nuts causes the production of rubbery copra with a high moisture content. At the same time, permitting nuts to fall naturally without picking the nuts from the tree may result in a 10% loss in the total harvest because of over-ripe nuts or germinated nuts. Losses resulting from nuts that are hidden or covered by thick weeds or shrubs could also range from 5 to 10% of the total harvest, if the coconuts are not harvested regularly.

The value-added products obtained from the palm and its wide utility make it one of the most useful trees in the world. Each and every part of the palm is useful to humanity in one way or the other. Hence, in Sanskrit, it is called the 'Kalpa Vriksha,' which means that it is a tree that provides all the necessities of life. It constitutes the part and parcel of all religious and cultural activities and forms a major source of income of the people in coconut-growing countries. It has a variety of uses centering around the nut, whether matured or green. Most parts of this tree are used medicinally especially in the Ayurvedic system, but the documented reports are scanty. The know-how is passed down from generation to generation by word of mouth, and its usage varies from place to place (**Figure 2**).

The palm plays an important role in the functioning of the local populations through its sustainable production of food, drink, and shelter. More than 100 products are available directly or indirectly from coconut, varying from simple cooking utensils to high-added-value products like cocochemicals and charcoal. The major cocochemicals are methylesters, fatty alcohols and glycerine.

Parts used

These include the root, trunk, leaves, inflorescence, bud, flower, fruit, and germinating nut.

Roots

Decoctions prepared from the roots are known for their astringent, diuretic, and antipyretic activities. It is used in mouthwashes and gargles, and is also used to treat uterine diseases. Roasted and ground roots can be used as a coffee substitute.

Trunk

The trunk is used for its starch. The juice that flows from the trunk when a coconut tree is cut down can be used as a drink, and the bark is used in some places for curing toothache and earache. The ash of the bark is sometimes sued as an antiseptic and is sometimes prescribed in scabies. The fibers of the trunk are recommended as a diuretic and are sometimes used in the treatment of tapeworm and inflammation of the throat.

Leaves

Coconut palm leaves are used for cattle as a fodder, after removing the midrib. The plaited leaves are used for thatching houses, fencing, religious ceremonies, and decorations, etc.

Bud

The terminal bud or growing point of the tree consists of a group of tightly packed yellow–white

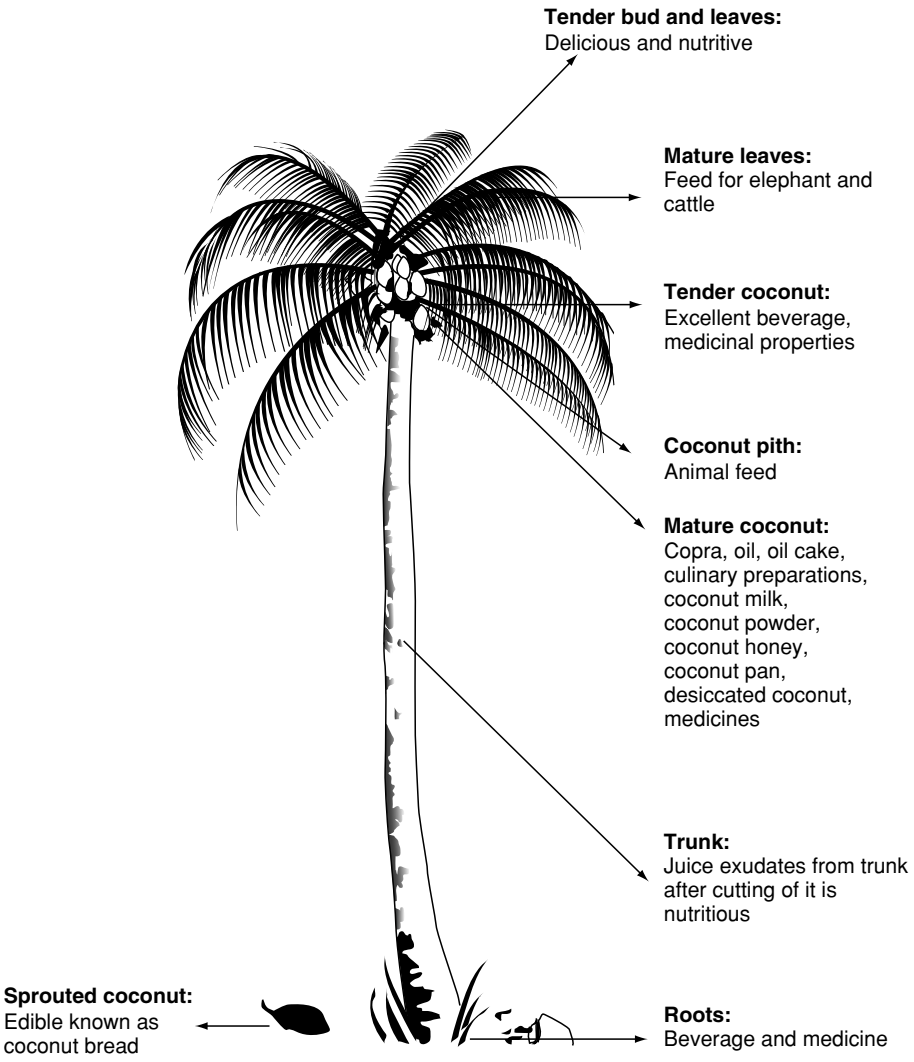

Figure 2 Coconut palm: the tree of life.

cabbage-like leaves. This forms a tasty food item known as 'millionaire's salad.' It is nourishing and digestible, and is considered to be cooling and diuretic.

Inflorescence

The inflorescence of coconut (Figure 3) is very attractive in appearance and has many medicinal properties. It is commonly used for decorations, religious functions, and several cultural and traditional rituals. It forms an ingredient of a large number of traditional medicinal preparations. Tender inflorescence as such is used for the preparation of many traditional food items, which is believed to act like a nutraceutical. It is tapped as a source of sap and is used for the production of coconut palm wine, vinegar, jaggery, and arrack.

Coconut palm wine In India and Sri Lanka, coconut palm wine is known as 'toddy,' in Philippines and Mexico as 'tuba,' and in Indonesia as 'tuwak.' It is an alcoholic beverage obtained by the natural fermentation of a sugar-containing juice from coconut palms and is obtained by tapping the unopened inflorescence of the palm. The methods of tapping the coconut palm are very ancient and vary from place to place (Figure 4). The tapping process can be summarized as follows. When the palm has reached the normal bearing stage, every leaf axils produce a spadix or inflorescence. The tapping begins when the inflorescence is 1 month old. This unopened flower inflorescence is prepared by slightly bruising it by gentle tapping with a small round piece of wood or bone (mallet). To prevent it from opening, the inflorescence is tightly bound with fiber or coconut leaves. When the inflorescence is nearly ready to produce juice, which is about 3 weeks, a length of about 5–8 cm is cut from the end. During the preparation,

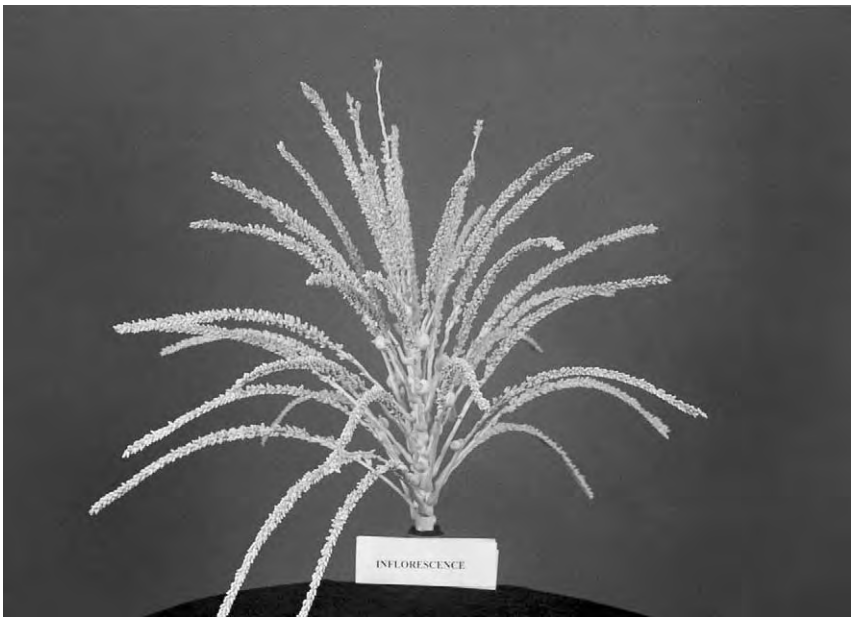

Figure 3 (see color plate 38) Inflorescence.

the inflorescence is gradually bent over, so that when the coconut palm juice flows from the vascular bundles, an earthen receptacle containing the crust of microorganisms formed from the previous fermentation is placed for its collection. The flow of juice increases gradually, and the pot is changed twice daily, at the same time shaving a thin slice from the end of the inflorescence, tapping slightly with the mallet, and smearing on a mixture of bruised leaves to stimulate the flow of palm wine from the inflorescence. When the collection of sap is over, fermentation sets in immediately, and the sap is converted into fresh coconut palm wine or sweet toddy. This product is a milky white and effervescent liquid (Figure 4a). Fermentation continues for few more hours after the sap has been pooled from various pots. The average yield of toddy per inflorescence for a tapping period of about 1 month is 18 l. Fresh coconut palm wine is sweet in taste and is considered to be a high-energy health drink. It contains a considerable amount of the natural antioxidant ascorbic acid, or vitamin C, and the amount of ethyl alcohol is 2–5% (Table 1). When fermentation proceeds, the nutritive value of fresh toddy and concentration of ascorbic acid decrease, while the concentrations of alcohol and acetic acid increase (Table 2).

Palm syrup Palm syrup is made by boiling toddy until it is thick. It can be consumed as a beverage after dilution with water. It is also a major ingredient in a number of dairy products.

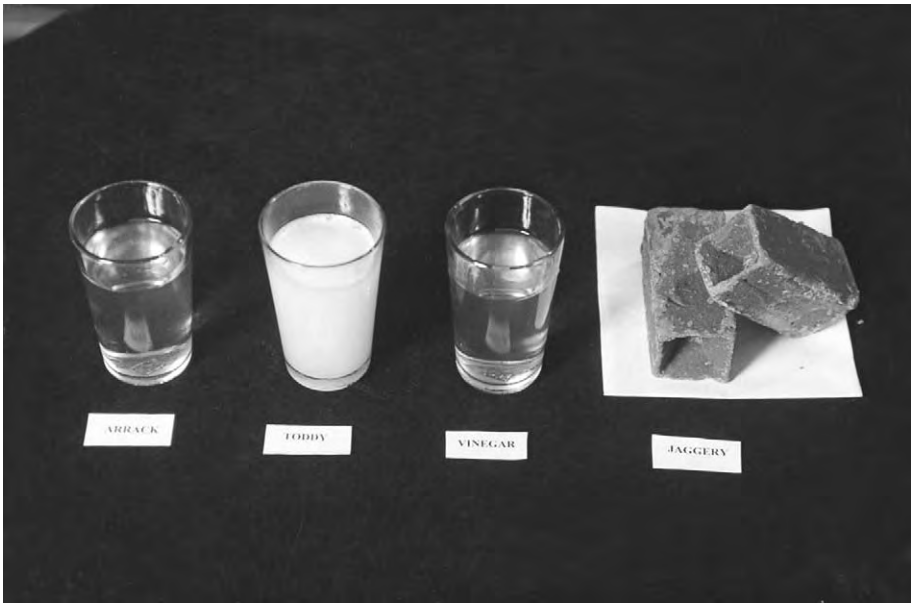
Jaggery Jaggery is a brown solid substance obtained by boiling sweet toddy up to the crystallization point (Figure 4a). It is used as a sweetening agent in bakeries and is also used in the preparation of several food items and in dairy products. The yield of jaggery from sweet toddy is about 12–15%. Owing to its flavor, color, taste, and nutritive value, nowadays, it is used as a substitute for cane sugar in several developed countries.

Fermented coconut palm wine The main fermentable carbohydrate in fresh coconut palm wine is sucrose (12–15%), and a mixture of natural microflora is used for fermentation. Isolation and culturing of microflora have revealed the presence of *Streptococcus* sp., *Lactobacillus* sp., *Acetobacter* sp., etc. The main fermentation products are lactic acid, ethanol, and acetic acid. The production of lactic acid reduces the pH from around 7.2 to 5.5 within 8 h. Acetic acid is produced from ethanol by *Acetobacter*. The low pH results in high levels of ethanol, thus providing more substrate for acetic acid production, and hence prolonged standing results in the production of acetic acid from ethyl alcohol. The concentration of ethyl alcohol in fermented toddy is 5.2–5.7%.

Different types of toddies are marketed, namely, mineral toddy, ultra toddy, total toddy, oxy toddy, etc. Techniques have also been developed to can toddy. The toddy is sterilized and canned immediately, to preclude any further fermentation and thus increasing its shelf-life to approximately 8 months.

Very few research studies have been conducted on the effects of ingestion of toddy. Studies on the lipid

(a)



(b)

Figure 4 (a) Toddy tapping. (b) Toddy products.

and carbohydrate metabolism in female rats fed commercially available toddy in India and its equivalent quantity of ethyl alcohol during gestation and lactation have shown that the biochemical alterations produced in fetuses and pups are different. The nonethanolic portion (congeners) of the toddy interferes with metabolic processes and increases the ethyl alcohol-induced toxicity.

Toddy yeast Freshly fermented toddy is a favorable medium for the propagation of baker's yeast. Hence, toddy is used as a source of yeast in the bread-baking industry. Various traditional food preparations like 'toddy bread' or 'kallappam' (a preparation of rice paste and toddy after overnight fermentation), 'vattayappam' or round bread, etc. are very common in coconut-growing areas.

Coconut vinegar Coconut vinegar (**Figure 4a**) is produced throughout South Asia, particularly Sri Lanka. It is a clear liquid with a strong acetic acid flavor and a hint of coconut flavor. It is made from

Table 1 Composition and specific gravity of fresh coconut palm wine

Ethanol	2–5 ml per 100 ml
Ascorbic acid	16–30 mg per 100 ml (little change during fermentation)
Total solids	15.2–19.7 g per 100 ml
Sucrose	12.3–17.4 g per 100 ml
Ash	0.11–0.41 g per 100 ml
Protein (N × 6.25)	0.23–0.32 g per 100 ml
Specific gravity at 29 °C	1.058–1.077

Table 2 Composition and specific gravity of 12-h-fermented coconut palm wine

Ethanol	5–5.7%
Acidity (as acetic)	0.32–0.67%
Water	90.3–96.3%
Protein	0.2%
Ether extractives	0.1%
Carbohydrates	1.3%
Mineral matter	0.01%
Calcium	< 0.01%
Phosphorus	0.01%
Vitamin B_1	< 5 IU per 100 ml
Specific gravity at 29 °C	0.998–1.033

toddy on a commercial scale. Toddy is stored in acetifying vats, permitting free access to air. Acidification usually takes about 10–14 days. The alcohol is converted to acetic acid by acetic acid-producing bacteria (*Acetobacter*) naturally present in toddy. Vinegar usually contains 4–5% acetic acid.

Arrack Arrack (Figure 4a) is obtained by distilling fermented toddy and is common in many countries, notably in the Philippines and Sri Lanka. It is also known as coconut fenny in the Indian State of Goa. In these regions, arrack obtained from toddy is considered to be superior to the arrack from molasses and hence is recommended as a potential agent, even for postnatal care.

Flower

The male and female flowers are separate and are arranged on the same inflorescence. The spadix of a mature palm produces on average 300 female flowers. These flowers are used in many Ayurvedic preparations. Pollen grains also have medicinal properties. The flowers are astringent and are used in the treatment of diabetes, dysentery, leprosy, and urinary discharges. Opened flowers in the inflorescence provide a good source of pollen for bees.

Fruit

The fruit is 25 cm or longer in length, ovoid, and obtusely triangular in cross-section. The tough fibrous outer husk (mesocarp) encloses a spherical nut comprising a hard, bony shell (endocarp) within which is a layer of fleshy meat or kernel (endosperm) just under 1 cm in thickness (Figures 5–7). The kernel is high in oil and protein when compared with other oil seed crops. Inside the shell is the liquid endosperm of coconut or coconut water. If the nut is allowed to germinate, the cavity of the fruit is filled with a spongy mass called 'bread.' This bread is eaten raw or toasted in the shell in coconut-growing regions. Sprouting nuts are also delicious edible items. The husks and small nuts from a variety of coconut trees found in the Pacific are also eaten. Religiously, the fruit plays an important role as an offering to God.

Husk Coconut husk is widely used in horticulture, especially for growing orchids. Experiments have also proved that coir pith from green fruits can be used as feed for pigs.

Coir pith Coir pith is a waste product obtained during the process of extraction of coir fiber from the husk. It is very light, highly compressible, and highly hygroscopic. It is used as a soil conditioner, surface mulch/rooting medium and as a desiccant. Composted coir pith is an excellent organic manure for indoor plants as well as for horticulture crops.

Shell Tarry oil prepared from the shell of the nut is used externally for the treatment of ringworm. It is also used to tenderize meat while cooking. It can also be made into attractive vessels, spoons, flower vases, etc. In rubber-growing regions, it is used for collecting latex in plantations. Being a natural product, nowadays, it is considered to be the best natural alternative for food packing.

Kernel Coconut kernel is consumed in the daily diet as a culinary ingredient in several parts of the world. It is either used in the normal state or ground to a paste. Tender coconut kernel is very delicate and is a refreshing and high-energy item. Several preparations with tender coconut kernel are popular in the coconut-growing areas of the world. Raw coconut kernel and fried coconut kernel are delicious items in several parts of the world and are used for several Ayurvedic preparations.

Factors such as the variety of the palm, stages of maturity of the nut, and conditions of growth determine the composition of the kernel. The moisture, protein, and ash content of the kernel decreases as the nut matures, whereas the fat content increases.

Since the coconut kernel contains 40% oil on average, the general notion is that its consumption could elevate cholesterol levels. Besides coconut oil, the

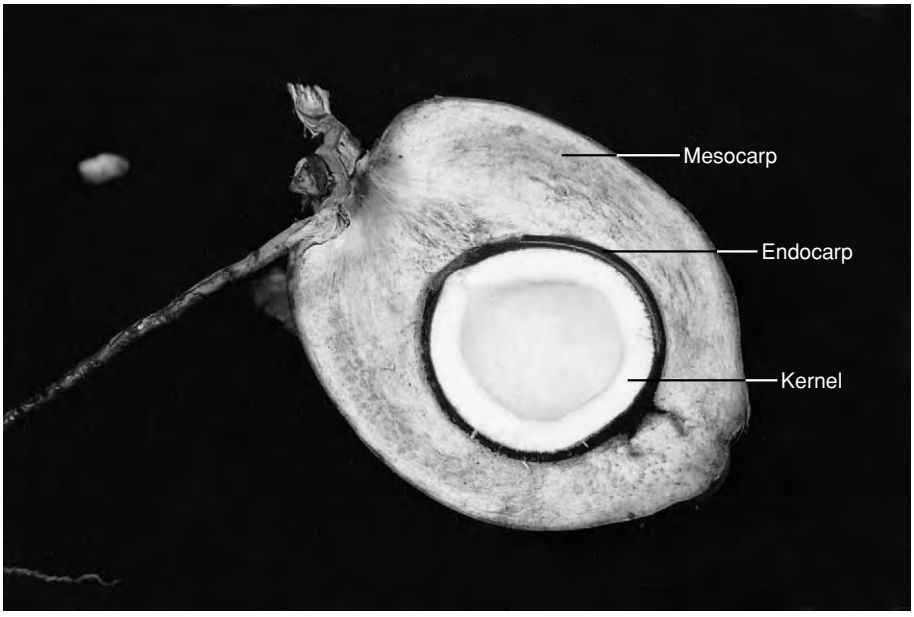


Figure 5 Vertical section: coconut.

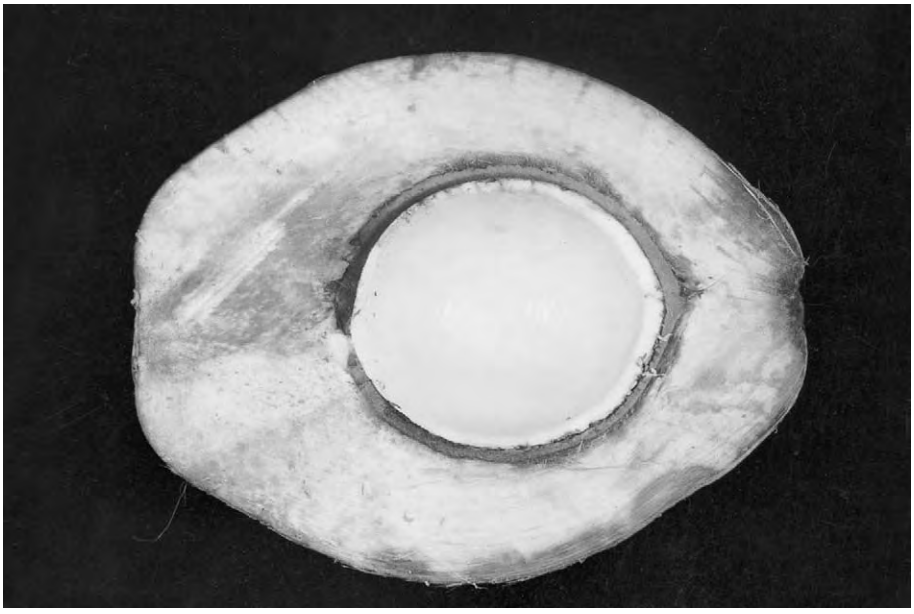

Figure 6 Vertical section: tender coconut.

kernel contains 3.6% dietary fiber (Table 3). Research studies undertaken in rats at the University of Kerala have strongly indicated a significant hypolipidemic effect of the neutral detergent fiber isolated from coconut. This effect is attributed to the presence of a hemicellulose component. Proteins isolated from coconut kernel have also been found to have a lipid-lowering effect in experimental animals. This beneficial effect of the kernel protein is attributed to its very low lysine/arginine ratio (2.13% lysine and 24.5% arginine). Recent reports have shown that feeding coconut kernel along with coconut oil in human volunteers reduced the total serum cholesterol and low-density lipoprotein-C (LDL-C) when compared with feeding coconut oil alone. Neutral detergent fiber extracted from coconut has been shown to decrease the levels of lipids and lipid peroxides in rats fed a fat-rich diet.

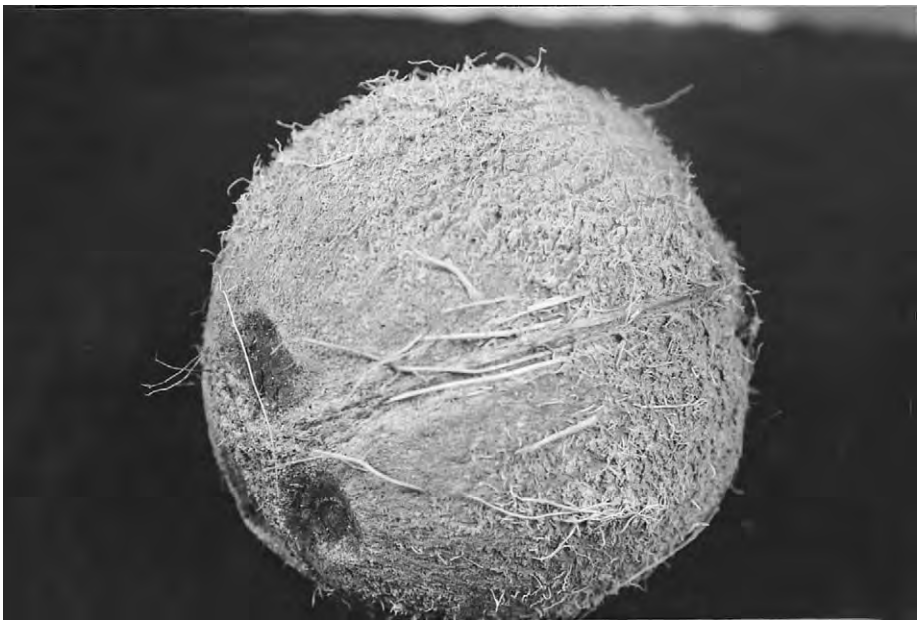

Figure 7 Dehusked coconut.

Table 3 Composition of fresh coconut kernel

Water	36.3 ml per 100 g
Protein	4.5 g per 100 g
Fat	41.6 g per 100 g
Carbohydrates	13.0 g per 100 g
Fiber	3.6 g per 100 g
Minerals	1.0 g per 100 g
Among the minerals present:	
Ca	10 mg per 100 g
P	24 mg per 100 g
Fe	1.7 mg per 100 g

Desiccated coconut Desiccated coconut is the disintegrated and dehydrated coconut kernel or pulp largely comprising the white portion of the kernel, after removing the brown testa or parings. It is referred to as 'farane de coco' in France. The process of preparation involves initial sterilization by washing in boiling water, followed by disintegrating or shredding and ultimately by drying at 60–75 °C to a moisture level of less than 2.5%. Desiccated coconut was first manufactured from imported nuts in England and in the USA in the early 1880s. It is pure white in color, crisp, and has a fresh taste. It contains 68–72% oil and has a nitrogen content of around 1.05%. The chief protein is globulin, the sugar present is mainly sucrose (6–7%), and the crude fiber amounts to 4%.

Coconut oil is important in the confectionery and bakery industry. It is mainly used in biscuits, confectionery, bakery, and other food industries, and also for household purposes in countries where coconut is not grown.

Byproducts of manufacture of desiccated coconut (brown testa or parings) The parings, which, under normal working conditions, amount to 12–15% of the kernel, are dried and pressed for oil (yield 55%). Parings oil differs somewhat in composition from ordinary coconut oil. Its iodine value ranges from 19 to 25, its saponification value ranges from 237 to 244, and its acid value is higher than that of commercial coconut oil. Parings oil is mostly used for soapmaking.

Coconut milk Coconut milk is the cold aqueous extract of coconut kernel (Figure 8) and is used in cooking. Techniques have been developed to preserve coconut milk, and so now it is available commercially. Various techniques have also been developed to manufacture coconut cream and spray-dried coconut milk powder.

Coconut milk after bottling can be used as a substitute for cows' milk. In Philippines, sugar and citric acid are added to coconut milk to produce coconut syrup, which is used in the confectionery. Coconut honey is also prepared from coconut milk after the addition of jaggery and glucose. This has a nutty flavor and can be used as a substitute for honey.

Copra Dried or dehydrated coconut is called copra (Figure 8). On average, 1000 nuts will produce about 180 kg of copra. Copra is used as a culinary ingredient and also for the production of oil. Copra processing is a widespread activity involving dehusking, splitting the nuts into two equal halves, and sun

Figure 8 Coconut products.

drying. Sun drying takes about 4–7 days, depending on the sunshine, to dry copra to the desired moisture level (below 6%). Improved drying methods to reduce the duration of drying include smoke drying and hot-air drying. Smoke drying, requiring a drying time of 36 h, and hot-air drying reduce the contamination of copra and fungal attack, thus improving the quality of the oil.

Feeding of copra to pigs and poultry has produced good results, but it is an expensive animal feed. As the fat in copra contains only small amounts of unsaturated fatty acids, its consumption leads to firm body fat and good flavor.

Table 4 Fatty acid profile of coconut oil

Common name	*Fatty acid*	*Percentage*
Caproic acid	6:0	0.2–0.5
Caprylic acid	8:0	5.4–9.5
Capric acid	10:0	4.5–9.7
Lauric acid	12:0	44.1–51
Myristic acid	14:0	13.1–18.5
Palmitic acid	16:0	7.5–10.5
Stearic acid	18:0	1.0–3.2
Arachidic acid	20:0	0.2–1.5
Oleic acid	18:1*n*-9	5.0–8.2
Linoleic acid	18:2*n*-6	1.0–2.6

Coconut oil Coconut oil (Figure 8) constitutes the major commercial product of coconut. Coconut oil is used as a cooking fat, hair oil, body oil, and industrial oil. Refined coconut oil is prepared exclusively for industrial purposes and is widely used in the manufacture of biscuits, chocolates, icecreams, margarine, and confectionery items. It is also used for the manufacture of paints and pharmaceutical agents. Desirable properties such as a low melting point, resistance to rancidity, pleasant flavor, and easy digestibility make it an ideal ingredient in the food industry. Coconut oil is a source of many oleo chemicals such as fatty acids, methyl esters, and fatty alcohol. For cooking and toiletry purposes, it is commonly used in the form of filtered coconut oil. Virgin coconut oil, which is a high-quality oil, is prepared from the milk extracted from the raw kernel. This type of coconut oil is most suitable as a massage oil for babies.

Coconut oil is a rich source of saturated fatty acids, and short- and medium-chain fatty acids account for 70% of these fatty acids (Table 4). It has a low content of unsaturated fatty acids with a negligible content of both *n*:6 and *n*:3 polyunsaturated fatty acids and a low *n*:6/*n*:3 ratio (< 4). The highly resistant nature of coconut oil to oxidative rancidity is attributed to its high concentration of saturated fat and low unsaturated fatty acids. This quality makes it suitable for storage without deterioration.

Copra, which is obtained by drying coconuts, is the source of coconut oil. Power-driven rotaries and expellers are used for extracting oil from copra. This oil extraction is immediately followed by the separation of cake residue and mucilage by filtering or by settling.

Because of the unique qualities of lauric acid (C:12) present, coconut oil is widely used in soaps and

cosmetic manufacturing industries. Lauric acid is known to possess antiviral, antibacterial, and antiprotozoal qualities. It is converted to the monoglyceride monolaurin in the human or animal body. Monolaurin is antiviral, antibacterial, and antiprotozoal. Reports indicate that monolaurin is capable of destroying lipid-coated viruses such as HIV, herpes, cytomegalovirus, influenza, various pathological bacteria, including *Listeria monocytogenes* and *Helicobactor pylori*, and protozoa such as *Giardia lamblia*. It is synthesized in babies from the lauric acid of mother's milk. Capric acid, another fatty acid found in coconut, also has antimicrobial activities.

Tocopherols are the natural antioxidants present in coconut oil. The volatile flavor constituent of crude coconut oil includes ketones, lactones and δ-lactones of which δL_8 to δC_{10} with undecan-2-1 as the major component at 290 p.p.m. and δ-decalactone as the major lactone component at 97 p.p.m. The flavor and aroma of coconut oil are attributed to δ-octalactone. Ketones are derived from the microbiological dissociation of fatty acids. The digestibility coefficient of coconut oil is higher (with 91.0% assimilable glycerides) than any other fat, including butter, and so it is digested more rapidly than any other fats. This easy digestibility makes it an essential ingredient for many ghee substitutes.

The consumption of saturated oil could hasten the onset of cardiac problems, as suggested by certain research studies. Coconut oil, being a saturated oil, caused concern that adversely affected the prospects of the coconut industry. The major fatty acids of coconut oil are medium-chain fatty acids. A shorter chain length allows fatty acids to be metabolized without the use of a carnitine transport system. Since the short- and medium-chain fatty acids can be rapidly oxidized, they are less conducive to fat deposits compared with long-chain fatty acids. Early studies conducted in experimental animals fed a synthetic diet containing coconut oil as the source of fat have shown it to be atherogenic, since it is deficient in essential fatty acids. Essential fatty acid deficiency is known to facilitate the development of atherosclerosis. But under normal conditions, the possibility of essential fatty acid deficiency as such is quite remote, since their presence in other food items will offset any deficiency in coconut oil. Thus, the increase in lipogenesis observed in earlier studies was due to the faulty design of the experiments. Feeding coconut oil at normal levels along with other fats adequately supplemented with linoleic acid renders coconut oil neutral in terms of atherogenecity. Epidemiological studies also support this. The University of Kerala conducted a study in 64 volunteers and found no statistically significant alterations in the serum total cholesterol, high-density lipoprotein (HDL) cholesterol, LDL cholesterol, HDL-C/total cholesterol ratio, LDL-C/total cholesterol ratio, and triglycerides from the baseline values. Feeding coconut oil results in an increase in HDL cholesterol.

Recent studies have shown that the presence of natural coconut fat in the diet leads to a normalization of body lipids, protects alcohol damage to the liver, and improves the immune system's antiinflammatory response.

Coconut oil is needed for the good absorption of fat and calcium from infant formulas. Hence, it has been recommended in infant formulas.

Coconut Cake

This is the residue left after the extraction of oil from copra and is widely used as cattle feed (Figure 8). The residual oil in the cake can be extracted by the process of solvent extraction, and the resulting defatted cake, containing less than 1% oil, is used in cattle-feed manufacture. The extracted residual oil is largely used for industrial purposes.

Uses of coconut cake Coconut cake, which is commonly used as a cattle and poultry feed, is soaked in water prior to feeding. Since it imparts a firm texture to butter and provides harder body fat, it is useful for dairy and fattening cattle, respectively. Field and laboratory investigations have shown that coconut cake can be used as a fertilizer (Table 5). Coconut cake is rather rich in fiber, and hence, its inclusion in pig diets is restricted. The maximum safe quantity of coconut cake with dairy cows is 1.5– 2 kg daily; feeding larger quantities may result in tallowy butter. Beef cattle can consume much more without any impairment in carcass quality.

Coconut flour This is essentially coconut cake in a more attractive and edible form. It is prepared by extracting oil from desiccated coconut, drying, and grinding the residue to a suitable degree of fitness. Its

Table 5 Composition of coconut cake after removing oil by the expeller method and solvent-extraction method

Composition	*Method of extraction*	
	Expeller (%)	*Solvent extraction (%)*
Moisture	7.0	8.9
Fat	6.7	2.4
Protein (N × 6.25)	21.2	21.4

Fiber	11.2	13.3
Mineral matter	6.5	6.6

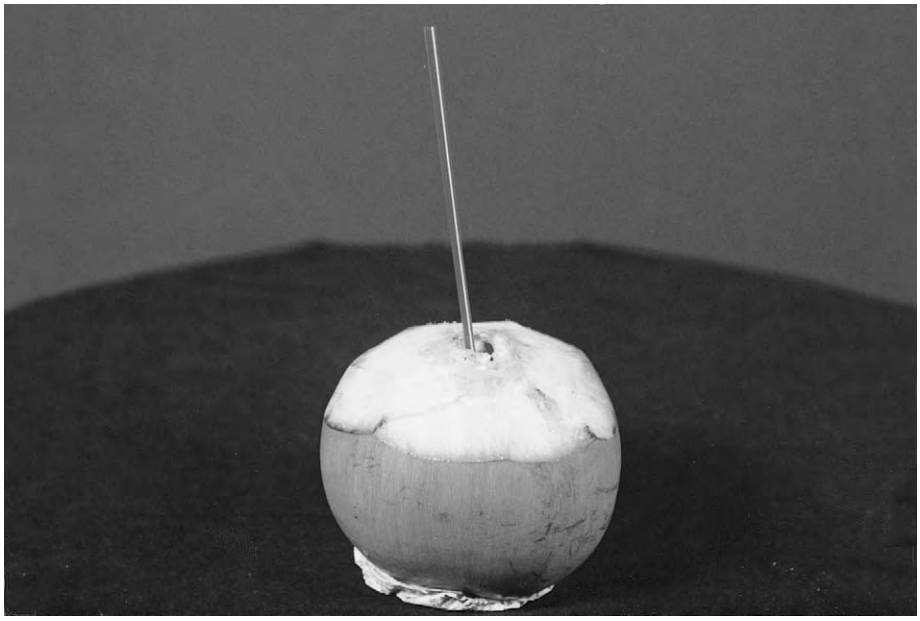

Figure 9 Tender coconut.

keeping qualities are not good, and it may be expensive.

Coconut water This is the liquid endosperm of coconut (Figure 9). The composition of coconut water changes during the course of ripening of the fruits and in germination. The concentration of total solids during the initial days is about 2.5 g per 100 ml. This increases gradually as the nut ripens, reaches a maximum of about 6 g per 100 ml at about the seventh month, and then declines. During germination, water completely disappears.

Sugars are the most important constituent. During the early days, only inverted sugars are present, and their concentration in the coconut water increases to a maximum by the fifth and sixth month. Thereafter, the level of sucrose rises, though the concentration of the total sugars declines rapidly, until its content reaches 2 g per 100 ml approximately.

Tender coconut water is commonly consumed as a beverage. It is enriched with various minerals such as potassium, phosphorus, magnesium, sulfur, chlorine, sodium, calcium, copper, iron, etc. Various proteins and amino acids such as arginine, cystine, alanine, etc. and the B vitamins are also present. Moreover, it is recommended as a useful alternative to glucose saline in cases of gastroenteritis and urinary diseases. It has a caloric value of 0.073 kJ per 100 g, potassium constitutes the principal inorganic constituent, and malic acid is the predominant organic acid (Table 6).

Experimental studies have indicated the presence of certain unidentified substances or combination of substances in coconut water that are capable of inducing rapid proliferative changes in plant tissues. Nate-de-coco is a gelatinous delicacy formed by the action of the microorganism *Acetobactor xylinium* in the culture medium of coconut water. Coconut water is also an excellent medium for the production of protein foods using a culture of the food yeast *Saccharomyces fragilis*.

A patent granted by the UK to the FAO involving a new technology permits manufacturers to bottle biologically pure and tasty coconut water that is rich in salts, sugars, and vitamins, as used by athletics. This technology employs a cold sterilization processing method that prevents the loss of flavor and other nutritional characteristics. It is also used in medicinal preparations. In the Ayurvedic ointment 'ilaneer-kuzhmbu' (from the Sanskrit terms 'ilaneer,' meaning tender coconut water, and 'kuzhambu,' meaning

Table 6 Composition of ascorbic acid and B vitamins in coconut water

Vitamin	*Amount*

paste) for the eye, coconut water is used as the principal ingredient.

Coconut water increases the blood circulation in the kidneys and causes profuse diuresis. It is also a urinary antiseptic and eliminates poisons through the kidneys in case of mineral poisoning.

Coconut water vinegar Despite its low sugar content, coconut water is considered to be a good base for vinegar. For this, coconut water is allowed to ferment for 7 days after adding sugar, as a result of which sugar is converted to alcohol.

Heart of the Palm

In some places, the heart of the palm is used raw or boiled for use in salads.

COENZYMES

J H Freeland-Graves, University of Texas at Austin, Austin, TX, USA
C Bavik, University of Sheffield, Sheffield, South Yorkshire, UK

Background

Life as we know it is made possible by enzymes, highly specific proteins that facilitate biochemical reactions. The term holoenzyme refers to an active enzyme complex. An apoenzyme is the protein portion of the active unit. The term prosthetic group is used to refer to minerals, activated vitamins or other nonprotein compounds that are required for full enzyme activity. Cofactors are nonprotein substances, typically mineral ions and activated vitamins that are required for the function of certain enzymes and other regulatory proteins. Some cofactors are essential at the active site of a reaction, while others help maintain the structural integrity of an enzyme or protein. Coenzymes are activated vitamins that participate in reactions with a stoichiometry equal to substrate. (*See* **Enzymes**: Functions and Characteristics.)

An overview of how vitamins and minerals participate as cofactors in the overall processes of

metabolism is illustrated in Figure 1. Cofactors are essential in numerous biochemical pathways, including the breakdown, or catabolism, of nutrients and the synthesis, or anabolism, of biological compounds. The vitamin and mineral cofactors complex with enzymes to convert nutrients into usable energy and produce biomolecules that are the basis of life. (*See* **Minerals – Dietary Importance**; **Trace Elements**; **Vitamins**: Overview.)

Nutrients as Coenzymes and Cofactors

Without the required vitamins and minerals, cofactor-dependent enzymes could not mediate metabolism or maintain normal cell function and biological processes that are essential for cell division, differentiation, growth, and repair. Nutrient cofactors are also necessary for the structural integrity of certain hormones and regulatory proteins.

Vitamins

All of the water-soluble vitamins and two of the fat-soluble vitamins, A and K, function as cofactors or coenzymes. Coenzymes participate in numerous biochemical reactions involving energy release or catabolism, as well as the accompanying anabolic reactions (Figure 1). In addition, vitamin cofactors are critical for processes involved in proper vision, blood coagulation, hormone production, and the integrity of collagen, a protein found in bones. (*See* **Retinol**: Physiology.)

The active coenzyme form of thiamin, vitamin B_1, is thiamin pyrophosphate (TPP) (Figure 2a). TPP is involved in oxidative decarboxylation and transketolase reactions. An example is the decarboxylation (removal of —COO^{-}) of three-carbon pyruvate to two-carbon acetyl coenzyme A (CoA), an important step in carbohydrate breakdown. (*See* **Thiamin**: Physiology.)

The active forms of riboflavin, vitamin B_2, are the coenzymes flavin mononucleotide (FMN; Figure 2b) and flavin adenine dinucleotide (FAD). These coenzymes serve as hydrogen carriers for oxidation reactions that affect energy nutrients in the citric acid cycle and in the electron transport system. (*See* **Riboflavin**: Physiology.)

The coenzyme forms of nicotinic acid are nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). These compounds assist dehydrogenase enzymes in the catabolism of fat, carbohydrates, and amino acids, and in the enzymes involved in synthesis of fats and steroids and other vital metabolites. (*See* **Niacin**: Physiology.)

Pyridoxal phosphate (PLP; Figure 2c) and pyridoxamine phosphate (PMP) are the coenzyme forms of vitamin B_6. These are cofactors for approximately 120 enzymes, such as the transaminases, racemases, decarboxylases, cleavage enzymes, synthetases, dehydratases, and desulfydrases. Both PLP and PMP participate in the metabolism of amino acids, including transamination, racemization, deamination, and desulfhydration, and the conversion of tryptophan to nicotinic acid. (*See* **Vitamin B_6**: Physiology.)

Pantothenic acid (PA) is a B vitamin that is a component of coenzyme A (Figure 2d). Coenzyme A is necessary for the metabolism of carbohydrates, amino acids, fatty acids, and other biomolecules. As a cofactor of the acyl carrier protein, pantothenic acid participates in the synthesis of fatty acids. (*See* **Osteoporosis**.)

The coenzyme forms of vitamin B_{12} are methylcobalamin (Figure 2e) and deoxyadenosylcobalamin. These assist in the conversion of homocysteine to the amino acid methionine, the oxidation of amino acids and odd-chain fatty acids, and the removal of a methyl group from methyl folate, which regenerates tetrahydrofolate. (*See* **Cobalamins**: Physiology.)

Biotin as the coenzyme biocytin functions in carboxylation reactions that convert odd-carbon-numbered amino acids and fatty acids to even-carbon-numbered compounds, which can then be metabolized. Biocytin is also necessary for the synthesis of pyrimidines and the formation of urea. Some holoenzymes containing biotin act as carboxylases to convert acetyl CoA to cholesterol precursors, and as transcarboxylases and decarboxylases in other important reactions. (*See* **Biotin**: Physiology.)

A coenzyme of folate is tetrahydrofolate (THF), a carrier of one-carbon units, such as methyl groups (—CH_3). One-carbon units arise primarily from the metabolism of amino acids. They are needed to interconvert amino acids and to synthesize purines and pyrimidines for the formation of RNA and DNA. (*See* **Nucleic Acids**: Physiology.)

Vitamin C (ascorbic acid) is a cofactor for the hydroxylases. Some examples are the hydroxylation of proline and lysine to create cross-links from intramolecular hydrogen bonds that are critical to the structural integrity of collagen, the hydroxylation of cholesterol to form bile acids, and the hydroxylation of tyrosine to form the hormone norepinephrine (noradrenaline). (*See* **Ascorbic Acid**: Physiology.)

The aldehyde form of vitamin A, retinal, is a cofactor for apoproteins in the eye called opsins. Opsins are responsible for dim-light vision in the rods (rhodopsin) and are involved in color and bright-light vision in the cone of the retina (iodopsin). When light strikes the retinal bound to opsin, the conformation of the retinal is changed (photoisomerization) such that photoreceptor cell membranes are

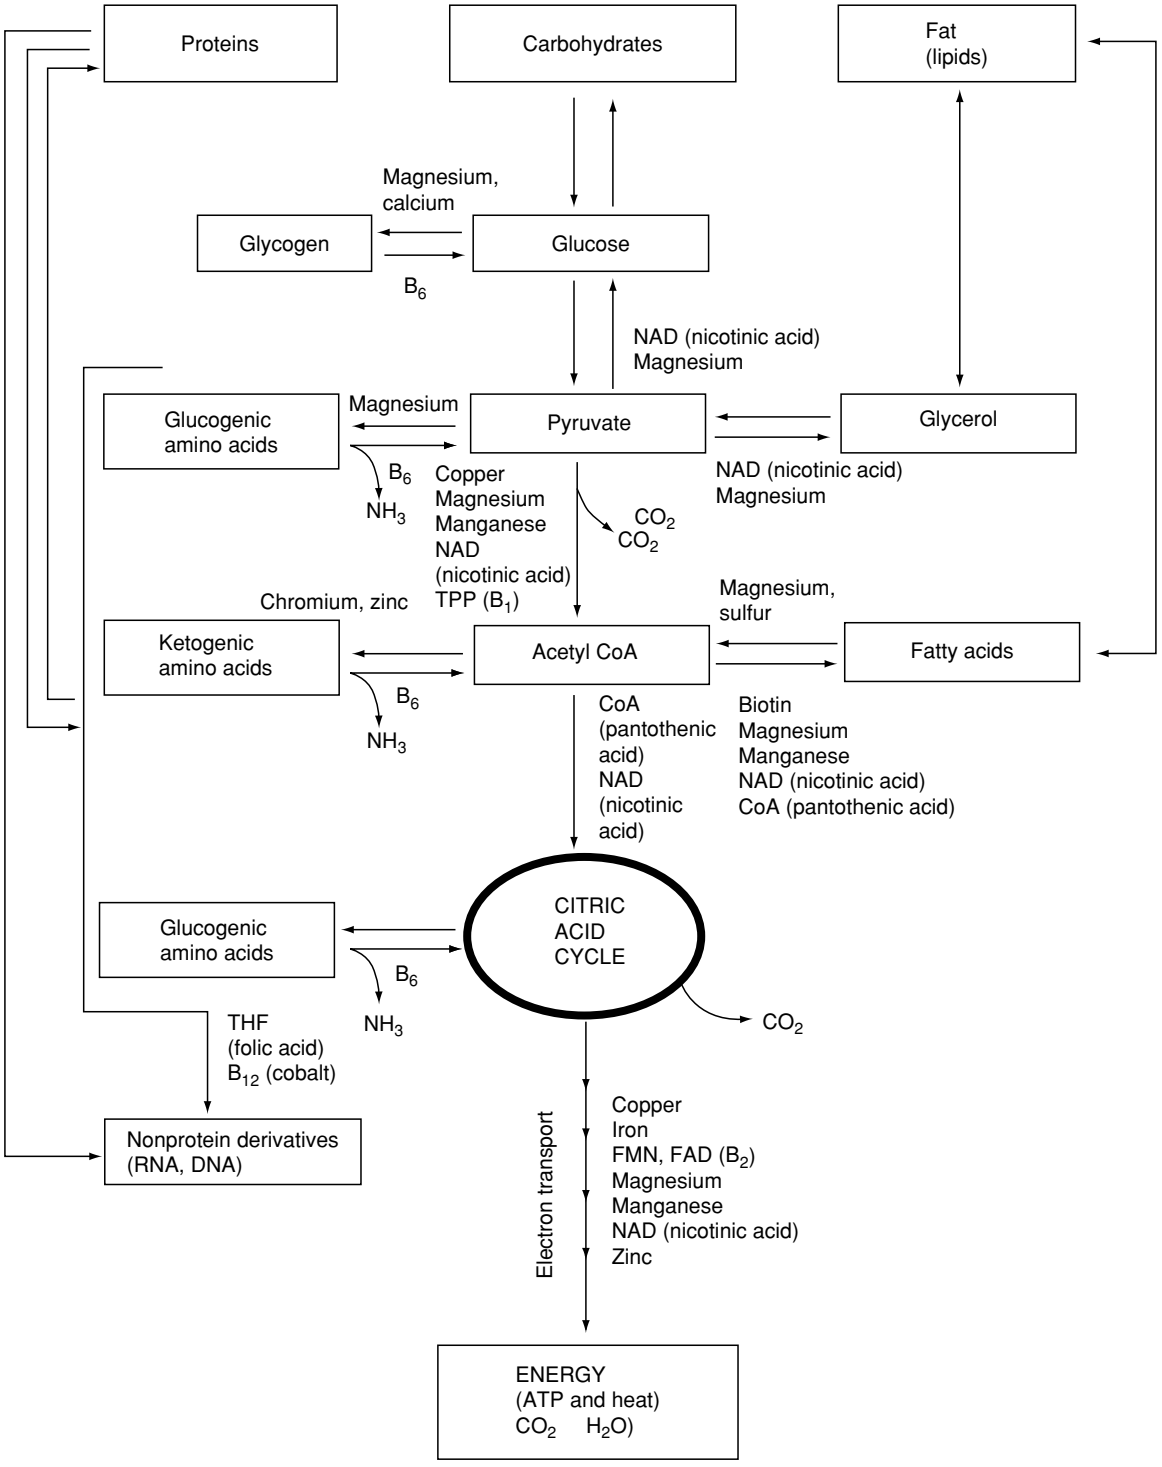

Figure 1 Overview of carbohydrate, protein, and lipid (fat) metabolism. Reproduced from Coenzymes, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK, and Sadler MJ (eds), 1993, Academic Press.

hyperpolarized and the optic nerve transmits signals to the brain interpreted as vision. Retinoic acid is the metabolite form of vitamin A that regulates genes. It binds to proteins called retinoic acid receptors (RARs) and retinoid X receptors (RXRs). These proteins are transcription factors belonging to the steroid/thyroid hormone receptor superfamily of proteins and are found throughout the body. The RAR/RXR proteins bind to and regulate the transcription of numerous target genes important for cell development.

Vitamin K acts as a coenzyme for γ-carboxylases, enzymes that transfer —CO_2 groups. The resulting carboxylic acid groups are available for calcium

binding. Gamma-carboxylation is necessary for the formation of osteocalcin, a protein important in bone remodeling, and prothrombin, a coagulation factor (II) involved in blood clotting (*See* **Vitamin K**: Physiology).

Minerals

Minerals participate as both catalysts and cofactors in biological reactions. As catalysts, minerals are not part of an enzyme or substrate, but accelerate the reaction between the two. As cofactors, they become a structural component that is essential for the function of an enzyme or protein. Minerals that play critical roles as cofactors for enzymes include magnesium, manganese, molybdenum, and selenium. Other minerals, such as calcium, cobalt, phosphorus, and iodine, act as essential cofactors for nonenzymatic proteins. Zinc, copper, and iron are cofactors for both enzymatic and nonenzymatic proteins.

Mineral Cofactors in Enzymatic Reactions

Some examples of how minerals serve as cofactors for enzymes involved in metabolism are as follows.

Magnesium (Mg) is required as a cofactor for over 300 enzyme reactions. One critical function is the stabilization of the structure of adenosine triphosphate (ATP). Energy provided by magnesium-dependent ATP hydrolysis is required during the catabolism of carbohydrates (glycolysis and the citric acid cycle) and fatty acids (β-oxidation) and the anabolism of proteins. Magnesium also plays a cofactor role in enzymes involved in the synthesis of DNA, and it helps maintain the double helical structure of DNA. (*See* **Magnesium**.)

Manganese (Mn) has been identified as an essential cofactor in several metalloenzymes. Some examples are: (1) superoxide dismutase, a mitochondrial enzyme which catalyzes the breakdown of superoxide free radicals to hydrogen peroxide and water, thereby protecting cells from free radical damage; (2) arginase, which helps in the production of nitric oxide and the urea cycle; and (3) phosphoenol-pyruvate carboxykinase, which participates in carbohydrate metabolism. Manganese is also important (but not essential) in activating the glycosyltransferases, which are necessary for the formation of glycoproteins and proline depeptidase, which catalyzes the final step in the breakdown of collagen.

Molybdenum (Mb) is a cofactor for several oxidation enzymes. Xanthine oxidase is necessary for the production of uric acid from purines; sulfite oxidase converts sulfite to sulfate; and aldehyde oxidase is involved in the hydroxylation of heterocyclic nitrogen compounds, such as nicotinic acid.

Selenium (Se) functions as a component of enzymes involved as antioxidants (glutathione peroxidase) and in thyroid hormone metabolism (5′-deiodinases). Although the metal is needed for activity, it is not a cofactor since it is incorporated in protein as the amino acid selenocysteine. (*See* **Selenium**: Physiology.)

Zinc (Zn) is an essential component for more than 100 enzymes. Examples of zinc-containing enzymes are found in all known classes of enzymes, including transferases, hydrolases, oxidoreductases, lyases, isomerases, and ligases. Zinc is a cofactor in key biochemical reactions in the body, such as carbohydrate, lipid, and protein metabolism, stabilization of membranes, and synthesis and catabolism of DNA and RNA. Consequently, zinc is an important contributor to the processes of replication (synthesis of new DNA), transcription (synthesis of messenger RNA), and translation (synthesis of enzymatic and nonenzymatic proteins). Some of the general biological functions depending upon the cofactor functions of zinc include cell replication, tissue growth and repair, bone formation, skin integrity, and cell-mediated immunity. (*See* **Zinc**: Physiology.)

Mineral Cofactors in Nonenzymatic Molecules

Minerals also serve as integral structural components of a variety of nonenzymatic proteins, as well as for hormones and vitamin B_{12}.

Calcium (Ca) functions as a cofactor when it forms a complex with two structurally related proteins – calmodulin and troponin C. Calmodulin is a protein with two globular lobes, each having two binding sites for calcium (Figure 3a). When calcium ions bind to calmodulin, a variety of calcium-dependent enzymes are activated, including membrane phosphorylase kinases and some forms of cyclic nucleotide phosphodiesterases and adenylate cyclases. These enzymes change the three-dimensional conformation of the target protein and influence the activity of signaling pathways whereby cell surface receptors transmit extracellular signals into cellular responses. For example, the hormones epinephrine (adrenaline) and glucagon react with their respective cell surface receptors to signal the cell to utilize glycogen (the storage form of glucose). These 'signals' induce phosphorylation of the enzymes involved in the synthesis (glycogen synthase) and degradation (glycogen phosphorylase) of glycogen.

Troponin C is a muscle protein that is structurally similar to calmodulin. When this protein is activated by calcium binding, it enhances interactions between actin and myosin, proteins involved in muscle contraction. (*See* **Calcium**: Physiology.)

Cobalt (Co) is a central atom in the structure of vitamin B_{12} (Figure 2e). This vitamin is essential for

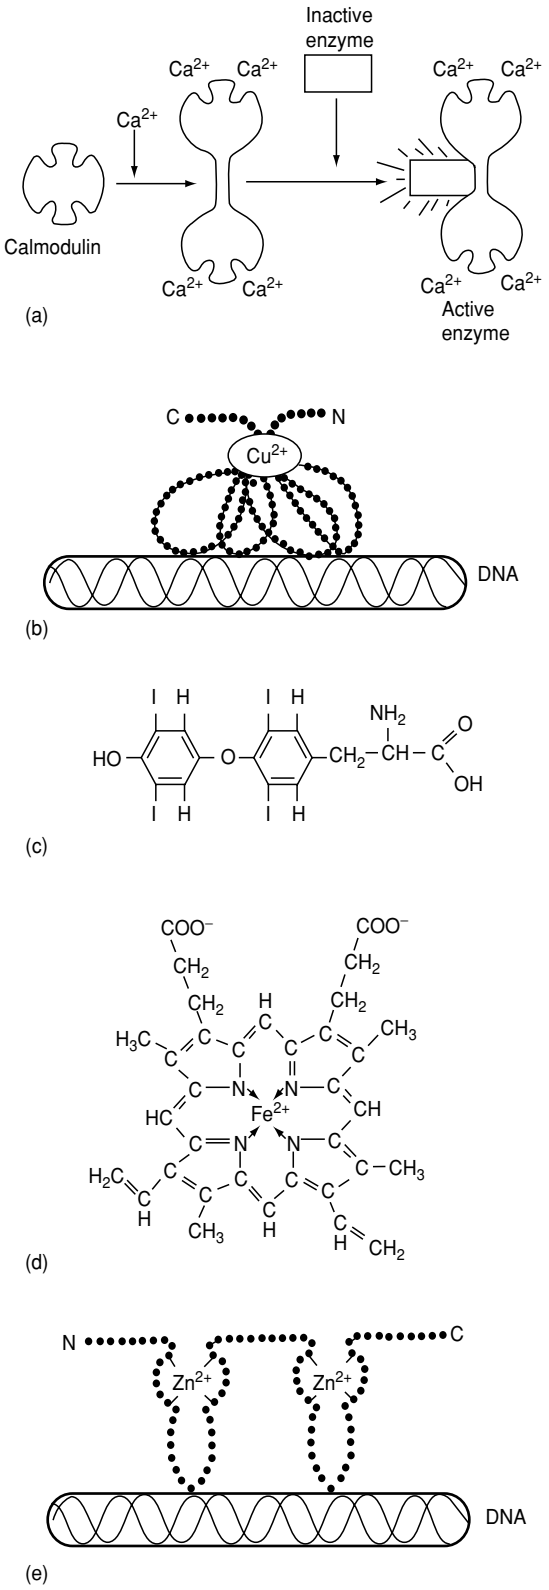

Figure 3 Selected examples of minerals as cofactors: (a) calmodulin; (b) copper-fist motif; (c) thyroxine or T_4; (d) heme; and (e) zinc-finger motif. Reproduced from Coenzymes, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

carbon transfer reactions involved in the synthesis of DNA and regeneration of methionine. (*See* **Cobalt**.)

Copper (Cu) ions play a critical role in the structure of some transcription-regulating proteins. In the presence of copper ions, certain transcription factors acquire a loop-like structure which forms a cluster close around the copper ions (Figure 3b). This complex is called a 'copper fist' since it appears to be similar to a fist clutching a small object. The loop 'knuckles' of the fist are thought to bind to a regulatory region (promoter) of the metallothionein gene. Once the transcription factor–copper complex (copper fist) is bound to the promoter region, another part of the transcription factor stimulates gene transcription. The translated metallothionein protein regulates copper levels and prevents toxicity. (*See* **Copper**: Physiology.)

Iodine (I) forms part of the thyroid hormones, thyroxine (Figure 3c), and thyronine. Both hormones help regulate the basal metabolic rate of organisms. (*See* **Iodine**: Physiology.)

Iron (Fe) is a critical constituent of heme (Figure 3d) which forms part of the hemoglobin and myoglobin molecules. Hemoglobin transports oxygen to and carbon dioxide away from cells in the body; myoglobin stores oxygen in muscles. (*See* **Iron**: Physiology.)

Phosphorus (P) forms part of the energy-storage compound ATP. The removal of phosphate (dephosphorylation) from ATP to form adenosine diphosphate (ADP) releases considerable biochemical energy. Adding the phosphate (phosphorylation) to ADP to form ATP again permits the body to store energy. The storage and release of energy via interconversions of ATP and ADP is one way the major components of food (carbohydrates, fats, and protein) ultimately provide energy for the body. Other types of reversible phosphorylation help regulate the conformation and activity of certain proteins such as enzymes.

Zinc ions are also needed for the structure of some transcription factors. The transcription of certain genes is regulated by DNA-binding proteins that contain important functional domains characterized as 'zinc fingers' (Figure 3e). Zinc stabilizes the folding of the transcription factor into a 'finger loop' which is capable of site-specific binding to double-stranded DNA. Zinc finger loops are present in the DNA-binding domains of receptors for glucocorticoids, mineralocorticoids, estrogen, progesterone, thyroid, 1,25-dihyroxy-vitamin D_3, and retinoic acid.

Effect of Nutrient Deficiencies

A primary deficiency of an essential vitamin or mineral cofactor is caused by inadequate amounts of the nutrient in the diet. A secondary deficiency occurs because

of something other than diet, such as a disease state or metabolic alteration, which leads to decreased absorption, impaired transportation, or increased requirements, utilization, or excretion. If a deficiency of a nutrient continues, body stores begin to diminish.

A continued insufficiency of a nutrient cofactor will impair or inhibit biochemical functions of the dependent enzyme. The lack of a functional enzyme–cofactor complex produces an accumulation of the substrate and a deficit of the enzyme product. At this point, measurements of biochemical parameters may indicate a problem that is not yet evident by a physical examination. This condition is known as a subclinical deficiency state. Eventually the deficiency state is developed to the point at which it can be observed physically and produces the classical clinical symptoms of a nutrient deficiency.

An example of this process is seen when a dietary deficiency of iron produces iron-deficiency anemia. Inadequate dietary intake of the minerals leads to declining stores in the body. A sensitive clinical test that measures the amount of the body's iron-carrying protein, transferrin, and the amount of iron it is carrying can detect a developing iron deficiency before many of the symptoms of anemia are observed. As body stores continue to be depleted, a lack of sufficient iron impairs the production of heme, a prosthetic group necessary for the formation of hemoglobin in red blood cells. The production of red blood cells declines and the reduced cell number can be determined by a simple clinical blood test called a hematocrit. When the decreased number of red blood cells cannot transport enough oxygen to the peripheral tissues, the result is fatigue, a clinical symptom associated with iron-deficiency anemia. (*See* **Anemia (Anaemia)**: Iron-deficiency Anemia.)

COFFEE

Contents

Green Coffee

R J Clarke, Donnington, Chichester, West Sussex, UK

Introduction

Green or raw coffee comprises green coffee beans; though, in trading practice, it may also contain small amounts of extraneous matter, derived from the harvested and processed coffee cherry and other foreign matter such as stones.

Classification of Green Coffee Beans

A green coffee bean, as defined in the International Standard, ISO 3509–1989 is 'a commercial term designating the dried seed of the coffee plant.' The coffee

plant or tree (not shrub) belongs botanically to the *Coffea* genus in the family Rubiaceae, with subdivisions and some 80 separate species, of which only two species are commercially important for green coffee; these are *C. canephora* (known in the trade as *C. robusta*), and *C. arabica* L. In each of these two species, there are a number of true botanical varieties, but also cultivars, developed by horticultural research and used in plantations for various agronomic advantages. In recent years, a number of interspecies hybrids have been developed, notably arabusta in the Ivory Coast, from the crossing of the arabica and canephora (robusta) species, but also with other lesser-known species growing wild in the hope of conferring advantage in respect of disease resistance, etc. None of these hybrids has yet developed much commercial success. Two particular 'original' varieties of arabica have been generally recognized, *C. arabica* var. *arabica* (syn. var. *typica*) and *C. arabica* var. *bourbon*. Cultivars are usually intraspecific by breeding/selection, such as caturra, mundo novo and catuai in Central/South America amongst the arabicas. Varieties in the *C. canephora* species are less precise, originally found in Africa; but *C. canephora* var. *kouillensis* is important and planted also in Indonesia and latterly in Brazil (where it is known as *Conillon robusta*); and also *C. canephora* var. *nganda*, especially found in Uganda. Whilst these varietal/cultivar names are not normally used in the trade, the different coffee types will contribute, along with other factors, to differences in flavor quality (after roasting/brewing).

Genetically speaking, most of the coffee species are diploid, as is *C. canephora*, but *C. arabica* is tetraploid, that is, arabica has $4 \times 11 = 44$ chromosomes in its genome, unlike *C. canephora*, which has 22. This phenomenon has given rise to problems in interspecific breeding. Arabica plants are self-pollinating, though they can be crossed, whereas canephora (robusta) plants are self-sterile and require cross-pollinating for seed development. Robusta plants are generally propagated by use of cuttings (Fr. *bouterage*), whereas arabica plants are generally grown from seeds in nurseries, and then transplanted. These two species differ in their optimal environment for growing. Robusta will grow at low altitudes, will tolerate high temperatures and heavier rainfalls, and requires a higher soil humus content than arabica, and is generally more resistant to diseases and pests (hence its common name). Whilst arabica is grown at higher altitudes (with quality connotations in respect of height above sea level) the plants are particularly susceptible to frost damage, which can occur from time to time, particularly in Brazil.

In general, coffee plants are only grown in those countries between the tropics. Arabica is generally believed to have originated in Ethiopia, and was first cultivated for large-scale export from the Yemen in about 1600 by the Turks. From the Yemen, seedlings were transported by Europeans to other parts of the world, so that it is now found mainly in Central/South America, and also in India, Kenya, Tanzania, and other countries. Robusta derives from the rain forests of Central Africa, but was only really discovered and commercialized from about 1880. It is now mainly grown in plantations in West Africa, and also in Uganda and Indonesia.

The flavor quality (after roasting/brewing) of robusta is generally considered to be inferior to arabica. It is certainly less expensive per unit weight of green coffee, and now constitutes about 25% of the world trade (imports into consuming countries). Its particular characteristics have been found favorable in the manufacture of some instant coffees, but robusta is also widely consumed as regular brewed coffee in countries such as France, Italy, and Spain, and often features in espresso coffees.

A further classification of coffee beans relevant to both arabica and robusta coffee is into (1) flat beans, a term characterizing the majority of beans produced, with their single flat side with a central cleft, and (2) peaberries, which are small rounded beans resulting from a false embryony within the original cherry. The latter have a specialty roaster interest, as do so-called Maragogype, with an abnormally large-size arabica bean, found in some parts of Brazil.

A further basis of classification is described in the next section.

Green Bean Processing

Since coffee is originally harvested in the various growing countries, as 'cherries' or 'berries' with a fleshy interior usually carrying two seeds, and an outer skin, a sequence of operations is carried out in those same countries, in order to remove their seeds and present them as beans (dried seeds) or the 'clean coffee' of commerce. Figure 1 illustrates the sequences.

Removal of Beans from within Coffee Cherries

Two procedures have been developed – one, called dry processing, and the other wet processing (for washed and pulped coffee). The first, also in historical order, requires the sun-drying of the coffee cherries laid out in layers (about 30 mm thick), which need to be periodically turned over during a period of some 3 weeks, until the moisture content is brought down at least below 13% w/w. This time period may be substantially reduced by the alternative use of specialized

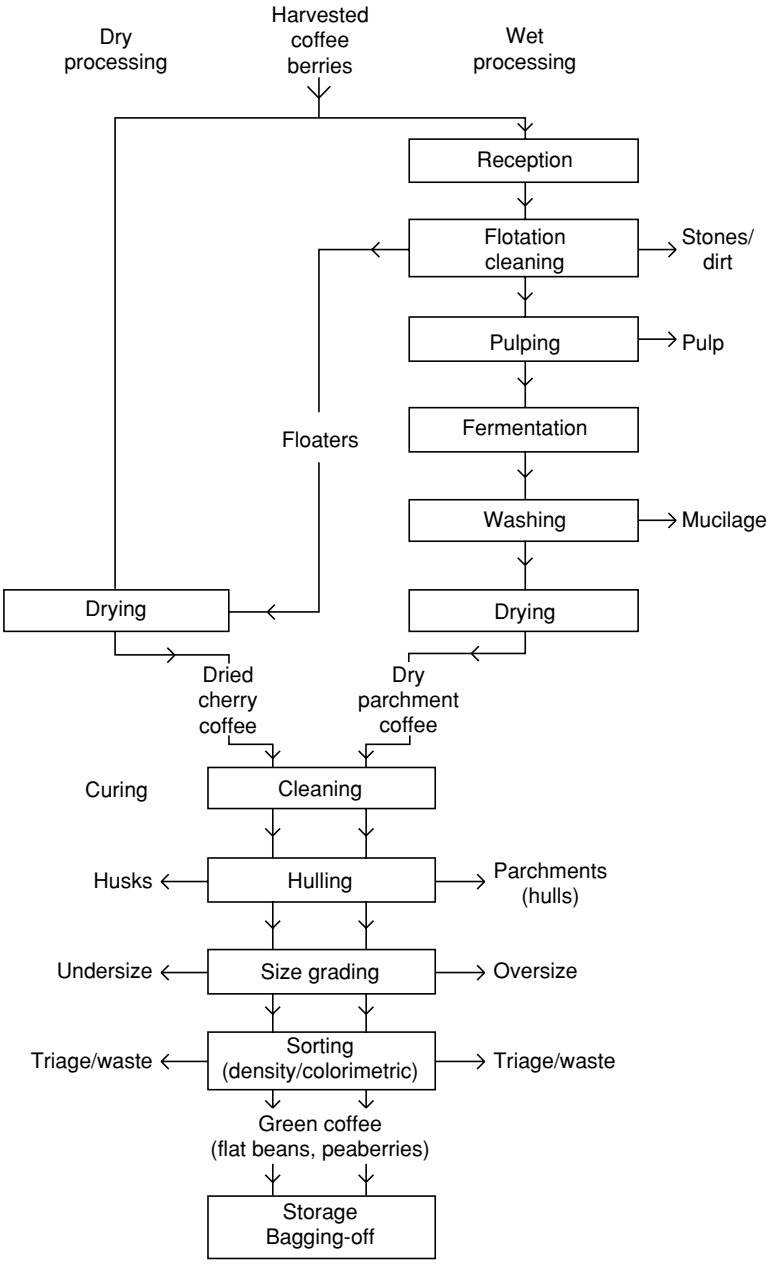

Figure 1 Flow sheet illustrating the stages of wet and dry processing. Reproduced with permission from Clarke RJ and Macrae R (1987) Coffee, vol. 2. Technology, p. 2.

machine air driers. This type of process is used for nearly all robusta coffee production in the world, but it is still used for most of the arabica coffee in Brazil and also in Ethiopia and Haiti. The product is now in the form of so-called husk coffee, that is, dried coffee cherries, carrying the dried seeds and all outer covering, which await the next stages known as 'curing,' usually carried out at a central large-scale curing station, which takes in consignments from various outlying plantations, both large and small. In curing, after cleaning, the beans are first separated from their outer coverings by dehusking machines, based upon a screw principle, of which there are a number of commercial designs. The final presentation as clean coffee is described in a subsequent paragraph. (*See* **Drying:** Drying Using Natural Radiation.)

The second procedure, known as wet processing, is more sophisticated than that of the first. In this procedure, it is important that the coffee cherries be first graded for ripeness, preferably by harvesting only those judged to be ripe and of a red skin color; water-flotation methods may be used for those

overripe cherries and dried on the tree, but not underripe cherries, which are equally, if not more, undesirable. These cherries are then fed into pulping machines of various commercial designs, which tear off and separate the skins and fleshy pulps (exocarp and mesocarp, respectively) in the presence of much water. Such machines will, however, leave a portion of the mesocarp, a mucilaginous layer adhering to the pericarp or a parchment layer directly surrounding the beans. The next stage in the process is therefore a means of removal by firstly loosening with fermentation, which is carried out in tanks. There are variants of detail of this operation in different countries, according to local 'know-how,' climatic conditions, and location height above sea level. Fermentation proceeds through the action of microorganisms or enzymes from within the semipulped coffee, over a period of about 24 h under either wet or dry (no added water) conditions. Care has to be taken that excess acidity does not develop, nor that of taints. After a dry fermentation, a water soak has been recommended (Kenya). The loosened mucilage is then completely washed off, by use of large quantities of water as the product is allowed to flow along long concrete channels, after which it is drained of excess water. An alternative system to pulping/fermentation/washing uses the Aquapulper; the manufacturer claims it will achieve all these operations within one machine. The resulting product is now known as 'wet parchment coffee,' which has to be dried. Air-drying is usually practised, that is, the parchment coffee is laid out on supported trays, with movable coverings that can be used during the hottest hours of the day, or again during cold nights. The drying time will be between 10 and 15 days to reach a desired moisture content of 11% w/w. Alternatively the parchment coffee may be machine-dried in a shorter time, or for part of the time. In either method, great care is necessary for quality reasons, and optimal conditions have been the subject of much study in research stations in Kenya, Colombia, and elsewhere, with many published papers. It is now necessary to remove the dry parchment layer to uncover the beans, by hulling machines similar in principle to those used in the dry process, already described, though the percentage amount of dried coverings to be disposed of is clearly much less.

Preparation of the Clean Coffee for Export

The next stages of curing from either of the two processes described above, after cleaning, involve firstly a size-grading stage, that is, by machines with rotating cylinders on a horizontal axis, fitted along their length with punched hole screens, of about three different hole sizes. Size grading is particularly needed for dry processed coffees (Figures 2 and 3). Each of the size grades is then subjected to a series of sorting operations. The first is a density separation, which enables residual extraneous matter originating from the cherry, such as pieces of husk, parchment, etc. (dependent upon the wet or dry process previously used), abnormally light density beans, and indeed of foreign matter, to be removed as much as possible. Separation methods generally rely on air levitation principles, for which a number of machine types are available. A second sorting based upon the color of beans has traditionally relied upon hand-picking as the beans move along a traveling belt, which also enables some other defects such as malformed beans and other residual defective matter to be removed. Electronic sorting is, however, becoming very widely used, with monochromatic light used to sort out, in particular, 'black beans,' regarded as especially unfavorable to quality, which may otherwise occur frequently in dry processed coffees. The target is to achieve substantially less than 1% by weight of black beans (or fewer than five per 300 g sample). Electronic sorting may also use multichromatic light, which enables a wider range of discolored beans to be discarded, though such sophisticated machines are more usual in the consuming countries. For wet processed arabica there has also been a considerable growth in the

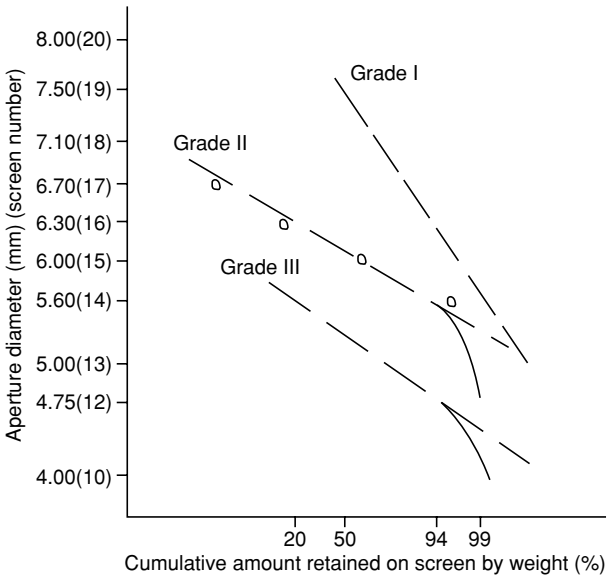

Figure 2 Typical screen analyses for different size grades of Ivory Coast robusta green coffee beans according to specifications (including allowable tolerances), plotting percentage cumulative amount by weight (probability scale) held at each screen size (aperture diameter, mm) for screens according to ISO 4150. o—o, actual experimental data for grade II sample. use of sorters, in the producing countries, based upon fluorescence differences, which are designed to remove any so-called 'stinker beans,' difficult to detect easily otherwise but especially undesirable to flavor quality if present, even in very small numbers.

The object of all the foregoing stages is therefore to provide 'clean coffee' at the right moisture content, which can then be bagged for export (or internal consumption) and documented according to origin, type, and grade. Commercial green coffees are further subdivided into wet-processed arabicas, known as 'milds' in the trade, dry-processed arabicas, and robustas (dry-processed).

Marketing, Grades, Shipping, and Storage

The marketing of coffee is a complex commercial operation, with an underpinning by the International Coffee Organization, based in London, which, for example, through international governmental agreements in force from time to time can organize quota systems for price stability. For the various green coffees under their control for export, the marketing authorities in different countries issue specifications, which may be either detailed or brief, without necessarily direct reference to flavor (i.e., when roasted/brewed). Test methods are available, many from the International Standards Organization on representative samples from consignments.

Grades and Types of Green Coffee

An important grade criterion is that of bean size (range), as can be characterized by a screen analysis using a number of internationally recognized screens with specific hole diameters (ISO 4150–1980, revised 1991). Different shorthand terms are used to express bean size distribution, e.g., letters such as A, B, C, etc., in Kenya, words (large–small with intermediates) in Brazil, and numbers (1, 2, 3) in robustas from the Ivory Coast. From Colombia, virtually only one size grade (excelso) is exported, all defined on screen no. 15 (6 mm) and most through no. 18 (7.5 mm hole diameter).

A second criterion is that of type, specifically defining the number of defects present per sample, that is, defective beans of various kinds, extraneous and foreign matter. Different systems are in force, though most adopt a black bean equivalency system, where one black bean per 300-g (or 1-1b) sample equals one defect, and where other kinds of defect are assessed as numbers required to equal one black bean. Total numbers of defects define the type, which may be expressed in words, e.g. supérieure in the Ivory Coast for robusta, or terms, e.g. NY numbers (1–8) in Brazil. Such type numbers are not, however, used for wet-processed coffees from Kenya, Colombia, and some other countries, where the number of defects in most of their exported coffee is very small (e.g., < 13 per 300-g or 1-lb sample). Numbers of particular defects such as moldy or insect-damaged beans are rigorously controlled in many countries (both importing/exporting); especially in the USA by the Federal Drug Administration with legislative backing, primarily for health and hygiene reasons.

A specification will, of course, refer to country of origin, maybe also growing area/port of embarkation and species/green bean processing method where this may be otherwise uncertain; and whether new crop or old crop. Purchase or otherwise may be primarily on the basis of exchange of samples, where the opportunity of inspecting for flavor quality and appearance is available.

Shipping and Storage

Some storage of green coffee is inevitable at various times from source to roaster, including of course during transit by ship (whether in bags in holds, or now more usually bags or loose in containers). It is generally recognized that green coffee should not be allowed to reach a moisture content in excess of 13% w/w; otherwise, mold growth will start to occur, which increases rapidly with increasing moisture content, causing flavor deterioration and the possibility of mold toxin formation. It should be noted that

green coffee at a moisture content of 12% w/w is in equilibrium with ambient air of a relative humidity of about 65% at 28 °C. Deterioration is also markedly accelerated by temperature, so that it has been stated that the temperature should not exceed 26 °C or even 20 °C. For a shelf-life of 6 months, the air humidity should also be kept low, and the green coffee at <11% w/w moisture content. However, there is some evidence that some storage of green coffee is desirable for flavor quality, with enzymatic generation of favorable aroma precursor before roasting. Holding of crop from one harvesting season to another, i.e., from new crop to old crop, even under favorable conditions, will give rise to changes in flavor and also in color (fading or whitening on long storage), so that the crop year needs to be known. (*See* **Spoilage**: Molds in Spoilage; **Storage Stability**: Mechanisms of Degradation.)

Compositional Data: Chemical Changes During Processing

The fully detailed composition of green coffee, which is quite complex, has been gradually unraveled by both classic methods of analysis and the more modern laboratory techniques, such as high-performance liquid chromatography. Green coffee, is, of course, especially characterized by its content of caffeine, trigonelline, and chlorogenic acids; otherwise, its composition is similar to that of other comparable vegetable substances with their protein, carbohydrate, vegetable oil, and mineral content. However, the carbohydrate portion consists mainly of polysaccharides, the exact nature of which has only recently been determined. A particular constituent is a mannan (of low degree of polymerization), responsible for the observed physical hardness of green coffee beans. The two main species of the *Coffea* genus, described previously, differ in composition in a number of respects, e.g., caffeine content, on a dry basis: averages are 1·2% in arabica and 2·2% in robusta. Like all natural substances, variations from an average can be found, to which can be added those lesser ones accompanying green processing and storage effects. It may be noted, however, that commercial shipments of green coffee of a particular origin often have a surprisingly uniform composition, resulting from bulking procedures over the range of producing centers arranged by marketing authorities in a given country. (*See* **Caffeine**; **Carbohydrates**: Classification and Properties; **Chromatography**: High-performance Liquid Chromatography.)

Table 1 shows the average composition of the two main species, in broad terms.

In finer detail, the quantity of free amino acids, whilst small, may well be of significance as an aroma precursor in subsequent Maillard reaction during roasting. The content of free amino acids and that of reducing sugars may well increase from zero during green processing through storage; though data are not available, primarily on account of difficulties in carrying out the sophisticated types of analysis on site in producing regions. (*See* **Browning**: Nonenzymatic.)

There are a number of well-characterized enzymes present in green coffee, such as the polyphenol oxidases, which may vary in activity according to their denaturation, relatable to quality by some authorities, though discounted by others. (*See* **Enzymes**: Functions and Characteristics.)

The distribution of these components within the bean has been a subject of study, facilitated by scanning and transmission electron microscopy. A distinction between cell wall polysaccharides and reserve carbohydrates can be observed, and the occurrence of a coffee wax at the surface of the bean can be seen. However, the majority of the lipid material is bound as a globular membrane between the cell walls and the cytoplasm.

Table 1 Green coffee composition

Component	*Typical average content (%, dry basis[a])*	
	Arabica	*Robusta*
Alkaloids (caffeine)	1.2	2.2
Trigonelline	1.0	0.7
Minerals (as oxide ash; 41% K and 4% P)	4.2	4.4
Acids		
Total chlorogenic	6.5	10.0
Aliphatic	1.0	1.0
Quinic	0.4	0.4
Sugars		
Sucrose	8.0	4.0
Reducing	0.1	0.4

Roast and Ground

R J Clarke, Donnington, Chichester, West Sussex, UK

Introduction

Green coffee itself has no comestible value for humans, and must first be roasted before use as a flavorful and stimulant aqueous beverage. Furthermore, roasted whole beans must be ground, either by the housewife or by the manufacturer, after which brewing in any one of a number of appliances, manual or automatic, is required.

Roasting Processes

Roasting is a time–temperature-dependent process, whereby chemical changes are induced by pyrolysis within the coffee beans, together with marked physical changes in their internal structure. In particular, a whole range of different volatile organic compounds are generated, many of which are responsible for the flavor/aroma of a prepared coffee beverage, and for the headspace aroma of the dry product; though it is still not entirely certain which compounds, either singly or in combinations, are crucial. The required changes will take place with a bean temperature from about 190 °C upwards, subsequently needing to be controlled on account of exothermic reactions occurring, so that bean temperatures up to 240 °C may be reached in a time that should be less than 12 min. The particular time–temperature chosen will determine the degree of roast from very light to very dark (with intermediate subdivisions) assessed in the first place from visual bean color. The choice of degree of roast is primarily a matter of consumer preference, with medium most usual for US and UK tastes.

In commercial roasting practice, green coffee beans under movement are subjected to heat by conduction from hot metal surfaces, or convection from hot air, or more generally a mixture of both methods of heat transfer, together with a contribution by radiation. Roasters may be broadly classified as in **Figure 1**. The modern types of roaster maximize the use of convective heating, whereas older household machines will rely mainly on conductive heating. The most widely used type has been the batch-operated horizontal rotating drum roaster (with either solid or perforated walls) in which hot air from a furnace/burner is passed through the tumbling green coffee beans. A typical example is shown in **Figure 2**. Dependent upon the air (with combustion gases) flow rate, the temperature of the hot gases/air has to be substantially above the bean temperatures to effect satisfactory heat transfer. In a batch operation, the roasted beans have to be quickly discharged at the end of the required roasting period into a cooling car, or vessel, allowing the upward passage of cold air. In addition, water may also be sprayed from within the

rotating drum, just before the end of the roast, the so-called water quenching. Not only does this operation assist necessary cooling, but it also adds a small percentage of water by weight to the roasted beans, which has been found to assist uniformity of particle size in subsequent grinding. Generated gases, mainly carbon dioxide, from the pyrolysis often carry solid particulate matter (chaff), which has to be continuously vented away and, with current environmental concerns, needs to be 'after-burned' before actual discharge to the outside air. After-burning requires very high temperatures (450 °C), and therefore further energy consumption, though lower-temperature catalytic convertors are also available. In recent decades, there has been a general movement towards incorporation of recirculation methods for the hot gases, in which they are passed back, boosted with additional air, through the furnace, though with controlled partial release to the atmosphere, still including some after-burning or catalytic conversion. A typically sized roaster of this type would hold 240 kg of green coffee, with an out-turn (charging to discharging) of 15 min. The furnace/burner will be either oil- or gas-fired, with a net energy requirement of about 320 kcal per kilogram green coffee (excluding after-burning). Recirculation techniques provide higher velocities of air flow, increasing heat transfer coefficients, and therefore shortening the roast time per unit weight of green coffee but do not necessarily offer energy savings per unit weight of coffee.

The rotating drum principle was first applied to continuous operation in about 1950 of Jabez Burns 'Thermalo' roasters. Since then, roasters based on other mechanical principles have been developed and widely used, e.g., the rotating bowl, vertical drum (with mixing blades) and fluidized air roasters of various designs.

A recent sophisticated type of fluidized bed roaster is the Nepro Vortex Fluidat Equipment, with three separately controlled roasting zones and two, cooling with continuous action, manufactured in Germany by Nolte GmbH.

The general improvement in heat transfer rates has now enabled shorter roast times (i.e., of the order of 3–5 min) in many of these roasters, with claimed advantages for the resultant coffee, so-called fast-roasted coffee of lower bulk density and 'high yield' on brewing.

Chemical and Physical Changes Taking Place on Roasting

Green coffee contains sucrose, polysaccharides, and proteins, together with free amino acids. Considerable potential therefore exists for the occurrence of Maillard-type reactions (essentially between reducing sugars, derived from partial inversion of sucrose during roasting, or already present, and amino acids), leading to the formation of both volatile compounds and high-molecular-weight polymers. Caramelization of sucrose also leads to the production of both volatile and nonvolatile compounds of sensory significance. Under roasting conditions, reactions are necessarily complex and difficult to unravel, with the effect of heat on proteins/carbohydrates in providing reactive centres and molecules to be also considered. (*See* **Sucrose**: Properties and Determination.)

To date, some 800+ different volatile compounds in roasted coffee have now been identified by modern gas chromatography–mass spectrometry (GC–MS)

techniques by numerous investigators since 1960. Many of these compounds have also been quantitatively determined by GC–MS methods, and their total amount found to match closely the actual 700–800 mg per kilogram of roast coffee by steam distillation or other extractive methods. Some 6000 mg of semivolatile acids per kilogram, e.g., acetic and formic acids, are also present. It is clear that amounts of individual compounds present will be in the milligram or microgram per kilogram range. It has been reported recently that the volatile complex comprises by weight 38–45% furan derivatives, 25–30% pyrazines, 3–7% pyridines, 3–5% benzenoid aromatics, 1% aliphatics, and 0.5 alicyclics and 1% of various sulfur compounds (which may well be particularly important for flavor/aroma) in a medium-roast arabica coffee. The mode of formation can be demonstrated by model heating experiments of selected components. Some compounds may also be generated by straight pyrolysis of single compounds, e.g., trigonelline in forming mainly pyridines, chlorogenic acids in generating phenols and of coffee oil in forming small amounts of aldehydes and hydrocarbons. Considerable work has been carried out in recent years on roast coffee volatile compounds with particular reference to those that really are significant for coffee aroma. About 27 are now believed to be important. (*See* **Chromatography**: Gas Chromatography; **Flavor (Flavour) Compounds**: Structures and Characteristics.)

After roasting, substantial amounts of the compounds present may be found to be unchanged, dependent upon the degree of roast by direct analytical determinations. However, there is a newly formed residuum of about 25% by weight of the roast coffee, which is of uncertain composition but variously described as melanoidins/humic acids. These are caramelized sugars/condensation products of carbohydrates and proteins, linked with breakdown products of chlorogenic acids or even these acids themselves. The protein content (assessed by hydrolysis into amino acids) holds up quite well, though the term 'protein' is more applicable, similarly, the polysaccharide content (assessable by hydrolysis into sugars), but the coffee oil is practically unaffected, as is the caffeine. Since there is a loss of mass on roasting, which will range on a dry basis from some 2–3% for a light roast up to about 12% for a very dark roast; indeed, the percentage content of coffee oil and of caffeine will show a slight increase from green to roasted coffee on a percent dry basis. The change of chlorogenic acid content (together with that of its individual component acids) will be marked on roasting; thus, there is an overall 40% residual content for a medium roast (with differential figures for the individual components), which observations can be used as an analytical measure of degree of roast. The fate of much of the chlorogenic acids destroyed during roasting remains obscure. Table 1 shows a typical average final composition for medium roast coffee. (*See* **Caffeine**.)

Physical changes in the roasted coffee can be equally significant, including, of course, color. Scanning electron and light microscopy studies have been undertaken of cross-sections of coffee beans during roasting; cell walls are generally intact, but with a softening of internal structure, and the formation of cavities/cracking of the surface.

There is a marked change in individual bean density through swelling during roasting, which will be reflected in bulk density measurements (both of the whole roasted beans, and of the roast and ground). For a medium-roast bean, the void volume percentage is about 47% compared with virtually zero in the green bean. The cavities are initially filled with gaseous products of pyrolysis, mainly carbon dioxide, which can amount to some 2% by weight of the roasted bean. On standing, this carbon dioxide is slowly released and of course, as a result of subsequent grinding, more rapidly.

Table 1 Roast coffee composition

Component	*Typical average content (%)*[a]	
	Arabica	*Robusta*
Alkaloids (caffeine)	1.3	2.4
Trigonelline (including roasted byproducts)	1.0	0.7
Minerals (oxide ash)	4.5	4.7
Acids

Grinding

Grinding of whole roast coffee beans may be conducted either as a small-scale household operation or on a large scale (e.g., typically of the order of 1000 kg h^{-1}). For the first, a variety of single-stage machines, either manually or electrically operated, have been available for some time. The use of a rotating serrated disk against a similar static disk with an adjustable gap is the most usual mechanical principle adopted. On the larger scale, however, multistage twin horizontal rollers are employed, primarily to insure a more uniform particle size distribution than would otherwise be possible. Up to four stages may be used, the first two essentially cracking or crushing the beans into smaller units, followed by stages for progressively finer grinding. The type of serrations on the rollers is important; the most successful type was originated and patented in 1905 by Lepage and still features in Gump grinders. The fast roller of each of the first three pairs has slanting U-shaped corrugations running lengthways from end to end, whereas the slow rollers have a straight U-shaped groove, 'ring-around' or helically cut. The gaps are again adjustable. Simpler corrugations are used in the fourth pair as required for fine grinding.

Different degrees of grind are defined from the results of screen or sieve analysis, with three or four different screens in a set or nest. The nests of screens need to be shaken/tapped under standardized conditions for a given time (e.g., 5 min for a 100-g sample). Especially important is the use of standard wire mesh screens with precisely defined mesh sizes or even certified screens, as described in BS 410-1976 or later, ISO 565-1983 and corresponding other national standards. Relating to roast and ground coffee, the number of different screen sizes numbered by aperture size within the range of about 1400 mm to 250 μm is quite large, so that it will be noted that there are a principal and two supplementary series described in ISO 565, which may result in some confusion. Care is needed in selection of appropriate screen sizes to give suitable weight distributions at each size. In addition, in the USA, there is another set of sieve sizes in the Tyler series. Plotting the results of test screenings will show a good straight line relationship between aperture size (plotted on a linear scale) and the cumulative percentage weight at that size (probability scale), except at the ends (Figure 3). The approximate average size of the particles will be given at the 50% cumulative weight point. More sophisticated statistical methods may be employed to assess average particle size. Newer methods of sizing by laser beams are becoming available.

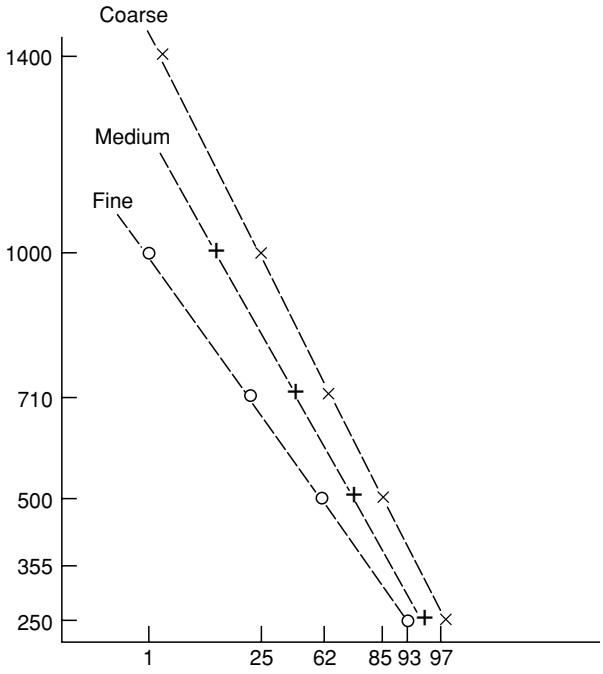

Figure 3 Screen analyses for different degrees of grind of roast and ground coffee, plotting percentage cumulative amount by weight held at each screen size (aperture in μm) according to the R.20/3 series of screens (ISO 565 or BS 410). ×–×, coarse; +–+, medium; ○–○, fine. Data from tabulation in BS 3999 part 8 (1982). Reproduced from Coffee: Roast and Ground, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Kluwer Academic, with permission.

The grind size required is related to the subsequent method of brewing to be adopted, and whether for home use or subsequent large-scale extraction. Grinds are usually defined as coarse – medium, fine, very fine – though the screen analysis that determines these may differ in, say, the UK to the USA. Coarse grinds were used for household percolators, with an average particle size of 850 μm (Europe), 1130 μm (USA), and fine grinds, as used for the now more popular filter machines, are 430 μm (Europe) and 800 μm (USA).

Even finer grinds are required for making Espresso coffees, around 30 μm average, and optimum conditions have been reported for their brewing.

Packaging

Roasted whole coffee beans (RWB) and roasted and ground (R and G) coffee are not really finished products until they have been packaged for sale to the consumer. The type of packaging needed depends upon the time interval between manufacture and sale/consumption. In the case of small speciality retail shops, with in-house roasting, simple packets of

paper or plastic are all that is necessary to maintain quality, provided the coffee is freshly roasted and ground and consumed shortly thereafter, say within a week for R and G coffee (or 10–12 days or longer for RWB).

However, packaged RWB and especially R and G coffee from large-scale manufacture have been available for some considerable time, accelerated by the advent of supermarkets. There are now twin problems in the inevitably longer time scale (e.g., 3–12 months or more) between manufacture and consumption. The first problem is that roast coffee, especially R and G coffee, deteriorates quite rapidly, in respect of headspace aroma and of flavor, in the presence of air/oxygen/moisture, and the second problem is that roasted coffee gradually releases substantial quantities of its entrapped carbon dioxide gas (and other minor gaseous components), R and G coffee much more quickly than RWB. In the case of the former, however, about half will be released in the course of grinding. The amount of gas still retained plotted against time is asymptotic in character to zero, which may well show some 1000 h to near completion for RWB but substantially less time for R and G coffee after grinding.

A fully closed package containing freshly ground roast coffee will therefore rapidly develop a high internal pressure, maybe sufficient to cause the package to burst, and is thus dangerous. RWB will cause a similar or greater problem, though the rate of development of internal pressure will be much slower.

In practice, these twin packaging problems have been solved in a number of ways: firstly, packaging under vacuum, allowing a low percentage oxygen content in the headspace to be established within the package (e.g., 25 mmHg pressure means less than 1% oxygen headspace level), and also accommodating release of carbon dioxide, so that the final pressure in the package may eventually just reach atmospheric; secondly, by allowing the R and G coffee in bulk to degas over a sufficient period of time to a low level, followed by gas purging whilst individual packages are being filled. In the first method, tin cans have been used for many years, and more recently plastic packages, closed by heat sealing and then fitted into cardboard boxes. Such plastic packages have raised a number of additional problems, not least of seal integrity due to the hazard of coffee dust, but also due to a smaller headspace volume than is possible in a tin can, to take up residual carbon dioxide, and some prior degassing may be necessary. The package must not be allowed to become soft, thus restricting the final internal pressure that is tolerable (around 500 mmHg abs. max.). These packages are so-called 'hardpacks,' though in fact a package that has gone soft does not necessarily indicate *per se* that the coffee has deteriorated in quality.

In the second method, where no vacuum is employed, various packaging materials can be used and heat-sealed, to give so-called 'soft packs.' Gas purging is used to ensure that, again, the residual percentage oxygen content in the headspace gas is preferably less than 1%. In both these methods, care is necessary in the selection of plastic packaging material (usually laminates) in consideration of gas ingress/egress, both of oxygen and carbon dioxide and also of volatile aroma compounds, and, importantly, high resistance to water-vapor ingress.

A third method that is especially popular in Europe is in the use of plastic packages to which a nonreturn valve (e.g., Goglio valve) has been securely attached, which allows release of excess carbon dioxide when the internal pressure exceeds a certain predetermined level. In this way, the amount of prior degassing is minimized, and the use of a vacuum is not necessary.

All of these methods allow a much longer shelf-life than is possible with simple air packs, though it should be appreciated that shelf-life is shortened once any package is opened. Stability is discussed in the next section.

Deterioration on Storage

As will have been evident from the previous section, both oxygen and moisture are the agents that are primarily responsible for flavor-quality deterioration together with the effect of temperature. It should be noted that like all foodstuffs, deterioration is continuously occurring from the time of harvesting and, in the case of roasted coffee, from immediately after roasting. Deterioration of flavor quality is, however, a subjective phenomenon, though accompanying chemical changes, only some of which may be directly related, can of course be detected by laboratory analytical techniques. Nevertheless, trained panels with statistical treatment of results can be used to assess deterioration in terms of rating scales/words. Considerable work has been undertaken at the Munich Technological University and others in recent years to study the deterioration of both RWB and R and G coffee under different conditions. They found it useful to rate on a scale (10→4→1), with word subdivisions of quality as 'high' (close to fresh) 'medium' (satisfying) and 'low' (still acceptable without emergence of stale or off flavours). Table 2 shows some of these findings. Other data are available for different conditions but are not directly comparable, showing the markedly increased rate of deterioration at (1) higher moisture contents of the R and G coffee beyond 4%, and (2) percentage oxygen headspace

Table 2 Shelf-life of roasted and ground coffee

Storage conditions			*Allowable time[a] before reaching quality rating of*			
Headspace oxygen (%)	*Moisture content (%)*	*Temperature (°C)*	*High 9→8*	*Medium 6–5 Satisfying*	*Low 4 Acceptable*	*Roast coffee type*
0.5	< 4	21–23	6	12–17	20–25	R and G
1.0	< 4	21–23	4	9–17	14–20	R and G
21.0	< 4	21–23			10 days	R and G
21.0	< 4	21–23	21 days	41 days	74 days	RWB

[a]Time in months, except where otherwise stated.

levels beyond 1% (though an air pack is already included in Table 2). The effect of temperature on stability has been estimated by saying that each 10 °C decrease doubles the shelf-life and vice versa. The advantages of storing roast coffee in a refrigerator is therefore clearly indicated, provided the moisture content does not rise, even if the package has been opened. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

Various attempts have been made to correlate flavor quality changes with determinable compositional parameters. It may be noted that the chemical changes occurring are primarily related to the volatile organic compounds, called staling; only after a very considerable storage time do the changes start to affect the coffee oil by the development of rancidity. Headspace aroma deterioration may be found to be more rapid than detectable flavor deterioration, but does not necessarily mean a corresponding deterioration in the latter.

Domestic and Catering Methods of Brewing

It has already been stated that roast coffee must be ground before brewing. There are three further factors in brewing: coffee-to-water weight ratio, the appliance used, and the temperatures employed. Some 14–28% w/w of soluble substances are extractable from roasted coffee by hot or boiling water, the so-called 'yield,' though the concentration of these solubles in the final brew (which will be between 0.75 and 4%, and optimally at 1.2% for US/UK tastes), most markedly affects the flavor. Brewing is the extraction not only of soluble substances contributing only to basic tastes but also of the volatile substances for overall flavor, which also is not necessarily exhaustive (40–80%). The less polar substances will tend to reside in the coffee oil within the roast coffee and will be more difficult to extract than the more polar substances but are likely to be the more important for coffee flavor.

Apart from the brewing conditions, the actual flavor quality will be determined by the choice of blend used, and the degree of roast. The choice of grind is also important. Different brewing devices or appliances (for home and catering use) have been developed over the centuries, from both the functional and artistic point of view, leading to a present apotheosis in the automatic electric filter machines. The appliances have been ascribed different names, often according to the maker, but the mechanical operation involved essentially is a means of separating the undesired so-called spent coffee grounds from the required brew formed by sufficient contact with water. The brew should contain as little of the spent ground particles as possible. At the same time, the brew must be presented hot (between 50 and 55 °C), having been prepared using water at or somewhat below boiling temperatures, ostensibly to minimize loss of volatiles to the air. Two main mechanical principles can be identified: (1) 'steeping' (slurrying) of the R and G coffee with water, with or without agitation, followed by sedimentation or filtration or both, and (2) percolation in fixed beds of R and G coffee held in an open or closed container. In the second method, the water may be passed through in a single pass under gravity, now perhaps the most popular, or under pressure (including steam, as in espresso making), or in multipass, in which the water may then include increasing amounts of soluble substances as in so-called household percolators. In the first method, two separate methods can be identified: infusion and decoction (using boiling water). Of the components of roasted coffee, only some will be extracted completely with variable amounts of the others to reach about 28% w/w total maximum, and about 21% optimum under household brewing conditions.

Some comparative studies have been carried out on exactly the same blend/roast degree of coffee in different types of appliance, with one study suggesting a flavor advantage for an automatic filter machine.

Instant

R J Clarke, Donnington, Chichester, West Sussex, UK

Introduction

Instant coffee is the dried soluble portion of roasted coffee, which can be presented to the consumer in either powder or granule form for immediate make-up in hot water, whilst the insoluble parts, or spent coffee grounds, are left behind at the factory, for the manufacturer to dispose of. Instant coffee is the name by which this product is now generally known, though there are two synonyms, soluble coffee and dried coffee extract, to express in different ways what the product is.

Definitions and Composition

Most countries have made a point of insisting that instant coffee be made from roasted coffee using water only (which includes steam), though allowance is needed for the commercial reality of added aroma oils prepared by mechanical pressing of roasted coffee or by other nonorganic solvent methods. This view is expressed in a standard of the International Standards Organization, ISO 3509–1989 (originated in 1970), which carries a simple definition, 'the dried water-soluble product, obtained exclusively from roasted coffee by physical methods using water as the only carrying agent which is not derived from coffee.' The European Economic Community (EEC) Directive for coffee and chicory extracts, 1977 and as amended 1983, in legislative force in all member countries has a somewhat longer definition, 'coffee extracts are the products in any concentration obtained by extraction from roasted coffee using water only as the medium of extraction and excluding any process of hydrolysis involving the addition of an acid or base and,

1. containing the soluble and aromatic constituents of coffee
2. which may contain insoluble oils derived from coffee, traces of insoluble substances derived from coffee, and insoluble substances not derived from coffee or from the water used for extraction.'

Instant coffee is then the dried product of such an extraction, and can only be labelled as such (or with synonyms, or foreign language equivalents) when the product so conforms. Products may of course contain other soluble beverage constituents, but then need to be appropriately labelled and all ingredients declared. Some soluble mineral constituents (e.g., 0–1000 p.p.m. of sodium or calcium ions, etc.) may be present from the water used in the extraction.

Historically, most instant or soluble coffees first contained added carbohydrates (about 50% w/w) such as corn syrup solids, since it was found that a simple aqueous extract of roasted coffee, extracted under atmospheric conditions (100 °C temperature), could not be dried (usually spray dried) to a satisfactory free-flowing low hygroscopic powder. It was only from about 1950 that instant coffee at 100% pure coffee solids became commercially available on a large scale. This step forward resulted from the discovery that the desirable carbohydrate (polysaccharide) substances could be obtained from the roast coffee itself, by a further aqueous extraction at temperatures up to 175 °C and addition to the simple extract before drying, and thus providing a powder of satisfactory physical properties. (*See* **Carbohydrates:** Classification and Properties.)

Instant coffees therefore have a higher yield of soluble substances from the roast coffee than that of a normal household brew prepared at 100 °C or below. The additional substances, though extracted or solubilized at temperatures above 100 °C, are fully soluble in hot or even cold water. It is often asked what is the difference in composition between cups of brewed and of instant coffees, when in fact there is a continuum, since they contain essentially the same substances, though the proportions or percentages of individual components will be different according to solubilization achieved for each. Commercial yields can differ considerably from one instant product to another and, for a short time, were subject to legislative control in the European Community, but this was abandoned in 1983. It is now recognized that

yield is only tenuously related to 'quality'; the extraction and retention of aromatic substances in the total manufacturing process is much more important in determining flavor quality. The yield (on a dry basis) of soluble solids from roasted coffee will be around 21% w/w in brewed coffee, up to 32% in exhaustive extraction at 100 °C, and typically 40–55% for instant coffees, dependent upon blend/roast color of the originating roasted coffee. A highly water-soluble substance such as caffeine will be extracted to about 85–100% under household brewing conditions, and to 100% in instant coffee manufacture, but the actual percentage content in the soluble solids of the former will be substantially lower in the latter. In a cup of coffee, the quantity present will be determined by its strength, typically from 2 g of instant coffee dissolved in 150–170 ml of water in a cup. Table 1 shows a comparison of approximate composition by the main individual components for a typical filter coffee brew and a corresponding instant coffee beverage. The manufacture of instant coffee is accompanied by some slight hydrolysis of the polysaccharides in the roast coffee, which is reflected in the slightly increased reducing sugar content (i.e., arabinose, mannose, and galactose) and probably assists solubilization of these polysaccharides, not otherwise easily possible at 100 °C. The quantity of volatile organic substances present in an instant coffee, which are so important to the flavor of a coffee beverage, will depend upon the particular process used in its manufacture, as described below. The moisture content of instant coffee is controlled by the drying stage, which should be less than 5% w/w. (*See* **Caffeine**.)

Physical Forms of Instant Coffee

In its earlier marketing, instant coffee was almost entirely sold as a spray-dried powder, light-to-dark brown in color, free-flowing, and, importantly, with a bulk free-flow density of between 180 and 220 g l^{-1}. The latter two properties enable easy spooning out from a container, such that a typical semiheaped teaspoon would carry about 2 g of instant coffee to a 150–170-ml cup, giving a strength typically representative of average UK and US consumer taste preference.

From about 1965 onwards, instant coffee in granule form became available, though having the same free flow and bulk density characteristics, but generally somewhat darker in color than the corresponding powder. With improved retention of aromatics also, such products were compared with brewed coffee far more favorably by most consumers than before.

Table 1 Approximate typical composition of brewed and instant coffees[a]

		Filter brew[b]			*Instant*[c]		
Component	*Roast coffee (%, dry basis)*	*R and G basis*[d] *(%, dry basis)*	*Extract basis (%, dry basis)*	*Per cup (mg)*	*R and G basis (%, dry basis)*	*Extract basis (%, dry basis)*	*Per cup (mg)*[e]

[d]R and G, roasted and ground.
[e]Beverage made up using 2 g of instant coffee per cup (150–170 ml).
[f]Assumed extraction efficiency of 85%.
[g]Assumed extraction efficiency of 90%.

Whilst freeze drying can produce powders from liquid feeds, its use for instant coffee was specially developed to provide a granular product. In a subsequent attempt to match the general appearance of freeze-dried granules, spray-dried powders were granulated by agglomeration methods (either simultaneously with spray drying, or subsequent to it), and now form a high percentage of instant coffees sold in the market place. (*See* **Freeze-drying**: Structural and Flavor (Flavour) Changes.)

Dilute or concentrated aqueous extracts of roasted coffee would also be 'instant,' but their stability at room temperature is poor. Nevertheless, recent reports show canned coffee liquid to be very popular in Japan. Frozen granules or chunks (−20 °C) would be quite stable, though they have only been commercialized in a very limited way; spoonable frozen instant coffee has been developed but requires the presence of gel-like additives.

Manufacturing Processes

The initial stages in manufacture, selection of green coffees, roasting, and grinding (coarse grind) are as for roasted coffee. The subsequent basic processes needed are extraction, drying, and packing, but with ancillary optional processes of concentration of extract, separate handling of aromatics and agglomeration. The know-how and patents are largely in the hands of large international companies. A typical scheme (simplified) is shown in Figure 1.

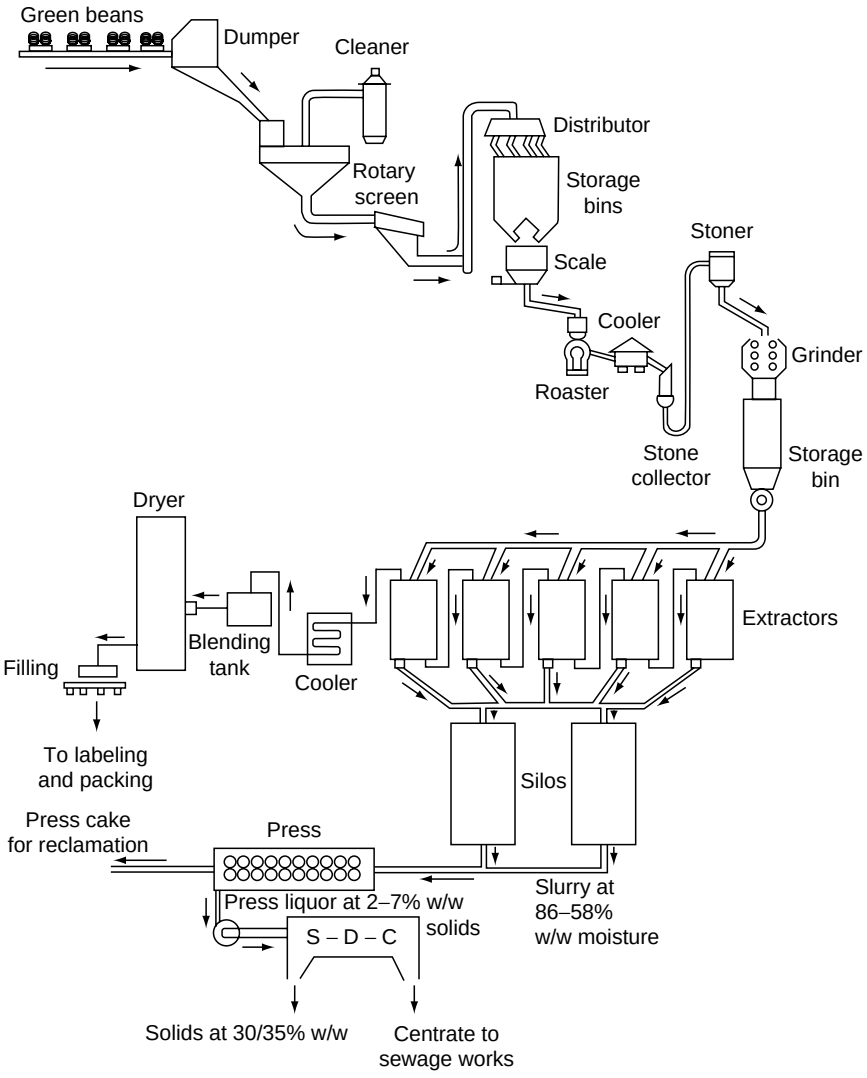

Figure 1 Instant coffee manufacturing process with spent grounds recovery (omitting volatile compound handling). Reproduced from Clarke RJ and Macrae R (1987), with permission from Kluwer Academic.

Extraction

Percolation batteries with five to eight interconnected columns holding roast coffee in different stages of exhaustion is the most widely used system for extraction to obtain coffee extracts of an economic soluble solids concentration (20–25% w/w) for subsequent drying. Its operation and variants are fully described in the literature, though it should be emphasized that the operation is intermittent (for draw-off of extract), countercurrent (in respect of water–coffee), and under pressure for all columns except the first (to keep the system hydraulic at temperatures in excess of 100 °C up to 175 °C). The first column contains fresh roasted coffee extracted with liquor at 100 °C from which draw-offs are made, whilst the most spent is contacted with pure feed water at the highest temperature. The operation is outlined in Figure 2. Recent patents suggest the use of ever higher temperatures for very short times in the final stages of extraction.

Concentration of Extract

The removal of water from a percolated coffee extract is more economically achieved if concentrated extract is fed to the driers. Evaporation is widely used and again, for reasons of heat economy, conducted in various types of multistage units. Short-contact-time evaporators are favored, such as plate and centrifugal film evaporators, coupled with close attention to operating temperatures to minimize undesirable changes in the extract. However, evaporation of water is always accompanied by evaporation and loss of organic volatile substances contributing to flavor. Certain prestripping techniques are available to overcome this problem.

Freeze concentration can be used alternatively, which has the marked advantage of substantially retaining the volatile substances whilst the water is removed as ice, but has the disadvantage of only allowing a final concentration of about 38% w/w soluble coffee solids, due to high viscosity problems.

Spray Drying

Extracts from a percolation battery as described above can be directly spray dried, though an intermediate filtration stage (centrifuges) may be included. To provide dried particles of an average size around 300 μm, needed for a satisfactory bulk density and flowability, specialized spray driers are used. The main features are:

1. tall drying chambers, e.g., of height 7.5 m or more;
2. use of centrifugal pressure nozzles rather than spinning disks for feed spraying, with their inherent narrow angle of discharge;
3. internal chamber separation arrangements between desired product and dust, though not essential.

Spray drying is conducted also to give powder of desired colour, and a final moisture content of less than 5% w/w.

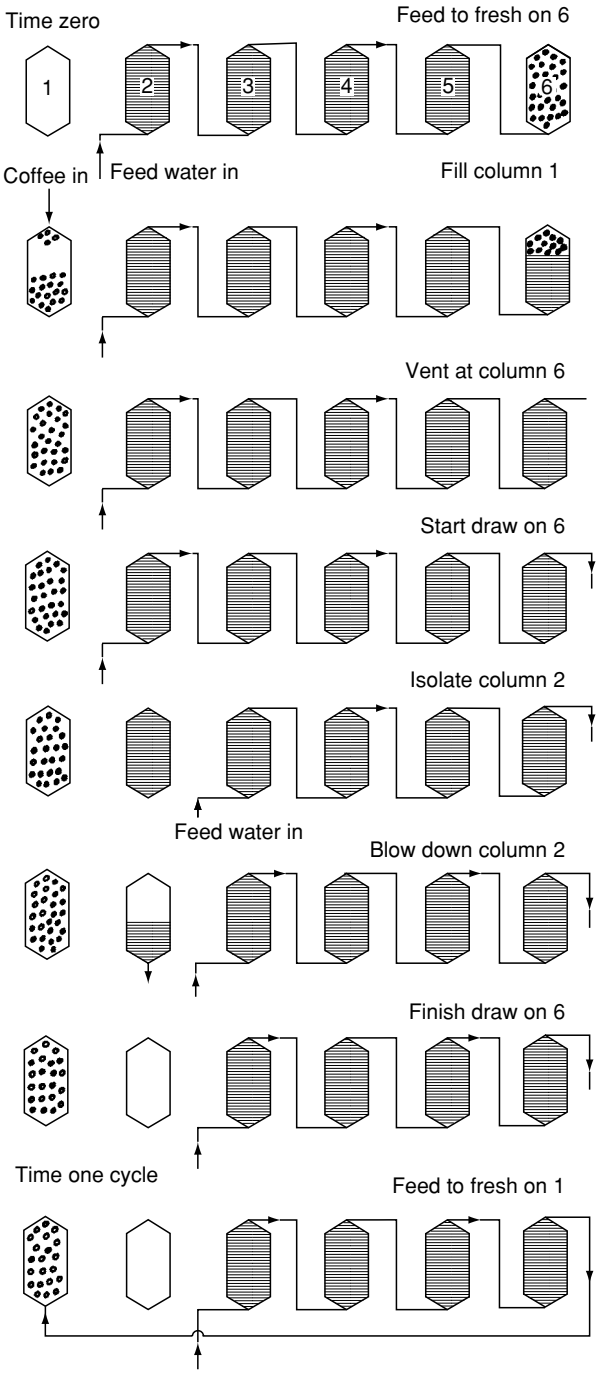

Figure 2 Typical sequence of events in the operation of a percolation battery for instant coffee. The shape, size, and number of columns are diagrammatic. Reproduced from Clarke RJ and Macrae R (1987), with permission from Kluwer Academic.

More concentrated extracts, say up to 60% w/w soluble solids, may also be spray dried, though some controlled foaming of extract with carbon dioxide or nitrogen gas is then generally required, if the desired physical properties are to be maintained. (*See* **Drying**: Spray Drying.)

Freeze Drying

Freeze drying has been particularly successful for coffee extracts, when its use for other foodstuff liquids/solids has markedly declined in the last decades. However, a specialized technique has been developed, first patented around 1965, whereby the coffee extract is first frozen, and then the slabs are granulated, whilst still frozen, to particles approximately the same size as desired in the finished dried product. Oversize/undersize particles are recycled. There are a number of designs of freeze drier available, which will generally handle the frozen granules in trays resting on heated shelves in a batchwise manner. The amount of time of freeze drying required is up to 7 h under a very high vacuum (approx 0.4 torr), and a carefully controlled supply of heat to the drying granules, by conduction and/or radiation.

Whilst satisfactory product can be obtained by freeze-drying extracts direct from a percolation battery, it is more usual for economic and other reasons for concentrated extracts up to 40% w/w by freeze concentration (q.v.) or by evaporation (40% w/w or higher) to be freeze dried. If a favorable bulk density of 180–220 $g\,l^{-1}$ is required, it is additionally necessary to foam the extract in the slush-frozen form, before full freezing and freeze drying. (*See* **Freeze-drying**: The Basic Process.)

Separate Volatile Compound Handling

In recent decades, instant coffee manufacture has become increasingly sophisticated, through greater attention to methods of maximizing extraction and retention of volatile compounds responsible for flavor/aroma, which earlier procedures of simple extraction and spray drying could not accomplish. The first method concerns headspace aroma of the finished powder, due to the presence of very highly volatile substances that cannot be retained by any method of spray or freeze drying. A convenient vehicle was found to be coffee oil, which can be sprayed or plated (at a level of about 0.5% or less) on to the powder/granules as already described, and will give an aroma similar to that of dry roasted and ground coffee when sniffed. The coffee oil can be that obtained by mechanical expression of part of the roast coffee blend to be percolated, or a spent grounds coffee oil purified and enhanced with suitable aromatics from other stages of the manufacturing process. The coffee oil and its aromatics are very susceptible to oxidation, hence the need for gas-packed product, as already described. Its application (so-called 'aromatization') will play only a small role in the flavor of the made-up beverage product, so that other methods are needed, of which there are many available, mostly patented. (*See* **Oxidation of Food Components**.)

Battery extraction, designed primarily for the extraction of soluble solids, can be fairly successful also for the extraction of volatile compounds, so that, when followed by freeze concentration and freeze drying, a flavorful product is formed. However, volatile compounds can be prestripped by steam from the roasted coffee before aqueous extraction, in the form of an aqueous condensate to be reincorporated later. Similarly, a percolated extract can be stripped of the important volatile compounds by partial evaporation (say 10–20% of the water), again to give an aqueous essence condensate. The stripped extract can then be further evaporated as required, with the condensate discarded.

The final solution after evaporation containing a high concentration of solubles, can then be slightly diluted back with either or both of the aqueous essence condensates, and used as feed for either spray or freeze drying. The retention of volatile substances in spray drying is known to be very markedly improved when feed extracts of high soluble solids concentration are spray dried. This will be true also of freeze drying, though, additionally, it has been found that parameters of the freezing itself are also very important (e.g., slow freezing to large ice crystals favors subsequent volatile retention).

Agglomeration

Agglomeration was a process first used for dusty skim milk powders to increase average particle size and, more importantly, for ease of rapid dissolution in water, so-called 'instantization.' Whilst the latter is not required for a satisfactory instant coffee powder, a similar agglomeration process, using steam/water to rewet the surface of particles followed by drying, is used to manufacture instant coffee granules that are not in fact freeze-dried. Precise details of processes differ, as the numerous patents will indicate. The diminution of volatile compound content from spray drying to granule formation will only be small.

Packing

Instant coffee was originally packed into tins but, since 1960, has now been almost entirely packed into glass jars. Under EEC prescribed weight

directives, allowable packed weights for retail sale are 50, 100, and 200 g, and certain multiples, accompanied by the average weight system to be assessed over a stipulated number of containers. Filling machinery is now very high-speed (e.g., 250 per minute for 50 g jars), operating by volumetric fill, and adjustable by vacuum level according to the bulk density of the product being packed. Two other operations may also be incorporated, simultaneous spraying of small amounts of coffee oil into the powder/granules for headspace aroma purposes and a final provision of a carbon dioxide/nitrogen atmosphere within the jar to lower the headspace oxygen level to 4% v/v or preferably less.

General Comments

In recent decades, all these process stages have been investigated fundamentally through the disciplines of chemical (food) engineering by a number of people, especially the late Professor Thijssen of Eindhoven Technical University, to provide considerable mathematical insight into their mechanisms.

Storage and Stability

Instant coffee is relatively hygroscopic, easily picking up moisture from the atmosphere and caking at about 7–8% w/w moisture content. For example, to keep instant coffee below 5% (dry basis) moisture content, the relative humidity of the air with which it is in contact must be below 35–40%, though the precise value depends upon the nature of the instant coffee in question, primarily due to differences in porosity of the particular particles made. It is necessary, therefore, that jars of instant coffee be well sealed prior to sale.

A simple spray-dried product, provided the dry matter content is kept above 95% w/w (i.e., < 5% w/w moisture content), will have a shelf-life of several years. The modern sophisticated products, containing substantial amounts of volatile compounds (especially plated coffee oils), need to be packed in jars also with no more than 4% in-pack oxygen content and preferably less, so that the shelf-life to acceptable quality is maintained up to 18 months.

Analysis of Coffee Products

L C Trugo, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil

Introduction

The composition of the coffee seed is complex, as is the case for other natural products. After roasting at unusually high temperatures many chemical reactions take place, with degradation of the original compounds as well as polymerization of intermediate products, which substantially increases its complexity. These reactions are indispensable for the characteristic coffee beverage. Analysis of the different coffee products may be relatively simple, involving inexpensive equipment such as that used for proximate analysis, or may demand a great deal of analytical expertise and sophisticated apparatus, such as chromatography coupled to mass spectrometers, infrared spectrometers, and capillary electrophoresis to assess coffee flavor composition and authenticity.

Proximate Analysis

Proximate analysis in food products is the analysis of the major constituents which together comprise nearly 100% of the food composition. This generally includes water, ash, total protein, and carbohydrates. Proximate analysis is the first approach for food product characterization and control and it is not dependent on expensive or sophisticated equipment. It is easily carried out by quality control laboratories, including coffee-processing plants.

Water

The control of the water content of coffee at different stages of processing, from green beans to instant coffee, is an important action to achieve a desirable final product. In the first stages of processing the ripe coffee cherries, containing 60–65% water, must be dried to a level of 10–12% which is normally found in the green beans, and to prevent undesirable

microbial growth which can alter the sensory quality of the final product. After roasting, the water level drops to about 5% and after industrial extraction and drying to produce instant coffee, the powder should present values in the range 2–4% of water. The simplest method for general moisture determination in food is oven drying at 105–110 °C until constant weight is reached, and this may be applied to coffee products. However, some inaccurate data may be obtained, particularly when roast or instant coffee is used, due to water formation by the browning reaction or by loss of volatile components at these conditions.

Empirical time–temperature procedures have been proposed, including a two stage drying process for green coffee samples, involving a drying period at 130 °C for 6 h, followed by another of 4 h after a rest period of 15 h in a desiccator. This procedure is recognized as giving reproducible data; however, it may not be convenient for routine analysis. Vacuum oven-drying methods are also recommended, particularly for roast and instant coffee, because it is possible to use lower temperatures of around 60 °C. However, in practice the overnight oven-drying method at 105 °C is still adopted. Nondestructive methods based on nuclear magnetic resonance, near infrared spectroscopy, and microwave techniques may also be used to assess the water content of coffee samples but their wide application may be limited due to the relative high cost. The alternative for more accurate water determination is the use of the Karl–Fischer method based on a specific quantitative chemical reaction of the water from the sample. Automated equipment based on the Karl–Fischer reaction is commercially available and may be useful for routine purposes.

Ash

Ash determination can easily be achieved by dry ashing the coffee sample at 550–580 °C for at least 6 h and usually up to 17 h to obtain constant ash weight. The ash content of green coffee is in the range 3.0–4.5%. This range does not alter significantly in roasted coffee but increases considerably in instant coffee, with values in the range 9–10%. The ash content gives a rough idea of the total mineral amount and it has been a useful parameter for coffee standardization and to detect instant coffee adulteration by the addition of coffee substitutes.

Crude Protein

The crude protein content of coffee products is usually assessed by the universally used Kjeldahl method for total nitrogen determination. Together with other data of proximate analysis this may be useful for quality control but is of very little use as an indicator of a food source of protein since coffee products are not relevant as protein sources in the diet; however, they are important for coffee aroma formation during roasting. The total protein content of green coffee is in the range 11–13% and this value is increased after roasting to 13–15% and 16–21% in the instant coffees. Although these data may be useful for quality control, one must consider that total nitrogen includes non-nitrogen proteins, particularly from trigonelline and caffeine which will inflate the actual protein results. Instant coffees analyzed only for protein nitrogen can present final protein values in the range 8–13% and if the actual protein value is needed, the non-nitrogen content should be subtracted from the crude protein content.

Oil

Total lipids as determined by organic solvent extraction are present in high levels in green and roasted coffees. Significant differences are found in different species, with Arabica coffee containing about 12–13% and Robusta 7–10%. They are important vehicles for coffee aroma and are relatively stable during roasting, showing a relative increase in roasted coffees: Arabica presents 14–20% and Robusta 11–16%. However, only minute amounts are found in the beverage or even in instant coffee since they are not very soluble during domestic or industrial hot-water extraction. The saponifiable fraction of the green coffee oil is the major component, with triglycerides accounting for 70–80% and free fatty acids 0.8–2%. The traditional Soxhlet procedure, based on organic solvent extraction, for example with petroleum ether, is usually applied for routine analysis; however, for green coffee samples it may be necessary to carry out a previous acidic hydrolysis for liberation of structurally bound lipids in order to obtain more accurate results.

Total Carbohydrates

The carbohydrate composition of coffee products varies considerably during processing. In the green coffee bean large amounts of both sugars and polysaccharides are found. In roasted coffee only polysaccharides are found since sucrose is destroyed by caramelization during roasting. However, in instant coffees, free sugars are again present, and these are mainly monosaccharides, due to hydrolysis of polysaccharides during industrial extraction. Colorimetric methods such as the phenol-sulfuric or the anthrone procedures may be applied to assess the total amount of carbohydrates, in green, roasted, or instant coffees; however, a great degree of interference is expected, particularly in roasted and instant

coffee, due to complex browning components formed during processing. Due to this general difficulty many laboratories simply calculate the total carbohydrates by substracting the total proximate results from 100%.

Protein and Amino Acids

Coffee presents a relatively high level of protein in the range 11–16% in the green bean with less than 0.5% corresponding to free amino acids. However, coffee is not considered to be a source of protein in the diet since most of this material will remain in the insoluble residue after water extraction to prepare the coffee beverage. The nitrogen-protein determination will give only a crude idea of the protein content. More accurate results may be obtained by amino acid analysis. The study of specific protein fractions may be achieved by gel permeation or ion exchange chromatography, hydrophobic and reverse-phase chromatography, or by electrophoresis. The importance of protein and free amino acids is related to their contribution to coffee aroma compounds formation during roasting and also to pigment formation though the Maillard reaction. The degradation of amino acids during roasting may lead to the formation of important volatile compounds such as pyrazines, oxazoles, and pyrroles. The analysis of amino acids by acid hydrolysis of protein will provide more accurate true protein data in green coffee. However, for roasted and instant coffees acid hydrolysis will liberate amino acids from Maillard condensed material with little relation to true protein composition. For tryptophan quantification a specific colorimetric method after basic or enzymatic hydrolysis should be applied, since this amino acid is not resistant to the current acid hydrolysis. One less common amino acid, pipecolic acid, has been used for coffee species characterization since it is present in *Coffea arabica* but not in *C. robusta*.

Amino acid analysis may be carried out using dedicated amino acid analyzers based on ion exchange chromatography followed by postderivatization with ninhydrin and detection by colorimetry. More recently, high-performance liquid chromatography (HPLC) using reverse-phase columns with prederivatization has been used. The protein hydrolysate may be treated with phenyl isothiocyanate to form phenylthiocarbamyl derivatives followed by chromatography and ultraviolet detection or submitted to reaction with *o*-phthaldialdehyde (OPA) to produce OPA derivatives for fluorimetric detection. Capillary electrophoresis has also been applied and shows great potential as a competitive technique in relation to sensitivity and resolution. Free amino acid analysis may be important as aroma precursors and their determination can be achieved by deproteination with 10% trichloroacetic acid and the amino acid analysis of the supernatant, as described above. (*See* **Amino acids**: Properties and Occurrence.)

Free Sugars and Polysaccharides

More sophisticated techniques are needed for a more detailed carbohydrate analysis. The determination of individual free sugars has become very important, particularly in instant coffee samples, since the sugar profile seems to be an accurate indicator of coffee authentication. Sucrose is the main sugar present in green coffee and it may easily be determined by HPLC with normal-phase chromatography (generally silica-amino), acetonitrile (70–80%) in water as mobile phase and refractive index detection, after hot water or aqueous ethanol (80%) extraction, in the ground and defatted beans. The extract should be cleaned up by means of Carrez solutions or activated charcoal and filtered before chromatography. The extract may be concentrated if necessary, particularly when roasted and instant coffees are used. However, due to rapid degradation of sucrose during roasting and the appearance of smaller amounts of other free sugars due to polysaccharide hydrolysis during instant coffee manufacturing, the analysis of sugars in both roasted and instant coffees is much more complicated. Chromatographic analysis may be difficult with the use of refractive index detector due to its low sensitivity. The application of evaporative mass detectors and pulsed amperometric detectors has produced better results.

The polysaccharide fraction of coffee is important as a substrate for pigment and aroma formation and also as a source of free sugars, particularly in instant coffee production. The industrial extraction at high temperatures during instant coffee manufacture promotes some degree of polysaccharide hydrolysis, liberating constituent monosaccharides and oligosaccharides from the polysaccharide backbone. Consequently, arabinose, galactose, mannose, and glucose from arabinogalactan, galactomannan, and cellulose are typical of instant coffees. The analysis of polysaccharides is mainly studied after separation of fractions by solvent extraction or by gel permeation chromatography and the subsequent analysis of the constituent monosaccharides after acid hydrolysis ($1\,\mathrm{mol\,l^{-1}}$ sulfuric acid) by gas chromatography or HPLC. Table 1 shows the sugar composition of the water-insoluble fraction from green coffee which contains most of the polysaccharides, before and after being submitted to roasting conditions. Arabinose shows greater lability to heating and this may be explained by the presence of short side chains with

Table 1 Composition of water-insoluble polysaccharide from Arabica coffee before and after roasting

Sugars in the polysaccharide fraction	*Nonroasted g% (dry basis)*	*roasted g% (dry basis)*
Arabinose	11.0	6.0
Galactose	24.8	23.9
Mannose	38.0	41.7
Glucose	20.0	22.0

From De Maria CAB, Trugo LC, Aquino Neto FR, Moreira RFA and Alviano CS (1996) Composition of green coffee water-soluble fractions and identification of volatiles formed during roasting. *Food Chemistry* 55: 203–207.

terminal arabinose in the arabinogalactan structure. Due to this characteristic, arabinose from the polysaccharide fraction decreases significantly during roasting and is found in relatively high levels in instant coffee.

Lipids

Lipids are present in green coffees at relatively high levels (7–13%); higher levels are usually found in Arabica coffee. They are relatively stable during roasting, showing a relative increase in roasted coffee (11–20%). The saponifiable fraction is predominant, with triacylglycerols accounting for over 70% of the coffee oil. The analysis of constituent fatty acids is achieved by usual transmethylation as a derivatization procedure of triacylglycerols, prior to gas chromatography of the fatty acid methyl esters. The fatty acid composition of coffee oil shows linoleic acid as the main component (45% of total fatty acids) followed by palmitic (35%), oleic (8%), stearic (7%), arachidic (3%), and linolenic (2%). The nontriacylglycerol fraction is quite different from other oil seeds. High levels of diterpenes and diterpene mono-fatty acid esters are found, particularly cafestol and kahweol, which account for about 20% of the oil fraction. Apparently, kahweol is present in Arabica but absent in Robusta coffee and for this reason it has been used for identification of coffee species. Cafestol and kahweol have received much attention recently since it has been confirmed that they can increase plasma cholesterol levels, as observed experimentally and by epidemiological studies. Curiously, the correlation between coffee consumption and high levels of cholesterol has been found only in the Scandinavian population drinking unfiltered coffee. It was observed that unfiltered coffee has small amounts of a floating oil material on the surface. This material was determined to be mainly cafestol and kahweol, which were proved to be cholesterol-raising factors in experimental animals. Coffee filtration appears to be sufficient to retain all the diterpenes in the filter, explaining why the correlation between high cholesterol and coffee drinking is not verified in consumers of filtered coffee. The isolation of diterpene alcohols and their esters has been carried out by paper, thin-layer, or column chromatography. The qualitative detection of kahweol is based on the reaction with potassium iodide (KI) in acetic acid medium; this produces a blue color after heating. Sterols are also important components of the unsaponifiable fraction, accounting for some 20% and consisting mainly of sitosterol, stigmasterol, and campesterol. Terpenes and sterols may be analyzed by gas chromatography after deesterification. To aid in structure elucidation, the use of gas chromatography–mass spectrometry may be helpful. The analysis of coffee wax has been carried out to detect the presence of 5-hydroxytryptamine, which appears to be an irritant of the gastric mucosa. The use of reverse-phase HPLC seems to be adequate for the analysis of this class of compound. Because coffee beverage is an aqueous extract, only a small amount of lipid will be dispersed in the liquid and only those with specific biological activity will have a greater impact for the consumer.

Minerals

More than 30 minerals have been determined in coffee products. An unusually high potassium content is found in both Arabica and Robusta coffees, representing about 40% of total mineral content. Particularly interesting is the fact that Arabica coffees present consistently a higher amount of manganese when compared to Robusta, indicating a genetic difference. In instant coffees the mineral profile is similar to green coffee; however, due to salt solubility in water the total mineral content will be higher than green and roasted coffees. The control of ash and also potassium contents of instant coffees may be useful as an indicator of extraction yield. The analysis of potassium may be easily carried out by inexpensive flame photometers. A more complete assessment of mineral composition may be achieved using more comprehensive techniques such as atomic absorption, thermal neutron activation, and plasma spectrometry or inductively coupled plasma mass spectrometry (ICP-MS), after sample mineralization.

Trigonelline and Niacin

Trigonelline is a pyridine derivative present in several species of fruits and seeds, including coffee. It is present in both Arabica and Robusta coffees in the average amount of 1%. It is extensively degraded during coffee roasting and when dark roasting conditions are used, only about 0.1–0.2% remains in the roasted

Table 2 Loss of trigonelline during coffee roasting and the correspondent increase in niacin

Type of coffee	*Type of roasting*	*Trigonelline g% (dry basis)*	*Niacin mg% (dry basis)*
Arabica	Light	0.9	4.9
	Medium	0.7	10.2
	Dark	0.4	14.2
	Very dark	0.2	15.0
Robusta	Light	0.7	9.9
	Medium	0.6	15.0
	Dark	0.3	23.4
	Very dark	0.1	27.0

From Trugo, LC (1984) PhD thesis. University of Reading, UK.

coffee (Table 2). Due to the high solubility in water, trigonelline is readily extracted from instant coffees, appearing in the range 0.9–1.7%. The final concentration in instant coffee depends on the extraction conditions used as well as on the original material and on the roasting degree. Many volatiles are formed by trigonelline degradation, such as pyrrols and pyridines which will contribute to the aroma fraction of the coffee. Nicotinic acid is another important product formed by demethylation of trigonelline. Nicotinic acid or niacin is a vitamin which is absent in green coffee and in fact is produced during coffee roasting, being present in both roasted and instant coffees, in the range 10–26 and 20–50 mg%, respectively. Because niacin is produced during coffee processing, the vitamin is highly bioavailable in the coffee beverage, in contrast with natural sources where it is present in the bound form.

The analysis of trigonelline in coffee products may be carried out by isolating it from coffee extract using a celite column followed by measurement by ultraviolet (UV) spectrophotometry, by paper chromatography followed by elution and UV measurement of the spot, or by HPLC. This last technique has been shown to produce more reliable results and is presently widely used. A simple reverse-phase method using a C_{18} column, water with a small amount of methanol as solvent, and monitoring at 265–272 nm has been quite adequate for routine analysis. Clarification of coffee extracts may be achieved by solid-phase extraction or precipitation of proteins and pigments by means of lead acetate solution or other adsorbent material except Carrez solutions, since trigonelline is strongly adsorbed by zinc ferrocyanide.

Nicotinic acid may be determined by microbiological, colorimetric (with cyanogen bromide and *p*-aminoacetophenone), or chromatographic methods. However, HPLC has frequently been the technique of choice. In this case better results have been achieved using reverse-phase procedures with a C_{18} column, and a buffered ion-paired mobile phase to attenuate the nicotinic acid polarity and increase its retention in the column and detection at 254 nm. As for trigonelline analysis, some clarification procedure of the coffee extract must be used.

Caffeine

Caffeine is widely consumed in many countries as a constituent of many food items such as coffee products, tea, cocoa products, and cola beverages. Due to its physiological and pharmacological effects, caffeine is the most studied compound present in coffee. Caffeine is the major alkaloid present in coffee, although low levels of theobromine and theophylline, which are other purine alkaloids, may also be found. Caffeine is the component responsible for the stimulant properties of coffee beverages. Green Robusta coffee has a higher content of caffeine (1.5–2.5%) than Arabica (1.0–1.2%) and it is relatively stable to heat, showing a small loss during the roasting process. Due to its solubility in hot water, caffeine is highly extracted during instant coffee production. The amount present in instant coffee strongly depends on the green coffee blend used and less so on extraction rate. Robusta coffee is widely used as a blend component in instant coffee manufacture and because it has considerably more caffeine than Arabica the final content depends on the proportion of these types of coffees. Usual figures would fall in the range 2.5–4.8% for regular instant coffee and 0.2% for decaffeinated coffee. (*See* **Caffeine**.)

The analysis of caffeine was carried out for many years using the method based on its extraction from the coffee matrix with chloroform, followed by extensive purification of the extract with celite or alumina and subsequent measurement of caffeine absorption at 272 nm. However, extensive extract purification procedures are needed to avoid the presence of significant amounts of interfering materials. The application of chromatographic techniques, particularly HPLC and gas chromatography, has produced more reliable results. HPLC has been widely adopted due to its simplicity, rapidity, and reliability.

Reverse-phase HPLC methods using a C_{18} column and aqueous methanol as mobile phase with UV monitoring at 272 nm have proved to be perfectly adequate for fundamental and quality control analyses. The water solution obtained from the coffee matrix may be easily purified by solid-phase extraction or by clean-up using Carrez solutions prior to chromatography. When analysis of a large amount of samples is continuously needed, an HPLC method may be relatively easily automated.

Chlorogenic Acids

Chlorogenic acid is a trivial name used to define the major phenolic components found in coffee. This name originates from early observations that green coffee extracts produced a green color after addition of a solution of ferric chloride. In fact, chlorogenic acids present in coffee are mainly esters of quinic acid with caffeic, ferulic, or coumaric acids. Significant amounts of three isomers (in positions 3, 4, and 5 of quinic acid) of each of these groups of caffeoylquinic, di-caffeoylquinic, and feruloylquinic acids are usually found in green and processed coffees. They are not resistant to heat and are degraded during roasting, contributing to the aroma fraction. Consequently, their levels in the coffee beverage are dependent on the roasting degree, with less than 10% of the original green coffee content found in very dark roasted coffees (Table 3).

Chlorogenic acids and their derivatives have received much attention due to recent investigations showing different biological properties of this class of compounds. A lactone of ferulic acid presented affinity to bind to opioid receptors in the brain. The antioxidant activity of caffeoylquinic acid has been demonstrated and di-caffeoylquinic acids presented strong inhibitory activity against integrase enzymes, which are important for virus replication. Although the biological significance of the ingestion of coffee chlorogenic acids is not well defined, their *in vitro* activities observed in different studies are sufficient to draw attention to the chemical and biological characteristics of these molecules.

Colorimetric and chromatographic methods have been applied to chlorogenic acid analysis. The first approach is used for determination of the caffeoylquinic group by reaction with molybdate or total determination using the metaperiodate reagent. The latter is useful for individual chlorogenic acid isomer analysis. Although gas chromatography has been applied to chlorogenic acid analyses, HPLC appears to be the preferred technique. Chlorogenic acid extraction is critical for obtaining accurate results. Different solubilities of different isomers can make quantitative extraction difficult. Hot solvent extraction appears to give more reproducible results since it will stop possible action of endogenous phenolases during green coffee solubilization. Comparison between different extraction methods showed that the use of aqueous methanol (40%, v/v), followed by precipitation of colloidal material using the Carrez solutions (sol. I, 21.9 g zinc acetate and 3 ml of glacial acetic acid dilute in distilled water up to 100 ml; sol. II, 10.6 g potassium hexacyanoferrate (II) in 100 ml distilled water). Reverse-phase HPLC with an ordinary C_{18} column, gradient elution from a pH 2.5 solution of 0.01 mol l^{-1} tripotassium citrate or trifluoracetic acid to methanol, increasing from 20% to 70% and UV detection at 325 nm, has become a popular procedure. The difficulties of commercial standards may be partially overcome by the isomerization of the commercially available 5-caffeoylquinic acid solution at pH 8 with ammonia and heating in a boiling-water bath. Using this procedure a mixture of the three caffeoylquinic isomers is obtained. The same procedure may be applied to other isolated fractions of feruloylquinic acid to help peak assignment. Quantification may be achieved by calculation based on extinction coefficients of different isomers found in the literature.

Other Organic Acids and Coffee Acidity

Together with chlorogenic acid, other organic acids such as citric, malic, oxalic, and tartaric acids are found in green coffee. Other acids may be generated

Table 3 Content of chlorogenic acid groups in green, roasted, and instant coffees

Chlorogenic acid groups	*Green Arabica*	*Medium roasted Arabica*	*Green Robusta*	*Medium roasted Robusta*	*Instant coffee (average of 13 samples)*
CQA	5.8	2.0	6.8	1.8	4.3
diCQA	0.9	0.2	1.4	0.1	0.4
FQA	0.3	0.1	0.6	0.2	1.1
Total	7.0	2.3	8.8	2.1	5.8

Results expressed in g% dry basis.

during coffee roasting, contributing to the acidity of the beverage. Consequently, organic acids such as lactic, pyruvic, succinic, glutaric, and others, although present only in small amounts, will contribute to the overall coffee acidity and flavor. Acidity is very important for the taste of coffee beverage. The term 'sour' is frequently used to define the undesirable taste of over-acid coffees. However, their harmonic composition also contributes to the desirable taste of good coffees. Coffee acidity can be assessed by pH measurement or by titration with an alkali solution. Undissociated molecules of acids may have specific flavor which is not exactly related to acidity and in some cases the analysis of individual acids may be useful for quality control. In this case, ion chromatography with electrochemical detection or gas chromatography after derivatization seems to be a more adequate analytical technique. The use of electrochemical detection with continuous-flow injection analysis may be useful for quality control involving a large amount of samples.

Aroma Analysis

The volatile composition of roasted coffee is extremely complex. The green coffee shows relatively simple volatile composition which is completely modified during roasting. Many classes of volatiles are generated during coffee roasting (Table 4). Over a thousand compounds have already been identified in the volatile fraction of roasted coffee but the composition of the characteristic coffee aroma is not yet completely established. The analysis of the headspace composition of coffee by gas chromatography is the most common approach. The use of mass spectrometry coupled to gas chromatography (GC-MS) has proven to be very useful for structure elucidation of the aroma composition. Sometimes it is necessary to concentrate the volatile fraction, which may be too diluted to be detected in the chromatogram. In those cases codistillation procedures using the Likens–Nickerson apparatus or entrapment in solid sorbents such as tenax and porapack may be very useful. Some volatiles, although present in only minute amounts, may have very low sensory thresholds and be extremely relevant for coffee flavor. Other useful purge-and-trap methods may involve freezing at very low temperatures in liquid nitrogen environment of the coffee volatiles carried by an inert gas in capillary fused silica tubes and thermal purging of the concentrated volatiles direct to the gas chromatography column.

Table 4 Volatile compounds important for coffee aroma and their possible precursors formed during roasting

Class of components	*Precursors*
Pyrrole and furan	Reaction products of amino acids + carbohydrate
Furanone	Sucrose
Furan aldehyde	Saccharose, arabinogalactan
Pyrazine	Hydroxy amino acids
Pyridine	Trigonelline, hydroxy amino acids
Phenol	Chlorogenic acid

Adapted from De Maria CAB (1995) PhD thesis. Federal University of Rio de Janeiro.

Due to the complex gas chromatograms obtained from volatile coffee analysis, some research has been carried out using the sniffing port technique. In this approach, part of the column effluent is diverted from the detector to the sniffing person who will register all characteristics of the compound corresponding to the detected chromatographic peak. This sensorial evaluation (aromagram) will provide very useful information about the sensory impact of specific components. Further chemical and structure research will then be directed to the selected peaks which are relevant for aroma composition. Electronic chemical gas sensor systems, called electronic noses, have recently been developed in order to assess the sensorial impact of specific volatile compounds. This kind of equipment has been applied to the analysis of food, cosmetic, and other related materials and, although producing some controversial results, it appears to present some potential for coffee and other food analysis. The gas sensors commercially available are mainly based on metal oxide semiconductors, organic conducting polymers, and piezoeletric crystal sensors. Sensors based on fiberoptic, electrochemical, and bimetal principles are due to become commercial. Statistical methods such as principal components analysis, cluster analysis, canonical discriminant analysis, artificial neural network, and radial basis function are generally used to treat the electronic nose data.

Roasted coffee is considered to be one of the more complex matrices regarding aroma composition and has been chosen to validate some commercial instruments. The instruments appeared to be capable of differentiating between Arabica and Robusta coffee. Sensor output and roasting level were found to produce highly correlated data submitted to another electronic nose equipment. However, it is apparent that there is a need for further investigation and development in this sort of equipment for it to be significant in coffee quality control.

Detection of Coffee Contaminants

The characteristic thermal conditions used for coffee roasting at very high temperatures make the coffee

beverage a product with very low risk of microbial contamination. However, during harvesting, drying, and storage, some extraneous material may be incorporated to the product, such as in any stage of food production. Inadequate storage conditions may favor fungi development, producing mycotoxins which may be resistant to coffee roasting. Ochratoxin A appears to be the most reported mycotoxin detected in coffee products. Although having potent nephrotoxin activity and being immune-suppressant, teratogenic, and carcinogenic, its eventual presence in coffee products does not appear to represent a public health risk due to the very low levels found ($< 8\mu g\ kg^{-1}$). In these cases the use of HPLC or enzyme-linked immunosorbent assay techniques is recommended for analysis. HPLC analysis usually needs extensive concentration and clean-up by means of solid-phase extraction, with polar, nonpolar, and affinity phases, reverse-phase chromatography, and fluorimetric detection (333 nm excitation and 470 nm emission). Atomic absorption spectrometry may be applied for the investigation of possible contamination with metals. HPLC and GC techniques may be indicated for the analysis of polycyclic aromatic hydrocarbons due to the use of direct fired roasters, or to the analysis of phenols and pesticide residues due to contaminated sacks or disinfection treatments. (*See* **Contamination of Food.**)

Sensory Analysis

Sensory analysis is still very important for coffee classification because there is no objective approach to define a clear correlation of chemical data with sensorial attributes. Expert coffee tasters are still important professionals in the coffee industry since they produce important information on coffee flavor directed to consumers' expectations. The use of sensory analysis has increased in both applied and fundamental investigations, coupled with the use of different statistical methods. Some statistical methods, such as analysis of variance (ANOVA), principal components analysis (PCA), cluster analysis (CA) and flash analysis, have been extensively used to assess coffee sensory attributes and consumer preferences. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.)

Coffee Authentication

Different approaches and techniques have been used to assess coffee authenticity. The application of unusually high processing temperatures for coffee roasting followed by grinding to produce roasted and ground coffee make it extremely difficult to compare the physical and chemical characteristics of the final product with the original green coffee beans used. This is further complicated during elaboration of soluble coffees where the roasted and ground material is extracted with hot water under pressure followed by concentration and water evaporation to obtain the dried solubles. Chemical analysis becomes more complex by the generation of a wide range of pigments which interfere with sample preparation.

Different groups of compounds have been used as recognition patterns to differentiate coffee species and varieties and also adulteration by the addition of extraneous material during processing. The analyses of specific lipids such as diterpene mono-fatty esters, particularly cafestol and kahweol which appear to be typical of coffee beans, have been used. Additionally, kahweol is only found in Arabica coffee, which may be useful for species characterization. The fatty acid composition and also the triacylglycerol profile are dependent on species and may produce discrimating data after statistical treatment by principal component analysis, cluster analysis, linear discriminant analysis, or other pattern recognition method. The determination of mineral composition may be used to compare coffee varieties and also as an aid to detect adulteration due to modification of the typical mineral composition of coffee. The volatile fraction may also be useful for coffee authentication due to the presence of typical coffee aroma from specific compounds such as furfurylthiol and kahweofuran. The combination of results from volatile and nonvolatile analyses coupled with statistical treatments also presents potential for coffee authentication. Results from gel permeation profile, chlorogenic acid composition, caffeine, and trigonelline combined with head-space analysis show a potential field for development of authentication methods. The appearance of free sugars in instant coffees from polysaccharide hydrolysis during industrial extraction has been explored as an approach for instant coffee authentication. The typical presence of arabinose, fructose, mannose, glucose, and galactose, with the clear predominance of arabinose, proved to be useful indicators of coffee authenticity. Adulteration of coffee with other plant materials will considerably alter the typical sugar profile. For example, the addition of chicory during instant coffee manufacture will abnormally increase the fructose content and the use of byproducts from green coffee production (husks, parchments, etc.) will show the appearance of mannitol and higher levels of fructose and sometimes xylose. After hydrolysis, pure soluble coffee is characterized by high amounts of total galactose and mannose, while the product adulterated with coffee husks and parchments will present high total glucose

and xylose. The analysis of these free sugars is not always easy and the application of both HPLC and gas chromatography may be necessary. Better HPLC results have been obtained by using pellicular anion exchange chromatography with detection using pulsed amperometry, and this has been adopted as an international standard procedure.

More recently, infrared spectroscopy has been studied as a possible tool for coffee authentication and it has been claimed to be an easy, rapid, and relatively inexpensive technique. The application of near- and mid-infrared spectroscopy by means of a Fourier transform infrared spectrometer to the analysis of Arabica and Robusta coffees produced differentiated spectra. The chemometric treatment of the generated data showed the potential for species identification. Further application of this approach seems to be useful to investigate adulteration of instant coffee, since spectra variation is observed depending on sugar composition of the coffee extract.

Enantiomeric separation of chiral components may be explored in greater detail in the near future for coffee authentication. The analyses of chiral volatile components or their precursors by means of chiral gas chromatography or HPLC may be extensively used for green coffee characterization and to analyze the sensorial impact of enantiomeric volatiles formed during coffee roasting. Enantiomeric profiles may then be useful to verify coffee authenticity and adulteration.

Decaffeination

R J Clarke, Donnington, Chichester, West Sussex, UK

Introduction

Decaffeinated roasted coffees have been available since about 1905, especially in Germany, and have become a substantial sector in the sales of both roasted and instant coffee in the last two decades.

Definitions and Composition

The International Standards Organization in ISO 3509–1989 (and earlier versions) has defined decaffeinated coffee as 'coffee from which caffeine has been extracted. NB. A maximum residual caffeine content would usually be stated in a specification for decaffeinated coffee.' In fact, there is considerable national legislation specifying this maximum residual amount. In the UK and most other European countries, the maximum caffeine content for decaffeinated roasted coffees is set at 0.1% (dry basis); in the USA there is no specific legislation but manufacturers generally claim that more than 97% of the original caffeine has been removed. There is no particular market for partially decaffeinated coffees. For decaffeinated instant coffee, in European Community countries, the maximum caffeine content is set at 0.3% (dry basis) by the European Community Coffee and Chicory Products Directive of 1977 (and as amended 1983). This figure is also generally accepted elsewhere in the world, whether by legislation or otherwise, except again in the USA, where a 97% elimination figure is usual. It should be pointed out that in commercial practice, both of these figures (0.1% and 0.3%) are in

fact higher than those normally obtainable, especially for decaffeinated instant coffee, so that legal enforcement problems rarely arise. The relationship between the maximum figures for roasted and instant coffee was originally based upon a purely nominal extraction yield figure of 33% soluble solids in extracting roast coffee. It can be seen therefore that a cup of brewed coffee (from 10 g of roasted coffee) will contain not more than 10 mg of caffeine, and of instant coffee (using 2 g of product) 6 mg. (*See* **Caffeine**.)

Decaffeination is the name of the process whereby caffeine is removed. Almost entirely in commercial practice the process is applied to green coffee, after which the decaffeinated green coffee is roasted and ground, or converted to instant coffee exactly as for the corresponding nondecaffeinated products. The composition of these decaffeinated products, apart from caffeine content, will therefore be almost correspondingly identical. However, there will be slight differences, and also of flavor, depending upon the particular decaffeination process employed.

Caffeine is the most studied physiologically active component of coffee. Though this activity is generally weak, it has been the subject of numerous publications and much investigative work. According to the US Food and Drug Administration in 1984, 'the evidence received does not suggest that caffeine at present levels of consumption poses a hazard to public health.'

Decaffeination Processes

The various decaffeination processes in use can be classified with subdivisions in various ways. However, the original process, still used, is based upon direct organic solvent extraction of the green beans; subsequent to that an indirect solvent process was devised, in which water is first used to remove the caffeine from the beans, and the aqueous extract is then treated with the same kind of organic solvent as before. Since 1970, a variant of direct solvent extraction has become available in which the solvent is supercritical carbon dioxide. In all these methods, it is necessary to be able to recover the caffeine from the extracting liquids, and generally to refine it to a pure form for sale. It is also necessary to eliminate all but traces of organic solvent from the decaffeinated coffee beans, which should finally have a normal moisture content of, say, 11% w/w for sale or further processing. In commercial practice, residues of organic solvent will be exceedingly small, less than $1\,mg\,kg^{-1}$ in decaffeinated green coffee and, in a recent survey by the US Food and Drug Administration of commercial coffees, less in roasted coffee ($11–640\,\mu g\,kg^{-1}$) and its brews, and even less in instant coffee ($0.49\,\mu g\,kg^{-1}$). No particular legislation for residues has been adopted by European Community countries, though it has been under consideration for a considerable time now, except that of the choice of organic solvent which may be used.

Decaffeination processes and their offshoots have been the subject of much patenting activity, since conventional processes in use can be time-consuming and complex, and furthermore have led to developing environmental concerns. Though it can be seen that residual solvent amounts are negligible in respect of consumer exposure, use of organic solvents at manufacturing sites has to be carefully controlled on account of various potential hazards. This situation has prompted the development of alternative processes, solvents, and caffeine adsorbents.

Direct Solvent Decaffeination

The first commercial process was developed and patented in Bremen, Germany, in 1905, and sold as Café Hag, which name is still in use. The process used benzene as the solvent upon previously steamed green beans. However, benzene is both flammable and toxic, and became replaced by chlorinated hydrocarbons as they became available, and cheaper. Trichloroethylene was particularly favored, though in 1976 it became the subject of US Food and Drug Administration investigations and was gradually phased out and replaced by methylene chloride, which was affirmed for use in 1985 by the above regulatory body. A number of other organic solvents have been proposed, though only ethyl acetate and vegetable oils (including coffee oil and purified spent grounds coffee oil) have been or are believed to be used in commercial practice.

It was early found that a dry organic solvent extracted relatively little caffeine, or only very slowly, from green coffee beans, even though the solubility of pure caffeine in methylene chloride is reported, for example, to be 19 g per 100 g of solvent at 33 °C or 1.82 g in trichloroethylene at 15 °C. By raising the moisture of the green beans, first by steaming and then soaking in warm water, to 20–55% w/w (optionally 42% for methylene chloride) at, say, 67 °C, the transfer of caffeine into the solvent is markedly expedited. The explanation for this effect is twofold: a swelling of the coffee beans to assist diffusion, and destabilization of caffeine–chlorogenate complexes in the coffee bean by heat/water.

The extraction itself is carried out in percolation batteries of five to eight columns (similar to aqueous extraction in the manufacture of instant coffee, though not under pressure), though the time of contact can still be as long as 10 h. About 4 kg methylene

chloride is required per kilogram of coffee. The column containing coffee at the required decaffeination level is then isolated and drained, and steamed to remove traces of solvent for about 1.5 h. The decaffeinated coffee is then dried. The methylene chloride with dissolved caffeine from the most spent column is sent to a refinery, where the caffeine is extracted and the caffeine-free liquid sent back to the battery. A typical operation is shown in Figure 1.

Methylene chloride is known to be quite selective for caffeine amongst the components of green coffee, e.g., trigonelline is very poorly soluble. There will be some loss of weight in decaffeination, apart from that due to the caffeine, but some of this may be accounted for by normal process losses. No published data are available. Vegetable oils, such as coffee oils, are also a suitable solvent for decaffeination use, from which the caffeine can be removed.

Indirect Solvent Decaffeination or Water Decaffeination

A process was patented in 1941 in which water was used to remove caffeine from the green coffee beans. However, there are other water-soluble constituents (up to about 20%) present, so to prevent their extraction the extracting water has to contain equilibrium quantities of these noncaffeine solubles, so-called 'green' extract, but little or no caffeine.

The decaffeination process is again conducted in a percolation battery. After an initial start-up, the caffeine-rich water extract at about 0.5% caffeine content is contacted countercurrently (e.g., in a rotary disk contactor) with an organic solvent (such as methylene chloride, also described under direct decaffeination) at around 80 °C in order to reduce its caffeine content to below 0.05%. This 'green' water extract is then stripped of its residual dispersed and dissolved organic solvent, and is then recycled to the battery to extract further caffeine, and so on. The decaffeinated beans from the most spent column are dropped to a container, after they are washed with water on a screen to remove adhering soluble material, with the wash water then being added to the caffeine-free water extract before recycling. The washed decaffeinated beans are then dried. The methylene chloride stream containing the caffeine is evaporated to leave the caffeine which is then refined, and the solvent returned for reuse in the contactor.

This process is somewhat more complex than the direct method, but has the claimed advantages of a faster (about 8 h) and higher extraction rate of caffeine, less heat treatment of coffee, retention of surface waxes, and purer recovered caffeine. Though no published data are available, it is probable that there is a slightly higher loss of noncaffeine water-soluble substances, including some aroma precursers like free

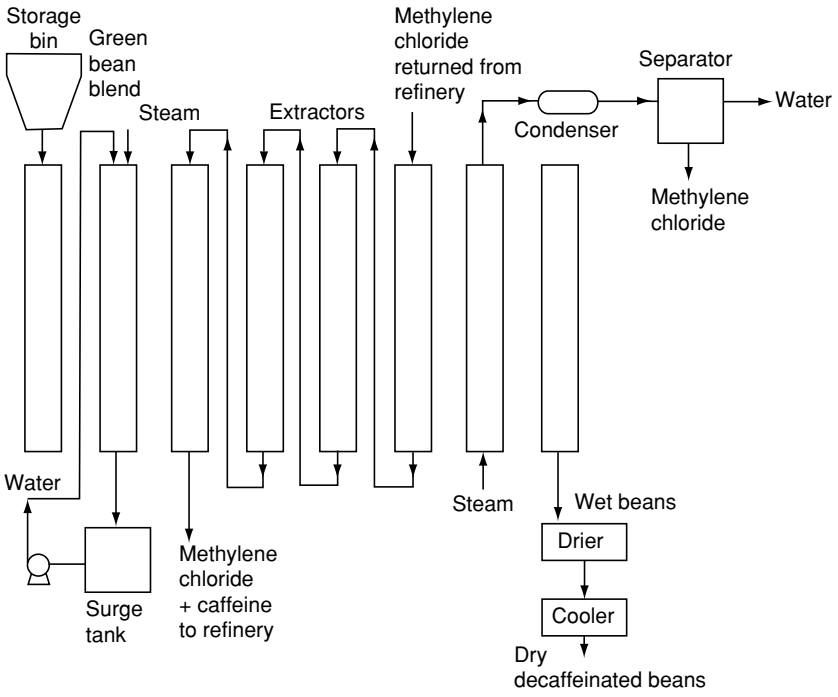

Figure 1 Solvent decaffeination. Reproduced with permission from Clarke RJ and Macrae R (eds) (1987) *Coffee*, vol. 2. *Technology*. Barking: Elsevier with permission.

amino acids, which may affect flavor/aroma on roasting.

Other Water Decaffeination Methods

An important aspect of both of the foregoing processes is the need to separate and recover solvent from the caffeine, usually for low-boiling solvents by multistage evaporation, with a high degree of efficiency. The caffeine itself in an impure form needs to be refined.

Recently, methods have been patented and some commercialized based on the removal of the caffeine from the aqueous 'green' extract by adsorbents of various kinds. The Coffex Company of Amsterdam, for example, proposed the use of an activated carbon which is preloaded with other coffee extract substances or with substitute substances of similar molecular structure or size, especially with carbohydrates, so that the charcoal will take up as few extracted substances as possible, other than caffeine.

The caffeine is eventually desorbed, and the charcoal may then be reactivated for reuse, or disposed of. These types of processes therefore avoid the use of organic solvents in any way.

Supercritical Carbon Dioxide Decaffeination

Certain fluid substances are known to have superior solvent powers in the supercritical state than when in the liquid state, of which carbon dioxide is perhaps the best known example. The supercritical state, however, is only achieved after reaching a minimum critical pressure (e.g., 75.2 bar for carbon dioxide) and critical temperature (e.g., 31.4 °C for carbon dioxide). Numerous diagrams have been published, plotting temperature against pressure and indicating in particular the supercritical region for carbon dioxide and other fluids, and incorporating lines of equal density (Figure 2). Superior solvent powers are associated with increased fluid density, though other factors will also dictate the particular temperature/pressure combination usable and economic in practice.

Zosel, in Mülheim, Germany, from 1970 published a number of patents relating to the supercritical use of carbon dioxide in extracting caffeine from green coffee beans. The claimed conditions were a temperature range of 40–80 °C and a pressure range of 120–180 bar, from which it may be seen that the single fluid phase has a density of the order of 0.5–0.6 g ml^{-3} compared with a gaseous density below the critical pressure of 0.1 g ml^{-3}. Carbon dioxide, being a nonpolar solvent, is quite selective for caffeine. As with organic solvents, it is still necessary to bring the green coffee beans before decaffeination to a moisture content of 30–50%

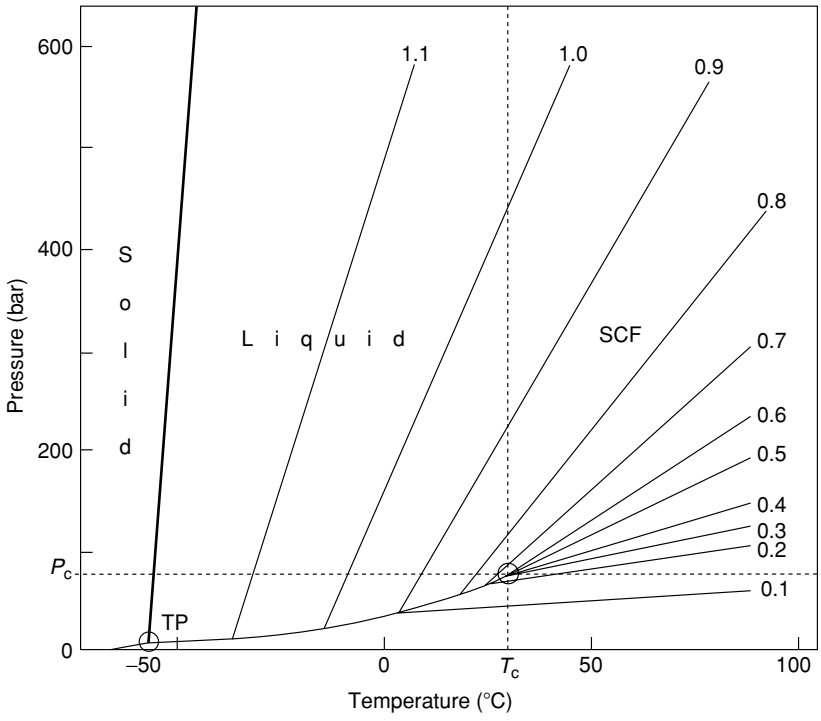

Figure 2 Pressure–temperature diagram for carbon dioxide, showing liquid, gaseous, and supercritical fluid regions (SCF), from P_c and T_c, and isodensity lines. TP, triple point; CP, critical point. Reproduced from Coffee: Decaffeination, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

w/w by steaming/wetting for the same reasons. The removal of the caffeine from the enriched supercritical carbon dioxide can be accomplished by a number of methods: (1) reduction of temperature/pressure; (2) adsorption in a closed circulating system on to activated charcoal; and (3) washing with water. The second method is to be favored in that a given quantity of supercritical carbon dioxide is loaded into and passed through an extractor vessel holding the moistened green beans; and then through a bed of activated charcoal held in a separate vessel, and recirculation performed in a closed-pressure system until the caffeine is sufficiently extracted from the coffee (Figure 3). At the end of a predetermined time the carbon dioxide is taken out to a holding vessel, and both the decaffeinated coffee beans and adsorbent are discharged. The decaffeinated coffee beans are then dried, whilst the caffeine is removed from the adsorbent, which may be reactivated for further use. A decaffeination process along these lines was commercialized by the Kaffee Hag Company, in Bremen, Germany. It can be appreciated that the high pressures necessary involve high capital expense, and the design and running procedures must be carefully considered to minimize energy and other running costs. Nevertheless, the process and the product have many advantages, especially from the marketing and consumer perception points of view; and, with the high selectivity of this solvent, it is claimed that roasted and soluble products from it are very similar in flavor quality to the corresponding nondecaffeinated products.

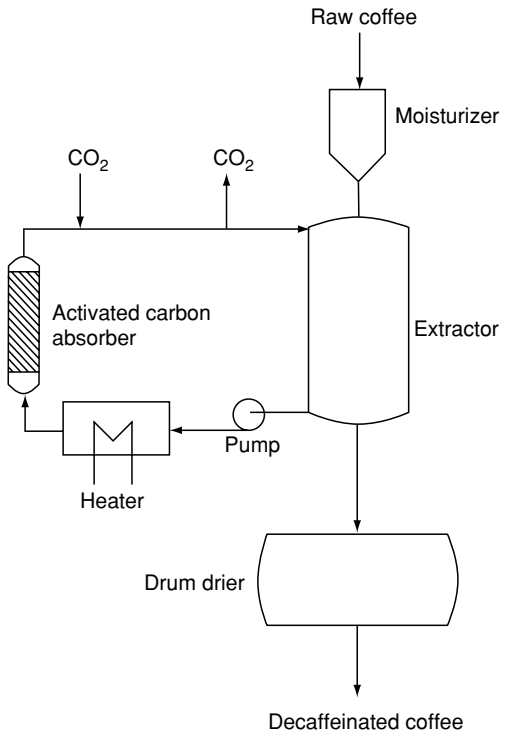

Figure 3 Carbon dioxide decaffeination process, schematic. From Clarke RJ and Macrae R (eds) (1987) *Coffee*, vol. 2. *Technology*. Barking: Elsevier with permission.

There are published and patented variants of this basic supercritical carbon dioxide decaffeination process, including use of other fluid such as nitrous oxide and hydrocarbon gases, and other modified systems of operation. Numerous patent methods have also been proposed for the effective removal of caffeine absorbed in the carbon.

Decaffeination of Roasted Coffee and Liquid Coffee Extracts

There are a number of patents relating to decaffeination of coffee products, rather than green coffee, including use of organic solvents and supercritical carbon dioxide. It would be necessary to remove first all the organic volatiles which are responsible for aroma/flavor before decaffeination; as indeed is already widely practiced in the manufacture of non-decaffeinated instant coffees, and add them back before or after drying.

Effective removal of organic solvent, though not carbon dioxide or vegetable oils, together with emulsification problems are likely to be deterrents to commercialization.

Caffeine Refining

Caffeine represents a valuable byproduct of decaffeination, though this substance can also be manufactured by synthetic chemical methods. Byproduct value may differ in economic terms from time to time. Pure caffeine has an outlet in soft drinks of the cola type, and also for medical purposes.

From the solvent decaffeination processes described, the caffeine will be in a state of 70–85% purity, so that a refining process is required to produce BP (British Pharmacopaedia) or USP (US Pharmacopedia) grade by eliminating coffee waxes and oils as well as water-soluble or other materials that impart a dark color. The series of interconnected and recycle steps involve use of activated carbon filtrations, and repeated recrystallizations from water. The final product consists of white, needle-shaped crystals, with a melting point of 236 °C but subliming at the much lower temperature of 178 °C. Recent studies have shown it to be, when crystallized from aqueous solution, a 4/5 hydrate with 6.95% water content. It has some unusual solubility characteristics in water, in that above 52 °C it is anhydrous caffeine which is stable in contact with aqueous solution and,

conversely, below 52 °C only the hydrate is stable. However, the interconversion is not very rapid, so that true solubility determinations must be obtained with the appropriate form of caffeine according to temperature. At 40 °C, caffeine will have a solubility of 4.6 g per 100 g of water, and at 70 °C, 13.50 g. Of special reference to decaffeination is its reasonable solubility in a number of organic solvents (though very low in carbon tetrachloride and aliphatic/petroleum ethers), and its capacity as a weak base for forming unstable salts, such as acetates and chlorogenates. In addition, it can form soluble complexes with polynuclear hydrocarbons, which may be found in roasted coffee and other roasted substances; this property can be used in their selective extraction.

Physiological Effects

R Viani, Corseaux, Switzerland

Consumption Levels in Different Countries

Approximately 1.7×10^9 cups of coffee are drunk each day in the world. The USA is the largest consumer country, and consumption, which had declined to less than two cups per capita per day, is now again increasing thanks to specialty coffee and in particular to espresso coffee. The Nordic countries and The Netherlands have the highest per capita consumption, with four to five cups per day.

Production and consumption figures are shown in **Table 1**. Patterns of consumption vary widely and evolve in time.

Table 1 Coffee production and consumption, average over period 1993–98

	10^6 tonnes per year	*Green coffee (kg) per person per year*

Brewing Techniques

The main coffee brewing techniques are:

- Boiled coffee – brew is prepared by boiling coarsely ground light roasted coffee in water (50–70 g l^{-1}); the infusion (1 cup = 150–190 ml) is drunk without separation of the grounds.
- Cafetière coffee – brew is prepared by pushing water through a bed of medium ground coffee with a plunger (6–7 g per cup).
- Espresso – brew is prepared by extracting very finely ground medium to dark roasted coffee (6–7 g per cup) with water at 92–95 °C and 8–12 bar (1 cup = 20–35 ml in Italy, up to 120 ml elsewhere).
- Filter coffee – brew is prepared by pouring boiling water over finely ground light to dark roasted coffee (30–80 g l^{-1}) in a paper filter or automatic drip machine (1 cup = 150–190 ml).
- Instant coffee – brew is prepared by dissolving 1.5–3.0 g of soluble coffee into 80–190 ml of hot water.
- Liquid coffee – ready-to-drink coffee mixture often containing sweeteners and creamers, consumed either hot or cold, mainly in Japan.

- Percolated coffee – brew is prepared by recirculating boiling water through coarsely ground light to medium roasted coffee (30–60 g l^{-1}; 1 cup = 150–190 ml).
- Mocca coffee – brew is prepared by forcing just overheated water through a bed of very finely ground medium to dark roasted coffee (6–7 g per 40–120 ml cup).
- Greek/Turkish coffee – brew is prepared by bringing to a gentle boil extremely finely ground dark roasted coffee (4–6 g) in water (50–60 ml) and sugar (5–10 g per 30–50 ml cup).

Espresso coffee consumption is also increasing in countries such as the USA, where more diluted types of coffee were common.

Boiled coffee consumption, previously quite common in the northern part of the Nordic countries, is now diminishing after the epidemiological link between its consumption and an increase in serum cholesterol has been confirmed with the identification of the responsible factor.

Nutritional Value of Coffee/Effects on Availability of Nutrients in Diet

The coffee brew is naturally poor in digestible proteins, fats, carbohydrates, and sodium, and is considered a nonnutritive dietary component, drunk for sensory pleasure and for its mild stimulatory effects. Its use as a vehicle for nutritious additives such as milk and sugar, and its contribution to the total water intake must, however, not be neglected.

Among the micronutrients found in coffee, niacin (nicotinic acid), formed from trigonelline during roasting, present at levels of 1–3 mg per cup, which corresponds to 5–20% of the recommended daily intake, has been shown to play a role in preventing pellagra in populations with a marginal diet. Animal studies have indicated that trigonelline itself can be transformed into nicotinic acid. (*See* **Niacin**: Physiology.)

Amounts of soluble dietary fiber (sum of the indigestible carbohydrates and of carbohydrate-like components formed at roasting) of the order of 10–25% of the total coffee solids present in the brew may explain, on one hand, the protective role of coffee against colorectal cancer, and, on the other, together with chlorogenic acids, the reduction in absorption of nonheme iron when coffee is consumed with or just after a meal. (*See* **Cancer**: Diet in Cancer Prevention; **Dietary Fiber**: Physiological Effects.)

The hypothesis that the phytate content of coffee (1–20 mg per cup) significantly lowers the gastrointestinal absorption of zinc needs verification. (*See* **Phytic Acid**: Nutritional Impact; **Zinc**: Physiology.)

Potassium, present at levels of 80–160 mg per cup, may contribute up to 10% of the daily intake for an adult. (*See* **Potassium**: Properties and Determination.)

The intake of magnesium and of manganese from coffee is significant. (*See* **Magnesium**.)

The importance of coffee in the calcium balance of the bone is still unclear. (*See* **Calcium**: Properties and Determination.)

Physiologically Active Components

Coffee is consumed for its characteristic flavor and the mild stimulation produced by caffeine, and all its proven behavioral effects appear to be related to its caffeine content. (*See* **Caffeine**.)

Flavor Constituents

Of the 230 components identified in green coffee aroma, most survive roasting and certainly contribute either positively – the aroma – or negatively – the defects, from poor processing – to the flavor of roasted coffee. Most of the volatile constituents formed during roasting of coffee are common to all roasted foods, and none of them alone can explain the aroma of freshly roasted or brewed coffee, so that the organoleptic appeal of the brew is still partially unexplained.

In order to evaluate the contribution of specific components to the aroma, the aromatic complex above a cup or from the cup is separated in a high-resolution gas chromatogram, and the composition of each peak is identified by mass spectrometry, while its smell is evaluated by sniffing at the exit port of the chromatograph, and described by notes such as cocoa-like, floral, or buttery for the aroma, and medicinal, earthy, or moldy for the defects. Some intensely aromatic substances, which alone have objectionable odors – like 3-mercapto-3-methylbutylformate, which pure has a catty-blackcurrant smell – contribute to the roasty character of a brew.

The aromatic threshold of each aroma component is then measured by sniffing at more and more dilute concentrations until only a few substances are perceptible to the nose. By this technique the most potent odorants in a brew can be selected among the about 1000 volatile substances present (Table 2).

The bitter taste of coffee is not just due to the presence of caffeine, itself a bitter substance, but accounting for no more than 10% of the total bitterness of the brew. The chlorogenic acids, like caffeine, are higher in robusta than in arabica coffees, and participate in the bitter taste. Bitterness increases with the degree of roasting, with the formation of bitter

Table 2 Concentrations of the most potent odorants in arabica and robusta

Odorant	*Arabica ($\mu g\,l^{-1}$)*	*Robusta ($\mu g\,l^{-1}$)*	*Odor threshold in water ($\mu g\,l^{-1}$)*
2-Furfurylthiol	19.1	39.0	0.01
E-β-Damascenone	1.3	1.5	0.00075
3-Mercapto-3-methylbutylformate	5.5	4.3	0.0035
3-Methylbutanal	550	925	0.35
Methylpropanal	800	1380	0.7
Methanethiol	210	600	0.2
5-Ethyl-4-hydroxy-2-methyl-3(^{2}H)-furanone	840	670	1.15
2-Methylbutanal	650	1300	1.3
2,4,6-trichloroanisole	If present, a defect		0.001
2-methylisoborneol	If present, a defect		0.0025
Geosmin	If present, a defect		0.005

volatile aromatic substances (pyrazines) and brown pigments, the melanoidins, from the pyrolysis of carbohydrates, polyphenols, and proteins. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Caffeine

Caffeine content per cup The amount of caffeine present in a cup depends on the type of coffee used and on its mode of preparation, and may vary between 1 and 5 mg for a cup of decaffeinated coffee, physiologically an insignificant amount, and 50 mg to more than 150 mg for a cup of regular coffee, corresponding to an intake of 1–3 mg per kilogram of body weight (Table 3).

These figures are well below those producing a urinary concentration of caffeine of $12\,mg\,l^{-1}$, defined by the Olympic Committee as the acceptable upper limit for competing athletes; such a limit could be reached only after a single oral intake of 900–1000 mg.

Physiological effects of caffeine Ingested caffeine is absorbed and distributed throughout all the tissues in the body within minutes, and is eliminated in a few hours, up to 4% as such in the urine, and the rest is metabolized, with a half-life of 2–6 h for a healthy adult. The half-life is increased during pregnancy and in those with an impaired liver function, like newborn babies and patients suffering from liver disease, and shortened in smokers.

The variation in the physiological response to the consumption of equivalent levels of caffeine could be explained by different rates of stomach emptying, as a function of the content of the stomach, or by genetic differences in the metabolic clearance of caffeine between slow and fast acetylators.

Consumption of caffeinated coffee increases the time needed to fall asleep and decreases sleep duration, particularly in older subjects. Caffeine shortens reaction time and prolongs the amount of time during which an individual can maintain auditory and visual vigilance, during boring tasks or when performing physically exhausting work. An improvement in visual acuity of as much as 40% in humans reported after doses of 180 mg of caffeine might be indirectly explained by an increased vigilance after ingestion. The effect of caffeine on short-term memory, if any, is slight. The decrease in hand steadiness (tremor) observed in some people after consumption of caffeine does not affect fine motor control. A link between caffeine consumption and anxiety or panic attacks has not been demonstrated, with the possible exception of psychiatric patients. The relationship between blood pressor and central stimulatory behavioral effects of caffeine at the concentration of a cup of coffee needs further investigation.

At the doses associated with coffee consumption, caffeine produces a thermogenic effect with an immediate increase of about 10% in the metabolic rate and elimination of carbon dioxide; a delayed lipolytic effect with an increase in the plasma level of free fatty acids has been observed in young lean subjects. Caffeine increases muscular oxygen consumption and glycogen–glucose transformation.

Caffeine in coffee has a rapid and short-lasting diuretic action with increase in urinary volume and sodium in subjects kept on a methylxanthine-free diet.

Table 3 Caffeine content of coffee products

Product	*Portion size*[a] *(ml)*	*Caffeine*[a] *(mg)*
Boiled coffee	200	130–170
Cafetière coffee	150–200	40–100
Filter coffee	100–200	40–180
Filter decaffeinated	100–200	3–5
Espresso coffee	20–60	20–60
Instant coffee	100–200	30–120
Instant decaffeinated	100–200	2–3
Mocca coffee	40–80	40–80
Percolated coffee	150–200	40–170
Ready-to-drink coffee	225–285	60–200

[a]Indicative.

Epidemiological evidence shows no casual relationship between caffeine consumption and miscarriages, low infant birth weight, or short gestation period, particularly if smoking is taken into account. The US Food and Drug Administration feels that 'there is insufficient evidence to conclude that caffeine adversely affects the reproduction functions in humans.'

Since caffeine is the most widely used psychoactive substance consumed by humans, the question of a possible caffeine dependence and whether it should be considered a drug of abuse is debated. The four major criteria for drug dependence are withdrawal, tolerance, reinforcement (viz., the ability of the drug in controlling a behavior depending on delivery of the drug), and dependence:

- Caffeine withdrawal symptoms, mainly headaches, usually starting within 24 h, with a peak after 20–48 h and lasting a few days, possibly unrelated to the quantity of caffeine ingested, are well documented.
- Doses of caffeine of at least 200 mg affect sleep by prolonging sleep latency and shortening its total duration. It is still under debate if the difference among individuals in the effect of caffeine on sleep must be attributed to interindividual differences or to tolerance.
- Doses of caffeine at the lower limit of those present in a cup of coffee (25–50 mg) have reinforcing effects, while higher doses (50–100+ mg) reduce the frequency of caffeine intake, and higher doses (400–600 mg) are avoided. The reinforcing activity of coffee may come from its flavor and be unrelated to caffeine.
- In contrast to caffeine, common drugs of abuse, such as amphetamines, cocaine, or nicotine, induce a dopamine release and an increase in glucose utilization in the shell of the nucleus accumbens, indicating a fundamental difference of action.

The consensus in the scientific community is that the relative risk of addiction to caffeine is low, even if it fulfills some of the criteria for drug dependence.

Contaminants

Contamination of green coffee beans by low levels of ochratoxin A (OTA) or, very seldom, aflatoxin B, has occasionally been observed. The presence of OTA has been linked with poor processing practices in the producer countries, particularly drying, and its presence is mainly concentrated in the outer husks. Its formation can also occur during transport or decaffeination, whenever there is a noncontrolled moisture pick-up. Decomposition of up to 85% the amount present in the green beans has been shown to occur during processing, most of it at roasting. OTA exposure from coffee consumption is estimated at around 7%, behind cereals (67%), and beer (10%), and followed by wine (6%).

Adulteration of soluble coffee with worthless husks considerably increases the risk of soluble coffee contamination by OTA. Although the discussion on OTA toxicity is not yet closed, experimental data obtained using combinations of mammalian biotransformation enzymes showed a lack of mutagenicity and that the formation of DNA-binding intermediates is unlikely. (*See* **Mycotoxins**: Occurrence and Determination.)

Formation of polycyclic aromatic hydrocarbons and, in particular, benzo[*a*]pyrene may occur, especially at nonoptimal roasting conditions. The analysis of brewed and soluble coffee indicates that these strongly lipophilic substances are, anyway, not released, but are retained in the spent grounds, both in home brewing and in industrial extraction. Thus, coffee does not constitute a significant source of dietary intake of polycyclic aromatic hydrocarbons. (*See* **Polycyclic Aromatic Hydrocarbons**.)

Health Implications of Coffee Consumption

Botanical species (arabica, robusta), roasting degree (light, dark), types of coffee (regular, decaffeinated), modes of consumption (boiled coffee, soluble coffee, etc.) or specific constituents (methylglyoxal, dicarbonyls) and contaminants (mycotoxins, benzo[*a*]pyrene) have occasionally been associated with different adverse symptoms: the only links clearly established, both in epidemiological and clinical studies, are the positive correlation between the presence on boiled coffee as drunk in the Nordic countries of sufficient amounts of cafestol (and kahweol) to explain the increase in serum cholesterol levels in high consumers, and the caffeine-withdrawal headaches. The polyphenol content of coffee (200–550 mg per cup), either free as chlorogenic acids or linked in the macromolecular melanoidins, may contribute to positive physiological effects, repeatedly shown by clinical and epidemiological studies (such as a protection against alcohol-derived liver disease), attributed to its antioxidant properties. Ongoing research would indicate that 3,4-diferuloyl-1,5-quinide (DIFEQ) (Figure 1), and similar compounds formed at roasting by chlorogenic acids inhibit the adenosine transporter at the concentrations of the brew. Further studies are, however, necessary to verify the suggestion that DIFEQ-like compounds in coffee are able to modulate the stimulant effect of caffeine, and may contribute to health-related effects of coffee.

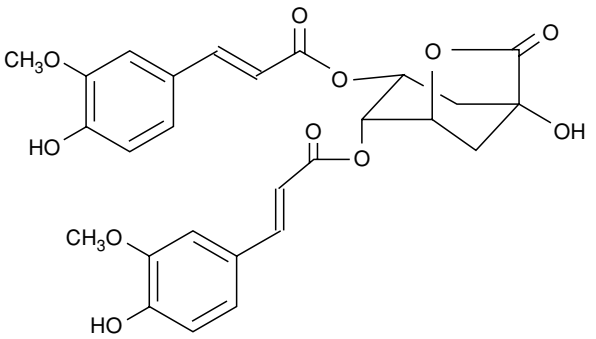

Figure 1 DIFEQ.

Cancer

There is no conclusive evidence from experimental and epidemiological studies that coffee and caffeine are carcinogenic. A doubt still remains on the possibility of a weak link between coffee consumption and cancer of the bladder and urinary tract. Conversely, more and more evidence is collected that coffee consumption may have a protective effect on colorectal cancer. In both cases confirmation is considered necessary.

***In vitro* mutagenicity tests** Hydrogen peroxide and methylglyoxal present in brewed, instant, and decaffeinated coffee are mutagenic in various *in vitro* tests on microorganisms in the absence of the *S*9 fraction containing mammalian microsomal enzymes. Mutagenic heterocyclic amines related to 2-amino-3,4-dimethylimidazo[4,5-f]quinoline (MeIQ) can only be extracted from roasted coffee beans in laboratory experiments under basic conditions. No MeIQ could be found, however, in either brewed or instant coffee.

Animal studies Several lifetime studies in rodents consistently failed to show any correlation between coffee consumption and cancer.

Green, roasted and instant coffee and coffee constituents, the diterpenes cafestol and kahweol and antioxidants, have been shown in animal models to have cancer chemopreventive activity.

Human studies There may be a weak positive relationship between coffee consumption and bladder/urinary tract cancer, but the results of the epidemiological studies are inconsistent, and a residual confounding effect of cigarette smoking or another bias cannot be ruled out. More and more studies, some of which had not been planned to verify the hypothesis, have indicated a protective effect on colorectal cancer. The studies on pancreatic cancer have given inconsistent results. All studies showed no correlation between coffee consumption and breast, gastric, and upper digestive tract cancers. The marginal increase in relative risk found in a few studies on ovarian cancer has been attributed on pharmacological arguments to bias from unknown sources or chance.

Cardiovascular Disease

The epidemiological evidence for a direct link between coffee/caffeine consumption and increased risk of cardiovascular disease is inconclusive. This may be explained by the different consumption modes between and within the populations studied or by atherogenic behaviors positively associated with coffee consumption, such as smoking and high dietary fat and cholesterol intakes. Moderate coffee consumption is not likely to be a significant risk factor for cardiovascular disease.

Serum cholesterol levels There is clinical evidence that high coffee consumption is associated with reversible increased levels of total low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) cholesterol, while high-density-lipoprotein (HDL) cholesterol levels remain unchanged. Cafestol (and kahweol) esters, substances specific to coffee present in the lipid fraction, have been identified as the responsible factor. Lipid concentration depends on the brewing method, and is relatively important in the Nordic-style boiled coffee brew, explaining why the first data clearly indicating a link between coffee consumption and cholesterol levels originated in northern Norway, where consumption of boiled coffee was high. Lipid content is negligible in both regular and decaffeinated filter and instant coffees.

Plasma homocysteine levels Elevated homocysteine levels have been suggested, but not yet confirmed, as a risk factor for cardiovascular disease. A link between consumption of high quantities of unfiltered coffee has been shown to increase plasma homocysteine levels by up to 10%. It has not yet been checked if cafestol esters could also in this case be the responsible factor.

Blood Pressure

Abstention from ingestion of caffeine for a period of several weeks may reduce both systolic and diastolic mean blood pressure by 1–4 mmHg. High single doses of caffeine produce after an abstinence of at least 12 h a 5–10% increase of both systolic and, particularly, diastolic blood pressure for 1–3 h. Tolerance develops rapidly with continued consumption and blood pressure stabilizes slightly upwards in a few days. (*See* **Hypertension**: Physiology.)

Cardiac arrhythmias The question of whether caffeine consumption increases the frequency or severity of ventricular arrhythmias is still partially unresolved as there may be particularly sensitive patients: the consensus is now that a 'moderate' coffee consumption, corresponding to 200–500 mg of caffeine per day, is unlikely to increase the frequency of arrhythmias both in healthy subjects and in patients suffering from tachycardia or fibrillation.

Other Health Questions Associated with Coffee Consumption

Coffee and the gastrointestinal function According to a complete review of all the available data '. . . there is no evidence for an association of coffee ingestion with peptic ulcer disease or functional dyspepsia.' The increase in heartburn due to a reduction of the lower esophagal sphincter pressure and consequent gastric acid reflux, associated with both regular and decaffeinated coffee consumption by sensitive individuals, has not yet been explained, and no clear link has been shown with the presence of specific substances in the coffee brew. An increase of the distal colon motility by about 30% of subjects within minutes after coffee consumption has been described in one study. In another study, consumption of two cups of coffee after an overnight fast produced no change in mouth-to-cecum transit time in healthy subjects. Coffee consumption produces contractions of the gallbladder, as is also the case with other foodstuffs. The size of the population suffering gastrointestinal discomfort after drinking coffee, the symptoms themselves, and the mechanism remain unclear, with the possible exception of dyspeptic complaints of patients suffering from duodenal ulcer.

COLLOIDS AND EMULSIONS

M M Robins and P J Wilde, Institute of Food Research, Norwich, UK

Introduction

In the strictest sense, colloids are dispersions of two or more immiscible materials, where the characteristic length of the inclusions (particles) is between 1 nm and 1 μm. However, in foods, the term 'colloids' generally includes dispersions containing larger particles, and foams, where the bubble size may approach millimeters. Food dispersions thus encompass suspensions such as sugar fondant (solid sugar particles in a saturated sugar solution), emulsions such as milk, cream, sauces, and spreads, and foams such as are found in bread, beer, and icecream. Icecream is an archetypal food dispersion, containing dispersed particles of solid (sugar and ice), liquid (fat), and gas (air). The key property that these foods have in common is the presence of particles, and the consequent high interfacial area between the particles and the continuous phase. The properties of food colloids are dominated by the particles and their interactions, which in turn are controlled by the properties of the interfacial region.

Although other food-relevant systems may contain microscopic particles, such as suspensions of yeast used in brewing, this article is confined to inanimate colloids whose composition and properties are formed naturally, as in milk, or deliberately engineered to manufacture a particular food, such as a dressing.

Figure 1 shows examples of the structure of the common forms of food colloid. Suspensions are usually formed by crystallization processes, which are outside the scope of this article (*See* **Crystallization**: Basic Principles). Similarly, foams have characteristic behavior and properties that are covered more fully in a companion article. Here we focus on emulsions, which are the most common type of food colloid.

Emulsions are liquid-based dispersions containing droplets of oil or water dispersed in water or oil respectively. In order to maintain the droplet structure, the oil–water interface is coated with a layer of emulsifier. In oil-in-water (O–W) emulsions the stability is highly dependent on the emulsifier. However, in water-in-oil (W–O) systems (such as butter) the continuous phase is partially solid, which enhances stability and gives the food a firm texture. Crystallization of the dispersed phase may also be used to generate texture, but in an indirect way, as partial crystallization of the oil droplets in cream and icecream enhances their whipping properties.

Below we outline the composition, formation, and characterization of food emulsions and refer briefly to their safety and nutritional aspects.

Formulation

Food emulsions can be simple O–W or W–O systems, or multiple emulsions where the dispersed phase is already an emulsion (W–O–W, O–W–O). They often contain a complex mixture of ingredients including proteins, polysaccharides, emulsifiers, water, and oil. Each of these ingredients contributes to the overall properties of the emulsion, as detailed in the following section.

Aqueous Phase

The role of the aqueous phase is chiefly as a solvent to the water-soluble components (salts, emulsifiers, proteins, polysaccharides, etc.), as either the continuous phase in O–W emulsions or as the dispersed phase in W–O emulsions. Water molecules possess strong orientation-dependent attractive hydrogen bonds, which result in a high interfacial tension. This makes breaking the dispersed phase into fine droplets difficult. Thus, the interfacial tension forces need to be reduced by the presence of emulsifiers. The pH, ionic strength, and emulsifier concentration influence the formation and physical characteristics of the emulsion, by altering the size of droplets and the interactions between them. The viscosity of the aqueous phase can be altered by the addition of hydrocolloids (gelling or thickening agents, usually polysaccharides such as starch or xanthan gum), which can also affect emulsion formation, rheology, and stability. This is utilized extensively in low-fat O–W emulsion-based food products such as dressings, yogurts, and desserts.

Oil Phase

The oil phase in food emulsions, whether from animal or plant sources, is mainly in the form of triglycerides. The oil also contains levels of di- and monoglycerides, polar lipids, and free fatty acids. The latter three lipids tend to be surface-active, more water-soluble, and sometimes used as food emulsifiers. The three most common fatty-acid chains are the saturated palmitic (C16) and stearic (C18) and the unsaturated oleic (C18:1) and linoleic (C18:2). Plant oils tend to

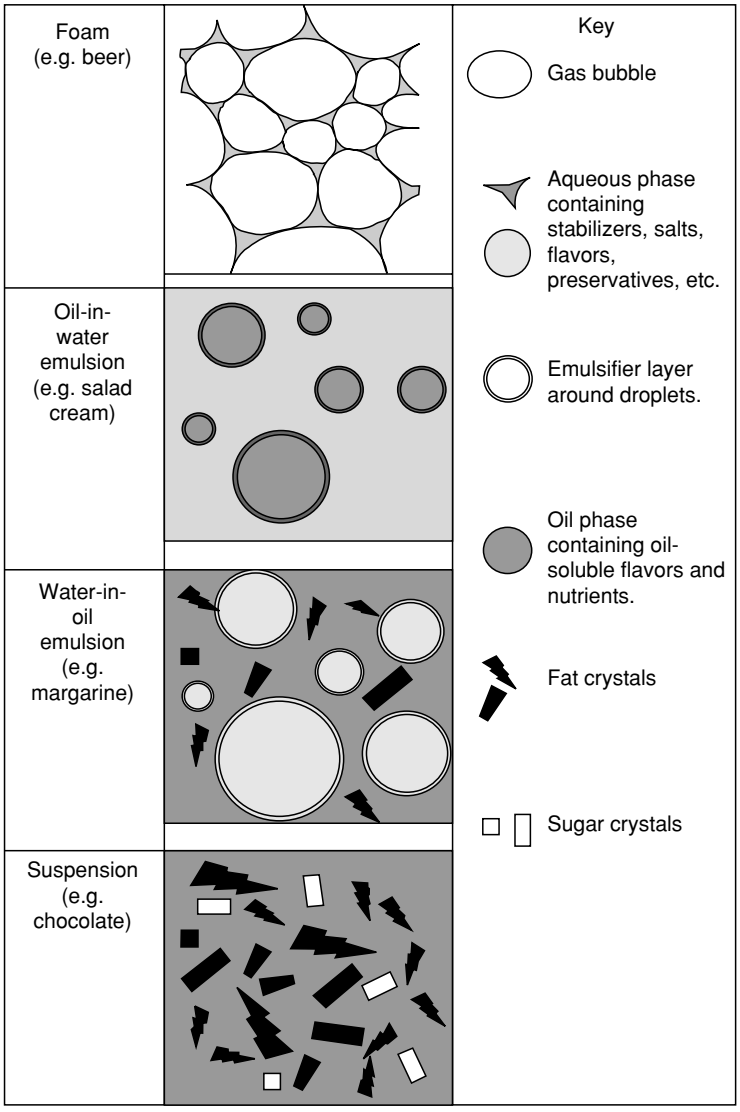

Figure 1 Types of food colloid and their structures.

contain more unsaturated fats than those of animal origin (with the exceptions of coconut and palm oils), and therefore tend to be liquid at room temperature. Fat is an essential nutrient, and the oil phase imparts a characteristic mouth feel to products such as cream, butter, and cheese. The oil phase is also used as a solvent for the more lipophilic emulsifiers, oil-soluble nutrients (e.g., oil-soluble vitamins and essential fatty acids) and some flavor and aroma compounds.

An important property of the oil phase is the solidification or crystallization of the fat. Solid fat in an emulsion has different rheological and textural properties to liquid oil, particularly in W–O emulsions. In addition, fat crystals can form structures that change the texture of fat-continuous products such as chocolate, butter, and cheese. Crystallization of the fat in the dispersed phase of ice cream and whipped cream allows the oil droplets to form solid networks that enhance structure and texture. The viscosity of the dispersed oil phase is also important for homogenization, as droplets made up of high-viscosity oil are less deformable and therefore more difficult to homogenize into smaller droplets.

Emulsifiers

The role of emulsifiers is to form an adsorbed layer around the emulsion droplets. This adsorbed layer lowers the interfacial tension, which aids emulsification, and stabilizes the droplets against flocculation and coalescence. Emulsifiers need to be surface-active, so that they will naturally assemble at an interface. They therefore need to be amphiphilic (i.e., possess both hydrophilic and hydrophobic parts). Emulsifiers can be either low-molecular-weight

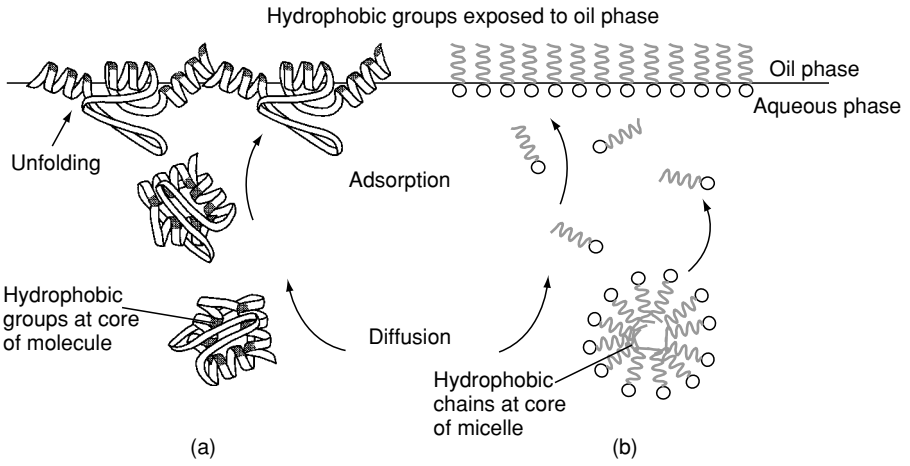

Figure 2 Emulsifier structure and adsorption of (a) proteins/polymers and (b) low-molecular-weight emulsifiers/surfactants. Hydrophobic groups are shaded in gray. Proteins form a folded structure in solution, keeping the hydrophobic amino acids away from aqueous solution. Upon adsorption, they unfold to expose these groups to the oil phase. Similarly, surfactants and emulsifiers form micelles, holding the hydrophobic chains in the core of the structure, which then dissociate and adsorb to the interface.

emulsifiers or macromolecular polymers, as shown in Figure 2. The low-molecular-weight emulsifiers have a small hydrophilic head group and one or more hydrocarbon chains; they include mono- and diglycerides, lecithins, polysorbates, and sugar esters. The most common polymeric emulsifiers in food systems are proteins, mainly from milk, but other sources include soya, meat, and fish, depending on the application. Other polymeric emulsifiers include modified cellulose and block copolymers, although block copolymers are not approved for food use.

Stabilizers

Although emulsifiers help stabilize emulsions, the term 'stabilizer' in the context of emulsions is specifically aimed at polymers which are added to the aqueous continuous phase to improve the stability of O–W emulsions. These polymers are often in the form of gums such as xanthan, guar, carageenan, etc. Addition of the polymers in sufficient concentrations to form a network results in the effective encapsulation of the emulsion droplets by the polymer. This immobilization prevents flocculation of the droplets and reduces creaming. Lower concentrations of polymer can induce flocculation by the depletion mechanism. Depending on the conditions, this flocculation can create a solid network of emulsion particles with enhanced viscoelastic properties (e.g., ice cream and whipped cream). Under different conditions, flocculation by polymers can induce rapid creaming or sedimentation.

Other Ingredients

From a purely physical standpoint, we tend to ignore components in an emulsion that do not contribute to its physical characteristics. However, in food emulsions the physical properties are not the only issue: flavor, sensory, and safety characteristics are also important. To this end, food emulsions contain salts, sugars, flavors, colors, and preservatives. However, these components highlight issues in colloids and emulsions that would not normally be of concern in other food products. Salt is perhaps the most important component as this can affect the solubility of functional ingredients such as proteins and polysaccharides. Specific interactions between, for example, calcium and caseins cause precipitation of the proteins. Salt also affects the electrostatic colloidal stability by screening the electrostatic repulsion forces between particles. Sugars are usually inert as far the physical properties of emulsions are concerned, but they can lower the dielectric constant of the continuous phase, which affects colloidal interactions, and certain sugars, such as trehalose, are known to protect proteins against denaturation during heating and drying. Flavors, colors, and preservatives are usually present at relatively low levels, and generally do not influence the physical characteristics. However, some components are volatile and partitioning can often occur, from one phase to the other. It is important to understand these processes, for example for efficient use of preservatives, so that they remain in the phase that allows them to achieve the desired function.

Formation

Formation is clearly a critical stage in the life of an emulsion. Many of the physical parameters of the emulsion are established here. If the emulsion is to remain stable for significant periods, then the emulsion droplets need to be small enough to slow down

the creaming and separation processes (typically < 1 μm diameter), which will be discussed later. The main factors which determine the 'quality' of the newly formed emulsion which will be discussed here are: (1) the adsorption of emulsifiers to the droplet surface; (2) the homogenization process; and (3) stability during formation.

Adsorption

Emulsion formation requires the dispersion of one phase into small droplets. This results in a massive increase in interfacial area between the dispersed and continuous phase. Classically, interfacial tension is defined as the work required to increase the surface area by a unit amount. The interfacial tension between the two phases is therefore extremely important. Interfacial tension forces act on droplets to minimize surface area, hence, liquid droplets form spheres in the absence of other forces. Lowering the interfacial tension means that less energy is required to increase the interfacial area by a unit value. This is achieved through the use of emulsifiers, which adsorb at the interface between the two phases and lower the interfacial tension by disrupting the hydrogen bonds between the water molecules at the interface. Emulsifiers can be simple lipid-like molecules or complex macromolecules such as proteins; however, they are all amphiphilic so that they naturally align themselves at the interface, as shown in Figure 2. The interfacial tension is determined by the structure of the emulsifier and the interfacial concentration, therefore the most effective emulsifiers are those whose structure allows the formation of a dense, close-packed interfacial layer. The dynamics are also very important because the homogenization process is rapid, so it is the dynamic interfacial tension over time scales < 1 s that is most important, not the equilibrium value. Rapid adsorption of the emulsifier to lower the interfacial tension will thus result in more effective emulsification of the dispersed phase during the homogenization process.

Homogenization

Homogenization is the process by which the dispersed phase is broken up into small droplets (*See* **Agitation**). Normally, rapid mixing of the ingredients is used to create a coarse premix. This is sufficient to break up the dispersed phase into large droplets, and allow adsorption of the emulsifiers prior to final homogenization. Figure 3 shows the three main methods of homogenization. Mechanical methods such as rotor–stator systems induce high shear fields to break up droplets. High-pressure homogenizers are now very common, and simply force the premix through a narrow orifice or valve at high pressures (typically 10–100 MPa or 1500–15 000 lb in^{-2}). Forcing the emulsion through a valve at high pressure creates turbulence and very high shear forces, thus breaking up the droplets. However, shear forces are not the most efficient way of breaking up droplets, as the shear field tends to lose energy rotating the droplet. Forcing the droplets through a simple orifice induces elongational flow forces that break up droplets more efficiently. The droplet size produced is, within certain boundaries, generally inversely proportional to the energy input during homogenization. More accurately, it is related to the energy dissipated into droplet break-up. This is affected by the interfacial tension, and viscosities of the dispersed and continuous phases. As continuous-phase viscosity increases,

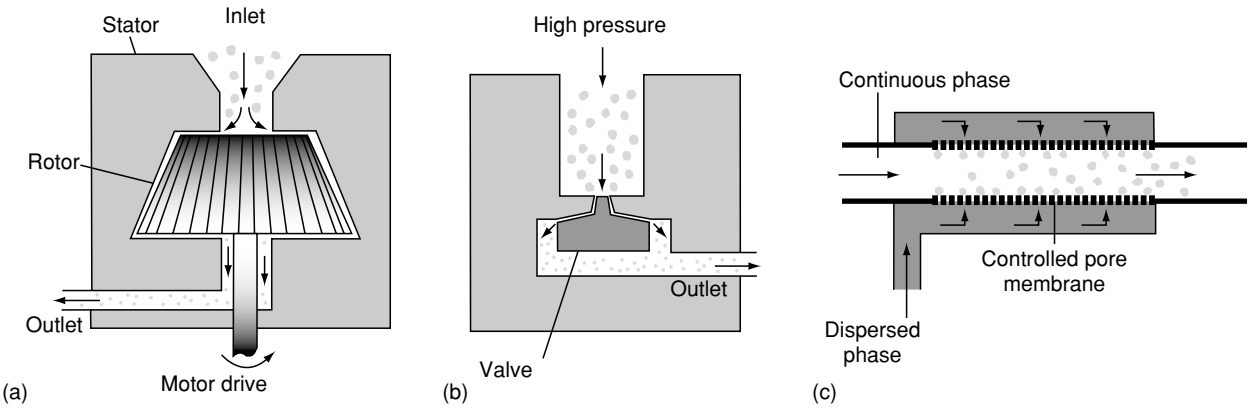

Figure 3 Basic principles of homogenization methods. (a) Rotor–stator device or colloid mill. The rotor, incorporating grooves or blades, spins at high speed, generating high shear fields to break up droplets. (b) High-pressure homogenizers force the droplets through narrow valves or orifices to break up droplets through high shear or elongational forces. (c) Porous membranes are used to extrude the dispersed phase into the flowing continuous phase.

droplet size will decrease, yet as dispersed-phase viscosity increases, the droplets become more difficult to break and droplet size consequently increases. The most energy-efficient process is the microporous approach, where the dispersed phase, or premix, is forced through a porous substrate into the continuous phase. The droplet size produced is dependent on the interfacial tension and the pore sizes. These microporous methods are still being developed and have not yet been widely utilized in the food industry, due to the low throughput.

Stability during Formation

Coalescence or fusing of droplets is a major instability process in emulsions, which will be discussed later. During formation, droplets are exposed to aggressive, turbulent conditions designed to break up droplets. These conditions also serve to increase the number and intensity of collisions between droplets. This increases the probability of recoalescence, particularly during the critical period when the adsorption process is not complete. Therefore, emulsifiers that adsorb slowly are particularly prone to this problem, and if the homogenization method is not optimized, then energy is wasted through recoalescence after breakup. This problem can be reduced through the control of the hydrodynamic conditions immediately after homogenization. This can be achieved by gently dispersing the droplets into a larger volume by either hydrodynamic methods or inert filler particles. This increases the interdroplet distance and reduces the probability of coalescence. However, in a commercial process it may not be convenient to form dilute emulsions and other strategies may be needed to produce acceptable emulsions.

In summary, by controlling the emulsifier type, concentration, and homogenization conditions, it is possible to control the droplet size distribution. It is the size and physical properties of the droplets which are the principal factors controlling the behavior of the whole emulsion, such as the rheology, stability, texture, and other quality characteristics of food emulsions, as described in the next section.

Characterization and Properties of Colloids and Emulsions

Particle/Droplet Size

The size of the dispersed particles or droplets is a key factor in the properties and stability of the dispersion. For example, for a product to appear turbid, the constituent particles must be able to scatter visible light, which means that their diameter needs to be at least 0.4 μm. However, very large particles tend to be less stable to the processes of flocculation (*See* **Flocculation**) and creaming, or impart a gritty mouth feel to the product. The particles in colloidal foods are generally very polydisperse, with a factor of 10 or more between the sizes of the largest and smallest particles present. It is thus very important to generate the optimum particle size distribution for each product, and to insure that it does not change during storage.

Typically, O–W food emulsions contain oil droplets of diameter in the range 0.5–2 μm, and W–O products such as spreads contain water droplets up to 20 μm. Solid dispersed particles, such as sugar crystals in chocolate, have diameters in the range 0.1–50 μm, although grittiness is detectable when the particles exceed about 20 μm.

Measurement of the particle size in colloidal foods or emulsions depends on the type of product and the size range of interest. Most foods can be examined microscopically, using optical methods for larger particles (> 3 μm) and electron microscopy in the submicron range. Microscopy is ideal for qualitative assessments of particle size and shape (*See* **Microscopy**: Light Microscopy and Histochemical Methods; Scanning Electron Microscopy; Transmission Electron Microscopy; Image Analysis), but quantitative measurement of a size distribution is less straightforward. Other direct methods such as sieving are convenient only for solid particles at the larger end of colloidal sizes. Indirect particle-sizing methods include optical and electrical techniques. The most common technique for droplet size determination is laser diffraction, based on the principle that the angle by which light is scattered from a particle is (inversely) related to its size. Measuring the intensity of light at a range of scattering angles enables the size distribution of the scattering particles (droplets) to be estimated. Another popular method for characterizing particle size distribution is the electric sensing-zone technique. In this method the particles are passed singly through a small gap between electrodes, and the volume of the particle is estimated from the change in capacitance during transit.

The light-scattering and electrical capacitance techniques both require very low particle concentrations (typically < 0.01% v/v), and recently there have been developments in methods that can characterize droplet size in concentrated emulsions. The principal techniques are acoustic, since ultrasound propagates readily through concentrated dispersions and detailed analysis of the frequency-dependent attenuation spectrum of ultrasound enables estimation of the particle sizes present. A similar technique is electroacoustics, where (charged) particles in a concentrated dispersion are made to oscillate in an electric field, which

generates sound waves whose characteristics are related to the particle charge and size.

Stability

Emulsions are inherently unstable and, given sufficient time, will eventually separate into bulk layers of oil and water. However, temporary stability can be achieved, and foods are engineered to remain comparatively stable for the required shelf-life. The mechanisms by which emulsions change in structure with time are shown in Figure 4. The figure also shows schematic drawings of the structural changes in the emulsions due to each type of instability. It is clear that creaming and flocculation involve the physical rearrangement of droplets into a layer or clumps (aggregates) respectively, whereas coalescence and disproportionation exhibit changes in the primary droplet size. Since emulsions are not thermodynamically stable systems, there are slow changes taking place from the start, and eventually the droplets grow to such an extent that the emulsion breaks into bulk layers of the component phases.

The interaction forces between droplets are crucial for the stability of the emulsion. If the droplets are highly charged, and there is a low ion concentration in the continuous phase, the droplets experience repulsive forces when they approach each other, and these forces keep them separated as individual

Instability type	Schematic mechanism	Factors promoting instability
Creaming Droplets move under gravity to the top (oil-in-water) or base (water-in-oil) of the container		Large density difference between droplets and continuous phase; large droplets; low continuous-phase viscosity
Flocculation Droplets clump together into aggregates, but retain original droplet size		Attractive interactions between droplets; low charge and/or high ionic strength; presence of adsorbing polymer to bridge between droplets; presence of nonadsorbing polymers to induce depletion flocculation
Coalescence Droplets clump together and then merge to form larger droplets		Flocculation or creaming to bring droplets together; an interfacial layer that ruptures easily
Disproportion-ation Swelling of larger droplets by molecular transfer of oil from smaller droplets, which eventually disappear		Polydispersity in droplet size; significant solubility of disperse phase (oil) in continuous phase; excess emulsifier; high interfacial tension

Figure 4 Emulsion instability processes.

particles. If an emulsion is stable to flocculation on a certain time scale, coalescence is also prevented because the droplets are repelled before the interfaces get near enough to merge. Certain additives used in food, e.g., polysaccharide 'stabilizers', may cause flocculation of the droplets in order to impart a particular texture, and then the interfacial composition is important in preventing coalescence of the adjoining droplets. The interfacial properties that are important in preventing coalescence of droplets in close contact are steric hindrance, interfacial viscoelasticity (of polymers and proteins), and interfacial mobility (of emulsifiers and surfactants).

Rheology

The rheological properties of emulsions are important functional properties, both during processing and in the final product where the texture is an important component of mouth feel. The response of the emulsion to mechanical stress may mimic simple liquids, as in dilute emulsions such as milk. At the other extreme, they may be designed to impart a solid-like texture, as in mayonnaise.

The rheological properties are controlled primarily by the concentration and size of the droplets, and by the composition of the continuous phase. (*See* **Rheology of Liquids**). Emulsions of low droplet concentration, where the droplets are unflocculated and the continuous phase is a simple liquid, will be of low, constant viscosity at a given temperature (Newtonian behavior). As the droplet concentration increases, and/or flocculation occurs, the emulsion becomes progressively more non-Newtonian. Its response to flow is now dependent on the magnitude of the applied stress, and the time scales of application. These characteristics are deliberately designed into many products, so the food rests on a plate without spreading, but is capable of flowing when dispensed. The apparent lack of response to a low stress (such as gravity) is sometimes attributed to the presence of a 'yield' stress, implying that up to a certain stress level the emulsion is solid-like and flows only when the applied stress exceeds a critical value.

Flavor

Controlling the flavor of foods is described elsewhere, but in emulsions the droplet composition and structure are additional variables. In many traditional foods, flavor components are present in both the oil and aqueous phases, and the full flavor is only released by droplet breakdown in the mouth. The droplet size and interfacial composition (emulsifiers) are also important factors.

Safety

Microbiological food safety relies on either sterilization or the existence of chemical conditions hostile to microbial growth. In an emulsion the foodborne bacteria can only grow in the aqueous phase, but the oil phase can affect the chemical environment for growth. This is because many antimicrobial agents, e.g., organic acids, are able to partition into the oil phase, thus reducing their preservative action in the aqueous phase. Food manufacturers are increasingly taking emulsion structure into account when formulating preservative systems.

Nutrition

The dietary impact of emulsions is the high fat content. Reducing fat intake is the principal target in the fight to reduce chronic heart disease in the developed world. Therefore one approach is to reduce the fat content in food emulsions, but retain the texture and flavor of the original product. A simple way is to increase the viscosity of the product with thickeners; however, the rheological behavior and hence perceived texture is very different. A better way is to produce dispersed droplets that behave like emulsion droplets, but with a lower fat content, by using gels, coacervates, or multiple emulsions (oil droplets containing water droplets). In margarines and spreads, large volumes of water can be dispersed into the fat continuous phase through the use of appropriate emulsifiers and processing. Another approach is to use fat replacers, which are not broken down and digested in the gut; however, use is limited due to other physiological side-effects.

Another important nutritional factor is the absorption of oil-soluble nutrients. Oil-soluble vitamins and antioxidants are crucial for health. They are thought to protect against heart disease and cancer. Their successful absorption is dependent on the processing of the raw materials, emulsion structure, and interfacial composition. Colloid science is now an important part of trying to understand the mechanisms involved.

COLON

Contents

Structure and Function

R J Levin, The University of Sheffield, Sheffield, UK
G I Sandle, University of Leeds, Leeds, UK

Structure

The adult human colon is about 100 cm long *in situ* and is divided anatomically into the ascending, transverse, descending, and sigmoid colon (**Figure 1**). Longitudinal muscle bands (taeniae coli) in its wall cause haustrae – characteristic puckerings and sacculations. Between these, the wall is thrown into crescent-shaped semilunar folds. The lumen is lined by a mucosa of simple columnar epithelium (colonocytes) containing numerous goblet cells. These cells secrete a mucus assumed to act primarily as a lubricant and protectant, allowing the solid and semisolid material to pass easily along the organ without damaging the epithelium. As the mucus contains secretory immunoglobulins (IgA) it also helps to protect the mucosa from luminal pathogens.

Unlike the small bowel, the colon is devoid of villi but has numerous straight tubular glands or crypts (sometimes called pits) (**Figure 2**) with openings on to the near-flat epithelial surface. These crypts are lined with cells similar to the surface colonocytes. At the crypt base, undifferentiated cells form a stem cell population for all the other epithelial cells of the large bowel. These divide by mitosis to replace those shed from the surface. The crypts also contain a few enteroendocrine cells. The lamina propria, containing plasma cells, macrophages, lymphoid aggregates, and mast cells, underlies the mucosa and extends down to the muscularis mucosae, a thin layer of inner circular

and outer longitudinal smooth muscle fibers. Beneath this is the submucous coat containing areolar tissue and the blood and lymph vessels serving the epithelium. The smooth muscle investing the organ consists of an inner circular and the outer longitudinal layer, the bulk of which is arranged in three longitudinal bundles (taeniae).

Nervous Innervation

The autonomic supply to the colon has three divisions: the extrinsic (1) sympathetic and (2) parasympathetic nerves link up with (3) the enteric supply in the bowel wall. The latter functions as an integrating system and consists of two ganglionated plexi. One is called the myenteric plexus, positioned between the circular and longitudinal smooth-muscle layers, and the other the submucosal plexus, lying in the submucosa under the muscularis mucosae. More recently, a third plexus, called the mucosal plexus, has been identified. The mucosal and submucosal plexi are involved in controlling epithelial function but the myenteric plexus interconnects to coordinate motility with absorptive functions by local and extrinsic reflex pathways. Colonic movements include segmentation contractions and peristaltic waves similar to those in the small intestine.

Luminal conditions are probably sensed by afferent nerve endings in the mucosa and the afferent information processed at the enteric plexus, cord, or brain level. The efferent output is then fed back via the extrinsic nerves to the muscle and epithelium.

Function

The colon has three major functions: (1) absorption; (2) secretion; and (3) bacterial fermentation.

Absorption

Salt and water While the jejunum and ileum are the major sites for the absorption of the salt and water ingested into and secreted by the upper alimentary tract, it is the task of the colon to absorb the remaining fluid. Many authors describe this as the 'salvage' function of the colon. Its efficiency can be judged by the estimate that daily, approximately 1000–2000 ml of the fluid enters the colon at the ileocecal valve, while less than 100 ml is lost in the feces. The colon is adapted to extract water and salts from the colonic contents to create initially semisolid and finally solid contents that become the feces. First, it has a much slower rate of luminal transit than is observed in the small intestine, allowing its contents a greater contact time with the mucosa. Second, the colonocytes can generate very large osmotic forces to extract the fluid from the lumen. Third, the tight junctions between the colonocytes are much less permeable to ions and water than those of the small intestine. Fluid absorptive capacity is determined primarily by sodium ion (Na^+) and chloride ion (Cl^-) absorption. The colonocytes actively transfer Na^+ into the convoluted lateral spaces between the cells and water follows osmotically, mainly through the tight junctions. (*See* **Sodium**: Physiology.)

Segmental differences The mammalian colon is not a single organ with a uniform distribution of electrolyte transport along its length. It is well known that different species exhibit segmental differences in their ion transport and also that the different segments of the colon, in the same animal, display differences in ion transport. The most studied animal colons have been those of the rabbit and rat. Although there are obvious similarities in the colonocyte functions in these two species with human colonocytes, neither matches exactly that of the human colon. *In vivo* studies in the human colon indicate that Na^+ and water are primarily absorbed in the ascending and transverse colon, with relatively little or no net absorption in the rectum. The human descending colon (like that of the rabbit) possesses colonocytes with apical membrane channels sensitive to amiloride which abolishes the electrogenic Na^+ absorption (and short-circuit current or net electrogenic ion transfer *in vitro*). In the ascending colon, however, the Na^+ absorption is mainly via an amiloride-insensitive or neutral transfer mechanism(s).

Sodium ion absorption mechanisms Active Na^+ absorption is accomplished by two mechanisms: (1) electrogenic Na^+ transfer, and (2) neutral NaCl transfer.

Electrogenic Na^+ transfer The Na^+ ion moves into the colonocyte across its apical membrane through channels (that can be blocked by amiloride) under the influence of a favorable electrochemical gradient as the inside of the colonocyte is negative to the lumen and has a low Na^+ concentration. It is then pumped out of the cell across the basolateral membrane by the agency of Na^+, K^+-ATPase (the sodium pump or Na^+, K^+-activated adenosine triphosphatase), creating an electric current (rheogenic transfer) and a positive potential difference at the serosa. The ATPase, and thus current and Na^+ transfer, can be inhibited by the cardiac glycoside, ouabain. Mineralocorticoids, especially aldosterone, enhance the entry of Na^+ across the apical membrane by the electrogenic route and thus also increase the absorption of water.

Neutral NaCl transfer This may represent coupled $Na^+ - K^+ - 2Cl^-$ cotransport, coupled $Na^+ - Cl^-$ cotransport, or the coupling of dual ion exchanges such as Na^+ for H^+ and Cl^- for HCO_3^- or OH^-.

Chloride ion absorption mechanisms Chloride ions can be absorbed passively or actively.

Passive absorption This is via an electrical potential difference (pd)-dependent process as the serosal side of the intestine is positive with respect to the lumen.

Active absorption This occurs either as neutral NaCl absorption (Na^+-dependent process) or as neutral $Cl^- - HCO_3^-$ exchange (Na^+-independent process). It has been estimated that in the human colon *in vivo* the $Cl^- - HCO_3^-$ exchange accounts for about 25% of overall Cl^- absorption, the other 75% being via the favorable electrical pd mechanism via the paracellular route.

Potassium ion absorption mechanisms Active K^+ absorption occurs in the distal colon of rat and rabbit and has been shown to be an electroneutral process which operates independently of Na^+ and Cl^-. In rabbit, this K^+ absorptive process seems to reflect a K^+–H^+ exchange which can be unmasked by the presence of ouabain or the removal of Na^+. Recent studies in rat distal colon have identified K^+-ATPase as the mediator of this apical K^+–H^+ exchange, although it is unclear whether a similar mechanism operates in human colonocytes. There is emerging evidence that K^+ movement across the basolateral membrane reflects K^+ recycling via K^+ channels, which are beginning to be characterized in biophysical and molecular terms. (*See* **Potassium**: Physiology.)

Calcium and magnesium absorption While considerable amounts of these ions are present in the lumen of the colon, most are unavailable for absorption as they are bound to insoluble macromolecules. Moreover, the total removal of the human colon (colectomy) does not upset the balance for these ions. There is evidence from rat experiments that the colon has a Ca^{2+} active transport system sensitive to enhancement by vitamin D and to low calcium intake. In the case of magnesium, other experiments with rats have indicated that the ion is absorbed passively, dependent on the electrochemical gradient and the solvent drag of fluid absorption. (*See* **Cholecalciferol**: Physiology; **Magnesium**.)

Secretion

The colon secretes the anions Cl^- and HCO_3^- and the cations K^+ and H^+.

Bicarbonate secretion In the human, approximately 70 mmol HCO_3^- leaves the ileum to enter the colon every day and although the organ secretes bicarbonate, only a few mmol appear in the feces. This is because the secreted HCO_3^- is titrated by the H^+ ions manufactured by the bacterial population of the colon. In diarrheal states, when there is an enhanced secretion of bicarbonate, stools can contain an increased amount of bicarbonate.

The mechanisms and control of bicarbonate movements are complex. Other ions move in association with, or in exchange for, bicarbonate. Bicarbonate can come from the plasma, passing between and through cells, and can also come from the intracellular hydration of CO_2, Hydrogen ions, produced from cellular metabolism, can be secreted into the lumen to influence the production and neutralization of bicarbonate ions. Net bicarbonate secretion is accomplished by a combination of bicarbonate and hydrogen ion transport as the blood, cell cytoplasm, and luminal contents contain bicarbonate and CO_2. A primary source of HCO_3^- and H^+ ions appears to be from the catalyzed hydrolysis of CO_2, as Na^+ and Cl^- absorption is modulated by ambient CO_2. The colonocytes are rich in carbonic anhydrase which can supply bicarbonate and H^+ ions at high catalyzed rates. The enzyme may also be directly involved in ion transfer. Inhibition of carbonic anhydrase reduces colonic absorption.

Chloride ion secretion The colon actively secretes Cl^- ions. The intracellular Na^+ and K^+ of the colonocyte are regulated by the basolateral Na^+–K^+ transport ATPase pumping out Na^+ in exchange for K^+. The K^+ can diffuse out across the membrane by a K^+ channel. This mechanism keeps the intracellular

Na^+ low and the K^+ high, and produces a negative intracellular pd. The uptake of Cl^- ions is by the coupled Na^+–$K^+ - 2Cl^-$ cotransport carrier in the basolateral membrane, and is sensitive to loop diuretics such as furosemide (frusemide) and bumetanide. Chloride ions leave the cell via apical Cl^- channels, under the influence of their intracellular–extracellular concentration gradient and the negative intracellular pd. These Cl^- channels are normally closed and are activated to open by increases in the intracellular calcium ion (Ca^{2+}) and/or cyclic adenosine monophosphate (cAMP) levels brought about by a variety of neurotransmitters, secretagogues, hormones, and paracrine agents. Because the efflux of the Cl^- ions depolarizes the apical membrane, the movement of Cl^- would gradually cease. To maintain the driving force for the Cl^- exit, an increase in the K^+-conductance of the basolateral membrane occurs shortly (20 s) after the increase in apical membrane Cl^- conductance. The exit of K^+ ions across the basolateral membrane induces a hyperpolarization and, because of electrical coupling between the basolateral and apical membranes, the hyperpolarization maintains the pd across the apical membrane. Thus the stimulation of Cl^- secretion in colonocytes (as in many other Cl^--secreting cells) requires the coordination of four independent systems, the apical Cl^- channels, the basolateral Na^+–$K^+ - 2Cl^-$ cotransporter, K^+ channels, and Na^+, K^+-ATPase. Observations in animals have indicated that secreting cells are located predominantly in the crypts, although surface colonocytes are also capable of secreting Cl^- ions.

Potassium ion secretion Although it is known that the colon absorbs and secretes K^+, the cellular sites have not yet been defined. Surface cells of rabbit colon absorb and secrete K^+, but it is not known whether such processes are also found in the cells of the crypts. In rats and rabbits fed high-potassium diets or given aldosterone, K^+ secretion is accomplished first by the active uptake of K^+ at the colonocyte's basolateral membrane by ouabain-sensitive Na^+-K^+–ATPase and Na^+-K^+–$2Cl^-$ cotransport. Its exit across the apical membrane is then by barium-sensitive K^+ channels that appear to be under the control of cAMP and Ca^{2+}, since raising their cAMP and or Ca^{2+} levels in the colonocytes increases the secretion of K^+. Adrenergic agonists also increase the secretion of K^+, which in rabbit colon is mediated by β_1-receptors. The mechanism involves both increases in the basolateral pump activity and in the conductance of the apical membrane to K^+. In diarrhea associated with colonic secretion (e.g., colitis) K^+ loss in the stools can be appreciable.

Short-chain fatty acids (SCFAs) Surprisingly, the major anion of the colonic contents comes from SCFAs (acetate, butyrate, propionate, etc.). These originate predominantly from the bacterial metabolism of carbohydrate passing into the colon from the ileum. In the human colon, the daily production of SCFAs is estimated to be greater than 300 mmol, while the fecal excretion is only 10 mmol. This indicates that 97% of the SCFAs are removed by the colon. Their absorption is rapid and they enhance the absorption of Na^+. (*See* **Essential Fatty Acids**.)

The SCFAs are weak acids that can exist in solution as two species, the undissociated molecule (acid form HA) and the dissociated anion (A^-). The balance of the species depends on the environmental pH and the p*K* values of the acid under question. In the colon, the luminal pH is normally approximately 7 and the SCFA p*K* approximately 4.8, so that the predominant species is the ionized or anionic form. The pathways of absorption of SCFAs across the colon are complex because several mechanisms can operate. These include the following: (1) the generation of luminal CO_2, either from bacteria or from colonocytes, to provide H^+ ions which combine with the anionic form of SCFA (A^-) in an acid microclimate, creating the undissocated acid form (HA) which could diffuse across the apical membrane; (2) luminal H^+ ions from the colonocytes exchange with Na^+, forming the HA; (3) the ionic form, A^-, could diffuse across the tight junctions between the cells; (4) anion exchange mechanisms (e.g., HCO_3^-–A^-) allow the movement of the anionic form across the apical membrane.

In the human colon it has been proposed that approximately 40% of SCFA absorption can be accounted for by the Na^+–H^+ exchange. As SCFA absorption is also associated with a rise in luminal HCO_3^-, the SCFA–HCO_3^- exchange mechanism is suggested to occur. In theory, changes in luminal pH should affect SCFA movements and alterations in acid–base balance should affect their absorption. However, the mucus and unstirred layers at the apical pole of the colonocytes act as a buffer and maintain the surface acid microclimate in the face of considerable changes in the luminal pH.

SCFAs increase the absorption of NaCl partly through the fatty acids acting as metabolic substrates for the colonocytes and partly as a result of the SCFAs directly influencing the transport mechanisms of the apical membranes. Paradoxical results have also been found in animal colons used *in vitro*, such as SCFAs inhibiting Cl^- absorption and in other cases actual secretion of SCFAs by colonocytes. Other studies have shown that SCFAs also cause electrogenic secretion of Cl^- by colonocytes which can be recorded both *in vivo* and *in vitro*. As the SCFAs have been

claimed to be a fundamentally important metabolic fuel for the colonocytes, their reduction or near absence in human conditions such as famine (starvation) and malnourishment (marasmus and kwashiorkor) has been suggested as a major cause of colonic dysfunction and – its consequence – diarrhea. Other studies have shown that colonic and rectal secretory function in starved or malnourished rats can be enhanced, which would again predispose to diarrhea. There are many unanswered questions and unsolved problems in relation to SCFA and colonic ion and fluid transfer. (*See* **Kwashiorkor**; **Marasmus**.)

Bacterial Fermentation

Composition of colonic microflora The bacteria of the human gastrointestinal tract form a complex ecosystem; over 400 species have been identified in the feces of a single subject. In healthy humans, the upper gastrointestinal tract is sparsely populated by bacteria as most are killed by gastric acidity (except acid-loving forms such as *Streptococcus, Staphylococcus*, and *Lactobacillus*) and the passage of intestinal contents is rapid. The bacterial flora of the small intestine is between 10^3 and 10^4 colony-forming units (CFU) per ml of content (mainly Gram-positive anaerobes); this increases to 10^6–10^7 CFU ml^{-1} in the distal ileum and Gram-negative bacteria now become dominant. After the ileocecal sphincter, the bacterial concentrations increase enormously, reaching between 10^{11} and 10^{12} CFU ml^{-1} of fecal material, which can amount to approximately 1.5 kg wet weight of bacteria. Viable bacteria are said to make up one-third of the fecal dry weight. The major species are *Bacteroides, Clostridium, Eubacterium, Peptococcus, Bifidobacterium, Streptococcus* and *Fusobacterium*. (*See* ***Clostridium***: Occurrence of *Clostridium perfringens*; Occurrence of *Clostridium botulinum*; **Microflora of the Intestine**: Role and Effects; ***Staphylococcus***: Properties and Occurrence.)

Metabolic capacity of colonic bacteria The metabolic capacity of the colonic bacteria is diverse. Luminal contents are potential substrates for bacterial enzymic transformation by hydrolysis (examples are estradiol glucuronide, cyclamate), dehydroxylation (bile acids, amino acids), or reduction (unsaturated fatty acids, food dyes, benzaldehydes). The bacteria can also synthesize vitamins such as vitamin K, biotin, and vitamin B_{12}. Antibiotic treatment of humans is known to lower the plasma levels of the first two, suggesting that the bacteria may play a role in supplying some of the daily requirements for these vitamins. (*See* **Biotin**: Physiology; **Cobalamins**: Physiology.)

Carbohydrates are fermented by the bacterial enzymes to SCFA. The major carbohydrate sources are plant cell wall polysaccharides (cellulose, pectins, hemicellulose), starch, intestinal mucus, and mono- and disaccharides. Depending on the amount of fiber in the diet, between 20 and 70 g of carbohydrate is estimated to be fermented per day in the human colon. The SCFAs produced by the fermentation process are absorbed by the colonocytes, for which they represent an important metabolic source and act as a promoter of NaCl and thus fluid absorption. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism; **Dietary Fiber**: Physiological Effects.)

Another important feature of the metabolic capacity of the colonic bacteria is the potential for creating candidate carcinogens and mutagens (e.g., nitrosamines) that may play a role in carcinogenesis, especially of the colon. In the USA this is the most frequently diagnosed cancer of internal organs. There is some evidence that the western diet (high in beef, fat, and protein, and low in fiber) is a possible cause of the much higher incidence of colon cancer than is found among Africans, Asians, and South Americans. (*See* **Cancer**: Diet in Cancer Prevention; **Nitrosamines**.)

Migrants show a cancer incidence that approximates the prevailing rate of their residence rather than their birthplace. There is, however, another side to the bacterial coin of the colon – the inactivation of carcinogenic compounds by bacteria such as *Escherichia coli, Lactobacillus* spp., and *Bacteroides* spp.

Urea, ammonia, and nitrogen Some 6–9 g of urea (approximately 20% of the daily urea synthesis) is broken down in the human intestine, mainly by the urease of the colonic bacteria. As only 0.4 g of this urea enters the colon from the ileum, and there is no urea and hardly any of its breakdown metabolite ammonia in the feces, most of the urea apparently has to enter the colon by another pathway in order to be metabolized. Unfortunately, the urea permeability of the cleansed human colon appears to be very low and excludes its transmucosal diffusion as a major route. There is evidence that the low permeability is caused by removal of the colon contents which normally increase the permeability of the mucosa to urea; thus the entry path of urea into the untouched colon is probably transmucosal. The catabolism of the urea load produces 200–300 mmol of ammonia and 100–150 mmol of bicarbonate per day. Practically all the ammonia (99%) is absorbed across the mucosa by nonionic diffusion for at colonic pH (6–7) ammonia is largely present as the ammonium ion (NH_4^+). The absorbed ammonium is transported by the portal system to the liver, where it enters the nitrogen pool and is synthesized to urea or amino acids. This metabolism of urea is of little importance to human

nutrition but the enterohepatic circulation of ammonia is important in the genesis of hepatic encephalopathy. In hepatic disease, the liver can fail to detoxify the ammonia and it then enters the general circulation to produce neuropsychiatric disturbances and even coma due to its cerebrotoxic action on the brain. (*See* **Liver**: Nutritional Management of Liver and Biliary Disorders.)

The origin of ammonia in the large intestine is mainly from the breakdown of urea, as described above, but it can also be produced by the bacteria from nonurea sources such as amine and amide nitrogen of proteins, peptides, and amino acids and from plasma glutamine. The colonic bacteria not only produce ammonia but can also utilize it as a nitrogen source for their own synthesis of amino acids and proteins. The oral administration of poorly digested carbohydrates is known to increase the fecal loss of nitrogen. The probable explanation for this is that the nondigestible carbohydrates are metabolized by the bacteria in the colon as a preferential energy source and stimulate the production of new bacteria which are then lost in the feces.

Effect of diet on microflora While there have been numerous studies both in animals and in humans on the effects of diet on the balance of the colonic microflora, the data are conflicting with regard to the ability of the diet to alter specific components of the adult bacterial population. For example, different studies on individuals fed on omnivorous and then herbivorous diets have reported no change, small increases, or decreases in fecal counts of *Bacteroides*. Subjects in the UK and the USA eating the western diet had more *Bacteroides* and fewer enterococci and other aerobics than subjects eating a vegetarian diet in Uganda, India, and Japan. Overall, it appears that eating a meat-poor, high-carbohydrate diet increases the fecal counts of aerobic bacteria, and decreases a number of anaerobic bacteria. (*See* **Vegetarian Diets**.)

Effect of dietary intake on colon contents Since the production of colonic gas (see below) and SCFA is so dependent upon the bacterial fermentation of unabsorbed carbohydrate, much attention has been paid to the proportion of dietary carbohydrate that remains undigested, enters the large intestine and is then broken down and 'salvaged.' Starch, rather than dietary fiber, is the major substrate. In healthy adults it is estimated that usually less than 5% of ingested starch is unabsorbed and enters the colon, although this may be increased to 12% by food processing.

Colon gas production The major components of intestinal gas are nitrogen, oxygen, carbon dioxide, hydrogen, and methane. Gases such as hydrogen sulfide, volatile amines, organic acids, mercaptans, and indoles, collectively amount to less than 1% of the total but as they account for the characteristic unpleasant smell of the flatus they are socially important. The colon is the only source for the production of hydrogen, which is used by the bacteria, expelled in the flatus or absorbed and excreted in the breath. Dietary substrates are the major source for its production as it is low in the fasting subject. Fermentable carbohydrates such as raffinose and stachyose (oligosaccharides found in beans), lactulose, and lactose (in subjects with hypolactasia) all increase the production of hydrogen. Measures of breath hydrogen can be used as an index of its colonic production and also as an indication of when food reaches the colon.

Colonic Function and Diarrhea

It is clear from the various accounts of colonic function that if its absorptive function is impaired or its secretory activity enhanced or both occur, then diarrhea results. A large number of factors can alter the basic net absorptive 'tone' of the colon to a net secretory one and thus induce diarrhea. Examples include bacterial toxins (cholera, *E. coli* STa (heat-stable enterotoxin) and LT (heat-labile enterotoxin)), mediators of inflammatory processes (eicosanoids, histamine, kinins, substance P), neurotransmitters (acetylcholine, vasoactive intestinal peptide (VIP), serotonin), hormones (neurotensin, glucagon, cholecystokinin) and specific endogenous luminal contents such as bile acids. Recently, studies on rats and mice to elucidate the enigma of the terminal diarrhea suffered by human victims of famine and severe malnutrition have shown that starvation induces hypersecretory responses of the enterocytes and colonocytes to neurotransmitters and agents that activate secretion. The mechanism of the hypersecretion is not yet understood but one locus is probably at the apical membrane after the release of the second messengers that activate the Cl^- secretion.

Diseases and Disorders

D N Moskovitz and Y-I Kim, University of Toronto, Toronto, Ontario, Canada

Diet and Nutrition in Inflammatory Bowel Disease

The term 'inflammatory bowel disease' (IBD) refers to primarily two disorders, ulcerative colitis (UC), and Crohn's disease (CD). Both diseases are chronic, relapsing disorders of unknown etiology. CD and UC, while different disease entities, share certain demographic, epidemiologic, and therapeutic features.

Crohn's Disease

CD is a chronic inflammatory disorder that can affect the small intestine and/or large intestine. It occurs throughout the world, with a prevalence of 10–100 cases per 100 000 people. The disorder occurs most frequently among people of European origin, is three to eight times more common among Jews than among non-Jews, and is more common among whites than nonwhites. Although the disorder can begin at any age, its onset most often occurs between 15 and 30 years of age. There appears to be a familial aggregation of patients with CD such that 20–30% of patients with CD have a family history of IBD.

Clinical presentation Diarrhea, abdominal pain, weight loss, and fever are the typical clinical manifestations for most patients with CD (**Table 1**). Diarrhea may have multiple causes, including excessive fluid secretion and impaired fluid absorption by the inflamed small or large bowel, bile salt malabsorption due to an inflamed or resected terminal ileum, and steatorrhea related to extensive ileal disease or ileal resection with loss of bile salts. Bacterial overgrowth from small bowel strictures, enterocolonic fistulae, and extensive jejunal disease may also lead to steatorrhea. Crampy abdominal pain is a common manifestation of CD. The transmural nature of the inflammatory process leads to fibrotic strictures that often lead to repeated episodes of the small bowel or, less commonly, colonic obstruction. Gross bleeding is much less frequent than in ulcerative colitis (except for some patients with Crohn's colitis). Transmural inflammation is also associated with the development of sinus tracts that can lead to serosal penetration and bowel-wall perforation. This complication may be associated with an acute presentation of localized peritonitis with fever, abdominal pain, and tenderness, and often a palpable mass on physical examination. Penetration of the bowel wall often presents not as an acute abdomen but as an indolent process related to fistulization. The actual clinical manifestation of the fistula depends on the area of involvement adjacent to the diseased bowel segment. Symptoms and signs related to perianal disease occur in up to one-third of patients with CD. These include perianal pain and drainage from large skin tags, anal fissures, perirectal abscesses, and anorectal fistulae. Weight loss and fever are the primary systemic symptoms in CD. There are many extraintestinal manifestations of CD (**Table 2**).

Pathology Inflammation, which may or may not be accompanied by noncaseating granulomas, extends through all layers of the gut wall. The inflammatory

process is often discontinuous, with normal bowel separating portions of diseased bowel. The key pathological feature of CD is an inflammatory process that extends through all layers of the bowel wall. Microscopic examination reveals (1) hyperplasia of perilymphatic histiocytes, (2) diffuse granulomatous infiltration, (3) discrete noncaseating granulomas in the submucosa and lamina propria, (4) edema and lymphatic dilation of all layers of the gut, and (5) monocytic infiltration within lymph nodules and Peyer's patches on the serosal surface of the bowel. Patients with CD can be divided into those with small bowel disease alone (30%), those with both small and large bowel involvement (50%), and those with disease involving only the colon (20%). When CD involves the small bowel, 80% of the time, the terminal ileum is involved. When the colon is involved in CD (Crohn's colitis), all segments of the colon can be affected. Although absence of rectal disease is more characteristic of CD than of ulcerative colitis, the rectum is involved in half those cases of CD in which colonic disease exists.

Etiology The etiological agent responsible for IBD has not yet been determined. One hypothesis explaining the developing of CD begins when the gastrointestinal immune system becomes exposed to a mucosal antigen, perhaps even an antigen normally present within the lumen. On this occasion, the antigen does not evoke the typical antigen-specific suppressor T-cell activity, mucosal unresponsiveness. Rather, because of an antigen-specific immunoregulatory defect, it evokes helper T-cell activity and sets in play an ongoing immune response. This immune response as an epiphenomenon leads eventually to the development of self-antigens and the appearance of autoantibodies. Subsequently, in an attempt to downregulate the antigen-specific response, antigen-nonspecific suppressor T-cells appear. Initially, these antigen-nonspecific suppressor T-cells may prevent disease progression; however, they are gradually depleted, leaving the unregulated antigen-specific helper T-cell activity to predominate. This unregulated antigen-specific immune response leads to the production of lymphokines, which stimulate migration of inflammatory and cytolytic cells to the region. Through this process, the microscopic and gross morphological changes of IBD are manifest.

Treatment The treatment of IBD has evolved over time (Table 3). Historically, therapeutic approaches were based on current beliefs of the disease etiology. The treatment of inflammatory bowel disease during the early 1900s included vaccination, dairy diets, astringents, antiseptics, opium, silver nitrate, and rectal instillations of boracic acid. Early treatment often consisted of rectal insufflation of hydrogen peroxide, irradiation of the right lower quadrant of the abdomen, liver extract, and injections of peptides. In the early 1900s, food was implicated in the cause of inflammatory bowel disease. As a result, dietary programs emerged as treatments. During the 1930–50s, clinical observations led to the use of psychotherapy and psychoanalysis. While such early treatment was a reflection of a lack of understanding of disease etiology, as theories of the pathogenesis of IBD evolved, so did the therapeutic modalities.

Medications have remained the mainstay of treatment. It was not until the 1940–50s that sulfonamides began to be utilized. Sulfasalazine, the first sulfonamide, consists of a 5-aminosalicylic acid (5-ASA) attached to sulfapyridine (an antibiotic). It was soon discovered that the active therapeutic moiety was the 5-ASA component. As a result, the 5-ASA group of drugs consisting of asacol, pentasa, and mesalamine was created, each drug differing in their type and place of delivery to the gastrointestinal

tract. The 1970–80s saw the emergence of antibiotics in the treatment of IBD. Studies have shown that metronidazole is effective in both inducing and maintaining remission in patients with IBD. Moreover, the use of ciprofloxacin has proven effective in inducing and maintaining remission in patients with CD. The discovery of adrenocorticotropic hormone and, subsequently, the glucocorticoids cortisone and prednisone in the 1950s provided a great impact on the treatment of IBD. As a scientific approach to the study of inflammatory bowel disease emerges, so do therapeutic interventions targeted at changes in the intestinal tract. As the study of the immune system evolved in the late 1800s, new techniques for the suppression of the immune response began to be developed. In the mid-1960s, 6-mercaptopurine, an immunosuppressant, was first utilized in the treatment of IBD. Decades later, the use of immunosuppressants cyclosporine and methotrexate became more prevalent.

Nutritional issues Malnutrition is common in patients with CD. It has been reported that up to 75% of hospitalized patients with CD are malnourished or may present with weight loss, low albumin, anemia, negative nitrogen balance, or vitamin D deficiency. Even in the absence of active disease, 20% of patients with CD were observed to be more than 10% below the desirable body weight. The mechanisms contributing to chronic malnutrition in IBD are multifactorial and include decreased oral intake, increased gastrointestinal (GI) losses, malabsorption, increased nutritional requirements, and drug–nutrient interactions. The nutritional problems of patients with IBD can be divided into those that concern macronutrients and those that concern micronutrients.

Anemia is a common finding in IBD, and it may be related to iron, folate, or vitamin B_{12} deficiency. Iron deficiency resulting from blood loss is seen in about 80% of patients with UC and in about 40% of patients with CD, resulting from poor intake, blood loss from the GI tract, and malabsorption. Macrocytic anemia caused by vitamin B_{12} malabsorption results from involvement of the distal ileum in patients with CD or from folate malabsorption and altered metabolism caused by drug–nutrient interactions and decreased intake of fresh vegetables in both CD and UC. Although rare, deficiency of water-soluble vitamins other than vitamin B_{12} and folate has been reported in patients with IBD, resulting in scurvy (vitamin C), Wernicke encephalopathy (thiamin), photophobia with dermatological changes (riboflavin), and pellagra (niacin). Fat-soluble vitamin deficiency results from malabsorption that may occur because of extensive mucosal inflammation or bacterial overgrowth.

Table 4 Nutritional deficiencies in IBD

Anemia – iron, folate, vitamin B_{12}
Water-soluble vitamins – vitamin C, thiamin, riboflavin, niacin
Fat-soluble vitamins – A, D, E, K
Zinc
Magnesium
Calcium

Vitamin K may be deficient in patients with malabsorption of dietary vitamin K and due to a lack of synthesis by gut bacteria in those who have received antibiotics. Zinc deficiency has been reported in about 40% of patients with CD and is particularly prevalent in patients with severe diarrhea or enteric fistulas. Magnesium malabsorption is relatively common in patients with IBD, especially in patients with extensive small-bowel disease, in those with magnesuria induced by corticosteroids, and in others who have binding of magnesium by malabsorbed fat. Metabolic bone disease in patients with IBD is well recognized, with prevalence estimates of bone disease ranging from 5 to 78%. Comparisons between patients with CD and UC reveal that osteoporosis may be more prevalent in CD. Thus, risk factors for development of osteoporosis include IBD, especially CD, and treatment with steroids (Table 4).

Nutritional management Nutritional support has been a focus of considerable interest in the management of patients with IBD. A dietitian should be consulted to prescribe suitable protein and energy intakes and to modify the diet to account for food intolerances or allergies.

A proper diet must correct calorie and micronutrient deficits caused by self-imposed or iatrogenic dietary restrictions. One must meet dietary goals that are adequate for the nutritional needs of the patient. Lactase deficiency is reported to occur in 5–15% of whites of North European descent. In one series of CD patients, 34% failed to absorb physiological doses of lactose. In most patients, elimination of dietary lactose decreases abdominal cramps and diarrhea, but objective proof of lactase deficiency should be obtained. Prolonged adherence to a milk free diet may contribute to negative calcium balance. Most patients with lactose malabsorption will require only diminution of milk or icecream intake.

While food intolerance has been shown in patients with IBD, it is not a universal problem. There is a significant correlation between incidence of CD and dietary changes. However, there is no role for elimination diets in the global management of IBD. Theories suggest that different diets affect CD by allowing the patients to absorb more food and thus not suffer

from malnutrition. Constant feeding will allow greater absorption of food, allowing for greater capability of fighting disease. The role of various diets, however, remains controversial. It is possible that certain fats or proteins exacerbate disease. There has been extensive research investigating the effects of different fat compositions and the course of disease. The main focus has been on the type of fat. Researchers have shown that the consumption of a diet with a high ratio of polyunsaturated to saturated fatty acid improves the intestinal function in CD patients. Specifically, the ω-3 fatty acids have been proven to be effective in CD management. Disease activity falls as the composition of long-chain triglycerides falls in the diet. For patients with UC, butyrate (a fatty acid with four carbon atoms) has been shown to induce remission. ω-3 fatty acids have also been shown to have antiinflammatory properties that induce remission in patients with ulcerative colitis. Whether nutrition can control inflammation in the same way as medication remains a controversial issue. It has been claimed that if a patient takes nothing by mouth, this will induce remission through bowel rest. Resting the bowel in this way may cause malnutrition and further harm.

In patients with narrowing of the lumen, the rationale for restricting dietary fiber is apparent. Fiber intake can be reduced by avoiding coarse wholegrain breads and cereals, nuts, and most fruits and vegetables. Fruit and vegetables may not pass through strictures and may cause a bolus obstruction behind a stricture. Patients with symptoms suggestive of mild or partial bowel obstruction should avoid the intake of raw fruits and vegetables.

Patients with CD involving the small bowel and patients with extensive small-bowel resection often have fat malabsorption. Fatty acids and their derivatives often exert a cathartic effect upon the colonic mucosa. There is also a direct correlation between loss of fat in stools and loss of calcium, magnesium, and possibly zinc. Patients with steatorrhea experience symptomatic benefit from decreasing their intake of dietary fat. A reduction in fat to 70–80 g often suffices to alleviate diarrhea. The calories lost by removal of calorie-dense fat from the diet must be replaced by more easily absorbed calorie sources such as sugars and starches.

The target protein–energy intake should be 126–146 kJ kg^{-1} day^{-1}, with 1.5–1.7 g per kilogram of protein per day (Table 5). Fluid and electrolyte deficiencies are best treated with an oral rehydration solution. Patients should receive a solution consisting of glucose 90 mmol l^{-1}, sodium chloride 45 mmol l^{-1}, sodium citrate 45 mmol l^{-1}, and potassium chloride 20 mmol l^{-1}. Iron deficiency is best treated with iron supplements. An appropriate dose is 300 mg of ferrous sulfate or gluconate one to three times per day. It is sometimes necessary to administer iron by intravenous infusion or intramuscular injection, as there is evidence that iron in the colon increases oxidative stress and may exacerbate inflammation. Magnesium deficiency is treated with oral supplements including magnesium heptogluconate (Magnesium-Rougier) or magnesium pyroglutamate (Mag 2). The total dose of elemental magnesium required to ensure normal serum magnesium varies between 5 and 20 mmol day^{-1}. Zinc deficiency as a result of losses through the stool is common in IBD. Zinc supplements should be considered in patients passing significant amounts of stool. Zinc deficiency can be treated by the administration of zinc gluconate, 20–40 mg day^{-1}. Patients with CD should take folic acid, 1 mg day^{-1}. Folic acid nutrition is important in light of recent data that folate supplementation may provide protection against both sporadic and IBD-associated colorectal cancer. Supplementation with thiamin, riboflavin, pyridoxine, niacin, and ascorbate should be recommended using a standard vitamin preparation. Calcium supplements of 1000–1500 mg of elemental calcium per day is appropriate, while vitamin D, 2000–4000 IU day^{-1} is often required.

Table 5 Target energy and nutrient intake in CD

Energy	126–146 kJ kg^{-1} day^{-1}
Protein	1.5–1.7 g kg^{-1} day^{-1}
Iron	Iron supplement 300 mg day^{-1}
Magnesium	Magnesium supplement 5–20 mmol day^{-1}
Zinc	Zinc gluconate 20–40 mg day^{-1}
Folic acid	1 mg day^{-1}
Calcium	Elemental calcium 1000–1500 mg day^{-1}
Vitamin D	2000–4000 IU day^{-1}

Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are polyunsaturated fatty acids derived from fish oil and marine mammals. Fish oil has been observed to have antiinflammatory effects. Fish oil modulates inflammatory mediators that are considered to be operative in CD. Fish oils have been shown to reduce the production of leukotriene B_4 and thromboxane A_2, inhibit the synthesis of cytokines, and scavenge free radicals. Clinical studies have shown a modest antiinflammatory effect of fish oils in psoriasis, atopic dermatitis, and rheumatoid arthritis. One study included 78 patients with CD in remission who were randomly assigned to 4.5 g of a fish oil preparation or to placebo capsules containing the same amount of medium-chain triglycerides. After one year, the number of patients still in remission was significantly higher in the fish oil group (59 vs. 26%). Another study from Spain found that a diet rich in cold fish meat significantly reduced the rate of relapse by 38% at 2 years follow-up. The difficulty in

evaluating the efficacy of trials is in the high drop-out rate of patients due to poor compliance with the fish-oil diet. The advantage in using fish oil is that there is no significant morbidity associated with fish oils. The side-effects, unpleasant taste and odor, are considered insignificant. A summary of trials suggests that fish-oil preparations can be effective for the maintenance of CD in remission. Further studies are necessary to evaluate the effects of fish oils in conjunction with currently available maintenance therapy for CD.

Patients with more severe symptoms unresponsive to medical therapy often require intensive nutritional support. For the patient requiring hospitalization, complete bowel rest, defined as the complete absence of oral intake, is often employed. However, such management causes malnutrition unless alternative forms of energy are given.

Elemental diets contain predigested forms of macronutrients, no lactose or fiber, and vitamins, minerals, and electrolytes sufficient to meet the recommended dietary allowances for healthy people. The diets are administered through flexible tubes placed into the stomach or duodenum. It is not certain how an elemental diet works. It may be that giving a patient a balanced nutritious diet improves overall well-being. Others have suggested that an elemental diet has a direct effect on the mucosa of the bowel. These feeds are effective because they provide minimal digestion, the reduction of fecal bulk, and a reduction in gastric and pancreatic secretions. Therapeutic value may also be related to induced changes in epithelial growth kinetics. Almost 20 randomized controlled trials have evaluated the efficacy of enteral feeding. All trials evaluated the short-term efficacy on the CD activity index. The trials compared either diet therapy versus standard pharmacotherapy or diet therapy where one formula was compared to another. The trials used small number of subjects, had high withdrawal rates, and contained a heterogeneous patient population. Initial controlled trials showed that feeding patients elemental diets was as effective as prednisone in inducing disease remission. Later studies suggested that remission was more likely to occur with the use of prednisone. In summary, nutritional support is likely more effective than placebo in inducing remission. Diets low in long-chain triglycerides may be as effective as prednisone.

The logic of minimizing trauma and irritation of inflamed bowel appears sound. Peripheral intravenous therapy during total bowel rest can maintain adequate fluid and electrolyte balance and ensure maintenance of vitamin and trace elements. The goals of total parenteral nutrition (TPN) therapy include weight gain, positive nitrogen balance, and remission of symptoms. Complications of TPN include pneumothorax during line insertion, catheter-related infections, cholestasis, and steatosis. TPN has been shown to be effective in patients with active disease, patients with fistula, patients with growth retardation, and patients with short bowel. Trials reported regarding TPN are small, with different types and severity of disease. The experience of the TPN team is highly variable. Several studies show that TPN can induce remission in acute CD. TPN with bowel rest achieved remission in 59 and 79% of patients in two randomized controlled trials. It has been shown that TPN may delay the time to surgery in some patients. There was early enthusiasm regarding the use of TPN in treating fistulous disease. TPN can improve the nutritional status and result in decreased fistula output, but better trials with a longer follow-up are required before TPN can be used as a first-line therapy for fistulous disease. TPN can reverse growth arrest and has therefore been increasingly used as the principal determinant of restored growth. Finally, parenteral therapy is important in the management of patients with short bowel. In short periods, it allows for gut adaptation to occur. Long-term use is required in patients whose functioning small bowel remains completely or partially inadequate for nutritional maintenance. In summary, data suggesting that TPN induces disease remission are indirect and inconclusive but should be used to give nutritional support to patients when other means of support are not possible.

Ulcerative Colitis

UC is an inflammatory disease of unknown etiology affecting the colonic mucosa from the rectum to the cecum. It is a chronic disease characterized by rectal bleeding and diarrhea. Histological features of the disease may be seen in other inflammatory states of the colon, such as those caused by bacteria or parasites. The diagnosis of ulcerative colitis, therefore, rests on the discovery of a combination of clinical and pathological criteria, investigation of the extent and distribution of lesions, and exclusion of other forms of inflammatory colitis caused by infectious agents (*Entamoeba histolytica, Clostridium difficile, Campylobacter*, *Escherichia coli*, and *Shigella*). UC is an inflammatory state confined to the mucosa. The colonic tissue displays small microabscesses, called crypt abscesses, which involve the crypts of Lieberkühn. Polymorphonuclear cells accumulate in the crypt abscesses, and frank necrosis of the surrounding crypt epithelium occurs; thus, the polymorphonuclear infiltrates extend into the colonic epithelium. These microabscesses in the crypts are not visible to the naked eye; however, several crypt abscesses may

coalesce to produce a shallow ulceration visible on the mucosal surface. Occasionally, lateral extension of crypt abscesses may undermine the mucosa on three sides, and the resulting hanging fragment of mucosa will appear endoscopically and radiographically as a 'pseudopolyp.' Following this mucosal destruction, highly vascular granulation tissue develops in denuded areas, resulting in friability and bleeding. The two most prominent symptoms of UC – diarrhea and rectal bleeding – are related both to the extensive mucosal damage that renders the colon less capable of absorbing electrolytes and water, and to the highly friable vascular granulation tissue, which bleeds readily.

Etiology It was once thought that UC was caused by food allergy. The food most likely to cause the reaction was cows' milk. Other foods implicated in the etiology of ulcerative colitis include eggs, wheat, tomatoes, oranges, and potatoes. Circulating antibodies to milk proteins are present in some normal subjects but are more common and in higher titers in patients with UC. Sensitivity to disaccharides, including lactose, is noted in patients with UC.

Nutritional management Five studies to date have investigated the effect of fish oil supplementation on chronic active UC. The studies, however, are small and of short duration, have varying doses of ω-3 fatty acids, have significant rates of drop out, and are confounded by the use of other medications. It can be concluded, however, that fish oil appears to have only a modest treatment effect on active UC and does not seem to be beneficial in maintaining UC in remission.

Short-chain fatty acids (SCFA) have been proposed as a topical treatment for active distal UC. SCFA are organic acids produced by anaerobic fermentation of undigested carbohydrates within the colonic lumen. Acetate, propionate, and butyrate, the two-, three-, and four-carbon SCFA, respectively, account for 90–95% of SCFA in the colon, with isobutyrate, valerate, iosovalerate, and caproate comprising the rest. Once inside the colonocyte, SCFA are an important energy source for the cell. Butyrate is the preferred SCFA to meet colonic energy requirements, acetate is second, and propionate is the least metabolized of the three. The SCFA could account for up to 80% of the energy requirements of the colon and for 5–10% of total body energy requirements. Colonic biopsy specimens from patients with UC have impaired utilization of butyrate as measured by carbon dioxide production. It has been suggested that UC may be the result of an energy-deficiency state of the colonic epithelium. The existence of a deficiency of SCFA production has not been consistently shown to exist in UC. It has therefore been postulated that the problem may lie in the uptake or oxidation of the SCFA by the colonocytes. The rationale behind using SCFA in UC is that supraphysiologic luminal SCFA concentrations may be able to overcome the partial metabolic defect of the colonic mucosa to oxidize SCFA. SCFA stimulate colonic cell proliferation, provide a more effective barrier between mucosa and the intraluminal contents, dilate the resistance arteries of the colon, and increase blood flow and mucosal oxygen uptake. Four uncontrolled studies investigating the effect of SCFA on distal active UC have been published. In all four trials, 50–78% of the patients had clinical improvement, some with complete remission, during the study period ranging from 4 to 6 weeks. Disease activity indices and endoscopic appearance all improved. Five randomized trials published to date also support the role of SCFA in the management of UC. These trials to date are limited by the small number of subjects, varying combinations and concentrations of SCFA, and differences in study design and patient populations. However, these trials collectively suggest that SCFA irrigation can effectively treat refractory distal UC that has failed to respond to standard topical, systemic, or combination therapies with a pooled clinical response rate of 70.6%. As a first-line treatment of mild to moderate distal UC, SCFA is associated with a modest clinical response. SCFA is as effective as topical corticosteroid and 5-ASA in inducing clinical, endoscopic, and histologic improvement in mild to moderate distal ulcerative colitis. SCFA is free of significant side-effects and toxicity, and is well tolerated. SCFA is associated with significant cost-savings compared with standard typical corticosteroids or 5-ASA. Unresolved issues regarding SCFA include their role in maintaining remission of distal UC once active disease is brought under control. Furthermore, the role of SCFA in preventing colon cancer has yet to be delineated. Finally, the most effective concentrations and compositions of SCFA have not yet been determined.

The impetus for using SCFA in the treatment of distal ulcerative colitis was the finding that topical SCFA could effectively treat colonic inflammation in diversion colitis. Diversion colitis is an inflammatory process that occurs in segments of the colon after surgical diversion of the fecal stream. Several studies have documented that endoscopic abnormalities and histologic changes occur in the distal colonic segment of most patients after intestinal diversion. Pathologic examination shows lymphoglandular complexes expanding the submucosa with increased lymphocytes and plasma cells. Cryptitis with abscesses, patchy neutrophil infiltration in the lamina propria, and superficial erosions overlying lymphoid follicles

are common findings. The disease is characterized by bleeding from inflamed colonic mucosa, tenesmus, mucus discharge, and abdominal pain. The majority of patients remain asymptomatic. Diversion colitis is likely caused by a deficiency of SCFA, which serve as luminal nutrients for colonocytes. The differential diagnosis for diversion colitis includes acute self-limited colitis, antibiotic-associated colitis, and preexisting UC or CD. The definitive treatment of diversion colitis is restoration of intestinal continuity. Surveillance for cancer in the diverted segment is not necessary, provided that the underlying condition for which the operation was performed has no malignant potential. Randomized controlled studies have not confirmed a beneficial role of SCFA in the treatment of diversion colitis, a peculiar finding. These studies were hampered by the small sample size and short duration of treatment. In those with preexisting IBD, SCFA combined with antiinflammatory drugs may be effective.

A low-residue diet is recommended during acute phases of colitis, the idea being that insoluble particles irritate the bowel and make diarrhea worse. Recently, however, the rarity of UC in developing countries, together with the ability of dietary fibre to affect colonic function and its bacterial content, has suggested that a low intake of fiber might be a factor in causing UC. A high-fiber diet can be prescribed for patients during quiescent phases of disease.

Initial studies suggested a reduced postoperative morbidity and mortality in patients with UC receiving TPN. However, parenteral nutrition is not an effective primary therapy for UC. Retrospective studies have failed to provide evidence for the use of TPN in inducing remission of UC. Moreover, five prospective studies investigating the use of TPN in inducing remission in UC failed to show any benefit for TPN versus control groups. In all five studies, there was a mean 37% initial response rate and only a 12% sustained response rate. TPN appears to have little influence on refractory patients with active disease, and rarely can TPN avert colectomy. TPN can be useful to prepare the malnourished patient for surgery as well as providing postoperative nutritional support. There have been relatively few studies looking at the use of elemental diets in UC. It is generally considered that enteral nutrition is not effective in achieving remission in active ulcerative colitis.

The role of diet and nutrition in patients with IBD remains controversial. By applying an orderly and comprehensive approach to management, many of the complications of IBD can be contained or prevented. While the role of diet continues to evolve, its efficacy in the management of IBD is undisputed.

Diet and Nutrition in Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is defined as a functional bowel disorder in which abdominal pain is associated with defecation or a change in bowel habit, with features of disordered defecation and distention. Criteria for IBS have been formalized in the Rome Criteria (Table 6). IBS is a disorder that can be diagnosed positively on the basis of a series of symptom criteria and limited evaluation to exclude organic disease. The incidence of IBS has been estimated to be 1% per year. Prevalence data estimate a range of 2.9–20%. Patients have been divided into subgroups based on the predominant symptom. Symptom subgroups include constipation-predominant IBS, diarrhea-predominant IBS, and IBS with alternating bowel movements. The prevalence of IBS is lower in the elderly and higher in female patients. Only 10–25% of patients with IBS seek medical care. The economic impact in the USA is estimated at $25 billion annually. IBS accounts for 2.4–3.5 million physician visits in the USA annually, making it the most common diagnosis in gastroenterologists' practice (12% of primary care visits, 28% of all gastroenterologist's patients).

Pathophysiology

There is no single physiological mechanism responsible for symptoms of IBS. IBS is considered a biopsychosocial disorder resulting from a combination of psychosocial factors, altered motility and transit, and increased sensitivity of the intestine or colon (Table 7). It has been hypothesized that altered peripheral functioning of visceral afferents and the central processing of afferent information are important in the altered somatovisceral sensation and motor dysfunction in patients with IBS. It has been postulated that persistent neuroimmune interactions after

Table 6 Criteria for the diagnosis of IBS

Manning criteria	Pain relieved by defecation
	More frequent stools at the onset of pain
	Looser stools at the onset of pain
	Visible abdominal distention
	Passage of mucus
	Sensation of incomplete evacuation
Rome II criteria	At least 12 weeks or more, which need not be consecutive in the previous 12 months of abdominal pain or discomfort with two of three features: relief with defecation, onset associated with a change in the frequency of stool, onset associated with a change in the appearance of stool

Table 7 Pathophysiology of IBS

Biopsychosocial disorder
Abnormal motility
Heightened visceral perception
Psychologic distress
Intraluminal factors – lactose, bile acids, short-chain fatty acids, food allergen
Postinfectious alteration of gut function

infectious gastroenteritis resulting in continuing sensorimotor dysfunction might be a cause of IBS. Infectious diarrhea precedes the onset of IBS symptoms in 7–30% of patients.

In some patients, carbohydrate intolerance may contribute to the symptoms of IBS. Data suggest that food allergens may play a role in IBS (Figure 1). Symptoms often improve with dietary exclusion. Stress and emotions affect gastrointestinal function and cause symptoms in patients with IBS. Psychologic symptoms that are more common in patients with IBS include somatization, anxiety, hostility, phobia, and paranoia.

Diagnosis

Many patients' symptoms fluctuate over time. Regardless, IBS is a 'safe' diagnosis. Patients with IBS have a benign course without any risk of developing organic disease. The diagnosis of IBS first involves a careful assessment of the patient's symptoms. Manning or Rome criteria can be used to identify patients with IBS. A thorough physical examination and a limited series of initial investigation are needed to exclude organic structural, metabolic, or infectious diseases. Investigations include hematology and chemistry tests, erythrocyte sedimentation rate, stool examination for occult blood, ova, and parasites, and possible flexible sigmoidoscopy.

Food Intolerance

Data from dietary elimination and food challenge studies support the role of diet in the pathogenesis of a subgroup of IBS patients. The term 'food intolerance' encompasses nonimmunologically mediated adverse reactions to food, which resolve following dietary elimination and are reproduced by food challenge. Food allergy or hypersensitivity is used to describe conditions in which an immunological mechanism may be demonstrable. Food aversion is a psychological avoidance response. A prevalence for food intolerance of 5% has been reported in the general population. Food hypersensitivity is a common perception amongst IBS patients with 20–65% attributing their symptoms to adverse food reactions. The effect of dietary exclusion followed by food challenge

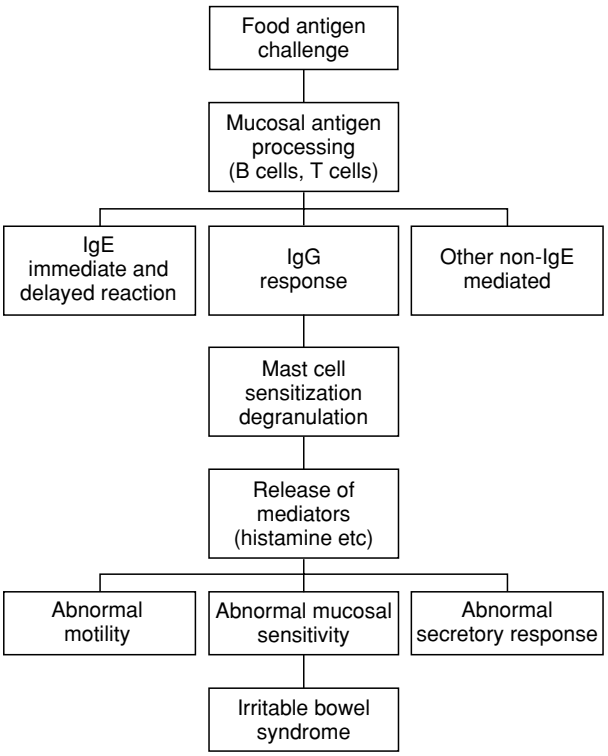

Figure 1 Pathogenesis of food hypersensitivity in IBS.

has been investigated in several trials. Food intolerances have been recognized in 6–58% of cases, with milk, wheat, and eggs being the most commonly implicated foods. In the largest study, the effect of an exclusion diet was evaluated in 200 IBS patients. Symptomatic improvement was reported in 91/189 (48%) patients and was maintained for a mean of 14.7 months. Following dietary challenge, 73/91 (80.2%) of responders identified one or more food intolerances. The investigators conclude that a portion of IBS patients may benefit from dietary manipulation.

The bowel mucosa acts as a physical barrier to a variety of intraluminal dietary and microbial antigens. Under normal physiological conditions intact food antigens can penetrate the mucosal barrier via transcellular or paracellular routes. The mechanism by which the mucosal immune system maintains a state of immunological tolerance is not clear. Studies demonstrating a positive response to elimination diets support the role of a food hypersensitivity reaction in IBS. An immune-mediated food hypersensitivity response involving IgE and IgG antibodies has been postulated as the underlying mechanism in patients with IBS.

While there is no clear evidence to suggest that IBS is an infective condition, up to 30% of patients develop symptoms after an episode of gastroenteritis.

Infective and inflammatory conditions of the bowel cause an increased mucosal permeability, thereby exposing the immune system to an increased load of dietary and microbial antigens. The production of a variety of proinflammatory and immunomodulatory cytokines may serve to prime the mucosal and submucosal immune system establishing a hypersensitivity response. Altered bowel flora has been reported in patients with IBS. Restoration of bowel flora whether by dietary manipulation or through the use of probiotics has been suggested as a treatment for IBS.

Treatment

The dietary treatment of patients with IBS has centered around bran supplementation, manipulating the dietary fiber content of the diet and the identification of food intolerance. There are currently no evidence-based guidelines on how dietitians should treat patients with IBS. An in-depth assessment of a patient's dietary intake is essential prior to any therapeutic dietetic intervention. A history regarding the onset of symptoms in relation to any dietary changes is often useful. Dietary intervention needs to be individualized with respect to the patient's symptoms. Of the eight studies evaluated, five identified food intolerance as a major contributor to symptoms. There are no randomized control trials in this area primarily due to the impracticality of constructing a trial design. In all trials, the methods used to assess the effect of intolerance to suspect foods on symptoms varied. In summary, seven studies mentioned dairy products, six coffee, and five wheat. Others cite eggs, corn, potatoes, onions, fruits, and vegetables. In the majority of the studies, the patients with diarrhea responded favorably to an exclusion diet compared to other subtypes of IBS. The recommendation that elimination diets control the symptoms of IBS is based on poorly designed and incomplete trials. The absence of any objective symptom assessment in the trials raises questions about their validity.

The mainstay of dietary therapy for IBS has centered around the manipulation of dietary fiber. Rees *et al*. conducted a critical review of clinical trials examining the effect of dietary fiber on symptoms in patients with IBS. In the review, it was shown that six out of eight investigations detected no significant difference in most of the symptoms of IBS between fiber and placebo. In the eight trials, the amount of supplement varied, the form in which the fiber was administered differed, and the type of fiber supplement was different. The literature does not support any beneficial effects of increasing insoluble nonstarch polysaccharides in IBS patients. Increasing insoluble wheat products in the diet may be of some benefit in patients with predominantly symptoms of constipation. Many patients complain of bloating with higher doses of fiber. Bran is reported to be no better than placebo in relief of overall IBS symptoms and may be worse than a normal diet for symptoms of IBS caused by intraluminal distention. Fiber may induce bloating by increasing residue loading and bacterial fermentation without accelerating the onward movement of the increased residue. Nonetheless, there appears to be significant improvement in constipation if sufficient quantities of fiber (20–30 g day^{-1}) are consumed. As a result, it is common practice to start with a low dose, increasing gradually, and abandoning high levels of supplementation (> 30 g day^{-1}) if patients experience worsening of symptoms. Therefore, it can be concluded that fiber may have a role in treating constipation with a minimal role in the relief of abdominal pain and diarrhea.

The role of carbohydrate and sorbitol is not routinely considered in the management of IBS. Trials cannot confirm a true malabsorption of carbohydrates in patients with IBS. Nonetheless, studies have shown that patients with IBS develop symptoms after being exposed to a sorbitol diet, when compared to controls. One-third of those with IBS reported lactose intolerance on a subjective basis. The percentage of lactose maldigesters in patients with IBS is the same as in healthy subjects, but the number of subjects reporting lactose intolerance is higher (60% compared to 27%). There is a strong relationship between subjective lactose intolerance and IBS. The inconclusive findings of, and association of, lactose intolerance and IBS can be explained by poorly designed studies. Lactose intolerance has been associated with GI symptoms, and whether this is due to lactase deficiency or increased sensitivity cannot be answered.

In summary, the goal of dietary manipulation in patients with IBS is to help patients control their symptoms. Dietary assessment is essential for all patients with determination of their present dietary intake. Any unusual or abnormal eating practices need to be assessed in relation to the patient's symptoms. It is important to obtain a detailed history of the onset of symptoms and their relation to the individual's eating pattern. Exclusion diets should be tried only when patients complain of multiple food intolerance, and single food avoidance has not helped control symptoms. Patients taking large quantities of sorbitol should be discouraged of such practice, especially if their symptoms are predominantly pain and diarrhea. A milk-free or lactose-free diet should be tried in those patients in whom dairy products are associated with symptoms. Patients continuing on this diet should take calcium supplements. A trial of

a wheat-free diet may be helpful. If a patient's predominant symptom is constipation, an assessment of fluid intake should be undertaken. Regular meal patterns should be encouraged in all patients. Finally, an assessment of the type and quantity of nonstarch polysaccharides consumed should be made. The addition of bran and insoluble fibers should be discouraged, unless the individual feels this is of direct benefit in symptom control. More emphasis should be placed on increasing the proportion of foods containing a higher concentration of soluble nonstarch polysaccharides.

Diet and Nutrition in Diverticular Disease

Diverticular disease is a term encompassing diverticulosis and diverticulitis. Diverticulosis occurs in at least one person in two over the age of 50 years. The prevalence of diverticular disease is age-dependent, increasing from less than 5% at age 40, to 30% by age 60, to 65% by age 85. A male preponderance was noted in early series, but more recent studies have suggested either an equal distribution or a female preponderance. There are geographic variations in both the prevalence and pattern of diverticulosis. Westernized nations have prevalence rates of 5–45%, depending upon the method of diagnosis and age of the population. Diverticular disease in these countries is predominantly left-sided. The findings are markedly different in Africa and Asia, where the prevalence is less than 0.2%, and diverticulosis is usually right-sided. Diverticulosis or diverticular disease of the colon is due to pseudodiverticula in that the wall of the diverticulum is not a full-thickness colonic wall, but rather outpouchings of colonic mucosa through points of weakness in the colonic wall where the blood vessels penetrate the muscularis propria. These diverticula are prone to infection or 'diverticulitis' presumably because they trap feces with bacteria. Among all patients with diverticulosis, 70% remain asymptomatic, 15–25% develop diverticulitis, and 5–15% develop some form of diverticular bleeding. Diverticulitis represents micro- or macroscopic perforation of a diverticulum. The primary process is thought to be erosion of the diverticular wall by increased intraluminal pressure or inspissated food particles; inflammation and focal necrosis ensue, resulting in perforation. If the infection spreads beyond the confines of the diverticula in the colonic wall, an abscess is formed. Patients present with increasing left lower quadrant pain and fever, often with constipation and lower abdominal obstructive symptoms such as bloating and distention. Some patients with severe obstructive symptoms may actually describe nausea or vomiting. This can occur with or without abscess formation. The diagnosis of acute diverticulitis is often made on the basis of the history and the physical examination. On physical examination, the patient often has localized tenderness in the left lower quadrant and, with severe infection and an abscess, may have rebound tenderness in the left lower quadrant. A palpable mass is often identifiable where the sigmoid colon (the most common site of diverticulitis) is infected. Computed tomographïc (CT) scanning has become the optimal method of investigation in patients suspected of having acute diverticulitis, being employed for diagnosis, assessment of severity, therapeutic intervention, and quantification of resolution of the disease. CT scan may be helpful in outlining the colon and identifying an abscess, and is preferable to barium enema for diagnosis in patients with acute illness. After resolution of an episode of acute diverticulitis, the colon requires full evaluation by colonoscopy, barium enema, or both to establish the extent of disease and to rule out coexistent lesions, such as polyps or carcinoma.

Etiology

It has been speculated that low dietary fiber predisposes to the development of diverticular disease. In one study, Burkitt and Painter demonstrated that individuals in the UK eating a Western diet low in fiber had colonic transit times of 80 h and a mean stool weight of 110 g day^{-1}. In comparison, Ugandans eating very high fiber diets had transit times of 34 h and greater stool weights (> 450 g day^{-1}). The longer transit times and smaller stool volumes were felt to contribute to the development of diverticular disease through the increase in intraluminal pressures that predispose to diverticular herniation. The etiology of diverticular disease is unknown. The leading theory suggests that altered colonic motility plays a major role in the development of diverticula. Higher resting, postprandial and neostigmine stimulated pressures in diverticular patients suggest that a delay in transport with augmentation of water reabsorption could cause excessively high pressures forcing mucosa to herniate.

A recent report that evaluated a cohort of over 47 000 men provided strong evidence for the role of dietary fiber. After adjustment for age, energy-adjusted total fat intake, and physical activity, total dietary fiber intake was noted to be inversely associated with the risk of symptomatic diverticular disease. The relative risk was 0.58 for men in the highest quintile compared to those in the lowest quintile for fiber intake. The observation that diverticular disease is less common in vegetarians than nonvegetarians is also compatible with a role for dietary fiber, since vegetables and fruits are important sources of fiber.

Other dietary factors that might contribute to the pathogenesis of diverticular disease have been examined. There is no substantially increased risk associated with smoking, caffeine, or alcohol. However, an association has been noted between obesity in men under 40 years and acute diverticulitis. This finding is compatible with observations that the risk of symptomatic diverticular disease is particularly increased (relative risk 2.35–3.32, 95% confidence interval) by a diet characterized by a high intake of total fat or red meat and a low intake of dietary fiber.

Treatment

The treatment of diverticular disease can be divided into prevention of diverticulosis, uncomplicated diverticulosis, and complicated diverticulosis (Table 8).

The mainstay of treatment for preventing diverticulosis is a diet high in fruit and vegetable fiber. This suggestion is based on observations that low-fiber diets are associated with colonic diverticulosis. Recommendations are also based on results from the Health Professionals Follow-up Study, which showed an inverse association between insoluble dietary fiber intake and the risk of developing symptomatic diverticular disease. In particular, the greatest reduced risk was in those consuming a diet high in fruit and vegetable fiber, with an average consumption of 32 g day^{-1}.

The management of uncomplicated diverticulosis involves a diet high in fruit and vegetable fiber. The majority of patients with diverticular disease will remain asymptomatic. Therefore, this group of patients consists of the largest treatment group. There are no data to support any therapeutic recommendations in this group of patients. There have been multiple uncontrolled studies demonstrating the effect of fiber in patients with diverticulosis, but the lack of a placebo group complicates the results. Other well-conducted studies have reported conflicting results regarding the use of fiber. Despite conflicting data, it appears safe to recommend a diet high in fiber for patients with uncomplicated diverticular disease.

Complicated diverticulosis includes diverticulitis and hemorrhage (Table 9). Patients with mild diverticulitis can be treated as outpatients with broad-spectrum oral antibiotics with activity against anaerobes and Gram-negative rods. Patients should be on the alert for symptoms of increasing pain, fever, or inability to tolerate oral foods. Such patients are treated with a clear liquid diet. Patients admitted to hospital with more severe diverticulitis should be placed on bowel rest with clear liquids or nothing by mouth. Intravenous fluid therapy is required. In addition, intravenous antibiotics should be initiated to target colonic anaerobes and Gram-negative rods. Improvement is expected within 2–4 days, at which point the diet can be advanced. In patients hospitalized with acute diverticulitis, 15–30% will require surgery. After resolution of acute diverticulitis, the likelihood of recurrence and the role of elective surgical resection are important to prevent further attacks. The risk of recurrence after an acute attack ranges from 7 to 62%. Recurrent attacks are less likely to respond to medical and diet therapy and often require emergent surgery. Therefore, elective surgery is often recommended after two attacks of acute diverticulitis.

Diet and Nutrition in Infectious Colitis

Infectious or noninfectious causes may be responsible for acute diarrhea, and in selected patients, both can occur simultaneously. Noninfectious causes of diarrhea include drugs, food allergies, primary gastrointestinal diseases such as inflammatory bowel disease, and other disease states such as thyrotoxicosis and the carcinoid syndrome (Table 10). A variety of infectious diseases cause acute diarrhea. Diarrheal diseases represent the second most common cause of death worldwide and the leading cause of childhood death. Diarrhea results in 300–400 deaths per year in children in the USA, approximately 200 000 hospitalizations, 1.5 million outpatient visits, and more than one billion dollars in direct medical costs. Acute diarrheal disease is generally defined as three loose stools (or two loose stools with abdominal symptoms) or more than 250 g of stool per day for up to 7 days. When diarrhea lasts for 14 days, it can be considered persistent; the term chronic generally refers to diarrhea that lasts for at least a month. It is useful to categorize infectious diarrheal diseases by the portion

of the intestine that they are prone to infect since the presenting symptoms vary by region. The initial evaluation of patients with acute diarrhea should include a history of the duration of symptoms and the frequency and characteristics of the stool. The clinical and epidemiologic history is central to patient medical evaluation and management. Diarrhea may be categorized as mild (no change in normal activities), moderate (forced change in activities), or severe (disability generally with confinement to bed). There should be an attempt to elicit the severity of illness, evidence of dehydration and extracellular volume contraction (e.g., with orthostatic vital signs), and character of stool pattern. Fever and peritoneal signs may be clues to infection with an invasive enteric pathogen (*Shigella*, *Salmonella*, or *Campylobacter*). Diagnostic clues may be provided by questioning about factors that might expose a patient to potential pathogens such as residence, occupational exposure, recent and remote travel, pets, and hobbies. A food history may also provide clues to a diagnosis. Consumption of unpasteurized dairy products, raw or undercooked meat or fish, or organic vitamin preparations may suggest certain pathogens. In addition, the timing of symptoms with regard to exposure to suspected offending food can be important clues to the diagnosis. Symptoms that begin within 6 h suggest ingestion of a preformed toxin of *Staphylococcus aureus* or *Bacillus cereus* (Table 11). Symptoms that begin at 8–14 h suggest infection with *Clostridium perfringens*. Symptoms that begin at more than 14 h suggest infection with viral agents, particularly if vomiting is the most prominent feature, or bacterial contamination of food with enterotoxigenic or enterohemorrhagic *E. coli*. It is also important to ask about recent antibiotic use (as a clue to the presence of *Clostridium difficile* infection). In the absence of specific clues in the history, a stool culture should be obtained in patients with the signs of more severe illness. Gross examination of the stool for blood, pus, and mucus is the single most important laboratory test to begin the evaluation of an acute diarrheal illness. This should be followed by microscopic examination of the stool for inflammatory cells. A stool specimen should be submitted for culture if the stool is inflammatory (i.e., with white cells and/or mucus). Specific media, methods, or stains may be required to isolate or identify organisms of interest. A routine stool culture will identify *Salmonella*, *Campylobacter*, *Shigella*, *Aeromonas*, and most strains of *Yersinia*. A stool culture that is positive for one of these pathogens in a patient with acute diarrheal symptoms can be interpreted as a true positive, although antibiotic therapy is not required for all of these organisms. Other organisms that should be considered in selected situations include enterohemorrhagic *Escherichia coli*, viruses, vibrios, *Giardia*, *Cryptosporidia*, and *Cyclospora*.

Treatment

The management of patients with acute diarrhea begins with general measures such as hydration and alteration of diet. Antibiotic therapy is not required in most cases, since the illness is usually self-limited. Nevertheless, empiric and specific antibiotic therapy can be considered in certain situations.

For most cases of acute diarrhea, the most important form of therapy consists of fluid combined with

Table 11 Infectious causes of diarrhea

Agent	*Clinical features*	*Syndrome*
Staphylococcus aureus, Bacillus cereus (preformed toxin)	Nausea, vomiting, watery diarrhea	Gastroenteritis
Enteric pathogen	Abdominal pain, cramps, voluminous stools	Acute watery diarrhea
Shigella, Campylobacter, Salmonella, Escherichia coli, Yersinia, Aeromonas spp., noncholera vibrios, *Chlamydia trachomatis*	Small volume stools, urgency, tenesmus, dysentery	Colitis, proctitis
Parasite (*Giardia, Cryptosporidium, Cyclospora, Microsporidium*), bacterial overgrowth	Depends upon location of disease	Persistent, chronic diarrhea

electrolytes. Particular attention should be given to the immunocompromised and the elderly. Solutions containing sodium in the range of 45–75 mEq l^{-1} are required. For dehydrated patients, aggressive fluid therapy is required. Oral fluids with Na 60–90 mEq l^{-1}, K 20 mEq l^{-1}, Cl 80 mEq l^{-1}, citrate 30 mEq l^{-1}, and glucose 20 g l^{-1} are often recommended. In non-dehydrated healthy persons with acute diarrhea, fruit juices with saltine crackers supplemented with broths and soups can meet the fluid and salt needs in most cases. In all cases, calories should be provided to facilitate enterocyte renewal. Historically, boiled starches/cereals with salt combined with crackers, bananas, yogurt, soup and boiled vegetables have been used successfully. Diet can return to normal when stools are formed. Starchy foods have the advantage of containing a small percentage of simple proteins that are easily hydrolyzed and well absorbed. Once rehydration is complete and food has been reintroduced, the oral electrolyte solution is continued to replace ongoing losses from stool and for maintenance. The rehydration fluid can be safely continued if other foods or fluids are introduced.

Oral rehydration solutions were first developed in the USA in the early 1950s following the realization that, in many small-bowel diarrheal illnesses, intestinal glucose absorption via sodium–glucose cotransport remains intact. Thus, in diarrheal disease caused by any organism that turns on small-bowel secretory processes, the intestine remains able to absorb water if glucose and salt are also present to assist in the transport of water from the intestinal lumen (Figure 2). From this point of view, it would seem desirable not to restrict food in acute diarrheal illnesses. Carefully controlled trials of various regimens and solutions for oral rehydration have been conducted in nearly every country in the world. The American Academy of Pediatrics Committee on Nutrition endorses the use of oral fluid therapy and posttreatment feeding.

A composition of oral rehydration solution (per liter of water) has been recommended by the World Health Organization (Table 12).

Homemade solutions of sugar and salt can also be used for oral rehydration. An appropriate mixture is half a teaspoon of salt (3.5 g) and 8 teaspoons of sugar (40 g) in 1 liter of water. These homemade solutions lack sufficient amounts of potassium. Moreover, potentially harmful errors in mixing have been reported. The electrolyte concentrations of fluids used for sweat replacement (e.g., Gatorade) are not equivalent to oral rehydration solutions, although they may be sufficient for the otherwise healthy patient with diarrhea who is not dehydrated. Diluted fruit juices and flavored soft drinks along with saltine crackers and broths or soups may also meet the fluid and salt needs in these less severely ill individuals. If available, racecadotril, an enkephalinase inhibitor, may be an effective adjunct to oral rehydration solutions. In one study, it reduced the output and duration of watery diarrhea in a study of 135 Peruvian boys, aged 3–35 months.

Several problems with glucose-based oral rehydration solutions have limited their use. While this therapy effectively replaces the fluids lost in the stool, it does not decrease the stool volume. The continued diarrhea often leads to self-imposed cessation of therapy by the user. Glucose-based solutions prepared with an electrolyte concentration higher than that of the recommended solutions as a result of the addition of too much solute can produce an increase in diarrhea and hypernatremia.

In summary, oral rehydration has become the mainstay for management of acute diarrheal illness caused by infection. Glucose electrolyte solutions should be used for rehydration (75–90 mmol of sodium per liter) and maintenance (40–60 mmol of sodium per liter). The ratio of carbohydrate to sodium should not exceed 2:1. Oral rehydration solutions may be used to treat mild, moderate, and severe dehydration. Mixing of dry ingredients and water at home is acceptable if guidelines are strictly followed. Feeding

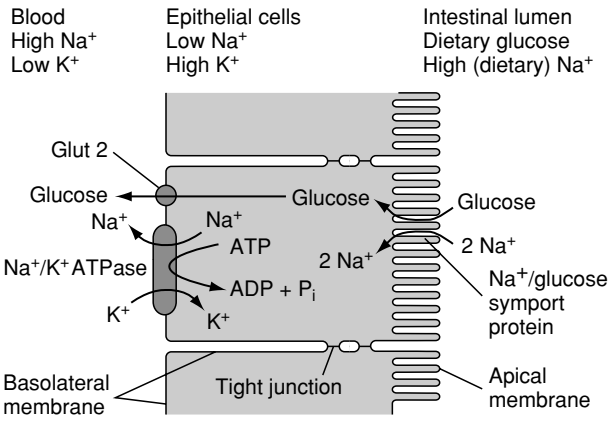

Figure 2 Sodium–glucose transporter.

Table 12 Composition of oral rehydration solution

Ideal	3.5 g of sodium chloride
	2.9 g of trisodium citrate or 2.5 g of sodium bicarbonate
	1.5 g of potassium chloride
	20 g of glucose or 40 g of sucrose
Homemade	1.5 teaspoons (3.5 g) of salt
	8 teaspoons (40 g) of sugar
	1 l of water

should be reintroduced within the first 24 h of the onset of diarrhea.

Cancer of the Colon

S-W Choi and J B Mason, Tufts University, Boston, MA, USA

Background

Colorectal cancer is the second most common cancer in terms of incidence and mortality for both men and women in most of the developed countries of the world. Molecular-genetic studies indicate that colon carcinogenesis is due to a time-dependent accumulation of aberrations in tumor suppressor genes and oncogenes in the colonic epithelial cell, leading to abnormal expression of critical, cancer-related proteins. These aberrations, the most well characterized of which are mutations, offer a molecular explanation for the generally accepted sequence of colon carcinogenesis: normal mucosa, hyperproliferative epithelium, adenoma, and carcinoma.

The majority of colorectal cancers (65–85%) are described as 'sporadic' and have no apparent underlying genetic predisposition, whereas it is estimated that at least 5% of colorectal cancers are due to inherited mutations in major genes ('hereditary' colon cancer), and up to an additional 30% may be due to minor susceptibility genes ('familial' colorectal cancer). Hereditary nonpolyposis colorectal cancer and familial adenomatous polyposis are the two major varieties of hereditary colorectal cancer syndromes.

Migrant studies and other epidemiologic studies indicate that the incidence of sporadic colon cancer is strongly associated with environmental determinants, in particular diet. A diet rich in foods from plant sources (vegetables, fruits, and whole grains) is associated with decreased risk, whereas diets high in animal fat and red meats are associated with increased risk for colorectal cancer. Making appropriate changes in dietary habits and/or supplementing the diet with particular nutrients that are thought to be protective is therefore an attractive approach to preventing this cancer, although it should be emphasized that the prevention of colorectal cancer by this means probably requires long-term changes

over a decade or more in order to effect a meaningful response.

Epidemiology

Rates of colorectal cancer vary considerably with geography. The disease is common in the USA, Australia, New Zealand, Scandinavia, and Western Europe, and is relatively uncommon in Asia, Africa, and South America. Incidence rates vary approximately 20-fold around the world, with the highest rates seen in the developed world and the lowest in India. The international differences, migration data, and recent rapid changes in incidence rates in Italy, Japan, urban China, and male Polynesians in Hawaii show that colon cancer is highly sensitive to changes in the environment. Among immigrants and their descendants, incidence rates rapidly reach those of the host country, sometimes within the migrating generation. The 20-fold international difference may be explained, in large part, by dietary and other environmental differences; indeed, although incidence rates in Japan have been low even until quite recently, the highest rates in the world are now seen among Hawaiian Japanese.

However, colorectal cancer has long been known to occur more frequently in certain families, and there are several rare genetic syndromes that convey a markedly elevated risk. For example, familial adenomatous polyposis, an autosomal dominant hereditary disease, has 90–100% penetrance, with essentially all affected individuals developing colon adenomas, and later colon cancer. Colorectal cancer arising in this setting is thought to have nearly a 100% genetic basis. Colorectal cancer is thus causally related to both genes and environment.

Fat

In Western diets, much of the fat is derived from animal products and may constitute 40–45% of total caloric intake. The relationship between dietary fats and cancer has long been recognized and has received considerable attention as a possible risk factor in the causation of colon cancer. A recent ecological study observed that mortality data of colorectal cancer for 22 European countries, the USA, and Canada were correlated with consumption of animal fat. Increased concentrations of bile acids and fatty acids in the intestine, resulting from a high-fat diet, is suggested as an explanation for the epidemiological association between high intake and high rates of colorectal cancer. Bile acids and fatty acids are considered to be major irritants of the colonic mucosa and are thought to link the high-risk Western-style diet to colon cancer. However, the link between animal fat and colorectal cancer is not entirely consistent. The majority of case-control studies of diet and cancer have shown no significant associations. Furthermore, prospective and intervention studies of fat in studies of the precursor adenoma have yielded conflicting results. The risk of developing an adenoma was reduced by a low-fat diet in a prospective study of 45 000 US health professionals, but not in an intervention study of 400 adenoma patients in Australia.

Not all dietary fats are detrimental in this regard. Intake of vegetable fat is usually shown not to be associated with risk of the cancer. Also, European epidemiologic studies indicate an inverse relationship between fish consumption and colorectal cancer and an inverse correlation with fish and fish oil consumption when expressed as a proportion of total or animal fat. These effects were seen in populations with a high fat intake, indicating that the type of fat in the diet is critical in determining cancer risk. Consumption of fish products rich in ω-3 polyunsaturated fatty acids (PUFA), such as eicosapentaenoic and docosahexaenoic acid, is associated with a low incidence of colorectal cancer and adenoma. Moreover, PUFAs have been shown to normalize altered proliferative patterns of the colonic mucosa in human subjects at high risk for colon cancer. These results emphasize that the enhancing effect of colon carcinogenesis by dietary fat depends on the type of fat as well as the fatty acid composition of the fat.

Meat

Most case-control studies show an increased risk for development of colorectal cancer in those individuals consuming high amounts of meat, especially red meat (this includes lamb, pork, and beef). A high intake of processed meat is also associated with colorectal cancer risk in two cohort studies. Possible mechanisms underlying this epidemiological association include the heterocyclic amines (which are carcinogenic and mutagenic) that are formed when meat is cooked. The possibility that meat alters nitrogen metabolism within the lumen of the intestine and enhances the production of endogenous promoters and carcinogens within the colon is also an attractive mechanism. In a review of several large prospective cohort studies, colon cancer risk was associated with red-meat consumption but not with total or animal fat, which suggests that the risk associated with red-meat consumption is independent of its fat content.

In contrast, consumption of fish or chicken is not associated with risk and might even reduce the occurrence of colorectal cancer. A cohort study in Iowa

women and European prospective studies did not found any significant association between overall meat intake and colon cancer, and two prospective studies show that consumption of white meat or fish is not associated with risk and might even reduce the occurrence of colorectal cancer. A study of Seventh-day Adventists – a predominantly vegetarian population – reported that meat intake was not associated with risk of colorectal cancer.

The data suggest an independent association between red-meat consumption and the risk of colorectal cancer; neither the total protein nor the total fat content of the meat seems to be responsible for this affect.

Calories

Case-control studies suggest that excess calories enhance the risk of colonic carcinogenesis, although it is very difficult to distinguish between energy intake and the intake of dietary fat. In an animal study, carcinogen-induced colon tumors were inhibited by calorie restriction, even though the calorie-restricted rats ingested twice as much fat as control rats. In other animal studies, the incidence and multiplicity of colon tumors were significantly inhibited in animals fed diets containing 20–30% fewer calories than controls.

Obesity appears to be a risk factor for colorectal cancer independent of dietary fat intake. Positive calorie balance and the resulting accumulation of body fat during adult life increase the risk of colon cancer. Even a moderate degree of overweight (body mass index $(\mathrm{kg\,m^{-2}}) > 26$) is associated with increased rates of colorectal cancer. Therefore, maintaining weight in a desirable range appears to be protective.

Vegetables and Fruits

Among the most consistent data that are available from the observational epidemiologic literature are those suggesting that a higher intake of plant foods lowers the risk of cancers at almost every site. The overwhelming majority of descriptive, case-control, and cohort epidemiologic studies have suggested an inverse relationship between consumption of vegetables and fruits and colorectal cancer risk.

There are many biologically plausible reasons why consumption of vegetables and fruits might reduce the likelihood of cancer. Numerous compounds in vegetables and fruits that might exert anticarcinogenic effects have been identified, such as carotenoids, vitamin C and E, folate, flavonoids, phenols, isothiocyanates, and fiber. Each of these phytochemicals and bioactive compounds has been shown to exert some anticarcinogenic activity in laboratory models of cancer.

Vegetables are observed more consistently to convey a protective effect against colorectal cancer than fruit in studies from many countries. This may be due to a difference in composition between vegetables and fruits. An average serving of fruit is substantially higher in sugar, calories, and vitamin C, but lower in carotenoids, vitamin B_6, and folate relative to vegetables. Conversely, raw vegetables tend to be lower in fiber (especially the soluble variety) than both cooked vegetables and fruits. Alternatively, a high vegetable intake, more than a high fruit intake, may merely reflect a generally healthier diet, that is, one relatively low in energy, fat, and sugar.

Although the vast majority of case-control and cohort studies have observed a protective effect of vegetables and fruits on colorectal carcinogenesis, the Iowa Women's Health Study, a large prospective cohort study, observed that total intake of neither vegetables nor fruits reduced the relative risk of colorectal cancer. Similar results were obtained when each vegetable or fruit item was independently analyzed, except garlic. The data from the meta-analyses of colorectal and stomach cancer suggest that a high intake of raw and cooked garlic may be associated with a protective effect against stomach and colorectal cancers. Garlic contains glutathione-*S*-transferase, which is thought to be involved in the detoxification of several potential carcinogens. Individuals consuming more than one garlic clove per week had a 32% reduction in the risk of colorectal cancer compared to those not eating any garlic.

Fiber

The fiber hypothesis is an old hypothesis that originated from an epidemiologic study in which African blacks consuming high-fiber, low-fat diets were observed to have a lower mortality from colorectal cancer than African whites consuming a low-fiber, high-fat diet. The majority of subsequent observational epidemiologic and case-control studies support a protective effect of fiber-rich diets. The effect is thought to be mediated by the shorter intestinal transit time that accompanies a high-fiber diet and the resultant decrease in duration of exposure of the colonic mucosa to potential carcinogens, as well as an increase in stool bulk, which would dilute the colonic contents, including any potential carcinogens.

Fiber is found in vegetables, fruits, whole grains, seeds, nuts, and legumes and consists of nonpolysaccharides (such as lignin) and nonstarch polysaccharides (including cellulose, hemicellulose, pectin, gums, and mucilages). Earlier data suggested that a

protective effect was largely related to less fermentable and more insoluble fibers, especially wheat bran. However, a recent prospective study found a reduced risk of distal colon adenoma with increasing intake of fiber from fruit but not cereals or vegetables. This result suggests that soluble fiber is more protective.

Studies in humans have not yet provided a convincing answer as to whether or not fiber is truly protective. In the Health Professionals Follow-up Study, a large prospective cohort trial, dietary fiber was inversely associated with a risk of developing colorectal adenomas in men, and all sources of fiber were associated with a decreased risk of adenoma. However, data from the Nurses' Health Study, a parallel study in women by the same investigators, failed to indicate any protective effect of dietary fiber on the development of colorectal cancer. A subsequent analysis of the latter cohort, with 10 additional years of follow-up and more thorough adjustment for confounding factors, also showed no protective effect in women with regard to adenomas or cancer. These large prospective epidemiologic studies raise the question as to whether the protective effect of dietary fiber against colorectal cancer may be a gender-specific phenomenon.

A few human intervention trials have demonstrated that wheat-bran supplementation favorably alters a number of biomarkers related to the risk of colorectal cancer, including fecal mutagenecity, fecal secondary bile acids, and rectal cell proliferation. However, two recent well-performed trials which utilized the most widely accepted intermediary biomarker of colon cancer, development of adenomatous polyps, have both yielded negative results: neither a daily dietary supplement containing 13.5 g of wheat bran fiber nor a low-fat, high-fiber diet over 3–4 years reduced the incidence of recurrent adenomas. The results of these two recent studies strongly suggest that dietary supplementation of fiber is not an effective chemopreventive strategy for the prevention of colorectal adenoma recurrence. Nevertheless, the results of these two trials should not be construed as definitive evidence that fiber is ineffective: the follow-up in these trials was relatively brief, and the research question that was addressed (adenoma prevention) is related, but not identical, to the question of cancer prevention.

Antioxidant Nutrients

The antioxidant micronutrients, including vitamin A, carotenoids, vitamin C, vitamin E, selenium, zinc, copper, and manganese, are part of the body's defense against free radicals and reactive oxygen species. These antioxidants are thought to possibly convey protective effects against a number of chronic degenerative diseases through a host of different mechanisms. In some animal studies, vitamins A, C, and E have been shown to have a direct inhibitory effect on tumor growth and damage to both cellular membranes and DNA. However, the epidemiologic literature for the protective effect of antioxidant vitamins in colorectal cancer has little in the way of a consensus. Although early clinical intervention trials suggested a possible preventive role for vitamin E, two recent prospective randomized trials with a more definitive endpoint (adenoma recurrence) have shown no benefit.

Selenium is an essential trace mineral found in cereal grains and seafood. Epidemiologic studies indicate an increased incidence of colorectal cancer in humans in geographic regions where selenium levels are low in the soil and a lower mortality rate of colorectal cancer in areas with high soil selenium levels. The selenium content of foods is determined by the soil in which the food is grown, so assessment of individual dietary intakes using a food content database is of limited value. Results from one study indicate that patients with low plasma selenium levels are at four times the risk for colorectal adenomas. Selenium may alter carcinogen metabolism, affect immune function, protect against oxidant stress, inhibit cell proliferation, and impair tumor metabolism. The most compelling data to data are from a randomized, placebo-controlled intervention trial, where daily supplementation of 200 μg of selenium reduced the incidence of colorectal cancer by 60%.

Folate

Findings from animal and epidemiologic studies indicate that decreased dietary intake of folate or reduced serum or RBC folate levels increases the incidence of colorectal cancer and adenomas. This relationship is underscored in patients with ulcerative colitis, where folate deficiency is commonly induced by increased requirements related to the high turnover of the colonic epithelium, reduced oral intake of nutritious diets, and reduced intestinal absorption resulting from competitive inhibition of folate absorption due to sulfasalazine. Two case-control studies found that folate intake may protect against neoplasia in ulcerative colitis, and the overwhelming consensus of over 15 epidemiologic studies in the general population suggests folate is equally protective in sporadic colorectal cancer. Results from a recent follow-up of the Nurses' Health Study confirmed that colorectal cancer risk was reduced with increased folate intake, as had previously been shown with adenoma recurrence. Interestingly, the study suggested that more

than 10 years of increased intake were necessary to observe a protective effect. Folate deficiency also has been considered as an important factor in alcohol-related enhancement of rectal carcinogenesis because alcohol alters normal folate metabolism in a variety of ways. Although several large multicenter trials are underway to definitively determine the chemopreventive role of folate supplementation in colorectal carcinogenesis, dietary folate intake appears to be inversely associated with the risk of developing colorectal adenomas and cancer.

The mechanism(s) by which folate depletion enhances colorectal carcinogenesis have not been clearly defined, although several candidate mechanisms have been proposed. Folate is an essential factor in a number of critical cellular metabolic pathways that involve the transfer of one-carbon groups, including the *de novo* biosynthesis of deoxyribonucleotides and many biological methylation processes. Therefore, folate deficiency could contribute to DNA damage, instability of the chromatin, impairment of DNA repair, or aberrant patterns of genomic, and/or gene-specific DNA methylation, all of which are phenomena thought to enhance carcinogenesis.

Recently, the relationship of a common polymorphism (C677T) of the methylenetetrahydrofolate reductase (MTHFR) gene (homozygous in 10–15% of the US population) and the risk of colorectal cancer has been examined. MTHFR catalyzes the irreversible conversion of 5,10 methylenetetrahydrofolate to 5-methyltetrahydrofolate. Men with this homozygous mutation have half the risk of colorectal cancer than do homozygous wild-type or heterozygous genotypes. Among men with adequate folate levels, a threefold decrease in risk was observed, but protection associated with the mutation was largely absent in men with a low systemic folate status in the Physician's Health Study. It has been suggested that the cancer protective effect of the MTHFR mutation is related to the increased availability of 5,10 methyleneTHF, and therefore increased ease of nucleotide synthesis. One might speculate that, under low but not high folate conditions, the availability of 5-methyltrahydrofolate for biological methylation constitutes a more critical determinant of whether the cell is pushed down the pathway towards neoplasia.

Calcium, Vitamin D, and Dairy Foods

Many epidemiologic studies suggest an inverse relationship between the risk of colorectal cancer and dietary calcium and/or vitamin D intake. However, the results of epidemiologic research have been inconsistent, even regarding adenomas.

Human clinical trials have been rather promising, although the magnitude of the protective effects have been rather modest. A recent blinded study demonstrated that the administration of low-fat dairy foods, which can double the calcium intake, significantly improved indices of proliferation and differentiation markers in the colonic mucosa. Furthermore, calcium carbonate supplementation (3 g (1200 mg of elemental calcium) daily) provided a significant reduction ($\sim$ 15%) in the risk of recurrent colorectal adenomas as well as reduced numbers of adenomas in a randomized, double-blind trial recently reported by the Calcium Polyp Prevention Study Group. The effect of calcium supplementation was independent of initial dietary fat and dietary calcium intake.

The underlying mechanisms are not clear, but the principal hypothesis is that calcium may precipitate fatty acids and bile acids that are potentially toxic to the colorectal epithelium. Both calcium administration and dairy food administration diminish concentrations of bile acids and fatty acids in the aqueous fraction of the feces, and this is accompanied by a significant decrease in *in vitro* cytotoxicity. Animal studies suggest that supplemental calcium can retard the hyperproliferative stimulus of dietary fat, bile salts, and fatty acids.

Iron

Iron, a necessary nutrient, has been associated with increased cancer risk in humans. *In vitro* and *in vivo* data suggest that iron may be capable of mutagenic effects mediated through free-radical generation or tumor promotion through nutritional mechanisms. As a transition metal, iron possesses loosely bound electrons that are capable of participating in lipid peroxidation reactions. Such reactions are thought to lead to DNA damage and, in some cases, neoplasia.

Prospectively gathered data from a large study suggest that the risk of colon cancer increases in parallel with iron intake throughout the colon for both men and women. A nested case control study similarly showed an increasing trend of risk of cancer of the proximal colon with increasing total iron intake. However, increased body iron stores were not related to the development of colorectal cancer. Even though increased iron intake is related to increased red-meat consumption, the putative relationship between iron intake and colorectal cancer risk remains rather tentative at this point that requires further confirmation.

Heterocyclic Amines

Heterocyclic amines (HCAs) are the carcinogenic and mutagenic chemicals formed from cooking muscle

meats such as beef, pork, fowl, and fish. HCAs form when amino acids and creatine react at high cooking temperatures and are formed in greater quantities when meats are overcooked or blackened. Seventeen different HCAs resulting from the cooking of muscle meats have been identified, which may pose human cancer risk.

HCAs develop a powerful carcinogenic potential when activated by cytochrome P450 1A2-mediated oxidation of the amino group, which is followed by acetylation or sulfation to form direct-acting reactive mutagens that attack key elements in DNA. When fed to rats, several of these HCAs can induce cancer of the mammary glands, colon, and pancreas. Reduction of HCAs in food can be accomplished by avoiding high-temperature cooking, addition of high-antioxidant-containing foods, or addition of soy protein. Nevertheless, there is no definitive evidence that the degree to which meat is cooked is a determinant of colorectal cancer risk.

Alcohol

A large number of epidemiologic studies have examined the association between the risk of colorectal cancer and alcohol consumption. The results are not entirely consistent. Although there are studies showing either increased risk or no association with alcohol intake, there are essentially no studies that show a reduced risk with higher intake.

Alcohol, particularly beer, consumption has been linked most convincingly with rectal cancer. However, there is no strong evidence to suggest that one source of alcohol (e.g., beer) is more associated with risk than alcohol as a whole. Studies of colorectal adenomas, which are colorectal cancer precursors, also have demonstrated an effect for alcohol. The mechanism for an increased risk with alcohol is not known for sure, but the carcinogenicity of acetaldehyde as well as folate and methionine depletion are plausible explanations. Although alcohol is not a direct-acting carcinogen, beer, wines and spirits contain at least 1200 different compounds, such as aldehydes, phenols, and amines, many of which are thought to be related to carcinogenesis.

Tea

Tea is grown in about 30 countries and, next to water, is the most widely consumed beverage in the world. Black tea is consumed primarily in Western countries and in some Asian countries, whereas green tea is consumed primarily in China, Japan, India, and a few countries in North Africa and the Middle East. Most of the studies showing the preventive effects of tea have been conducted with green tea; only a few studies have assessed the usefulness of black tea. Green tea contains polyphenolic compounds, which include flavanoids, flavandiols, flavonoids, and phenolic acids. In black teas, the major polyphenols are theaflavin and thearubigin.

(−)-Epigallocatechin-3-gallate (EGCG) is the primary component of green tea, accounting for 40% of the total polyphenolic mixture. Numerous *in vitro*, human, and animal studies have identified these antioxidant polyphenols, in particular EGCG, as cancer-chemopreventive agents. EGCG inhibits cancer cell growth and represses the catalytic activities of several P450 enzymes such as P450 1A and 2B1. Repression of phase I enzymes involved in cancer initiation, and enhancement of enzymes that play a role in carcinogens detoxification, are thought to guard against carcinogenesis.

Animal studies show that tea consumption protects against colon cancer induced by chemical carcinogens. A cross-sectional study showed a 30% lower risk of adenomatous polyps of the sigmoid colon in persons consuming five or more cups of green tea per day. However, human studies on tea drinking and colorectal cancer are still inconclusive.

Soy

Epidemiologic data suggest that populations that regularly consume soy foods have a lower incidence of colon cancer than populations that do not. Soy is abundant in isoflavones such as genistein and daidzein, which, because of their structural similarity to estrogen and/or their biological activity, are considered to be phytoestrogens. Several other cancer-related properties have also been reported for soy-derived genistein, such as antioxidant activity, an antipromotional effect, inhibition of tyrosine kinase, inhibition of cell-cycle progression and growth and inhibition of angiogenesis. Studies in laboratory animals have further shown that a soy-rich diet inhibits chemically induced carcinogenesis. However, animal studies of the effects of single phytochemicals from soy on intestinal cancer have yielded conflicting results. The relationship between soy intake and the risk of colonic cancer still needs further investigation.

Dietary Recommendations

Diet is important in preventing colorectal cancer. With our current knowledge regarding the dietary risk factors of colorectal cancer, the following suggestions are offered: (1) avoid overweight (BMI > 26), (2) reduce total fat intake to less than 25–30% of total

Table 1 Dietary components that may prevent colorectal cancer

Food or nutrient	*Proposed mechanism*	*Common diet source*	*Estimated effective dose*
Calcium[a]	Reduces bile acid/fatty-acid-induced irritation in colon as well as proliferation	Dairy products, dried beans, kale, broccoli	1200 mg day^{-1}
Vitamin D	Reduces cell proliferation and DNA synthesis, modulates signal transduction pathway, induces apoptosis, promotes repair of membranes and DNA	Fortified milk, salmon, mackerel, fortified cereals, egg yolks	400 IU day^{-1}
Selenium[a]	Reduces risk of excessive oxidative DNA damage and cell toxicity, induces apoptosis, reduces proliferation, restores immune function	Meats, fish, grains, brazil nuts	200 μg day^{-1}
ω-3 fatty acids	Inhibit arachidonic acid metabolism and oxidative reactions, reduce proliferation	Tuna, salmon, sardines, mackerel, and lake trout	3–4 g day^{-1}
Folate[a]	Corrects imbalance of DNA synthesis and DNA methylation, enhances DNA repair	Fortified cereals, citrus fruits and juices, asparagus, spinach, baked beans	400 μg day^{-1}
Fiber	Increases stool bulk, binds with bile acids and other potential carcinogens, reduces fecal pH and anaerobic fecal flora, ferments to short-chain fatty acids	Whole grains, legumes, wheat bran, nuts, barley, beans	20–30 g day^{-1}
Vegetables and fruits[a]	Block the formation of carcinogens, induce a multiplicity of solubilizing and activating enzymes, suppress DNA and protein synthesis		5 more servings day^{-1}
Tea	Antioxidant activity, represses phase I enzymes involved in cancer initiation, and enhances enzymes involved in carcinogen detoxification	Green tea	5 more cups day^{-1}
Soy	Antioxidant activity, antipromotional activity, inhibits cell-cycle progression and growth, and inhibits angiogenesis	Soy bean, tofu, soy milk	

[a]Existing data are particularly compelling.

Table 2 Dietary components that may enhance the risk of colorectal cancer

Food or nutrient	*Proposed mechanism*	*Common diet source*
Animal fat, calories, and red meat[a]	Increasing DNA damage and/or promoting carcinogenesis	Beef, lamb, pork
Heterocyclic amines	Direct-acting reactive mutagens that attack key elements in DNA	Meats cooked at very high temperature (fry, broil, barbecue)
Alcohol	Folate and methionine depletion and carcinogenicity of acetaldehyde, phenol, and amines	Beer, wine, spirit
Iron	DNA damage by lipid peroxidation reactions and mutagenic effects through free-radical generation	Red meat

[a]Existing data are particularly compelling.

calories and saturated fat to less than 10% of total calories, (3) eat five or more servings of fresh vegetables and fruits daily, (4) eat other foods from plant sources, such as breads, cereals, grain products, rice, pasta, or beans several times each day, (5) choose foods low in fat, (6) replace red meat with chicken, fish, nuts, and legumes, (7) eat processed meat in moderation, (8) eat low-fat dairy products, (9) if you drink, keep alcohol consumption moderate (< 2 drinks per day), and (10) consider taking a multiple vitamin containing folic acid, particularly if alcohol is consumed daily. These recommendations are based on the guidelines by the American Cancer Society and currently accepted dietary modulations for the prevention of colorectal cancer (Tables 1 and 2).

Daily supplementation with fiber (20–30 g day^{-1}), calcium (1200 mg day^{-1}), folate (400 μg day^{-1}), fish oils, and selenium (200 μg day^{-1}) have not been proven by prospective randomized control trials to prevent cancer but have considerable potential (Table 1).

COLORANTS (COLOURANTS)

Contents

Properties and Determination of Natural Pigments

A Lea, The University, White Knights, Reading, UK
B Henry, Phytone Ltd, Burton-on-Trent, UK

Background

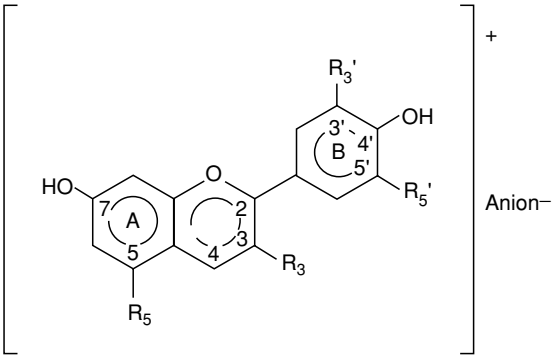
Natural colors in foodstuffs may arise in basically three ways. They may be present originally in the plant or animal tissue from which the food is derived (e.g. chlorophyl in green vegetables), they may be generated during processing (e.g., brown Maillard products in fried onions), or they may be added deliberately (e.g., β-carotene in orange squash). This article considers the major pigments in these three groups. (*See* **Browning**: Nonenzymatic; **Carotenoids**: Occurrence, Properties and Determination; **Chlorophyl**.)

Naturally Occurring Pigments

The range of compounds responsible for the natural colors of foodstuffs is surprisingly limited. Plants are the primary sources, yielding anthocyanins, carotenoids, and chlorophyls as the major groupings, with limited contributions from compounds such as betanins and curcumin.

Anthocyanins

The anthocyanins are responsible for most of the red, purple, and blue colors in plant foodstuffs. The skins of red apples, plums, and grapes are rich in anthocyanins, as are strawberries, rhubarb stalks, and red cabbage leaves. Chemically, most anthocyanins are based on the six common benzopyrilium aglycones (anthocyanidins) shown in **Figure 1**. These aglycones are not stable, and the 250 or so anthocyanins which are known in nature reflect the fact that the aglycone is stabilized by substitution with different sugars at different positions. Substitution at the 3 position is



Anthocyanidins: R_3 = OH, R_5 = OH

		R_3'	R_5'
Pelargonidin	(Pg)	H	H
Cyanidin	(Cy)	OH	H
Peonidin	(Pn)	OCH_3	H
Delphinidin	(Dp)	OH	OH
Petunidin	(Pt)	OCH_3	OH
Malvidin	(Mv)	OCH_3	OCH_3

Anthocyanins: Pg. Cy. Pn. Dp. Pt. Mv with
R_3 = *O*-Sugar or *O*-acylated sugar
R_5 = OH or *O*-glucose

Figure 1 The common anthocyanins and anthocyanidins. Reproduced from Colours: Properties and Determination of Natural Pigments, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

most widespread, but 5 and 7 substitution is also common. The substituent sugars may be simple (e.g., glucose, galactose) or complex and unusual (e.g., rutinose, sambubiose). The sugars themselves are sometimes acylated with other complex organic acids – grapes, for instance, contain significant quantities of the caffeic and *p*-coumaric acid conjugates of malvidin 3-glucoside. The polar nature of anthocyanins means that they are soluble only in water or polar organic solvents – they are not associated with lipid in the plant cells and they are not soluble in oils or in organic solvents such as chloroform or hexane.

The color chemistry of anthocyanins is complex. The benzopyrilium structure can exist in four major equilibrium forms depending upon pH (Figure 2). The flavylium salt is the most stable and intensely colored, predominating at low pH. Hence the well-known observation that red cabbage pigment is intense and stable when cooked in the presence of acid, but rapidly turns blue and degrades at a pH near or above neutrality. The blue color is due to the generation of the quinoidal base (which is stable under nitrogen, even at pH 10), which rapidly degrades in the presence of oxygen.

The perceived color of anthocyanins is also highly dependent on copigmentation effects. In the concentrated environment of intact plant cells, the proximity of pectin, metal ions, organic acids, and other polyphenols act to stabilize and to augment anthocyanin color to a remarkable degree. Hence the skins of red grapes seem intensely dark blue or black but, when the pigment is extracted by ethanol during wine-making, the native anthocyanin is revealed as bright red. The visible absorbance maximum of isolated anthocyanins is somewhat dependent on structure, moving from 506 nm (orange) for pelargonidin derivatives to 534 nm (purple-red) for malvidin, delphinidin, and petunidin. A very few anthocyanins are naturally blue, even in the extracted state, due to internal copigmentation with their own sugar-acylating groups.

Even at low pH, the anthocyanins are not stable indefinitely, and they tend to polymerize with other polyphenols or reactive carbonyls. After only a few months' aging, therefore, very little monomeric anthocyanin remains in most red wines and the specific E_{520} drops dramatically. The overall visual chromophore is only slightly affected by polymerization, however, giving a color shift from purple to red. In these circumstances, tristimulus colorimetry is a far more accurate measure of perceived color than is a spot measurement at 520 nm.

Carotenoids

The carotenoids are a range of lipid-associated pigments widely present in higher plants and algae. They are responsible for many of the orange-yellow colors of fruits and vegetables such as red peppers, tomatoes, carrots, and bananas. They are also responsible for the yellow skin ground color of apples such as Golden Delicious. The structure of carotenoids is more diverse than that of anthocyanins and does not fall into such well-defined groups. The basic unit is a C_{40} hydrocarbon structure and those consisting of carbon and hydrogen only are collectively called carotenes, whilst those containing oxygen are called xanthophylls. Some carotenoids are acylic (e.g., lycopene), though the majority contain a six-membered ring at either one end or both ends (e.g., β-carotene). Apocarotenoids are those compounds where an end group has been removed from the normal C_{40} structure.

A few carotenoids appear in animal flesh, such as salmon and shrimp, which acquire them via their diet. The dark blue of the live lobster is a carotenoid–protein complex which is destroyed when the animal is boiled and only the pink carotenoid then remains. Butter, cheese, and egg yolks contain carotenoids which derive ultimately from the vegetable diet of

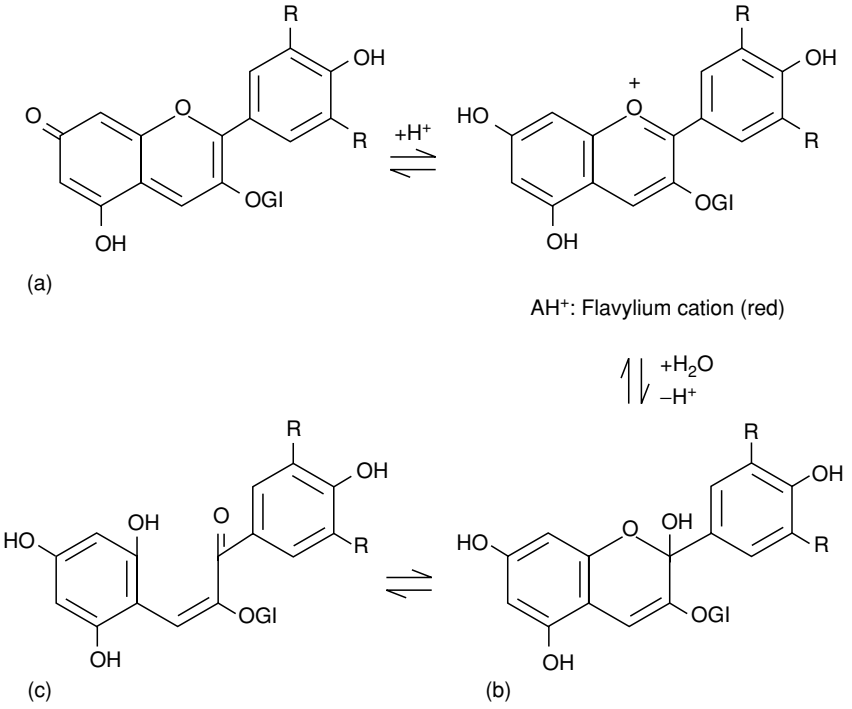


Figure 2 Equilibrium forms of anthocyanins. (a) Quinoidal base (blue); (b) carbinol pseudobase (colorless); (c) chalcone (colorless). Reproduced from Colours: Properties and Determination of Natural Pigments, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

the animals producing them. In animals, many carotenoids act as vitamin A precursors, so have additional value in addition to their properties as pigments. (*See* **Retinol**: Physiology.)

Although some 500 or so carotenoids are known in nature, very few of them are water-soluble – those that are have achieved a disproportionate importance as food colors, as described later. Their general water-insolubility means that they tend to be more stable in processed foods than do anthocyanins, since they remain attached to cellular fragments. Thus, the carotenoid pigments of canned tomatoes are more stable than the anthocyanins of canned strawberries. Nevertheless, carotenoids are still prone to degradation once freed from their cellular matrix, and are particularly susceptible to light and oxygen.

Chlorophyls and Heme Pigments

Chlorophyls are amongst the most noticeable of all plant pigments due to their central photosynthetic role. Like carotenoids, they are water-insoluble and are associated with the lipid portion of plant cells in specialized organelles (the chloroplasts). The bright green of native chlorophyl in plants is determined by the presence of a central magnesium atom in a large porphyrin ring. When green-leaf vegetables are cooked under normal (slightly acid) conditions, this magnesium is easily lost to form the dull green pheophytins. Although this process can be prevented by the use of alkali during cooking and the green color thereby retained, this is no longer a common practice since it leads to oxidation and loss of vitamin C. The green color can also be retained and stabilized if the central magnesium atom is replaced by copper. (*See* **Chlorophyl**.)

The bright red heme pigments, characteristic of animal blood and therefore of fresh meat, contain similar porphyrin ring structures, but the central atom is iron which shifts the chromophore into the red region. Like chlorophyl, the heme pigments are soon degraded when meat is cooked in the normal way. If preserved in the presence of nitrite, however, as in traditional curing, the nitrosohemoglobin stabilizes the pigment and a red color is retained. (*See* **Curing**.)

Other Plant Pigments

Although most orders of higher plants can synthesize anthocyanins to provide red and purple shades, the Centrospermae lack this ability and synthesize instead a group of nitrogenous pigments known as the betalains. These occur in both red forms (betanins) and yellow forms (vulgaxanthins) (Figure 3). The betalains are water-soluble and are generally stable

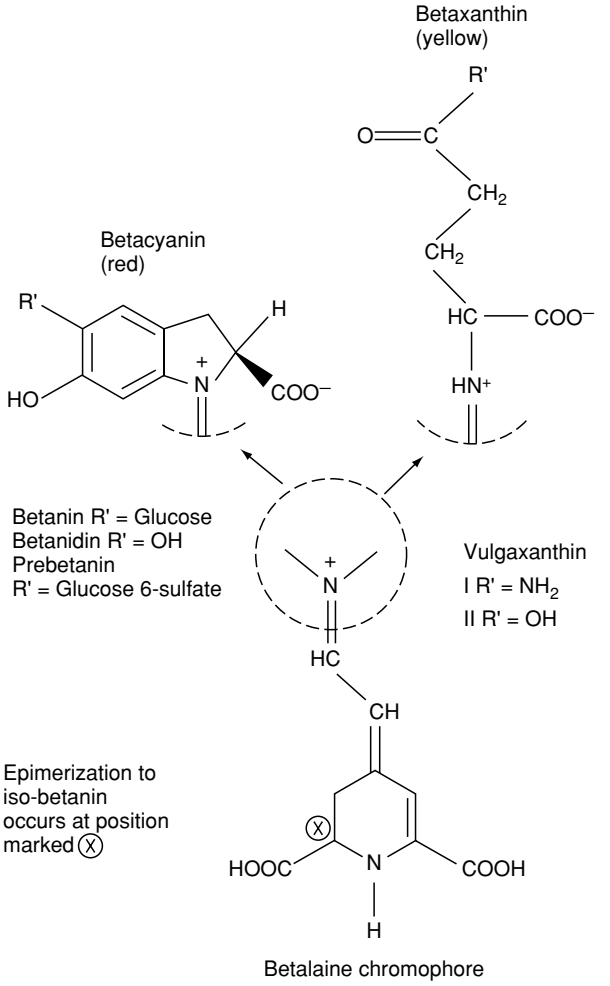

Figure 3 The structure of betalains. Reproduced from Colours: Properties and Determination of Natural Pigments, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

at moderately acid pH, although heat, light, and oxygen will hasten their decomposition. Although of restricted natural distribution, the importance of betalains, particularly the red betanins, is enhanced by their presence in a number of important food crops such as amaranth, chard, and beetroot.

The yellow tubers of turmeric (*Curcuma longa*) are well known as both a spice and a coloring material for food when dried and ground into a powder. The pigment, known as curcumin, has the extended conjugated structure shown in Figure 4. This is subject to keto/enol equilibrium and the pigment converts to an unstable orange form above pH 7.

Pigments Generated During Processing

Pigments generated during processing or cooking are amongst the least well defined in terms of chemical

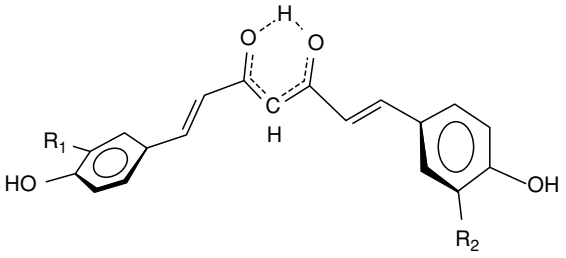

Figure 4 The structure of curcumin. R = H or OCH_3. Reproduced from Colours: Properties and Determination of Natural Pigments, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

structure. They fall into two broad groups – those produced by enzymatic browning (principally from natural phenolics and polyphenoloxidase) and those produced by (nonenzymatic) Maillard reactions between reducing sugars and amino compounds.

Enzymatic Browning

Colors of this sort are generated by the action of polyphenoloxidase or peroxidase enzymes on natural phenolic substrates. The development of color in a freshly cut apple is a typical example. The principal substrates involved are the catechins or procyanidins, although in older literature the phenolic acids are often mentioned. It is now known that phenolic acids do not themselves brown, although they may play a part in coupled oxidation systems which allow the procyanidins to generate the color. The pigments derived from procyanidins have no specific λ_{max} in the visible region of the spectrum, although those derived from simpler phenolics such as catechins may initially display yellow-orange chromophores about 400 nm before further polymerization occurs.

In some food systems, such as apple juice or white wine, only a limited amount of color development is desirable before the product becomes unacceptably dark. In these cases, color formation may be inhibited by antioxidants such as sulfite or by a drop in pH which reduces enzyme activity. In other foods, such as black tea or cocoa, the development of color during processing is critical to the product and is also associated with flavor development processes. The tea system has been well studied and is known to generate two types of phenolic pigment from catechins. These are the theaflavins, which are bright orange-red, and the thearubigins, which are dull brown. Most oxidized phenolic pigments tend to become browner and duller with time, particularly if further nonspecific oxidation takes place. (*See* **Antioxidants**: Synthetic Antioxidants.)

Nonenzymatic (Maillard) Browning

This form of color development is usually associated with heat and is a type of caramelization, in which the temperature for degradation of a reducing sugar is lowered by the presence of catalytic amino groups. The sugar degrades to give aldehydic functions which polymerize to give visible chromophores, intensifying after further complex formation with amino groups. Typical desirable examples include the browning of fried onions, the roasting of meat, or the manufacture of toffee confectionery.

Almost inevitably, Maillard browning is associated with flavor development. The pigments generated are even less well defined than those from the phenolic browning reaction. Although temperatures above 80 °C will generate Maillard pigments rapidly in suitable systems, the reactions will also proceed slowly at room temperature if the water activity is low enough. Thus, apple juice concentrate held at 20 °C for several weeks shows discernible color development from Maillard reactions between fructose and amino acids (in addition to any enzymatic browning which may have taken place earlier). Similarly, tinned condensed milk or dried milk powder develops color in storage due to reaction between lactose and the lysine ε-amino groups in milk protein. Such slow Maillard reactions are generally considered undesirable, in contrast to the fast reactions which are under control during cooking.

Natural Pigments Deliberately Added to Foodstuffs

Most of the natural pigments added to food are derived from one of the categories described above. A list of those permitted in the European Union is given in Tables 1 and 2.

Table 1 Natural and nature-identical colorants (and those of natural origin) covered by European Union regulations

Colorant	*E number*
Reds	
Anthocyanins	E163
Beetroot red	E162
Cochineal, carmines	E120
Orange-Yellow	
Annatto	E160(b)
β-apo-8′-carotenal	E160(e)
Canthaxanthin	E161(g)
Mixed carotenes and β-carotene	E160(a)
Curcumin	E100
Ethyl ester of β-apo-8′-carotenoic acid	E160(f)
Lutein	E161(b)
Lycopene	E160(d)
Paprika extract	E160(c)
Riboflavin, riboflavin-5-phosphate	E101
Greens	
Chlorophyls and chlorophyllins	E140
Copper complexes of chlorophyls and chlorophyllins	E141
Brown	
Plain caramel	E150(a)
Caustic sulfite caramel	E150(b)
Ammonia caramel	E150(c)
Sulfite ammonia caramel	E150(d)
Black	
Vegetable carbon	E153

Table 2 Inorganic colorants covered by European Union regulations

Colorant	*E number*
Calcium carbonate	E170
Titanium dioxide	E171
Iron oxides and hydroxides	E172
Aluminum	E173
Silver	E174
Gold	E175

Blues and Reds

Most anthocyanin extracts are derived from grape skins as a byproduct of wine or grape-juice manufacture. Some extracts are also available from black carrot, elderberry, red cabbage, purple corn, and blackcurrant. A particularly interesting extract is that from red cabbage which contains highly copigmented anthocyanins of much bluer shade than most fruit-derived anthocyanins. The extracts are generally made using acidified water or alcohol, sometimes in the presence of sulfite (which is later removed). The extracts are then concentrated to a liquid or dried to a powder. None of the extracts are pure compounds but consist of a variety of anthocyanin structures complete with polymeric degradation products.

Anthocyanin extracts are well suited to aqueous systems but they cannot be directly used in fatty foods or in foods of pH much greater than 4.5. They are susceptible to copigmentation and complexation effects – for instance, the presence of tin, iron, or aluminum (as in canned fruits) can cause noticeable blueing.

Native (monomeric) anthocyanins are reversibly bleached by sulfite but are irreversibly degraded by ascorbic acid. Polymeric or copigmented anthocyanins are generally more resistant to degradation and are therefore particularly suited to use in soft drinks. Other phenolic compounds such as procyanidin tannins will tend to cause coprecipitation or haze formation. The crude extracts of grape skin which

are high in tannins may also react with food proteins such as gelatin. Anthocyanins, particularly those derived from grapes or black carrot, have found considerable application in providing a natural coloring for soft drinks where they are stable at low pH and moderately resistant to light and pasteurization.

Betanin extracts are prepared from beetroot juice which may be fermented to remove sugar and then dried to a powder. Although generally stable between pH 3 and 7, they are adversely affected by heat, light, oxygen, high water activity, and sulfite. However they have found considerable application in frozen and short-shelf-life dairy products such as icecream and yogurt, and in dry-mix desserts.

The traditional red color cochineal is derived from the dried South American insect (*Coccus cacti*) and consists of a polyhydroxy anthroquinone pigment known as carminic acid. Its aluminum lake, known as carmine, is produced as an insoluble powder which can be converted to a water-soluble product by dissolution into dilute alkali. It is very stable to heat, light, and oxygen and finds application in a wide range of foodstuffs, including meat and dairy products, sugar confectionery, and certain soft drinks.

Orange and Yellow

The carotenoids are generally oil-soluble and therefore well suited for coloring fatty foods such as margarine and dairy spreads. Natural sources include paprika, lutein from *Tagetes erecta* (Aztec marigold), carotenes from palm oil, and lycopene from tomato. Natural carotenes may be incorporated into an oil-in-water emulsion to facilitate their dissolution into soft drinks. A commonly used extract is annatto, which is obtained from the seeds of a tropical shrub, *Bixa orellana*. This consists mainly of bixin, the fat-soluble methyl ester of a carotenoid carboxylic acid known as norbixin, which is a particularly intense colorant providing distinctive colors at dose levels as low as 10 p.p.m. It can be rendered completely water-soluble by alkaline hydrolysis to yield the sodium or potassium salts. These readily complex with protein and are therefore ideally suited as colorants for smoked fish, cheese, and other dairy products. Norbixin can precipitate out at low pH and thus an annatto preparation formulated to color cheese cannot be used to color a soft drink where special-application forms of norbixin are required. Bixin, however, is not affected by pH.

Another traditional water-soluble carotenoid is crocin, an ester of the dicarboxylic acid crocetin, which is the pigment from saffron (the stigmas of *Crocus sativus*). This pigment is also extracted from the seeds of certain oriental *Gardenia* spp.

Synthetic but 'nature-identical' carotenoids are also available as food colorants, principally β-carotene and β-apocarotenal. These are generally used in oil-based systems but may also be made water-dispersible by physical means (emulsification and encapsulation), and thus are commonly used for coloring cloudy-orange soft drinks. Canthaxanthin may be incorporated into the diet of farmed salmon to replace the carotenoids which wild fish would naturally consume, thereby insuring a pink flesh. Synthetic carotenoids and natural paprika and lutein extracts are also used in poultry feed to insure either that egg yolks are of the required color or that the skin of the chicken is of a suitable shade of yellow.

Curcumin, a deodorized turmeric extract, also provides a useful yellow pigment, although its application is limited by its sensitivity to light and its pH dependence. New application forms, however, now allow for its use in toppings and fillings for flour confectionery as well as its more common use in dairy products, desserts, sugar confectionery, soups, and sauces. It has found considerable application, together with annatto, in providing the yellow shade required for vanilla icecream and certain cookies (biscuits) and cakes.

Greens

Chlorophyl extracts are prepared using organic solvents from sources such as grass and lucerne leaves. The green extracts may be used to color fatty foods directly, but are more usually converted into their copper complexes to give a brighter green, followed by preparation of water-soluble sodium or potassium salts. In this form they are used to color sugar confectionery, frozen desserts, and dairy products.

Browns and Blacks

These colors are principally obtained by the use of synthetic caramels and carbon blacks. Four types of synthetic caramel are recognized, which differ in their solubilities and isoelectric points. This affects their stability towards such factors as protein binding (in beers) and alcohol-solubility (in spirits). The appropriate caramel must therefore be chosen for the product in hand. Class IV caramels E150(d) are used throughout the world to color cola beverages. Recently, 'natural' caramels based on malt extracts have also become available. All these colors are based on Maillard browning reactions. Brown pigments based on enzymatic oxidation have not generally been used for addition to food systems, principally

on account of their low tinctorial power and instability to further oxidation.

Carbon black is an insoluble pigment derived from the controlled combustion of plant material and is usually converted into a liquid suspension by milling into a carrier such as sugar syrup or fat. In this form it is used in the manufacture of black sugar confectionary.

Analysis of Natural Colors

Analysis of natural colors as individual pigments is really only possible using chromatographic techniques, although the use of tristimulus colorimetry is valuable in defining and maintaining the exact visual specification of a color in a foodstuff. Extraction of pigments requires specific techniques, e.g., acidified alcohol/water mixtures for anthocyanins, ethyl acetate or dichloromethane for carotenoids. Most analyses are nowadays carried out by high-performance liquid chromatography (HPLC) on reverse-phase columns. For anthocyanins, water/alcohol gradients at pH 1.5 are suitable. For carotenoids and chlorophyls, mixtures of dichloromethane, acetonitrile, and tetrahydrofuran are often used. Detection must be in the visible spectrum – diode array detectors can be helpful in confirming peak identity. Isolation of standards is often a major difficulty since few are commercially available.

In processed food the added pigments may be degraded or oxidized during processing, or may become so tightly bound to the food matrix that their total recovery is impossible. For these reasons the quantitation of added anthocyanins or carotenoids to a foodstuff is only approximate at best, especially if these pigments have themselves been added as naturally occurring mixtures without a defined composition. If simple synthetic β-carotene has been added to a food, it can be extracted by saponification under nitrogen followed by ether extraction and HPLC, and then quantified with reference to an external standard. However, the qualitative identification of pigment origin can be a powerful tool. For instance, fruit desserts colored with grapeskin or with black carrot extracts can be readily identified from each other, and likewise sauces colored with paprika extracts or β-carotene can be easily distinguished. Caramels and phenolic oxidation products cannot be analyzed as single chemical entities due to their heterogeneous nature, although the presence of byproducts such as hydroxymethylfurfural may be useful for the indirect assessment of caramel addition. New techniques such as capillary zone electrophoresis show promise for the analysis of charged materials such as the class IV E150(d) caramels.

Properties and Determinants of Synthetics Pigments

M J Scotter, Central Science Laboratory, Sand Hutton, York, UK

Introduction

This article will review the use of synthetic coloring materials in foodstuffs, structural classification, chemical stability, interactions with other food additives, usage in foods, and their qualitative and quantitative analysis.

Classification

Synthetic food colors classification can be simplified by grouping into the following chemical classes:

Table 1 Synthetic food colors currently permitted in the European Union and USA

Name	*E number*[a]	*FD&C classification*[b]	*Color index no.*[c]	*Structure type*	*Color shade*
Tartrazine	E 102	Yellow no. 5	19140	Azopyrazolone	Yellow
Quinoline yellow	E 104	None	47005	Quinoline	Greenish yellow
Sunset yellow FCF	E 110	Yellow no. 6	15985	Monoazo	Orange yellow
Carmoisine	E 122	None	14720	Monoazo	Bluish red
Amaranth	E 123	None	16185	Monoazo	Red
Ponceau 4R	E 124	None	16255	Monoazo	Orange red
Erythrosine	E 127	Red no. 3	45430	Xanthene	Bluish pink
Red 2G	E 128	None	18050	Monoazo	Bluish red
Allura red AC	E 129	Red no. 40	16035	Monoazo	Yellowish red
Patent blue V	E 131	None	42051	Triarylmethane	Violet blue
Indigo carmine	E 132	Blue no. 2	73015	Indigoid	Deep blue
Brilliant blue FCF	E 133	Blue no. 1	42090	Triarylmethane	Greenish blue
Green S	E 142	None	44090	Triarylmethane	Bluish green
Black PN	E 151	None	28440	Disazo	Bluish black
Brown FK	E 154	None		Azo[d]	Orange brown
Brown HT	E 155	None	20285	Disazo	Dark brown
Lithol rubine BK[e]	E 180	None	15850	Monoazo	Bluish red
Citrus red[f]		Red no. 2	12156	Monoazo	Scarlet red
Fast green FCF		Green no. 3	42053	Triarylmethane	Bluish green
Orange B[g]		Orange B	19235	Azopyrazolone	Orange

[a]As given in European parliament and Council Directive 94/326/EC on colors for use in foodstuffs.
[b]As published by the US Food and Drug Administration.
[c]As published by The Colour Index, Society of Colourists and Dyers, Bradford, UK.
[d]Mixture of six main components; only used for coloring kippers.
[e]For coloring of cheese rind only.
[f]For coloring of orange skins only.
[g]For coloring of casings or surfaces of frankfurters and sausages only.
Note: Yellow 2G is no longer permitted in the European Union.

- Azo (monoazo, disazo, and trisazo)
- Azo-pyrazolone
- Triarylmethane
- Xanthene
- Quinoline
- Indigoid

Table 1 lists the food colors currently permitted in the UK, European Union (EU), and USA and gives their structural classes.

Azo Food Colors

Azo dyes contain one or more chromophoric azo groups which are usually associated with aromatic systems containing salt-forming substituents generally in the *meta* or *para* position to the azo group. Azo dyes span a wide range of colors: one example is sunset yellow FCF (Figure 1a).

Azo-Pyrazolone Colors

Azo dyes which also contain a pyrazolone group exist essentially as keto-hydrazine tautomeric systems. A well-known example of an azo-pyrazolone dye is tartrazine (Figure 1b).

Triarylmethane Food Colors

Triarylmethane colors are characterized by the presence of a chromophoric system containing a central carbon atom attached to three aromatic moeties with amino, substituted amino and hydroxyl groups substituted in the *para* position, which act as auxochromes. One example of a triarylmethane food dye is green S (Figure 1c).

Xanthene Food Colors

Xanthene dyes are characterized by a chromophoric system comprising essentially a dibenzo-1,4-pyran heterocyclic ring system with amino or hydroxyl groups in the *meta* position with respect to the oxygen bridge. Erythrosine is the only example of a xanthene dye currently permitted for food use in the EU and the USA (Figure 1d).

Quinoline Food Colors

Quinoline yellow (Figure 1e) is the only example of a quinoline dye currently permitted for food use in the EU. The chromophoric system is based on the 2-(2-quinolyl)-1,3-indandione (or quinophthalone) heterocyclic ring system.

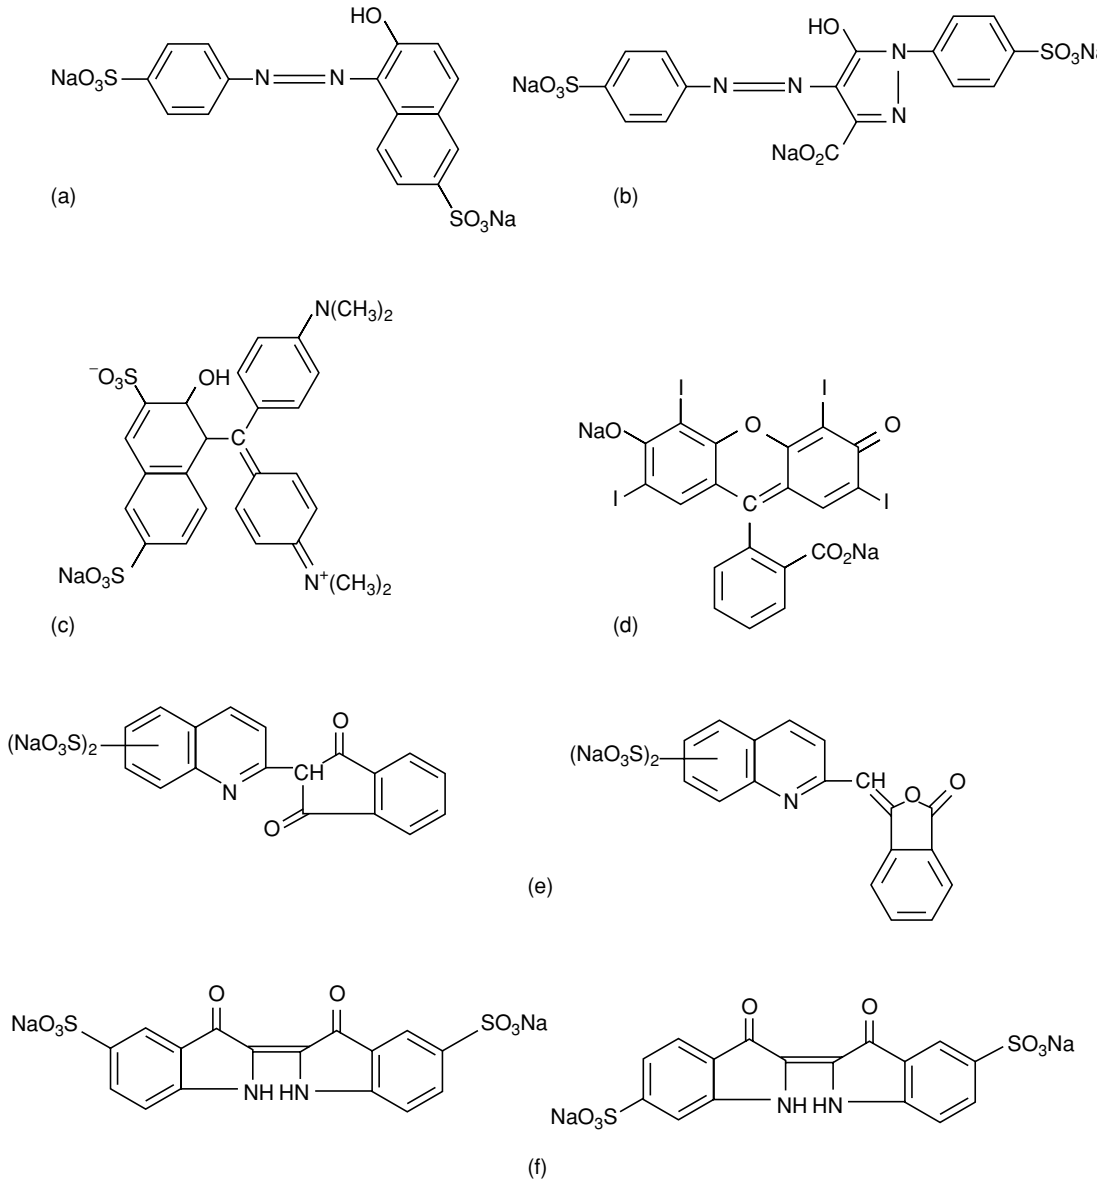

Figure 1 (a) Chemical structure of azo dye sunset yellow FCF. (b) Chemical structure of azo-pyrazolone dye tartrazine. (c) Chemical structure of triarylmethane dye green S. (d) Chemical structure of xanthene dye erythrosine. (e) Chemical structure of quinoline dye quinoline yellow, showing the two main coloring components. (f) Chemical structure of indigoid dye indigo carmine, showing the two main coloring components. Reproduced from Colours: Properties and Determination of Synthetic Pigments, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds) 1993, Academic Press.

Indigoid Food Colors

The only example of an indigoid dye currently permitted for food use in the EU and the USA is indigo carmine (Figure 1f), a blue-violet sulfonated analog of indigo, a naturally occurring dye which exists as a resonance equilibrium between two hybrid structures.

Pigments and Lakes

Pigments are dyestuffs which are generally insoluble in aqueous and organic solvents and have to be dispersed into foodstuffs to effect coloration. Precipitation of water-soluble dyes on to an inert substrate such as alumina forms water-insoluble pigments known as lakes:

$3(\text{Dyestuff-}SO_3^-) + Al^{3+} \rightarrow (\text{Dyestuff-}SO_3^-)_3Al^{3+}$ precipitated and extended on to $Al_2O_3.3H_2O$.

No synthetic liposoluble dyestuffs are permitted in the EU for the coloring of food. Synthetic nature-identical dyestuffs are generally not considered as synthetic food dyes.

Chemistry and Stability

All of the synthetic coloring materials permitted for food use in the EU and USA (except lithol rubine BK and citrus red, which have restricted use), apart from the lake colors, are soluble in water to a greater or lesser extent and insoluble in fats. The degree of water-solubility is determined by the number and relative position of salt-forming groups present in the dye molecule. The most common of these is the sulfonic acid group $-SO_3H$ and the less common carboxylic acid group $-CO_2H$, which form water-soluble anionic dyes. Cationic dyes contain basic groups such as amino $-NH_2$ or substituted amino $-NH.CH_3$, $-N(CH_3)_2$.

Most food dyes are soluble in certain nonaqueous hydrophilic solvents such as glycerine, propylene glycol, and sorbitol, and this allows the preparation of solutions and pastes for use in certain food products. The triarylmethanes and erythrosine are appreciably soluble in the lower alcohols ethanol and isopropyl alcohol. Turbidity or precipitation of color may be experienced upon interaction with hard water.

Coloring materials exhibit excellent stability when stored under cool, dry, and dark conditions. Many factors can and do contribute to colorant stability, such as heat, light, pH, redox systems, other food ingredients (especially preservatives), and trace metals.

Photodegradation

Light is capable of inducing photochemical changes in all dyestuffs, eventually leading to total decolorization. Resistance to photochemical degradation is termed light fastness. Heat, other various agents, and food ingredients are known to accelerate the photodegradation of dyestuffs, whereas others prove to have a stabilizing effect. True azo dyes can undergo three principal types of photochemical reaction; *cis-trans* photoisomerism, photoreduction, and photo-oxidation.

Thermal Degradation

Heat can cause losses of color during food processing and cooking. Coloring materials are added to products at the latter stages of and at the lowest possible temperatures during food processing when further heating is unlikely to take place. For all dyes, processing at very high temperatures will lead to an inevitable loss of color or change in shade due to carbonization.

Acids, Alkalis, and Redox Systems

Not all colors can be used over all pH values and some coloring materials, such as erythrosine, may precipitate from solution at acid pH, whereas others such as indigo carmine will fade rapidly. Color lakes often exhibit amphoteric properties, with both acids and alkalis tending to solubilize the inorganic substrate and thus releasing the free colorant (i.e., color 'bleed').

The majority of permitted food colors exhibit instability when used in combination with oxidizing and reducing agents. Since color depends on the existence of a conjugated unsaturated system within the dye molecule, any substance which modifies this system (e.g., oxidizing or reducing agents such as hydrogen, sugars, acids, and salts) will affect the color.

Metals

All dyes, those with the azo group in particular, will exhibit accelerated fading under both acid and alkaline conditions in the presence of metals including zinc, tin, aluminum, iron, and copper, especially at higher temperatures. This is mostly due to the reducing effect of liberated hydrogen. Dyes will often react with the metal in food cans at a rate proportional to their concentration.

Interaction with Other Food Additives

Preservatives

Canned products containing added color may degrade in the presence of tartaric and citric acids, which may react with the metal of the container to liberate hydrogen. The stability of nine red colors in comminuted meat products in the absence and presence of nitrite has shown that most of the dyes are destroyed to some extent but with nitrite more of the color survives. Subsidiary dye components and colorless fluorescent products are formed as a result of heat processing and in certain cases additional products are observed in the presence of nitrite. Nitrite can also cause rapid detinning to produce Sn^{2+}, a strong reducing agent. Sulfur dioxide is known to cause rapid decolorization of dye solutions. The interaction between sulfite and carmoisine results in the formation of a hydrazo compound via hydrolysis.

Ascorbic Acid

Azo dyes are known to degrade under accelerated conditions in the presence of ascorbic acid at pH 7 but are more resistant to degradation at pH 3. However, ascorbic acid at a concentration of 50 mg l^{-1} can affect all synthetic coloring materials at pH 3 after 3 days' storage at 20 °C.

Sugars

Reducing sugars such as glucose and fructose can reduce azo dyes in aqueous solution. Amaranth in particular may degrade when incorporated into reducing sugar-containing foods which are baked. The presence of baking soda can promote the degradation of the dye markedly in the presence of glucose.

Model Food Systems

During accelerated storage in model soft drink systems, tartrazine degrades very little. Amaranth and sunset yellow FCF are also stable to most additives, with the exception of ascorbic acid and sodium metabisulfite. In the latter case the degradation products appear to be higher-sulfonated analogs of the parent dyes. Prolonged storage under these conditions can therefore cause irreversible degradation leading to colorless products. The formation of specific amines from the degradation of amaranth has been used to estimate the amounts of dye added to soft drinks. Red dyes have been shown to degrade both before and after storage in fish paste products. Ponceau 4R may be reduced to a yellow by hydrogen sulfide or sulfur compounds liberated during processing and storage of certain foodstuffs, and erythrosine may lose iodine to produce fluorescein when incorporated in canned cherries and stored in unlacquered cans.

Color Usage in Processed Foods

Certain food processes have been associated with the use of food coloring matter for some time, principally to:

- reinforce colors already present in foods to meet consumer expectations
- insure uniformity of colour in batch productions
- restore the original appearance of certain foods when color has been, or will be, diminished during processing or storage
- give color to otherwise colorless foods such as candies (sweets), instant desserts, and ice lollies

Table 2 gives a brief summary of color usage in foods in the UK in 1987.

Dye Purity

Most of the dyes used for coloring foods comprise several colored components as well as the main dye. These are collectively known as subsidiary colors. The manufacture of a dye from its starting materials usually involves a number of synthetic stages and transformations such as reduction, amination, sulfonation, diazotization, condensation, and oxidation. The side-reaction products and the precursors of the dyes themselves are collectively known as 'intermediates' and in food dyes these are often sulfonated compounds. Table 3 lists those most commonly found in food colors. Coloring material specifications in general therefore contain criteria for limitations on subsidiary dyes and intermediates as well as certain unsulfonated or free aromatic amines. Separate criteria are prescribed for inorganic impurities such as transition metals, heavy metals, and certain salts.

Inorganic Impurities

The most commonly found inorganic impurities in food colors are sodium chloride and sodium sulfate. Small amounts of phosphate, acetate, carbonate, and iodide may also be present. The criteria for purity with respect to inorganic matter are somewhat different for lake colors.

Organic Impurities

The most common organic impurities present in synthetic coloring materials are small amounts of reaction intermediates. There may be various unsulfonated aromatic compounds as well as the sulfonated analogs present in the finished colorants owing to impurities in the starting materials. Triarylmethane dyes are prepared by condensation reactions during which an uncolored leuco base is formed as an intermediate. The leuco base is then oxidized to the fully conjugated colored dyestuff using oxidizing agents such as lead dioxide, manganese dioxide, or dichromate, which might then be present as low-level inorganic contaminants in the finished dye.

Analysis of Synthetic Food Colors

The major components of synthetic water-soluble food color formulations are active dye (including subsidiary dyes), inorganic salts, and moisture. Other constituents may be permitted diluents or extenders which may be added for standardization purposes or to facilitate the incorporation of the colorant for certain applications.

Table 2 Guide to synthetic food coloring usage in the UK[a]

Commodity class	*Food types*	*Stability requirements*[b]	*Additional comments*	*Permitted colors*[c]	*Typical levels of application (mg kg^{-1} or mg l^{-1})*
Soft drinks and other nonalcoholic beverages	Ready-to-drink cordials, vending machine concentrates, instant teas	LF, AC, PR, FL, TM	Must not accelerate corrosion of metal containers	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT	10–100 Proportionally higher in concentrates
Alcoholic beverages	Beers, ciders, fortified and aromatized wines, spirituous beverages	SD	Limited use	TZ, SY, AM, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN	Up to 200
Confectionery	Boiled sweets, toffees, caramels, gums, jellies, pastilles, licorice, chewing gum Decorations and coatings	TM, SD, FL, AC	Added as late as possible during production; colors often bright/intense	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN	50–300
Fine bakery wares	Biscuits, wafers, cakes, baking ingredients	TM	Raising agents may be present	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN	Up to 200
Soups		TM, AC	Requires consistent staining of product relative to carrying liquors	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN	Up to 50
Meat products	Breakfast sausage Burger meat Luncheon meat	TM, PR	Must show stability in and affinity for protein	AR, R2G AR, R2G AR	25, 20 -, 20 25, -
Meat and fish analogs	Based on vegetable proteins	TM, PR	Must show stability in and affinity for protein, Lakes often used	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN	Up to 100
Fish and fish products; shellfish	Smoked fish Salmon substitutes Surimi Fish roe Fish paste and crustacean paste Precooked crustaceans Kippers	TM, PR	Must show stability in brine and affinity for protein; surface coloring often used	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN; AM only in fish roe[e] BFK	100 500 500 300 100 250 20
Cheese	Flavored processed cheese Edible cheese rind Edible cheese casing	AC, PR	Color must not migrate from rind/casing into cheese	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN (LBK cheese rind only)	100 QS QS
Special dietary foods	Solid food supplements Liquid food supplements Complete formulae	Various	Most have special requirements	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN	Up to 300 Up to 100 Up to 50
Preserves	Jam, jelly, and marmalade Preserves of red fruits Candied fruits	TM, AC	Must be stable to high temperatures found in jam-making and migration	GS, P4R, SY, QY	Up to 100
Desserts, including flavored milk products	Blancmanges, custards, mousses, dry mixes, sauces Edible ices, icecream	TM, LF, GE	Lakes often used but must not show speckiness in product	TZ, SY, P4R, CA, BB, GS, AR, BV, IC, QY, BHT, BPN	Up to 150

Dye Content

Azo, triarylmethane, and indigoid dyes are readily reducible by tin (II) chloride, which forms the basis of the titrimetric assay method for dye content. Erythrosine (xanthene type) and quinoline yellow (quinophthalone type) are not reducible and have to be assayed by other means. However, erythrosine is the only commonly used food dye which is insoluble in dilute acid and which can consequently be assayed gravimetrically.

Simple spectrophotometric methods are commonly used for the assay of food dyes. Measurement in the ultraviolet/visible range on instruments with scanning and recording facilities is common. The use of high-performance liquid chromatography (HPLC) for the determination of dyestuff purity is also widespread.

Inorganic Salts

The classical method for the determination of chloride is by the precipitation of chloride as its silver salt. Sulfate may also be determined gravimetrically as the barium salt. Electrometric procedures may also be used for specific ion determination. Chloride, sulfate, and other ionic species may also be determined simultaneously using ion chromatography.

Moisture

Standard procedures for moisture determination are loss on drying, or by nonaqueous titrimetric techniques such as the Karl–Fischer procedure.

Lakes

Alumina is one of the major components of food lakes but is rarely determined. Food lakes are generally soluble in hot dilute ammonia solution and all alumina lakes, with the exception of erythrosine, dissolve readily in hot dilute hydrochloric acid. The resultant solutions give the identifiable reactions of aluminum with base and with alizarin. Qualitative identification of the parent dyes and quantitative analysis of the major and minor components of lakes can be carried out using similarly prescribed procedures as for the water-soluble analoges. Certain lake colors such as erythrosine may prove difficult to analyze and may require special procedures for analysis.

Table 3 Intermediate compounds commonly found in synthetic food colors

Intermediate name	*Trivial name*	*Occurrence*[a]
Aminobenzene	Aniline	R2G
1-Aminobenzenesulfonic acid	Sulfanilic acid	BPN,SY,TZ,Y 2G,BFK
4-Aminonaphthalene-1-sulfonic acid	Naphthionic acid	AM,CA,P4R,B HT
6-hydroxynaphthalene-2-sulfonic acid	Schaeffers acid	AM,P4R,SY,A R,GS
3-hydroxynaphthalene-2,7-disulfonic acid	R-Acid	AM,GS,P4R,S Y
7-Hydroxynaphthalene-1,3-disulfonic acid	G-acid	AM,P4R
7-Hydroxynaphthalene-1,3,6-trisulfonic acid		AM,P4R
4-Acetamido-5-hydroxynaphthalene-1,7-disulfonic acid	Acetyl K-Acid	BPN
8-Aminonaphthalene-2-sulfonic acid	1,7 Cleves acid	BPN
4-Amino-5-hydroxynaphthalene-1,7-disulfonic acid	K-Acid	BPN
4-Hydroxynathalene-1-sulfonic acid	N & W Acid	CA
5-Amino-4-hydroxynaphthalene-2,7-disulfonic acid	H-Acid	R2G
5-Acetamido-4-hydroxynaphthalene-2,7-disulfonic acid	Acetyl H-Acid	R2G
4,4∋-Diazoaminodi(benzenesulfonic acid)	Triazene	SY,TZ,Y2G
6,6∋-Oxydi(naphthalene-2-sulfonic acid)	DONS	SY
Tetrahydrosuccinic acid	Dioxytartaric acid	TZ
4-Hydrazinobenzenesulfonic acid		TZ
5-Oxo-1-(4-sulfophenyl)-2-pyrazoline-3-carboxyllic acid	SPCZ	TZ
2,5-Dichloro-4-(3-methyl-5-oxo-2-pyrazolin-1-yl) benzenesulfonic acid	CSPMZ	Y2G
Fluorescein		ERY
2,4,6-Triiodoresorcinol		ERY
2-(2,4-dihydroxy-3,5-diiodobenzoyl)benzoic acid		ERY
1-H-Indole-2,3-dione (and analogous sulfonic acids)	Isatin	IC
5-Sulfoanthranilic acid		IC
1-H-Indole-2,3-dioxo-1-H-indole-5-sulfonic acid	Monosulfonated indigo	IC
2-, 3-, and 4-Formylbenzenesulfonic acids		BB
N-Ethyl-N-(3-sulfobenzyl)sulfanilic acid	ESBSA	BB
m-Phenylenediamine		BFK
4-methyl-*m*-phenylenediamine		BFK
4,4∋-Bis(dimethylamino)benzhydrol alcohol		GS
4,4∋-Bis(dimethylamino)benzophenone		GS
N,N∋-Diethylaniline		BV
m-Hydroxybenzaldehyde		BV
2,4-Dihydroxybenzylalcohol		BHT
5-Amino-4-hydroxy-2-toluenesulfonic acid		AR
p-Hydroxybenzaldehyde-*o*-sulfonic acid		FG
α-(N-Ethylanilino)-*m*-toluenesulfonic acid		FG

[a]BPN, Black, PN; SY, Sunset yellow, FCF; TZ, Tartrazine; Y2G, Yellow 2G; BFK, Brown FK; AM, Amaranth; CA, Carmoisine; P4R, Ponceau 4R; BHT, Brown HT; R2G, red 2G; Ery, Erythrosine; IC, Indigo carmine; BB, brilliant blue FCF; GS, Green S; BV, patent blue V; AR, Allura red AC; FG, Fast green FCF.

Minor Components

Water-insoluble matter is calculated on the basis of 100% dye content and is usually determined by gravimetric procedures. Atomic absorption spectrophotometry has largely superseded the use of wet methods for trace heavy metals, mainly because of the speed with which analyses can be carried out and the high levels of accuracy and precision which can be attained. Other emergent techniques which have been used with limited application because of their high costs are inductively coupled plasma spectroscopy (ICPS), X-ray fluorescence (XRF, for mercury), and neutron activation analysis (NAA).

Organic Impurities

Ether-extractable matter content is usually determined by Soxhlet extraction and is applicable to all dyes except erythrosine.

Primary aromatic amines are usually determined by diazotization and coupling (to N-1-naphthylethylenediamine, NED) of an appropriate extract, followed by spectrophotometric measurement or

HPLC. HPLC has superseded classical column chromatographic procedures as the most widely used technique for the separation and quantitation of intermediate species. Both gas and thin-layer chromatography have also been used for the determination of certain intermediate compounds. The leuco base content of triarylmethane dyes is determined by carrying out further oxidation of the parent dyestuff and measuring the subsequent increase in absorbance.

Analysis of Foodstuffs for Synthetic Coloring Materials

Essentially food colors must first be extracted from the food matrix, purified to remove potentially interfering coextractives, and concentrated prior to identification and quantitation. Some form of sample pretreatment is often required, such as defatting of meat products or dilution of sugars and gums in confectionery products, before the extraction can proceed.

Leaching

Leaching may be used to remove colorants from the surface of foodstuffs such as sausages, and also from food-packaging materials. In the simplest application, the sample is soaked in an appropriate (usually alkaline) solvent which is then filtered or centrifuged to clarify the colorant solution. Further clean-up is performed as necessary. Newer techniques such as supercritical fluid extraction (SFE) may prove to be useful for the extraction of colorants, intermediates, and interaction products from foods.

Solvent-Solvent Extraction and Ion-Pair Techniques

These are widely used and effective methods of colorant isolation. Simple immiscible solvent pairs may be used where one solvent acts as a carrier for a dye-complexing reagent or soluble ion-exchange resin. The higher alcohols, particularly 1- and 2-butanol, are the most useful solvents for this technique. Amberlite LA-2, a liquid anion-exchange resin dissolved in butanol (or hexane), has been widely used as a dye-extraction medium for foodstuffs.

Quaternary ammonium compounds such as cetylcyclohexyl-dimethylammonium bromide (biocidan) and cetyltrimethyl-ammonium bromide (cetrimide) have been used for the extraction of synthetic dyes from food. More recently, reagents such as tetra-*n*-alkylammonium halides and cetylpyridinium chloride have also been employed for the rapid extraction of anionic dyes, as hydrophobic ion-pair complexes, from food using organic solvents.

Enzymatic Digestion

Pretreatment of a food sample by enzymatic digestion may be used prior to extraction of the colorants in order to release those colorants which may be highly bound or associated with the food matrix. Enzyme–substrate combinations that may be selected include papain (for protein digestion), lipase (lipids), phospholipase (phospholipid), amyloglucosidase (starch), pectinase (pectin), and cellulase (cellulose). Optimization of the pH and temperature conditions is necessary in each case.

Adsorption Techniques

Adsorption, generally referred to as solid-phase extraction (SPE), techniques have been developed for the isolation of food colorants utilizing a variety of adsorption materials such as wool, powdered leather, cellulose, alumina, and polyamide powder. More recently, semimicro adsorption cartridges containing reverse-phase bonded silica materials have found widespread use. Adsorption is achieved by either adding adsorbent directly to a pH-adjusted sample solution or by passage of the sample solution through a column packed with adsorbent. The absorbent is freed of other sample matrix components by washing with appropriate solvents and the colorants selectively desorbed using a different solvent, similar to those used in HPLC.

Dialysis Techniques

Dialysis has had limited application in the extraction and concentration of synthetic dyes from foods but has been used for the isolation and concentration of certain dyes from soft drinks and sugar-rich foods such as jellies and boiled sweets. These techniques are usually automated and employ SPE cartridges followed by HPLC.

Qualitative and Quantitative Analysis of Food Extracts

Spectrophotometry

Numerous techniques are available for the spectrophotometric analysis of colorants: measurements at ultraviolet and visible wavelengths are the easiest to perform. Beer's law can simply be applied to extracts containing single colors, whereas extracts containing two or more colors can be problematic. If the identities of the coloring components are known, their concentrations can be determined providing there is no interaction between them. The distinguishing features of the spectra obtained for single colors may be significantly affected by careful adjustment of the pH

of the solution with acid or alkali, characterized by shifts in absorption wavelength maxima and intensities. Simultaneous spectrophotometric determination of mixtures of food colorants without prior chemical separation has been applied to mixtures of up to five dyes. The data obtained are processed by chemometric approaches which utilize normal absorbance spectra as well as first- and second-order derivative spectra.

Other spectroscopic techniques, such as infrared, Raman (e.g., surface-enhanced scattering techniques), and nuclear magnetic resonance, have been used for the analysis of food colors but do not lend themselves to routine application.

Mass Spectrometry

Because of their inherent lack of volatility, direct analysis of sulfonated azo (and other) food dyes by mass spectrometry (MS) is very difficult. Several reaction schemes may be used to obtain various volatile neutral derivatives to facilitate analysis. Alternative ionization techniques other than electron impact (EI) and chemical ionization (CI) may be used for the analysis of food dyes but so far have had limited application. The most useful of these are fast-atom bombardment (FAB), field desorption (FD), and secondary-ion MS (SIMS). Liquid chromatography–mass spectroscopy techniques are beginning to find use as 'benchtop' instruments become more widespread. Atmospheric pressure chemical ionization (APCI) in positive and negative ion modes as well as pneumatically assisted electrospray have been used to determine mono- and disulfonated azo dyes.

Polarography

Differential pulsed polarography and differential pulse adsorptive stripping voltammetry may be used to estimate dye concentrations in food matrices. The addition of gelatin has been found to be advantageous in the partial identification and determination of food colors due to its pronounced affects on measured peak currents.

Electrophoresis

Of the various electrophoretic techniques available, paper electrophoresis has been the most widely used for the analysis of food colors, utilizing a range of different buffer systems and applied potentials. Cellulose acetate and polyacrylamide gel have been used for the electrophoretic separation of azo and triarylmethane dyes.

Capillary zone electrophoresis (CZE) is an analytical technique that has proven to be applicable to the analysis of food dyes, especially when coupled to photodiode array detectors. The separation of synthetic dyes is influenced by buffer composition, pH, and additives such as cyclodextrins. The related technique micellular electrokinetic capillary chromatography (MEKC) has also found application in the analysis of synthetic food dyes. Mixtures of food dyes may be separated and determined simultaneously. Buffered mobile phases modified with acetonitrile or methanol and containing other additives are often used. Both techniques may be automated readily.

Gas Chromatography

Gas chromatography cannot be used for the direct analysis of food dyes owing to their inherent lack of volatility. It is however a useful technique for the analysis of volatile derivatives and certain intermediate compounds.

Paper Chromatography

Paper chromatographic techniques have been widely used in the past for the identification of food colors but have nowadays been largely superseded by thin-layer, column, and HPLC techniques. Paper chromatography maintains popularity in some laboratories because of its relatively low cost and ease of use, and many suitable solvent systems are available.

Thin-Layer Chromatography

The use of thin-layer chromatographic systems for the separation of food dyes is fairly widespread, but is gradually being superseded by HPLC. Silica gel is the most commonly reported adsorbent used, though alumina, microcrystalline cellulose, and high-performance reverse-phase bonded silicas have widespread use. High-performance thin-layer chromatography with densitometric detection has been used for the determination of dyes in alcoholic and nonalcoholic beverages.

High-Performance Liquid Chromatography

HPLC has become the major analytical technique for the determination of synthetic coloring materials in foodstuffs. The most widely used separation modes are ion-exchange and reverse-phase. Spectrophotometric detection is applied in the visible wavelength range for dyes and subsidiary colors or in the ultraviolet range for intermediates and other organic impurities.

Ion-Exchange HPLC

Dyes, subsidiary colors, intermediates, and impurities have all been characterized using ion exchange,

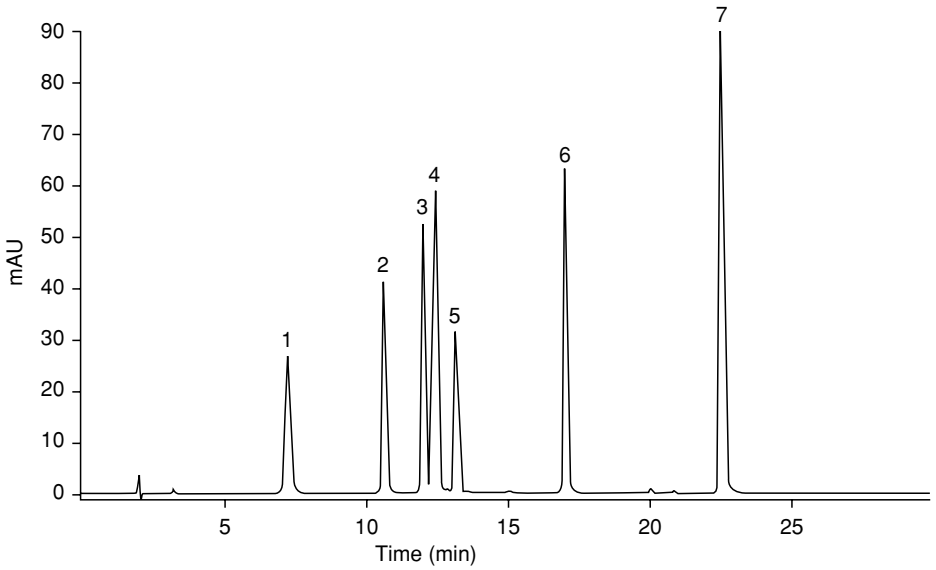

Figure 2 High-performance liquid chromatographic (HPLC) chromatogram of red dye mixture separated by reverse-phase ion-pair gradient elution. Conditions: solvent A = 0.005 mol l^{-1} tetrabutylammonium bromide (TBAB) in methanol, solvent B = 0.005 mol l^{-1} TBAB in 0.01 mol l^{-1} KH_2PO_4. Gradient elution profile: 50:50 to 100:0 (A:B) over 30 min linear, 10 min hold; solvent flow rate = 0.4 ml min^{-1}; column: ODS 20 cm; detection wavelength: 520 nm. Peak identification: 1, amaranth; 2, allura red AC; 3,red 10B – nonpermitted analog of 4, Red 2 G; 5, ponceau 4R; 6, carmoisine; 7, erythrosine. Reproduced from Colours: Properties and Determination of Synthetic Pigments, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds) 1993, Academic Press.

mostly on strong anion exchange (SAX) columns using buffered mobile phases such as borate and perchlorate mixtures and gradient elution. Azo dyes and sulfonated intermediates can be separated using weak anion exchange (WAX) columns with citric acid mobile phase at pH 2.8. Because of poor reproducibility (notably with the use of gradient elution), the requirement for aggressive buffer systems and its consequently relatively short column life, ion exchange has been largely superseded by reverse-phase HPLC for the analysis of synthetic water-soluble dyestuffs.

Reverse-Phase HPLC

Synthetic dyes require buffered eluants to achieve optimum pH conditions for desired separations on reverse-phase HPLC, usually with organic mobile phase modifiers methanol or acetonitrile. The column materials used are short-chain (C_2), octyl (C_8), and octadecyl (C_{18}) alkyl-bonded silicas, though other bonded phases such as amino ($-NH_2$) and cyano ($-CN$) have also been employed. Considerable interest has been shown in the use of macroporous and highly cross-linked polystyrene-divinylbenzene copolymer column packing materials. The mobile phase may alter the affinity of ionic species for the stationary phase by both ion suppression and ion-pairing mechanisms.

Reverse-phase-HPLC with ion suppression has been used to separate and identify various dyes, eluting with phosphate buffers at various pH values and methanol. Ammonium acetate has recently been successfully used in this mode of reverse-phase HPLC.

Ion-pair HPLC is perhaps the most widely used chromatographic technique for the analysis of dyes, subsidiary colors, and uncombined intermediates in foodstuffs. Many published methods are available. Most favored are ion-pair reagents derived from quaternary ammonium compounds such as cetyltrimethylammonium bromide (cetrimide) and tetrabutylammonium phosphate. Again, buffered mobile phases modified with organic solvents are generally used.

Both isocratic and gradient systems can be employed to separate dye mixtures; the latter is often preferred for the separation of complex mixtures. Modern high-performance and computer-aided instrumentation permits the use of many powerful techniques which may be readily applied to aid in the analysis of dyestuffs. These include:

- automated sample handling and processing
- automated chromatographic methods development
- high-sensitivity multiple-wavelength and diode-array detectors

- postrun qualitative and quantitative analysis
- liquid chromatography–mass spectrometry interfacing

Figure 2 shows a typical chromatogram of the separation of red food colors by gradient ion-pair HPLC. It is possible to separate many of the UK-permitted and several nonpermitted dyes on a single column system by employing a combination of ion-pair gradient elution and selective wavelength detection.

Diode Array Detection

Diode array detectors have the ability to record the entire spectral range of an eluting dye component during an analysis. Absorbance data may be collected simultaneously from 190 nm to as high as 800 nm and is achieved in real time. The diode array detector allows the precise determination of absorption maxima of adequately separated solutes and facilitates positive peak identification and peak purity analysis by rapid spectral scanning. Chromatographic peaks may be identified by reference to spectral libraries of previously run reference compounds. Multiple wavelength monitoring with absorbance rationing may be used to characterize and identify multicomponent dye mixtures in single chromatographic runs. Chemometric techniques similar to those used in direct spectrophotometry have been used to characterize and quantify dye mixtures.

These and other analogous methods and techniques are also used for the detection and quantification of nonpermitted dyes in foods.

COMMUNITY NUTRITION

J Cade, University of Leeds, Leeds, UK

Introduction

Community nutrition incorporates the study of nutrition and the promotion of good health through food and nutrient intake in populations. This article will consider aspects of community nutrition relating to dietary goals and recommendations for populations; methods of assessing diet in population groups; and promoting healthy eating at the community level.

Community nutrition (public health nutrition) requires a population approach. The community rather than the individual is the focus of interest. This area of nutrition focuses on the promotion of good health and the primary prevention of diet-related illness. The emphasis is on maintenance of health in the whole population, although it will also include working with high-risk groups and other subgroups within the population. Community nutrition includes nutritional surveillance; epidemiological studies of diet; and also the development, implementation, and evaluation of dietary recommendations and goals. A community may be any group of individuals, for example, the population of a town or country, or the residents of an old people's home.

Advice to the Community

Dietary advice to the community has changed over the years, depending on the nutrition-related diseases of importance at the time and our understanding of how they are caused. In the 1930s, for example, the primary concern in Europe and North America was the elimination of deficiency diseases. The concept of a balanced diet was developed to try to provide the minimum requirements of protein, vitamins, and minerals. By the late 1950s, research suggested that some chronic diseases could be related to overnutrition and dieting to lose weight became popular. For example, it was recommended that bread and potato intake should be restricted to help avoid overweight. However, by the 1980s, wholemeal bread and jacket potatoes were being promoted as good sources of dietary fiber.

Recommended dietary allowances (RDAs) for populations were first set in the 1930s and have been revised at regular intervals. The current UK recommendations were published in 1991, and are known as dietary reference values (DRV). They include the reference nutrient intake (RNI) level which is the amount of a nutrient (excluding energy) which is sufficient for almost any individual. The RNI is 2 standard deviations higher than the estimated average requirement and as such is higher than most people need. RNI must be interpreted carefully when used in nutrition education and is not intended to be used by individual members of the public as a guide.

Dietary goals or guidelines, on the other hand, aim to reduce the chances of developing chronic degenerative diseases and are based on data from animal experiments, metabolic studies, clinical trials, and epidemiological research. They give targets for the population to aim at for some future time. The first set of dietary goals was published in Sweden in 1968. The UK has published its own goals. Nutrition goals were included in the Health of the Nation White Paper (1992). Further goals were included in the Department of Health's report in 1994 from the Committee on Medical Aspects of Food Policy (COMA) on diet and cardiovascular disease. The World Health Organization (WHO) has also published population nutrient goals in 1990. These are recommended for use in all parts of the world and have been expressed in absolute terms rather than increases or decreases in existing nutrient intake. The desirable change will then vary with the population. For example, in some developing countries the goal for fat intake (lower limit) suggests the need to increase average intakes slightly. Conversely, for most industrialized countries a reduced fat intake is desirable. Table 1 summarizes the COMA, Health of the Nation, and WHO nutrient goals.

The recommendations are based on the best available evidence and may need to be changed in future. For example, in the future they may need to address optimal nutritional status.

Assessing Adequate Nutritional Status

In order to advise the community we need to know what the community is already eating. The nutritional status of the community can be defined as the presence or absence of diet-related diseases and is related to the health and well-being of the community. There is no simple or single way to measure it so that information has to be gathered from many sources.

Food and Nutrient Supply

National level Information on national food availability is collected annually by many governments in the form of food balance sheets. The Food and Agriculture Organization (FAO) collects and publishes

Table 1 Comparison of dietary goals from the World Health Organization (WHO), Committee on Medical Aspects of Food Policy (COMA), and Department of Health, Health of the Nation

	WHO		*COMA*	*Health of the Nation goals by 2005*	*Dietary reference value*[a]
	Lower	*Upper*			
Total energy (MJ)	[b]		Maintain desirable body weight	↓ Obesity –	
Males				to no more than 6% men	10.6[c]
Females				to no more than 8% women	8.1
Total fat	15	30	↓ to about 35%	↓by 12%, to no more than 35%	33 (35)[d]
Saturated	0	10	↓to no more than 10%	↓ by 35%, to no more than 11%	10 (11)[d]
Polyunsaturated	3	7	*n*-6 PUFA: no further ↑ *n*-3 PUFA: ↑ from 0.1 to 0.2 g day^{-1}		6 (6.5)[d]
Cholesterol (mg day^{-1})	0	300	No increase		
Total carbohydrate (CHO)	55	75	50		47 (50)[d]
Complex CHO	50	70	Increase		37 (39)[de]
Free sugars	0	10	Increase from fruit and vegetables		10[f](11)[d]
Dietary fiber (g day^{-1})	27	40			18[g]
Protein	10	15			
Salt (g day^{-1})		6	6		1.6
Alcohol					

Units are percent total energy unless otherwise stated.
[a]Values are population averages.
[b]Energy intake to allow normal growth, pregnancy, lactation, work, activities and to maintain appropriate body reserves. Body mass index (kg m^{-2}) in adults = 20–22.
[c]Estimated average requirement for men and women, aged 19–49 years, physical activity level 1.4.
[d]Figures in brackets represent percentage of food energy.
[e]Intrinsic and milk sugars and starch.
[f]Nonstarch polysaccharides.
[g]Nonmilk extrinsic sugars.
PUFA, polyunsaturated fatty acids.

these statistics. It lists the total quantity of different foods available for consumption in a country during a specified time (usually one year). Data are limited since there is no information available about subgroups of the population by region, ethnicity, age, or socioeconomic level. Its accuracy is variable, especially for areas with subsistence farming.

Food balance sheets can be used to assess available energy and nutrient intakes per capita. Comparing changes over years can indicate trends towards or away from national food security.

Household level The National Food Survey carried out by the UK Ministry of Agriculture, Fisheries and Food (MAFF) assesses trends in food supplies and, by inference, the food eaten. Nutrient intake can be calculated from these data. It records food purchased rather than food eaten and does not distinguish between the intakes of men, women, and children, nor does it include alcohol, candies (sweets), and soft drinks.

As shown in Table 2, the National Food Survey is particularly useful for assessing trends in food and nutrient intake. In general, the food supply was consistent with the amounts recommended to cover the needs of most of the population.

Itemized till receipts have also been shown to be a good reflector of energy and fat intake in the household in families which purchase the majority of their food at supermarkets.

Individual level Assessing diet at the individual level is usually done by survey. These use several different methods such as a weighed intake, dietary recall or record, or a food frequency questionnaire. Attempts have been made to validate the resulting nutrient levels by measuring biological markers. Surveys may look at a representative sample of the population or a particular at-risk group. The UK government has commissioned a series of regular surveys known as the National Diet and Nutrition Surveys. The first one of British adults was published in 1990. It aimed to recruit a nationally representative sample of adults aged 16–64 living in private households in the UK to inform food and health policy development and evaluation. Subsequent surveys have studied preschool children, the elderly, and young people. A second national survey of adults is currently underway.

Anthropometric Measurements

Weight and height can be used to assess the level of malnutrition or obesity by comparison with reference data. Height can give evidence of past chronic malnutrition, whereas weight is more useful in assessing recent nutritional experience. Overweight or obesity

Table 2 Nutrient intake from the UK National Food Survey, expressed as a percentage of recommended intakes current at the time of the survey

	1958[a]	*1968*[b]	*1978*[b]	*1988*[c]	*1998*[d]
Energy (kcal)	104	108	94	91	93
Protein (g)	100	127	121	123	147
Calcium (mg)	107	191	181	159	119

Report on Health and Social Subjects 41*. London: HMSO. Nutrient values from Ministry of Agriculture, Fisheries and Food National Food Survey for years stated.

is most practically assessed using the body mass index (weight in kg/height in m^2).

Health Statistics

Birth statistics such as neonatal, perinatal, or infant mortality rates provide indirect information about the nutritional status of a community, particularly its disadvantaged groups. Death rates for diseases which have a nutritional cause can also indicate nutritional status in the community.

Qualitative Data

Useful information about community food and nutrient patterns can be obtained using qualitative methodologies, such as informal interviews or focus group discussions. If carefully carried out, these methods can supplement data collected in the quantitative methods described above and provide an indepth understanding of issues such as motivations, food choices, and particular food habits.

Success Level of General Advice

In order to change a population's diet, DRVs and goals must have scientific credibility, political and technical support, and be recognized as being necessary and acceptable to the consumer. It may take years to achieve the desirable change.

Is the population meeting the DRVs for the UK population? The results of three National Diet and Nutrition Studies (NDNS) in the British population showing the percentage who met the UK dietary goals are presented in Table 3. Most subjects ate more total fat, saturated fat, and refined sugars and less carbohydrate and fiber than recommended. A comparison with a subgroup of 15 000 women from the UK Women's Cohort Study shows that in this health-conscious group more people were able to achieve the dietary goals than in the earlier NDNS study of adult women.

People who consume diets which meet the nutrient goals are more likely to eat cereals, wholemeal and brown bread, skimmed or semiskimmed milk, polyunsaturated margarine, fruit, vegetables including potatoes, low-fat meat, and nonfried fish. They also eat less white bread, butter, margarine, whole milk, high-fat cheese, eggs, fatty meat, and fried fish than those who do not meet the goals. To achieve a particularly healthy diet independent predictive factors have been found to be spending more money on food, being a vegetarian, having a higher energy intake, and a lower body mass index, and being older. Extra costs of the food may make the cost of a diet which meets the dietary goals too expensive for the elderly, unemployed, and low-paid. It is worth noting, however, that it is possible to consume a diet which meets the dietary goals which is substantially cheaper than the average cost of a diet which does not meet the goals.

The National Food Survey can monitor progress made by a population towards meeting the goals. It has been analyzed for a 50-year period from 1940 to 1992. There has been a decline in the percentage of food energy from carbohydrate and an increase in the proportion from fat (Figure 1). There have been substantial changes in the types and quantities of foods consumed over this period. Bread consumption has fallen over this period from around 250 g day^{-1} in 1940 to 110 g day^{-1} in 1992 (Figure 2). Fresh potato consumption has also declined, but fruit and other vegetable consumption has increased from about 200 g day^{-1} to 300 g day^{-1} (Figure 3).

Community versus Individual Advice

Public health examines risk factors for disease in the population as a whole and then designs prevention strategies to reduce them. Meanwhile, the clinician does the same for the individual patient.

Dietary goals for the population are based on identifying population intakes to maintain health. Health is defined as a low rate of diet-related diseases. In assessing whether a population is meeting the dietary goal it is the entire range of nutrient intake which matters. If the intake is normally distributed within the population, then it can be summarized by the average intake of the population and its standard error.

Dietary goals require a population approach to dietary change leading to a change in the average intake. This will result in some individuals consuming more and some less than the stated goal.

Table 3 Percentage of population meeting dietary goals

Dietary goal	*NDNS UK adults (1986–87)*[a]		*NDNS 1½–4½ years (1992–93)*[b]		*NDNS 65 years + free-living (1994–95)*		*UK Women's Cohort (1995)*[d] *Health-conscious women*
	Men	*Women*	*Boys*	*Girls*	*Men*	*Women*	
Total fat $\leq$ 35% food energy	12	15	42[e]	42[e]	46	41	
Saturated fat $\leq$ 15% food energy	11	12	38[f]	38[f]	59	48	43[g]
Total carbohydrate > 50% energy	9	12	60[h]	57[h]	31	30	54[i]
Refined sugars[k] < 10% food energy			12	13	30	36	
Fiber > 25 g day^{-1}	45	16			3[l]	1[l]	32[j]

Note that the goals are not meant to refer to children – the preschool age children survey has been included for comparison.

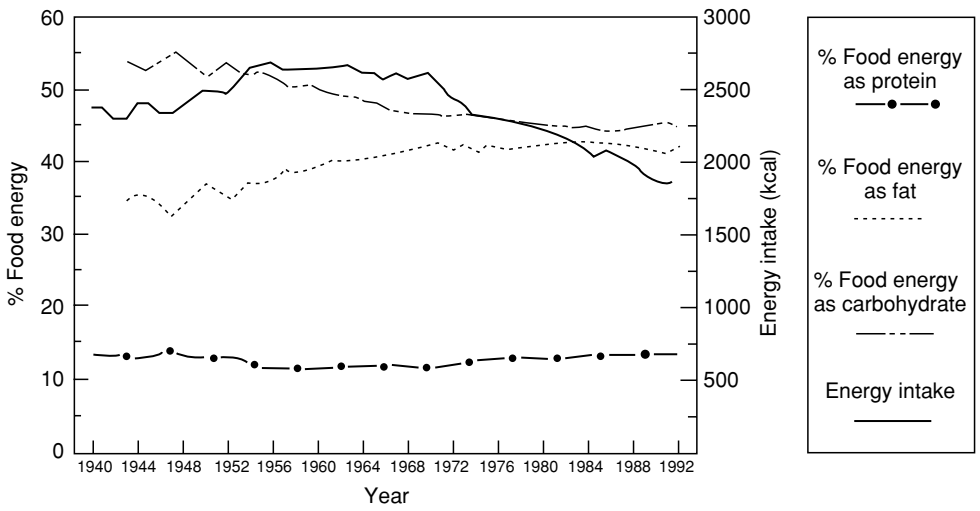

Figure 1 Trends in proportion of daily energy intake in the British diet derived from carbohydrate, fat, and protein (National Food Survey 1940–1992). From Department of Health (1994) *Nutritional Aspects of Cardiovascular Disease. Report on Health and Social Subjects 46*. London: HMSO with permission.

Methods of Giving Advice to the Community

Much can be done to change a population's diet. Diets are chosen by individuals; government should not enforce recommendations concerning diet and health by restrictive legislation. Legislation concerning the production and sale of food does however affect a nation's diet. An alternative approach to change is to increase people's knowledge and awareness of food and its relationship to health.

Health Promotion

Traditionally, nutrition education campaigns have involved only one or two sections of the community such as schools or the media. Success, if it was measured at all, was limited. A more integrated approach is to involve as many groups of the community

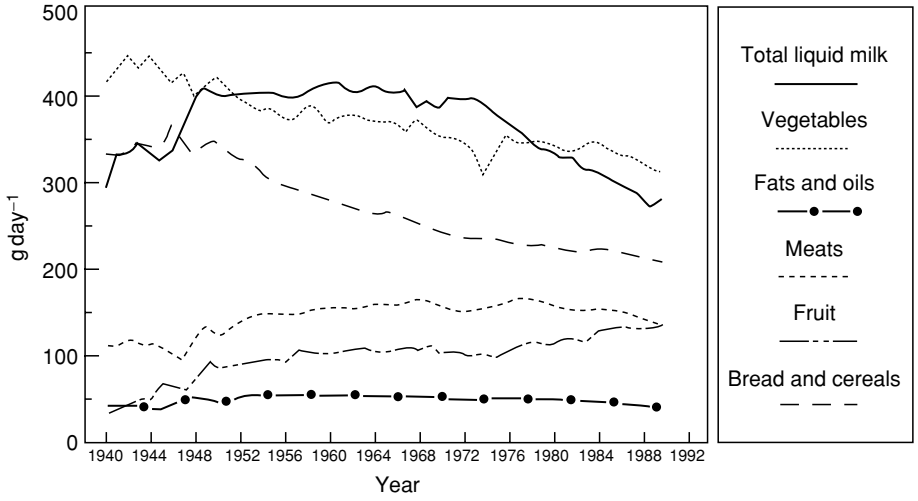

Figure 2 Consumption of selected foods. From Department of Health (1994) *Nutritional Aspects of Cardiovascular Disease. Report on Health and Social Subjects 46*. London: HMSO with permission.

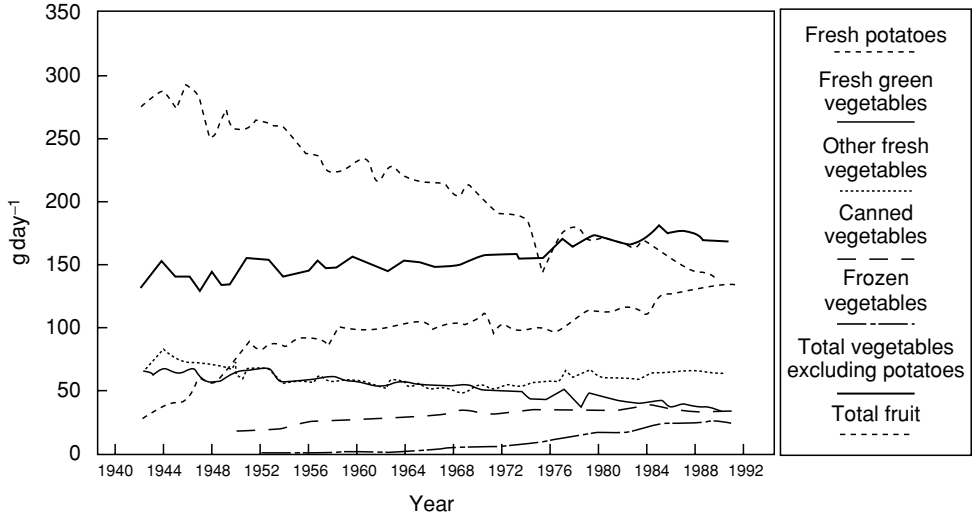

Figure 3 Trends in consumption of vegetables and fruit. From Department of Health (1994) *Nutritional Aspects of Cardiovascular Disease. Report on Health and Social Subjects 46*. London: HMSO with permission.

as possible and to use a variety of educational approaches. For example, Heart-Beat Wales is a health promotion program which involves public education, lay groups, schools, factories, retailers, and others. Look After Your Heart is a multidisciplinary government-backed campaign to reduce risk factors for coronary heart disease. Evaluating the success of these campaigns in terms of reduction of deaths from heart disease is difficult. With regard to lowering fat intake, general recommendations to the public without individual dietary counseling are not very effective. Despite educational campaigns to lower fat intake, the level of saturated fat intake in Europe remains considerably higher than desired.

Knowledge of the health risks of a food does not inevitably lead to a change in its consumption. Why people eat what they do is determined by a number of factors; the health effects of a food may only have a minor influence. Understanding these factors involves the application of psychological models such as the Theory of Planned Behavior or the Stages of Change model. These models explore issues such as beliefs about food and motivations for changing intakes. Health education can change consumers' purchasing and eating habits. For example, the national promotion of low-fat milk immediately increased its consumption by 20%. Leaflets are often used, but are ineffective with mass distribution.

The media can have an important influence on choice of foods consumed. This has been demonstrated recently by the concerns over new-variant Creutzfelt–Jakob syndrome from infected beef and unknown risks associated with genetically modified foods. Media reports have raised awareness of these issues and people have altered their food intake patterns, although there is no evidence to suggest that these changes have been detrimental to overall nutritional status.

Health Professionals

General practitioners are encouraged to provide health promotion, but have little training in nutrition. Patients are rarely referred to a dietitian; the practice nurse often provides most of the advice. Dietary advice provided by untrained members of the primary health care team can be misleading. Community dietitians can provide group-based training and education. The UK Nutrition Society is now recognizing a group of nutritionists with experience in community nutrition and awarding an accreditation in public health nutrition.

Most district health authorities have their own food and health policies which are often limited to measures within their own services. Potential contributors to these policies are groups within the community such as local shopkeepers, industry, and trade unions. Health action zones have been set up to address inequalities in health in the community. Some have incorporated nutrition and access to food as priorities.

Food Labeling

Food should be appropriately and comprehensibly labeled to aid consumer choice. As yet, there is no standard format for labels. The format for nutrition labeling of foods and food claims is regulated by Codex Alimentarius, or the food code. This is a global reference point and deals with creating food standards. Nutrition labeling is often difficult to understand. Supplying the consumer with nutrition information through the internet or in-store computer terminals as well as highlighting the most important information may solve the problem of demands for both more and understandable information.

Web-based Resources

Knowledge of nutrition and health can be acquired from the internet. Recent figures suggest that around 16 million people have access to the internet in the UK. This figure is increasing. It is important for sites to be rated in terms of content, credibility, and usability. A number of sites are on the fringe of conventional nutrition and may be promoting information which is unhelpful or confusing. NHS Direct has been set up to provide telephone or web-based health advice and includes a nutrition component.

Reaching Vulnerable Groups

Nutrition advice should take account of the special needs of particular subgroups, who may be vulnerable to malnutrition due to their physiological requirements, their cultural traditions, or their economic problems.

Babies and Young Children

The health professions have a role in promoting breast-feeding and the preparation of culturally acceptable and appropriate weaning foods. In the UK, in order to meet the current dietary goals the diet is likely to increase in bulk and so reduce energy density. It is important to maintain adequate energy intakes by not changing babies on to low-fat milks too early. Children in lone-parent families tend to have lower carotene and vitamin C intakes than other children. Growth monitoring, particularly in developing countries, can be used to detect growth faltering. Remedial action can then be taken.

Adolescents

On the whole this group is adequately nourished. There is some concern, however, at the low levels of iron intake in teenage girls. Adolescents on slimming diets may be at risk of low intakes of some micronutrients. Appropriate nutrition education at school, backed up with the provision of healthy school meals, may help to encourage suitable nutritional habits in this group.

Pregnancy and Lactation

Most pregnant and lactating women in the UK consume an adequate diet. This is, however, a time when women come into contact with health care services and may be open to nutrition education. Young girls and other women at risk of having a low-birth-weight baby should have particular attention paid to their dietary intake. Periconceptual folate supplements are recommended to prevent neural tube defects.

Elderly

The current dietary goals are appropriate for the elderly. Energy intakes tend to decrease with increasing age and there is a need for the elderly to consume diets with an increased nutrient density. Health professionals and other carers need to be aware of the potential for the elderly to be consuming an inadequate diet. The NDNS for people aged 65 and over found that intakes of vitamin D, Mg, K, and Cu

were low. A substantial proportion of people living in institutions had low biochemical status indices for vitamin C, Fe, and folate.

Low-income Groups

Families on a low income and those living in temporary accommodation may find it difficult to eat a diet which meets the recommendations. There is particular concern for people living in socially disadvantaged areas since there is a greater risk of birth abnormalities and a higher incidence of diseases such as coronary heart disease and cancer in the adult population.

Ethnic Groups

Many aspects of different ethnic dietary patterns will promote health, such as high fruit or vegetable intakes. Some ethnic groups, however, also consume diets which are characterized by a high fat intake and certain groups have a higher prevalence of obesity, diabetes, and coronary heart disease. In some communities women and children may be at risk of vitamin D deficiency. Culturally acceptable nutrition education needs to be in a form that can be understood by the whole community. Personal intervention by a trained member of the local community may give the best results.

CONDENSED MILK

H J Hess, Nestec Ltd, Vevey, Switzerland

Background

Industrial production for both sweetened and unsweetened condensed milk started around the middle of the nineteenth century. However at the beginning of the nineteenth century, food scientists in Europe, mainly in France and England, and in the USA had been working on the possibility of preserving milk as a concentrated liquid. Both products have their industrial roots in the USA.

The first sweetened condensed milk in hermetically sealed cans was manufactured and sold in 1856 by Gail Borden in the USA. The business grew rapidly and spread to Europe by 1866 where a sweetened condensed milk factory was set up in Cham, Switzerland, by Charles A. Page, a US consul assigned to the country. The rapid success of this Swiss-based company within Europe led eventually to an expansion of its manufacturing facilities in the USA. This organization, registered as the Anglo-Swiss Condensed Milk Company, sold its US interest in 1902 to a company established and registered at the end of the nineteenth century as the Borden Condensed Milk Company. In 1904, the remaining European interests of the Anglo-Swiss Company merged with Henry Nestlé, of Vevey, Switzerland, who also manufactured this product. The new company was called the Nestlé-Anglo-Swiss Condensed Milk Company.

Until the early 1880s, unsweetened condensed milk was also produced and was sold open in the market

due to the lack of knowledge and success of long-life preservation at that time.

The basic process for preservation of unsweetened condensed milk by heat sterilization was conceived by John B. Meyenberg in 1882, a Swiss citizen, and an employee of the Anglo-Swiss Condensed Milk Company. The idea of preserving milk without the addition of sugar was made possible by his invention of a revolving sterilizer working with steam under pressure. Lacking sufficient support from his company to continue his work, he migrated, in 1884, to the USA and also obtained a patent for his invention in that country. In 1885, Mr Meyenberg was cofounder of the Helvetia Milk Condensing Company in the State of Illinois, and during the same year, he achieved the first successful manufacture of unsweetened condensed milk. The name of this product was changed to evaporated milk for a clearer distinction from sweetened condensed milk, a situation that prevails today.

The initial phase of commercial production of both products was hampered by various problems and quality defects. Only at the beginning of the twentieth century were constant quality standards reached.

Definition of Products

Sweetened Condensed Milk

Sweetened condensed milk is made by the addition of sugar to whole milk and the removal of water from the milk to about one-half of its original volume. The product is canned or packaged in other containers without sterilization, with the sugar acting as a preservative. International standards prescribe:

- a minimum milk fat content of 8%;
- a minimum milk solids content of 28%.

The minimum sugar content is often not specified precisely but should be sufficient to avoid spoilage.

Permitted stabilizers are usually specified as sodium, potassium, and calcium salts of:

- hydrochloric acid;
- citric acid;
- carbonic acid;
- orthophosphoric acid;
- polyphosphoric acid.

The name of the product may be:

- sweetened condensed milk;
- sweetened condensed whole milk; or
- sweetened full-cream condensed milk.

Legislation in some countries requires a somewhat higher milk solids and fat content, usually 9% milk fat and 31% total milk solids. However, there are also provisions for skimmed sweetened condensed milk with a milk solids content up to 24% and low-fat compositions, in principle, of 4% fat and 24% total milk solids.

Frequently, this product is fortified by the addition of vitamins, mainly A, D_3, and B_1. (*See* **Food Fortification**.)

Evaporated Milk

Evaporated milk is made by removal or evaporation of water from milk but without the addition of sugar or any other preservative material. The canned product is heat-sterilized at 118–122 °C for several minutes. The product also may be packed in any other sterilizable container.

International standards prescribe:

- a minimum milk fat content of 7.5%;
- a minimum milk solids content of 25.0%.

Permitted stabilizers are usually specified as sodium, potassium, and calcium salts of:

- hydrochloric acid;
- citric acid;
- carbonic acid;
- orthophosphoric acid;
- polyphosphoric acid.

In addition, some legislation permits the addition of carrageenan up to 150 p.p.m.

The main name of the product is:

- evaporated milk;
- evaporated full-cream milk; or
- unsweetened condensed full-cream milk.

Legislation in some countries requires a somewhat higher fat and milk solids content, up to 9 and 31%, respectively. However, there are also provisions for either skimmed or low-fat evaporated milks:

- skimmed evaporated milk with a minimum of 20% milk solids;
- low-fat evaporated milks, 4 or even 2% milk fat and a milk solids content of 20–24%.

Fortification with vitamins of either or both A or D_3 is common practice.

Recombined Milk Products

Sweetened condensed milk and evaporated milk are often recombined in countries outside the traditional dairy belt. (*See* **Recombined and Filled Milks**.)

For recombining, imported skim milk powder and anhydrous milk fat are used to make up the milk

components. In recent years, the production of filled milks has become increasingly important. In this case, the milk fat is replaced by locally available and cheaper vegetable fats.

Storage and Packing

An adequate keeping quality of up to 12 months can be achieved for both sweetened condensed milk and evaporated milk, but this largely depends on the storage conditions. At a storage temperature above 25 °C, the aging process and related physical, as well as organoleptic, defects appear more rapidly. For recombined products, the normal shelf-life stability, without major deviations from the original aspect, is reduced by about half of a fresh-milk product. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

The most commonly used packing is the tin plate can, which offers absolute protection against light, is basically crash proof, and has advantages for handling and storage. Recycling is also an important factor. As alternative packing, glass containers or paper/plastic laminates can be used; however, depending on the packing material, a considerable shelf-life reduction should be taken into account. For paper/plastic laminates, aseptic filling techniques are used, especially for evaporated milk. (*See* **Canning**: Principles.)

Nutritional Considerations

Owing to the concentrated form, both sweetened condensed milk and evaporated milk have an increased compositional analysis compared with milk (Table 1). For sweetened condensed milk, the figure for carbohydrate includes the sucrose content necessary for product conservation; the carbohydrate in evaporated milk and unconcentrated milk is lactose only. The rather high energy value of sweetened condensed milk is due mainly to the amount of carbohydrates present, whereas the protein and fat contents compare more or less with evaporated milk. (*See* **Milk**: Dietary Importance.)

Production and Usage

World production amounts to over 4.5 million tonnes. About one-third is produced as sweetened condensed milk and two-thirds as evaporated milk. As recently as 35–40 years ago, infant feeding was still a major application for either sweetened or unsweetened concentrated milk. Owing to the nature of the products, somewhat distinct usages are common practice.

Sweetened Condensed Milk

Owing to the high sucrose content of > 40% and its viscous consistency, this product is frequently used as a jam-like bread spread.

An early, but no longer popular, use of sweetened condensed milk was to dilute it with water and consume it as a drink. Presently, coffee or tea whitening and sweetening is the major use of sweetened condensed milk. In many countries, it is also used in combination with cocoa or other milk modifiers in the preparation of homemade drinks.

A growing application is in sweet dessert preparations like icecreams, cakes, cookies, etc. Specific to the Latin American continent is its use for Dulce de Leche, basically a caramelized sweetened condensed milk obtained by boiling the can in water for 2–3 h. Different applications vary from country to country and from one geographical region to another, according to traditional consumption habits.

Evaporated Milk

A large area of application is coffee and tea whitening and the preparation of milk-based beverages. The other main field for general usage is in the culinary sector to enhance the taste and texture of mashed potatoes, pasta, quiches, soups, and a wide variety of savory and sweet recipes. The main uses can also vary specifically from one country to another.

Manufacturing Principles

The raw material used for both products is usually cows' milk, although in certain regions, it may be a mixture of cows' and buffalos' milk. (*See* **Buffalo**: Milk.)

Sweetened Condensed Milk

A flow diagram for the manufacture of sweetened condensed milk is shown in Figure 1.

Table 1 Typical comparative figures for standard concentrated products and milk (all values in grams per 100 g)

Product	*Protein*	*Fat*	*Carbohydrates*	*Minerals (ash)*	*Calcium*	*Phosphorus*
Sweetened condensed milk	7.8	8.0	55.2	1.8	0.28	0.23
Evaporated milk	6.5	7.5	9.8	1.4	0.24	0.19
Milk	3.2	3.5	4.6	0.7	0.12	0.09

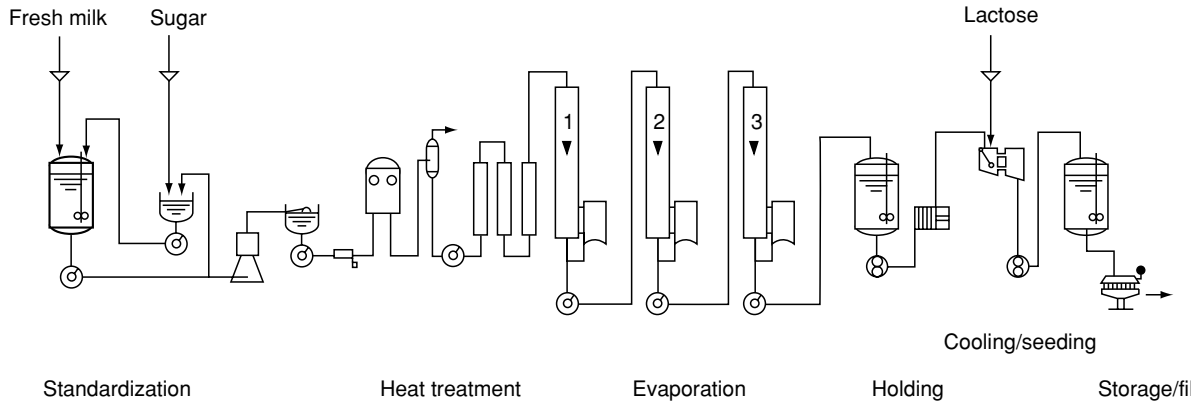

Figure 1 Basic flow diagram for the manufacture of sweetened condensed milk (continuous process). Reproduced from Condensed Milk, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Raw milk is collected and selected according to the usual quality criteria. The milk is analyzed for fat and solids-nonfat (SNF) content and the ratio between both components is adjusted according to the fat/SNF ratio of the final product to be manufactured by the addition of either cream or skim milk.

If the final product should have a composition of 8.0% fat and 21% SNF, the raw milk should be adjusted to the same fat/SNF ratio (see Table 2).

Sugar is dissolved in the cold milk, in principle by recirculation through a dissolving vat. The amount of sugar is determined by the quantity of milk prepared for a batch standardization, its fat content, and the compositional requirement of the sucrose content of the final product, e.g.,

$$\frac{10\,000 \text{ kg of milk} \times 3.25\% \text{ fat}}{100} \times \text{sugar factor}\left(\frac{\text{sugar content of finished product}}{\text{Fat}}\right).$$

After standardization, the milk/sugar mixture undergoes a heat treatment, which consists of a temperature/time combination usually above 100 °C and holding for seconds or minutes. This heat treatment eliminates nearly all the bacteriological flora of the milk, but the choice of temperature/time combination greatly influences final product characteristics such as the consistency and shelf-life stability. (*See* **Heat Treatment:** Chemical and Microbiological Changes.)

The viscosity of the product is an important factor. It is rather difficult to indicate precise heat treatment conditions, since they depend on the equipment used and the characteristics of the raw material milk which can produce different behavior through regional, climatic, and seasonal influences. Constant observation of viscosity and age thickening is necessary to counteract any negative effect. In general, lower heat treatments favor increased viscosities, and higher, intensive heating tends to give lower viscosities. The viscosity should be sufficient to avoid phase separation during storage, and age thickening should be moderate in order to keep the product pourable during its storage life.

Table 2 Example adjustment of the fat and SNF content of raw milk to achieve a final product composition of 8.0% fat and 21% SNF

	Final product	*Ratio*	*Standardized milk*	*Ratio*
Fat (%)	8.0	0.381	3.25	0.381
SNF (%)	21.0		8.52	

Concentration after heat treatment takes place under vacuum and usually in a multiple-effect evaporator.

Sweetened condensed milk is not a sterilized or sterile product; its conservation is assured by the bacteriostatic effect of the high sucrose concentration. The sugar-in-water ratio in the concentrated product must be above 61%. However, osmophilic organisms can develop in this medium, so it is important that the equipment after heat treatment and up to filling is of a hygienic design and is operated under the best hygienic conditions to avoid reinfection. Strict controls for equipment cleaning and sterilization are essential.

After evaporation, the concentration must be as close as possible to the final product's total solids content; an adjustment by, for example, water should be omitted because of the risk of contamination.

After evaporation, the product is cooled to normally 20–25 °C, and at the final concentration, part of the lactose contained in the product is

oversaturated. To avoid autocrystallization, fine-milled and pasteurized dry lactose crystals are added to the concentrate to initiate instant and controlled crystallization. During storage, product stirring should be maintained for several hours to finalize the crystallization process.

Filling, usually into metallic tin plate cans, is the last delicate operation. Cans and lids must be sterilized, and this is often achieved by passing them through a flaming installation. Air in the filling area must be filtered and of an excellent bacteriological quality; the air space in the can must be as low as possible to restrict mold growth. It is not necessary to perform an aseptic operation, but excellent hygienic conditions must prevail.

Evaporated Milk

A flow diagram for the manufacture of evaporated milk is given in Figure 2.

In principle, this product is poststerilized, which is a conventional process, whereby after filling and closing operations, the product is sterilized in the final container (e.g., tin plate cans, glass bottles, etc.).

For stability reasons, the product contains a small percentage of stabilizing salts (either one or a combination of the earlier-mentioned salts). Where legislation allows, the hydrocolloid, carrageenan, may be added. Stabilizing salts are indispensable as manufacturing and technological aids for adjusting or regulating the heat stability of the product during the poststerilization process. Carrageenan influences phase stability (creaming and protein sedimentation) during the product's storage life.

During the last 20 years, aseptically filled evaporated milks, mainly in soft packs, have been developed and commercialized. To realize aseptic filling, the product has to be heat-treated in-line for final sterilization. Ultrahigh temperature (UHT)-type installations are used for this purpose. (*See* **Heat Treatment: Ultra-high Temperature (UHT) Treatments.**)

The processing steps for milk standardization, heat treatment, and concentration/evaporation are similar or identical to those described for sweetened condensed milk, with the exception of the addition of sugar.

After concentration, evaporated milk is homogenized, cooled for intermediate storage, and sterilized after filling.

Heat treatment/heat stability The ability of concentrated milk to withstand high-temperature sterilization is essential. This is commonly described as heat stability and refers to the resistance of milk concentrate to coagulation during sterilization in containers.

Milk has a natural heat stability, which is influenced mainly by compositional factors, like mineral salt content, protein content, degree of acidity, etc. The natural heat stability also varies according to season and lactation period. In order to obtain milk sterilizable at different levels of concentrations, this natural heat stability must be improved and adapted. In practice, this is achieved by temperature/time combination of preliminary heat treatments on the milk before concentration and the addition of certain mineral salts. Precise indications are rather difficult, owing to the various influencing factors. The optimal heat stability has to be found by an empirical approach. In principle, more intensive heat treatments increase the heat stability, but above optimum conditions, a reverse effect is attained.

It must be understood also that processing operations, such as concentration and homogenization,

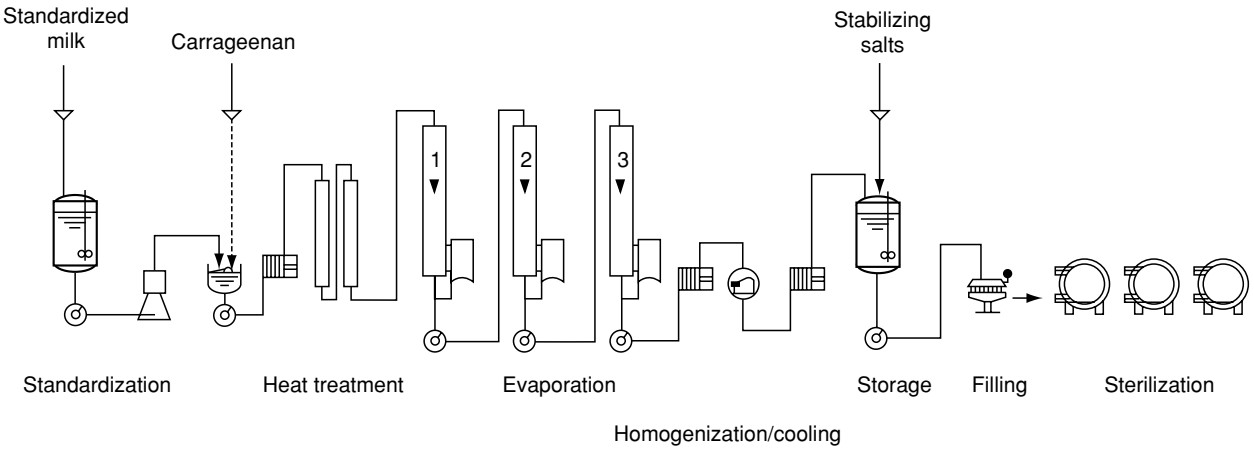

Figure 2 Basic flow diagram for the manufacture of evaporated milk. Reproduced from Condensed Milk, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

have a destabilizing effect on the concentrate. The various operations must be balanced so as to ensure a product of optimum quality.

Concentration After preheating, the milk is evaporated under vacuum. It is of utmost importance that the evaporator works under optimal hygienic conditions, despite the fact that the product is sterilized afterwards. In general, falling film evaporators are commonly used today.

Homogenization In order to obtain a satisfactory homogenization effect, the homogenizer and, in particular, the homogenizing valves must be kept constantly in the best mechanical conditions.

The homogenization temperature should preferably be around 65 °C.

A homogenizing pressure of 200–250 bar is usually applied, and the best results are obtained by a two-valve system in series. In principle, the second valve is adjusted to 20–25% of the total pressure. Excessive pressure has a destabilizing effect, which is irreversible. Following homogenization, the product is cooled for intermediate storage.

Pilot sterilization It is advantageous to fill some cans and to sterilize them under the given conditions in order to verify the heat stability of the concentrate. Corrective actions are further possible by addition of stabilizing salt and adaptation of the sterilizing conditions.

Sterilization After filling into containers (cans), the product is sterilized. The purpose of sterilization is to obtain physical and bacteriological stability. According to practical application, one speaks of commercial sterility.

The effect of sterility is expressed by the *F* value as an integral function of the lethality of the microorganisms present, related to *C. botulinum*, at the specific destruction temperature of 121 °C. Usually, an *F* value of 4 is considered satisfactory.

Today, modern instruments are available for measuring the time/temperature profile within any type of sterilizer.

Usually, rotary and continuous sterilizers are used.

Major Product Defects

Bacteriological Problems

For evaporated milk, the sterilization processes usually applied are proven and sufficiently safe to guarantee product safety and commercial sterility. If problems arise, they are mainly traced back to an insufficient can integrity. Faulty soldering, welding of can bodies, or closure seams are the weakest points. However, the presence of excessive numbers of thermophilic spores can cause severe spoilage. Appropriate line and finished product controls must be put in place. (*See* **Spoilage**: Bacterial Spoilage.)

Sweetened condensed milk is less vulnerable to spoilage because of its high sugar content, but it is not protected against osmophilic organisms. Plant and manufacturing hygiene are the keys to success.

Physical Instability

Instability may be of various individual defects, some of which may be interrelated. Separation problems can, and mainly are, a result of inadequate product viscosities. Certain texture problems may be related to nonoptimal heat treatments, but for sweetened condensed milk, it may also be a result of coarse lactose crystallization.

Age thickening is a constant problem for sweetened condensed milk. The increase of viscosity over the storage time is always present and, from a manufacturing point of view, can be corrected only by an optimal heat treatment of the milk prior to concentration. Considerable practical experience is required to keep this phenomenon under control.

Age gelation of evaporated milk is a similar phenomenon to age thickening for sweetened condensed milk but often appears only and suddenly after long storage times. The product can remain with normal physical properties up to 10 months or more and can then thicken within a few weeks. This gelation is strictly a storage defect and should not be confused with thickening or coagulation during the sterilization process or with coagulation resulting from microbiological activity. The main factors influencing age gelation are, as above, insufficient and nonoptimal preheating conditions of the milk before evaporation, marginal sterilization conditions, and an insufficient stabilizing salt level.

Inferior raw milk quality and final product storage conditions can also play an important role within the complex context of age gelation or thickening for either evaporated or sweetened condensed milk.

Products Manufactured by Recombining

As already mentioned, traditional dairy products like sweetened and unsweetened condensed milk are made by recombination using skim milk powder and anhydrous milk fat for the dairy components. The following is a brief description of these processes. (*See* **Recombined and Filled Milks**.)

When recombining sweetened condensed milk (see Figure 3), according to a process using only flash

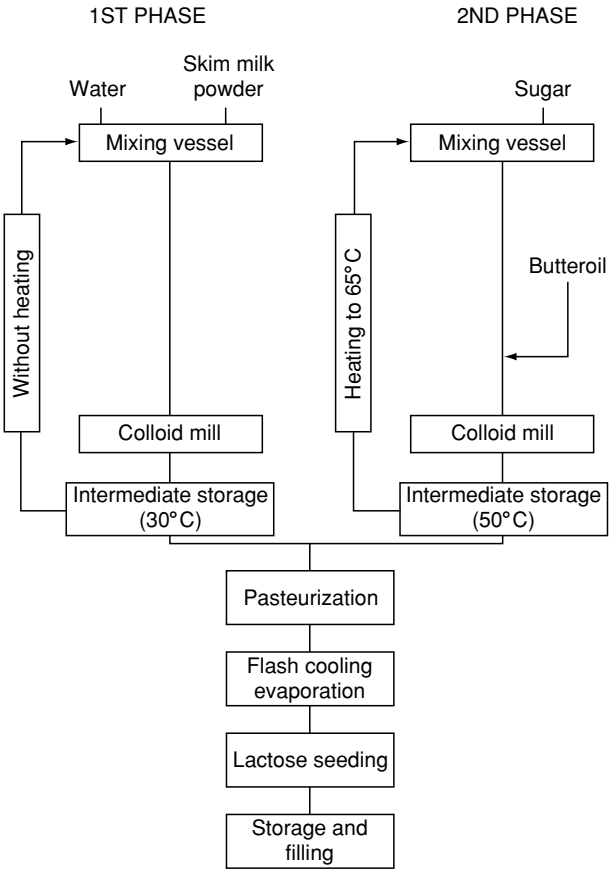

Figure 3 Flow chart for the recombination of sweetened condensed milk. Reproduced from Condensed Milk, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

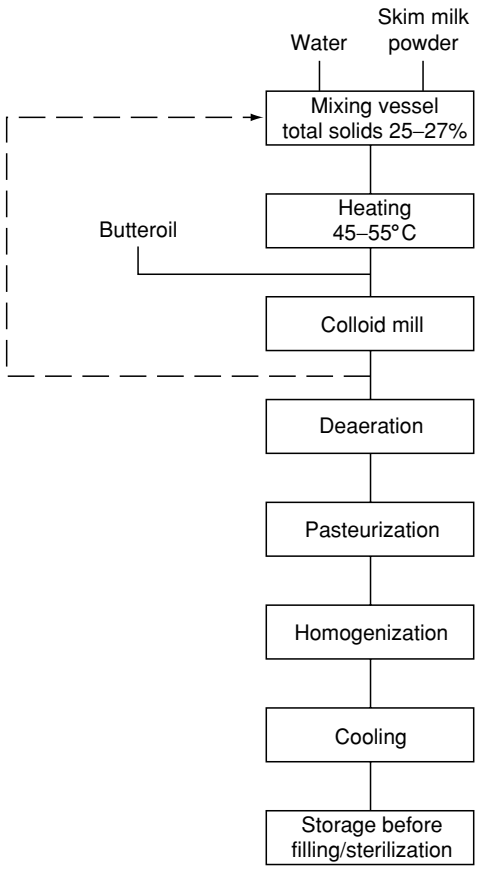

Figure 4 A flow chart for the recombination of evaporated milk. Reproduced from Condensed Milk, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

cooling evaporation, the skim milk solids have to be dissolved at a concentration of 40%, where some formation of lumps is practically unavoidable. However, these lumps are easily dispersible by mechanical force, as obtained through a colloid mill. A recirculation system has a beneficial effect on skim milk powder hydration.

In principle, dissolving sugar in a low-temperature medium does not pose a major problem but is somewhat time-consuming. Therefore, the circulated solution is heated after powder dosage in order to make the sugar dissolve rapidly.

A slightly simplified process for recombining can be used for evaporated milk (see **Figure 4**).

Dissolving skim milk powder at a low concentration generally poses less problems. Skim milk powder is certainly the most critical raw material and, depending on its characteristics, directly affects the physical properties of the final recombined product. This influence depends to a large extent on the heat treatment given to the liquid skim milk before drying. Seasonal and regional influences may also play a role.

Since milk proteins are sensitive to heat, the extent of their denaturation reflects the heat treatment applied and is used for classifying skim milk powders. The latter have been classified by the American Dairy Products Institute into three groups according to the level of undenatured whey protein nitrogen present in the powder after manufacture. In general terms, this is expressed as the whey protein nitrogen index (WPN index) (see **Table 3**). Whereas the high-heat-type powders are, in principle, the most appropriate for sterilized products, the low-heat range powders are usually more suitable for nonsterilized recombined products such as sweetened condensed milk.

Anhydrous milk fat is the principal source of fat used in recombined dairy products. It contributes significantly to the taste and milky character of the product. This is a clear indication for the quality requirements for this raw material. In certain cases,

Table 3 WPN index (values are in milligrams of nitrogen per gram of powder)

Classification	*WPN index*
High heat	≤ 1.5
Medium heat	1.51–5.99
Low heat	≥ 6.0

vegetable oils are used as butterfat substitutes, primarily for economic reasons. Such products are internationally recognized as 'filled milks.' The vegetable oils used in filled milks should be double-refined and deodorized and have a low peroxide value.

Water is a basic ingredient of all recombined dairy products. In general, a good drinking water quality is sufficient and acceptable. However, as water taste, odor, and possibly also color may influence the final product, special monitoring of water quality is important.

Buttermilk powder can be and is used in recombined products. From the technological point of view, buttermilk powder is an emulsifying aid for the fat, since it contains a relatively large amount of the phospholipids that are lost in the separation process of skim milk and anhydrous milk fat. For most applications, only sweet buttermilk is suitable; buttermilk powder obtained from acidified cream for butter production is not suitable. (*See* **Emulsifiers**: Uses in Processed Foods.)

As the natural vitamin content of fresh milk is usually reduced slightly during processing of the raw materials for recombining, vitamins A, D, and B are usually added. For filled milks, further addition of vitamin E is carried out and is recommended for nutritional purposes.

Various processing aids, mainly phosphates but also other emulsifiers or stabilizers, are added to achieve specific product characteristics and consistencies.

All additives must be in accordance with legal prescriptions or comply with the Food and Agriculture Organization/World Health Organization standard (Code of Principles). (*See* **Legislation**: Additives.)

CONJUGATED LINOLEIC ACID

C E Fernie, Scottish Crop Research Institute, Invergowrie, Dundee, UK

What is Conjugated Linoleic Acid (CLA)?

Conjugated Linoleic Acid (CLA) is the collective name given to a group of 18:2 free fatty acid positional and geometric isomers, containing two conjugated double bonds (**Figure 1**). Most fatty acids commonly occurring in nature contain methylene-interrupted double bonds, e.g., *cis*-9, *cis*-12 18:2 (linoleic acid). However, conjugated dienes have been known for more than 50 years. They are seen as the products of both autooxidation and of partial hydrogenation of polyunsaturated fatty acids, as well as being minor components of dairy and ruminant lipids. There is increasing interest in CLA, as in animal trials, it has shown potentially beneficial effects on a variety of medical conditions such as cancer and type 2 diabetes, as well as affecting body composition parameters such as bone composition and lean body mass. As a result, this is an area of

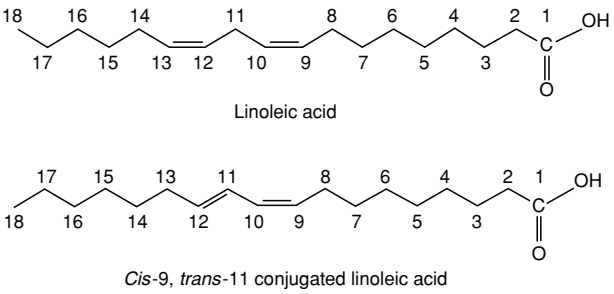

Figure 1 Linoleic acid is a *methylene-interrupted* fatty acid, i.e., it has a CH_2 group between the two double bonds, at position 11. CLA is a *conjugated* fatty acid as there are no groups between the double bonds in the carbon chain.

continuing growth in research in a wide variety of scientific fields. This review will attempt to give an overview of the current state of knowledge in this developing area of interest.

Occurrence in Natural Products

The most common source of natural CLA in the human diet is from the meat and milk products of ruminant animals. CLA isomers are present in these materials at levels of approximately 0.5% of total fat on average, although seasonal variations are observed. The predominant isomer is the *cis*-9, *trans*-11 acid, at levels of 80–90% of the total CLA, with minor amounts of a wide number of other isomers present, ranging from the 6,8 through to the 13,15 positional isomers, in almost all of the different geometric configurations possible (i.e., *cis*, *cis*; *cis*, *trans/trans*, *cis* and *trans*, *trans*), particularly in milk fat and cheese. Biohydrogenation of linoleic acid is thought to be the main mechanism of formation of natural CLA. The process involves the action of the ruminant bacterium *Butyrivibrio fibrisolvens* on dietary linoleic acid (via linoleic acid isomerase) to give CLA as an intermediate in the formation of *trans*-11 18:1 (vaccenic acid) and subsequently 18:0 (stearic acid). As levels of CLA produced by this mechanism do not seem to be high enough to account for the amounts of CLA in ruminant tissues, a second mechanism has been proposed, involving the action of the Δ-9 desaturase enzyme on vaccenic acid within adipose and mammary tissues to give the *cis*-9, *trans*-11 CLA isomer (Figure 2).

The variety of conjugated isomers in ruminant milk and tissue is thought to be due to a combination of double bond migration, and the action of specific *cis*, *trans* isomerases in the rumen.

Altering the feeding regime of the animals can vary the levels of CLA in ruminant fats. Pasture-fed animals have higher levels of CLA than those given

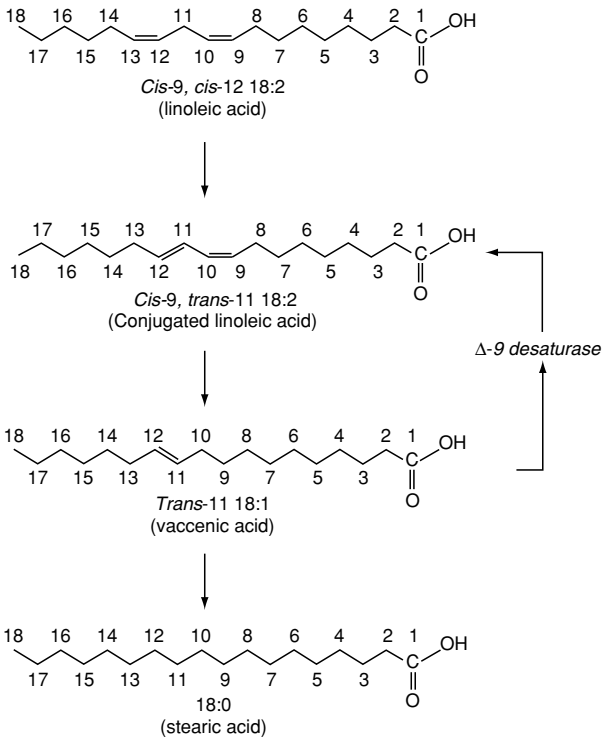

Figure 2 Biohydrogenation of linoleic acid to produce CLA, both as an intermediate towards stearic acid and by desaturation of vaccenic acid.

commercial feed. However, feed enriched with unsaturated fatty acids can also increase the CLA levels in milk and meat. There can be wide variations in CLA production between animals of different breeds, and at different stages of lactation. This may relate to the Δ-9 desaturase level of the individual animals.

CLA has been reported in fish, and its occurrence in farmed fish is probably due to the CLA content of vegetable oil in fish food. However, there is concern that CLA can be misidentified in fish tissues, as it elutes on some gas chromatographic columns in the same region as the naturally occurring 18:4 isomers. This may have been the case in early reports of low levels of CLA in trout, shrimp, and mussels, as currently no mechanisms are known to account for CLA formation in marine foods.

CLA is also present in small amounts, as a result of the hydrogenation process, in margarines, cooking oils and other partially hydrogenated fats.

Commercial Production

Mixtures of CLA isomers are available commercially, for use in scientific studies and as reference standards, and also as dietary supplements. These products, which are usually in the free fatty acid form, are typically produced by the alkaline isomerisation of a

linoleate-rich vegetable oil, such as sunflower or safflower oil. The CLA produced from this process in aqueous solution generally contains four main CLA isomers: *trans*-8, *cis*-10; *cis*-9, *trans*-11; *trans*-10, *cis*-12, and *cis*-11, *trans*-13. Under harsh reaction conditions, these isomers can be present in approximately equal proportions. It is possible, however, to manipulate the reaction temperature and time to give a mixture that is greater than 90% of the *cis*-9, *trans*-11 and *trans*-10, *cis*-12 isomers, in approximately equal proportions. This is more desirable, particularly for supplement usage. By using propylene glycol instead of water, with an appropriate basic catalyst (e.g., potassium hydroxide), the amounts of the minor isomers can be reduced to around 1%, but small amounts of isomerization will always occur.

The processes described above all give mixtures of CLA isomers. It is also possible to obtain CLA enriched in one particular isomer. Enzymes derived from fungi such as *Candida rugosa* and *Geotrichum candidum* show a preference for the *cis*-9, *trans*-11 isomer, and, by preferentially esterifying this CLA isomer, give an unesterified fraction that is rich in the *trans*-10, *cis*-12 isomer. This has been demonstrated on a laboratory scale, but has yet to be optimized for commercial production. Alternatively, a series of selective crystallisations can be used to fractionate the *cis*-9, *trans*-11 and *trans*-10, *cis*-12 isomers, to give material of high isomeric purity. In the future, the production of CLA is likely to expand to include production of CLA-containing triacylglycerols, as this is the form of lipid most generally present in foodstuffs.

Analysis of CLA

The primary concern in analyzing CLA is the complete separation and quantitative identification of the individual isomers in the sample. The form of the sample will also determine the approach to analysis. Samples are generally either in the free fatty acid form, or present as esterified CLA as a component in a biological matrix, from which the CLA needs to be extracted first. A number of analytical techniques have proven useful. ^{13}C NMR allows identification and quantification of all the positional and geometrical isomers in a single analysis, but has the drawback of requiring a comparatively large amount of sample, so it is not helpful for analyzing biological extracts. Gas chromatography (GC), gas chromatography–mass spectrometry (GC-MS) and high-performance liquid chromatography (HPLC) can all give large amounts of information regarding sample composition, but for these methods, the sample must be extracted and also derivatized prior to analysis. A combination of the above techniques is often required to give a comprehensive analysis.

As CLA is prone to isomerization, care must be taken in the extraction method chosen to obtain CLA from tissue samples. A mild alkaline hydrolysis can be used, for instance, to give the CLA as free fatty acid, which can then be derivatized for analysis using one of the methods described below.

Prior to GC analysis, fatty acids must be converted to derivatives (usually methyl esters). Although there are standard methods used to derivatize methylene-interrupted fatty acids, it has become apparent over the last few years that some of these methods, in particular those using an acidic catalyst, are unsuitable for use with conjugated free fatty acids. Under vigorous conditions, they lead to isomerization of the sample and artefact formation. Though base-catalyzed methods do not normally esterify methylene-interrupted free fatty acids, esterification of free CLA can be achieved, but some of the methods used have also shown artefact formation on reaction with CLA. Phase transfer methods using methyl iodide in a basic buffer solution have been utilized on a small scale with consistent results. Despite the drawbacks, acidic methods can give good quantitative results providing that the reaction is carried out under mild conditions with fresh reagent. Esterified CLA can be converted to the methyl esters by the standard method of transesterification with sodium methoxide in methanol solution. The most useful GC columns for resolving complex mixtures of CLA isomers are longer, more polar columns such as the 100-m Cp-Sil 88 or the 120-m BPX-70 capillary columns. Neither of these columns will completely resolve a complex mixture of CLA isomers, although they will give good results on most commercial samples. For this reason, complex mixtures of biological CLA should also be analyzed by either HPLC, or GC-MS, or both.

HPLC has proved especially useful in the analysis of conjugated dienes, such as CLA. A UV detector is usually employed as conjugated dienes show a strong absorbance in the region of 230–235 nm. Silver-ion HPLC, employing more than one column, can be used to separate all the positional and geometric isomers in a commercial CLA mixture, as methyl esters. Reversed-phase HPLC has been used successfully to concentrate the CLA methyl esters of biological samples for further analysis.

For GC-MS, a different type of derivative, usually containing nitrogen, is required to give good-quality spectra of CLA. Both dimethyloxazoline (DMOX) derivatives and 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) adducts are commonly used and can be used to locate the conjugated double bond positions in both CLA and its metabolites.

Biological Activity

As mentioned above, CLA has exhibited biological effects in a number of major medical conditions. However, many of the CLA mixtures used for early trials were poorly characterized. As a result, there is little conclusive information as to which CLA isomers are the most active and under which circumstances. It is only recently that individual pure *cis*-9, *trans*-11 and *trans*-10, *cis*-12 isomers have become available for clinical trials. Consequently, the discussions below assume that studies were carried out with commercial isomer mixtures of free fatty acids, although where a particular isomer has demonstrated a reproducible effect this is indicated.

Anticarcinogenicity

The interest in CLA as a biologically active material, rather than as a minor lipid component or an oxidation product, began in the early 1980s, when researchers at the University of Wisconsin reported the discovery of an extract from grilled minced beef, which was found to inhibit mutagenesis. Since then, many studies have been performed, both *in vivo* using a number of different animals, and *in vitro* with a variety of animal and human cell lines. Although other lipids, such as fish oil, have been shown to have anticarcinogenic effects, CLA appears to be potent at much lower concentrations (e.g., from 0.1% w/w in rat tumors). A number of studies have concluded that the *cis*-9, *trans*-11 isomer is the active CLA isomer against cancer, but this remains to be proven.

In vivo, dietary supplementation with CLA decreased the number and size of mammary tumors in rats and mice, independent of the amount and types of other fat in the diet. However, no effect was seen in trials using tumor cells from hormone nonresponsive cell lines such as the WAZ-2T (-SA) and MDA-MB-231 cell lines. Further studies are required in this field, as this may be relevant to elucidating the mechanism by which CLA acts on tumors. In tests on skin carcinogenesis in mice, topically applied CLA was found to be effective in reducing the size and number of skin tumors, although dietary supplementation with CLA only affected the number and not the size of the tumors. Fewer data have been published on the effect of CLA on prostate cancer and on forestomach and colon cancers, with conflicting data being obtained in different mouse and rat models.

Much of the *in vitro* work on carcinogenesis has been done on the estrogen-responsive MCF-7 human breast cancer cell line. In the majority of these studies, CLA has been shown to reduce cell growth in a dose-dependent manner. Again, however, estrogen-unresponsive cell lines failed to show tumor inhibition on treatment with CLA. Limited numbers of studies on a variety of other human cancer cell lines have also shown tumor inhibition in colorectal, liver, prostate, and lung cells.

A number of studies have been conducted to try and elucidate the mechanism by which CLA acts on cancer cells. Initial suggestions that CLA acts as an antioxidant have recently been contradicted by a number of trials. CLA can block the formation of carcinogen DNA adducts in rats in certain organs. Another potential mode of action would be by affecting the production of eicosanoids implicated in tumorigenesis. CLA is incorporated into both neutral lipids and phospholipids, at varying levels, depending on the tissue type, and can be metabolized to give 18:3, 20:3, and 20:4 fatty acids containing conjugated double bonds. Dietary supplementation with CLA has also been shown to reduce the synthesis of the eicosanoid prostaglandin E_2 in mouse epidermis. However, the direct method of action has still to be determined.

There appears to be a direct link between levels of CLA in breast tissue during maturation and the limiting of lateral branching of the terminal end bud cells of the developing breast, leading to a decreased risk of breast cancer in later life. Again, the mechanism for this effect has yet to be shown. Interestingly, a number of studies examining human dietary CLA intake and breast cancer risk world-wide have failed to show any consistent positive or negative effect of dietary CLA on cancer development. This may be due to limitations of the accuracy of the dietary surveys conducted.

Body Composition

In animal studies, CLA reduced body fat and increased lean body mass in growing animals, for a number of species, including mice, rats, and pigs. Other physiological factors connected with these effects in different studies were a reduction in lipoprotein lipase activity, an increase in the enzyme carnitine palmitoyl transferase (associated with β-oxidation of lipids), and reduction in adipocyte size (but not cell number). Reduced body fat and increased body protein and water have been directly associated with the *trans*-10, *cis*-12 isomer. Potential mechanisms for these effects include alteration of membrane structure, effects on eicosanoid and cytokine production, and changes in peroxisome proliferator-activated receptor (PPAR) activity.

Feeding of CLA also leads to a loss of monounsaturated fatty acids, which is an effect seen in treatment to reduce obesity. It has recently been demonstrated that this effect is due to repression of the expression of the stearoyl-coenzyme A desaturase gene in fat cells by the

trans-10, *cis*-12 isomer, leading to smaller lipid droplets containing lower levels of monounsaturated fatty acids. This is not seen with the *cis*-9, *trans*-11 isomer.

A few studies of the influence of CLA on human body composition have been conducted. The amounts of CLA fed were variable (between 1.7 and 7 g per day), and a number of the subjects studied were either athletes or body builders. In general, although there was little effect on body weight, in most of the subjects, body fat was either reduced or stayed constant, and lean body mass was either constant or increased. However, these variations were in most cases not significant. The existing data are not consistent enough to show a dose-dependent response, and the effects of exercise should be taken into consideration. Also, studies in humans were conducted on adults, whereas animal data were collected from growing subjects. It has been speculated that feeding CLA affects plasma leptin levels and thus acts as a control on food intake. However, recent data in humans showed that, although supplementation decreased leptin levels in the short term, after approximately 7 weeks levels returned to baseline values, and no alterations in either appetite or body composition were observed. Further studies are required with individual isomers, in particular the *trans*-10, *cis*-12 isomer to assess fully the effects and the potential to treat obesity.

Immunity

In mice, dietary CLA is incorporated into liver lipids by displacing linoleic and arachidonic acids, thus modifying the *n*-6 fatty acid composition of the phospholipids. Subsequent experiments in rats have shown that this phospholipid modification affects eicosanoid production. For instance, feeding 1% CLA for 2 weeks reduced serum prostaglandin E_2 levels by approximately 50%. CLA can also lower the levels of some leukotrienes (e.g., LTB_4) in rats. This may then affect cytokine production, but further studies are required in this area. It has effects on immunoglobulin production, specifically increasing levels of IgA and IgG, which are both associated with antiallergic effects.

Few data are currently available from human studies, but a recent trial on women showed no changes in immune function during the course of the study. This may be due to a dose effect, as the levels of CLA per weight in animal models tend to be much greater than the levels fed in the human studies.

Atherosclerosis

Experiments on atherosclerosis have been conducted on both rabbits and hamsters. Feeding CLA at 0.1–0.5% of the diet in rabbits for 22 weeks showed a reduction in plasma triacylglycerol, total cholesterol, and LDL-cholesterol levels. There was also an effect on plaque formation, with a reduction in the CLA fed animals. In hamsters, CLA feeding at similar levels was found to reduce total cholesterol and fatty streak area, although linoleic acid feeding showed similar effects. An isomer effect was seen in the hamster model, with only the *trans*-10, *cis*-12 isomer decreasing triacylglycerol and cholesterol. Contradictory data have been obtained in C57BL/6 mice, in which an increase in aortic fatty streaks was reported.

Bone Metabolism

Lipids play an important part in bone metabolism as they are known to influence both bone modeling and remodeling. Both CLA and *n*-3 fatty acids modulate the production of prostaglandin E_2 in chicks and rats, leading to increased bone formation and decreased resorption. CLA is thought to act on prostaglandin E_2 production by influencing the cyclooxygenase enzymes, which produce prostaglandin E_2 from arachidonic acid. This may occur through the production of competitive 20:4 conjugated CLA metabolites. As also seen in other studies, CLA reduces the level of LTB_4, which is a strong bone resorption factor. CLA may influence cartilage functions in growing animals. As yet, few experiments have been conducted with CLA, and further data are required to elucidate its mechanism of action.

Diabetes

In type 2 diabetes, treatment aims to reduce insulin resistance and improve glucose uptake. In *in vitro* tests, chemicals such as thiazolidinediones show these effects by directly affecting PPARγ expression. CLA, in particular the *cis*-9, *trans*-11 isomer, has also been shown to bind to, and activate, PPARγ, as have other unsaturated fatty acids. In Zuker diabetic fatty (*fa/fa*; ZDF) rats, a diet containing 1.5% CLA produced normal glycemic responses to tolerance tests, as well as reduced hyperinsulinemia.

Enhanced CLA Levels and Food Production

In animals, there are two different reasons to try to increase the levels of CLA in tissue and/or milk. Firstly, CLA has effects on body composition, leading to, for instance, increased lean meat and lowered levels of fat in pigs and cows. This is becoming more desirable as public concern increases due to suggested links between increased dietary levels of fat and conditions such as heart disease and obesity. The second reason is because of the potentially beneficial effects of CLA itself in a number of diseases. Although

current dietary levels of CLA have been shown to have little or no direct effect on various conditions, enhanced levels in food are hoped to lead to a protective effect against conditions such as cancer.

Most studies that aim to increase CLA levels have been conducted with cows. Feeding of mixes containing unsaturated lipids such as vegetable or marine oils leads to increases in CLA levels of up to fivefold. Increasing CLA, however, generally causes a concurrent increase in the level of other *trans* fatty acids, in particular the *trans*-10 octadecenoic acid, which has negative effects in both cows and humans. The levels of this fatty acid have been suppressed by feeding a buffer.

Feeding CLA to chicks has also shown an effect on their immune response, such that less tissue wasting occurs on immune stimulation, thus reducing the need for antibiotic treatment and improving meat quality.

CLA is present in human milk, but not infant formula, and it has been suggested that this is a factor in the lower levels of food allergies, immune deficiency, and diabetes in children that are breast-fed. This, however, has not been tested in sufficiently large data sets.

Enhancing CLA in dietary components is only one way of increasing CLA intake. Other methods include supplementation and production of a functional food. CLA supplements are already available in the USA and Europe, and currently are mainly targeted at the body building population and at slimmers. These products are either liquid or encapsulated CLA, of a composition similar to that of the commercial products described above.

A functional food is defined as a food product that has been enhanced to give specific, beneficial, biological effects. Examples include margarines containing stanol esters, which have demonstrated a cholesterol-lowering effect in humans. These products are designed to be available on supermarket shelves to the average consumer. CLA would be an ideal candidate for incorporation into a food item such as a dairy product, if it could be shown to have specific biological effects in humans at reasonable (i.e., non-toxic) levels.

Safety Issues

There are few data available upon the toxicological effects of CLA. Most of the information comes from animal models, and the data are contradictory. Although few effects have been seen in rats and hamsters, experiments conducted with a variety of mouse models have shown increases in liver weight, transaminase levels, and steatosis. Insulin resistance has also been reported. These effects may be relevant purely to the mouse model. In humans, in a study on overweight or obese volunteers undergoing CLA supplementation, at levels of 3.4 g of CLA per day, blood lipids, liver factors, and other hematological end points, as well as physical parameters such as blood pressure, were examined, but no differences were found between the supplemented and control groups.

This is an area requiring urgent review, particularly with the prospect of CLA incorporation into a functional food and considering the lack of data on specific CLA isomers.

Summary

Conjugated linoleic acid shows potential as a treatment for a variety of human ailments, as well as a means towards obtaining meat products with a fat-to-lean-meat profile closer to that which we currently regard as healthy. However, the data available so far come mostly from animal studies and show conflicting results in some cases. A lack of consistent analytical methodology has further complicated the situation. There is a need for clinical trials in humans with specific CLA isomers, in order to elucidate the mechanisms by which these compounds show their effects, as well as to ascertain the appropriate dosage levels, with no significant side-effects.

CONSUMER PROTECTION LEGISLATION IN THE UK

J Carton, Manchester Metropolitan University, Manchester, UK

Background

We are all consumers throughout our lives. Every member of society is a consumer in one form or another, whether they consume goods, services, or intangibles such as gas or electricity. For the purposes of this article, it is assumed that a consumer is someone who buys or uses such goods or services for private use or consumption. What we consume may depend upon the amount of disposable income that we possess and what stage we have reached in our lives. Factors such as availability and price will also play an influential role. Food is a particularly important consumable, since we all need it to survive.

Protecting the consumer is usually something which political parties agree upon as being a good thing to do, but how they go about achieving it differs. There are also various ways of trying to ensure that consumers are protected, such as education, advice, and industry self-regulation. The emphasis here will be on *legislation* as a means of protecting consumers and on *food* as a major consumer product. In addition, only the main pieces of legislation will be addressed. Discussion will also be mainly confined to the laws which apply in England and Wales, although other countries throughout the world will have similar consumer protective measures.

Consumer protection legislation has only really developed in the UK since the 1960s, and three government-initiated reports have assisted with this development. They are the Final Report of the Moloney Committee on Consumer Protection (Cmnd 1781, July 1962), the Crowther Committee (Cmnd 4596, March 1971), and the White paper, modern markets: confident consumers (July 1999).

The Legal System

Both criminal and civil law play a role in protecting the consumer, and much of the current legislation emanates from the UK's membership of the EU. Sometimes, the aim is not necessarily to protect consumers: it could be to ensure fair trading in the business environment with the protection of consumers as a side-effect.

Criminal law aims to protect the public at large and creates criminal offenses for which penalties, such as fines and even imprisonment, can be invoked by the courts. Action is normally taken by public bodies such as local authority trading standards or environmental health departments. Civil law, however, seeks to settle disputes between two private parties, providing a remedy for someone who has been injured or harmed in some way.

The nature of much legislation in this field is strict liability, which means that it need not be shown that the perpetrator knew or intended to commit an offense or breach a provision, only that they did so. This is illustrated in criminal law by the case of *Parker v Alder (1889) 1 QB 20* in which the seller was found liable for the adulterated milk he was selling even though it was satisfactory when it left his control. In civil law, the case of *Frost v Aylesbury Dairy Co (1905) 1KB 608*, in which milk infected with typhoid germs was sold, demonstrates the strict liability nature of the legislation. It is unlikely that either seller was at fault in any way but both were nevertheless held to be in breach of the relevant legal provisions.

Criminal Legislation

The Food Safety Act 1990

This is the main piece of criminal legislation which specifically regulates food. It is concerned with both the safety of food and hygiene of premises as well as the quality, description, labeling, and composition of food.

There are four main offense sections within the Act which between them cover the areas mentioned above. In addition, there are a great many sets of regulations, orders and codes of practice made under the Food Safety Act which provide detailed requirements to supplement its provisions.

Food Not of the Nature, Substance or Quality Demanded by the Purchaser

Selling food which is not that which was demanded by the purchaser is an offense contrary to section 14(1) of the Act. In fact, there are three separate offenses, selling food which is not, first, of the nature demanded, second, of the substance demanded, and, third, of the quality demanded. Examples of cases prosecuted serve to illustrate what these phrases mean, although it is generally accepted that there is some overlap between the three.

It is generally accepted that 'nature' would refer to foods not being of the variety requested by the purchaser, e.g., where cod is requested, and haddock is supplied as a substitute. In *Shearer v Rowe (1985) 149 JP 698*, butchers were convicted of selling 'minced beef' and 'minced steak,' which were not of the nature demanded since they contained 10% pork and 10% lamb. Prosecutions relating to 'substance' are often taken when a food contains a foreign body or mold as in *Southworth v Whitewell Dairies Ltd (1958) 122 JP 322*, in which a bottle of infants' school milk contained a small sliver of glass which the child drinking it was able to suck up the straw being used to drink the milk. Allegations of food not being of the 'quality' are generally made when there is a failure to meet standards set by regulations or when there is a shortfall in what an ordinary consumer would expect. In *TW Lawrence & Sons Ltd v Burleigh (1981) 146 JP 134*, a regular consumer made a telephone order for mince and, when it was delivered, was shocked at the appearance of the product, in that she felt that there was too much visible white fat. The mince was found to contain 30.8% fat, and the court was satisfied that this was in excess of what the purchaser expected.

Food Which Does Not Meet the 'Food Safety Requirements'

Section 8 of the Act deals with the safety of food. It is an offense, contrary to section 8(1), to sell food which fails to comply with food-safety requirements. In fact, the offense is wider than that in section 14, since it is not restricted to a sale. The offense is committed if such food is offered, exposed, advertised, or in possession for sale [s.8(1)(A)], or has been deposited with, or consigned to, someone else in preparation for sale. This thereby ensures that the whole supply and distribution chain is regulated.

Consumers are further protected in that there is a presumption in section 3 that food is for human consumption. Therefore, if the trader wishes to argue that the food was not ready for consumers, e.g., because it had been rejected or had not yet been checked, then the onus is on him prove so.

There are three ways in which food may fail to comply with food-safety requirements. First, the food may be 'unfit for human consumption' (s.8(2)(b)), e.g., because it is putrid or decomposed. This is illustrated by the case of *Chibnall's Bakeries v Cope Brown (1956) Crim LR 263*, in which a used, dirty bandage was found in a loaf of bread. Second, the food may fail to comply with the food-safety requirements if 'it is so contaminated that it would not be reasonable to expect it to be used for human consumption in that state' (s.8(2)(c)). Food could be contaminated in a number of ways, e.g., by mold, heavy metals, mites, foreign bodies, radioactive substances, or unauthorized additives. In *Kwik Save Group plc v Blaenau Gwent Borough Council (1995), unreported (CO/2246/95)*, a packet of crumpets was found to breach this provision when the crumpets contained mold spots 5 hours after being purchased. Third, the food may have been rendered injurious to health (s.8(2)(a)) as in *Cullen v McNair (1908) 72 JP 376*, in which the addition of a particular preservative to cream rendered the product injurious to the health of a substantial portion of the community, namely invalids and children. To create the offense, the food must have been rendered injurious to health by one of the operations detailed in section 7(1) with the intention that it would be sold for human consumption. The operations are '(a) adding any article or substance to the food; (b) using any article or substance as an ingredient in the preparation of the food; (c) abstracting any constituent from the food; and (d) subjecting the food to any other process or treatment.'

Food Rendered Injurious to Health

As well as supplying, etc. such food, the actual act of rendering the food injurious to health in one of these ways is an offense contrary to section 7(1). This is one of the few consumer protection offenses which does not require the perpetrator to be acting in the course of a trade or business. Generally, this provision is not used as a consumer protection measure but potentially could be used to deal with those who deliberately sabotage food products.

There are many sets of regulations made under the Food Safety Act 1990 which also help to ensure that consumers receive safe food. The Food Hygiene Regulations 1995 regulate the cleanliness of food premises and the use of practices within the food industry. There are specific regulations for the meat, dairy, and egg industries. In addition, there are requirements for the registration and or licensing of certain premises and a prohibition or restriction on the use of certain processes, ingredients or additives.

Food Falsely Described or Presented

Consumers are not only concerned about their food being safe but also require it to be accurately described and presented. Section 15 of the Food Safety Act creates a number of criminal offenses to cover this area. Labels and adverts which depict or describe food must not be false or mislead as to the nature, substance, or quality of the food (see above), otherwise an offense may be committed contrary to section 15(1), (label) or 15(2), (advert). There have been many cases alleging false descriptions of food, although most of them have been taken under other legislation, e.g., *Henderson and Turnbull v Adair (1939) JC 83* in which a product was falsely described as 'Scots Whisky' when it was a blend of 33% Scotch 'pot-still' and 67% Irish 'patent still' spirits. An example of a misleading label is illustrated by the case of *Van den Berghs & Jurgens Ltd v Burleigh (1987) unreported*. The products in question were cream substitutes 'Elmlea Whipping' and 'Elmlea Single.' The use of cream type cartons, the words 'single' and 'whipping,' the coloring of the words, and the rural scene on the carton were considered to be misleading. It was felt that an ordinary consumer would think that that the products were real cream. This is an example of labels, which, when examined in their entirety, were considered to be misleading even though all the information on them was factually correct. The cartons were clearly labeled 'the real alternative to cream.' There is also the possibility that the food can describe itself, and to that end, it is an offence to sell, etc. 'any food the presentation of which is likely to mislead as to the nature or substance or quality of the food' (s.15(3)).

Food Standards Regulations

Again, there are various sets of regulations requiring specific labeling and even the composition of certain foods. Consumers can only make informed purchasing decisions if they know what is in the product. What has to be on a food label depends on what the food is, how it is packed (prepacked or loose), and where it is sold (retail, wholesale, or from a catering establishment). The Food Labelling Regulations 1996, which implement EC Directive 79/112 (now consolidated as Council Directive No. 2000/13/EC), require most prepacked foods, by virtue of regulation 4, to be marked with the general labeling requirement (r.5), i.e., the name of the food, its ingredients, (including the percentage quantity of certain ones) 'best before' or 'use by' date plus the name and address of the manufacturer. In addition the origin of the food and instructions for use must also be indicated if the consumer would be misled without them. Consumers are also interested in knowing whether foods contain any irradiated or genetically modified ingredients, and so there are requirements relating to such processes.

Some regulations lay down compositional standards for certain products as well as additional or alternative labeling requirements, e.g., the Meat Products and Spreadable Fish Products Regulations 1984 require declarations of minimum amounts of meat and fish (regulations 7 and 8) and also declarations of water content on certain sliced products (regulation 9). Regulation 4 and Schedule 4 prescribe minimum meat contents for products such as burgers (80%), pork sausages (65%), cooked potato and meat pies and fish pate.

The Trade Descriptions Act 1968

This piece of legislation can be used as an alternative to section 15(1) or (2) of the Food Safety Act 1990 to deal with falsely described food. It also covers oral descriptions which section 15 does not. The offenses are contained in section 1, and whereas the Food Safety Act is obviously restricted to food, this Act covers 'goods' generally, including food. The offenses within section 1 are for actually applying a false trade description (defined in s.2) to goods (s.1(1)(a)) and for supplying and offering to supply goods to which a false trade description has been applied. Section 14 also contains offences of recklessly or knowingly making false statements in relation to accommodation, services or facilities which could include references to food services such as hotel meals.

The Agriculture Act 1970

Since our food products are derived from crops and animals, it also necessary to control animal feeding stuffs and fertilizers so that what ends up in the human food chain is nutritious and not harmful in any way. There is a great deal of legislation in this area and two of the most relevant pieces are the Feeding Stuffs Regulations 2000 and the Fertiliser Regulations 1991.

The General Product Safety Regulations 1994/SI 2328

These Regulations cover the safety of consumer products generally and are supplemented by Part II of the Consumer Protection Act 1987 and various specific sets of Regulations governing particular products. The General Product Safety Regulations implement those parts of Council Directive 92/59/EEC on general product safety not already covered by the Consumer Protection Act.

The main requirement is that producers (defined in r. 2(1)), should only place safe products on the market. This is known as the 'general safety

requirement' and is laid down in r.7. A breach of this provision may amount to an offence contrary to Regulation 12. Product is also defined in r.2(1) and is confined to consumer products. Whether or not a product is safe depends upon its presenting no or only minimum risk (r.2(1)). The labeling, presentation, packaging, and instructions, as well as its actual design and construction can all be taken into account when trying to assess whether a product is safe. There are various standards available against which safety can be measured as detailed in r.10. These include specific UK laws, European Standards, British Standards, Industry Codes of Practice, and the current practises within a particular industry. As well as these guidelines, the 'safety which consumers may reasonably expect' should also be borne in mind. It is unlikely that these regulations would be used to take a prosecution in relation to a food product, although food clearly falls within the definition of a product in r.2(1). The Food Safety Act 1990 will almost inevitably be a more appropriate act to use, and in any event, it is arguable that the Food Safety Act, or more specifically Council Directive 89/397/EEC which implements it, falls within the exemptions detailed in regulation 3 of the General Product Regulations 1994: 'These Regulations do not apply to . . . .(c) any product where there are specific provisions in rules of Community law governing all aspects of the safety of the product.' If it could be argued that there is some aspect of the safety of food which is not covered by the Directive then presumably the General Product Safety Regulations could be used to deal with that aspect.

The Weights and Measures Act 1985

Legislation in this area covers goods, equipment, marking, and units. In addition, there are specific provisions regulating packers and importers and the average quantity system which is used for most prepacked goods throughout the European Community (Part V, Weights and Measures Act 1985 and the Weights and Measures (Packaged Goods) Regulations 1986). Consumers are protected by the creation of offenses in relation to supplying short-weight products, including food, and using suitable and accurate weighing and measuring equipment. Certain foods are required to be sold in prescribed quantities, e.g., bread in multiples of 400 g, so that consumers can make meaningful comparisons between producers (Weights and Measures (Miscellaneous Foods) Order 1988). Also, certain units have to be used in the sale of food (Units of Measurement Regulations 1986, 1994, and 1995). This is well illustrated by the case of *Thoburn and others v Sunderland (2002) 3 WLR 247*, in which a prosecution was mounted against Mr Thorburn who had continually refused to sell his fruit and vegetables in metric quantities.

The Prices Act 1974

Consumers need full and accurate price information to be able to make informed purchase decisions and compare prices between traders. The legislation in force goes some way towards ensuring that this happens.

Regulations made under this act require price indications to be given, and the Consumer Protection Act 1987 creates an offense of giving a misleading price indication (Part III, s.20). The Price Indications (Food and Drink on Premises) Order 1979 requires written price indications to be given in premises supplying food and drink for consumption on those premises. The Price Marking Order 1999 requires written indications of unit prices, e.g., price per 100 g, as well as the selling price, to allow for comparisons to be made by consumers. Finally, in the area of pricing, the Price indications (Method of Payment) Regulations 1991 require it to be made clear to consumers if there is a charge made for different methods of payment, e.g., a surcharge for using a credit card.

Loosely connected to the area of pricing is the issue of buying on credit. This may be relevant, for example, if consumers buy food hampers on credit terms or pay for a restaurant meal using a credit card. This area is covered by the Consumer Credit Act 1974 and various detailed regulations. Provisions are both criminal and civil in nature requiring certain information in advertisements (Consumer Credit (Advertisements) Regulations 1989) and also in the documentation containing the agreement (s.61 and the Consumer Credit (Agreements) Regulations 1983). There are also important provisions imposing liability on the creditor as well as the supplier in certain circumstances (sections 56 and 75). This could be particularly relevant in relation to some of the civil provisions discussed below.

The Trade Marks Act 1994

This act implements Directive 89/104/EEC and allows traders to register their trade mark to prevent it being used by anyone else. This is very important in the food industry where brand loyalty is a big issue. Any discrete sign capable of being represented graphically and which is distinguishable may be registered as a trade mark (s.1(1)). This may be the shape of a container, or a sound, or a smell. Company names can also be trade marks, e.g., Coca-Cola and Kelloggs. Although the provisions are mainly about traders protecting their brands and their products, it could be argued that there is a consumer protection angle in that consumers come to expect a certain quality and

safety from a particular trader, which they may not receive from someone using the trade mark without the authorization of the holder. The act contains both criminal and civil provisions, and in addition there is a civil tort of 'passing off' which 'is concerned with the protection of marks that identify the goods as emanating from a particular trade source and yet have not necessarily been registered as trade marks.' An example is the case of *J Bollinger v Costa Brava Wine Co Ltd (1961) RPC 116*, in which the latter company was prevented from calling sparkling wine (now known as Cava) 'Spanish Champagne' as it did not originate from the Champagne region of France (Edenborough M (1995) *Intellectual Property Law*, Cavendish Publishing Ltd.)

Reasonable Precautions and Due Diligence

The vast majority of the offenses described above are strict liability. This could be considered necessary to protect the consumer thoroughly, particularly when it comes to issues such as safety. However, it does seem a little unreasonable to attach criminal responsibility to someone when they have done all they can to try and avoid committing the offenses in the first place. Thus, to counteract the strict liability nature of the offenses, most of them will be subject to a reasonable precautions and due diligence defense (s.21(1) Food Safety Act 1990). The exact wording and nature of the defense provision will vary between the acts, but broadly speaking, they are based on the trader being able to demonstrate that they have set up a system (reasonable precautions) and ensuring that the system works (due diligence). There is much case law in this area illustrating what the courts will accept as satisfactory, although it must be remembered that this is a question of fact, and every case will turn on its own circumstances. However, generally speaking there are a number of principles which can be extracted from the cases as guidelines for the setting up and execution of a suitable system. This will include areas such as staff training (*Knowsley MBC v Cowan (1991) 156 JP 45*), sampling (*P & M Supplies (Essex) Ltd v Devon (1991) MR October 20*), documented checks (*Ellis v Price & Company Bakeries Ltd (1968) MR Aug 183*) and specific warranties from suppliers (*Amos v Melcon (Frozen Foods) Ltd (1985) 149 JP 712*). It is important to carry out some form of risk assessment, identifying where problems are likely to occur and putting in place systems to deal with them. This is known as Hazard Analysis of Critical Control Points and forms the basis of any worthwhile quality-assurance program.

Any system must be preventative, all-encompassing, open to review and amendment, and under the direction of the controlling minds of the company. Although, obviously, the resources of the company will be taken into account, what is necessary for a large retail or manufacturing organization is not necessarily appropriate for a small company (*Garrett v Boots Chemists Ltd (1980) (unreported)*).

Civil Provisions

Civil law deals with situations between affected parties, as opposed to issues affecting the public at large. It is concerned more with remedies, usually monetary, for damage or injury rather than punishment. The tort of 'passing off' has already been discussed, and there are several more areas which would be relevant for food. First, the law of negligence is also a tort and is one of the few areas which is fault-based. The person making a claim is not restricted to the purchaser. Second, the law of contract governs, amongst other things, the terms which may be implied into a contract. The nature of a contract is such that usually only the purchaser will have a remedy. Third, the area of product liability aims to make the producer of a product liable for damage it causes if it is deemed to be a defective product. As with negligence, this is not restricted to purchasers.

Contract Law

The Sale of Goods Act 1979 is the principal piece of legislation which implies terms into contracts. There are in fact several pieces of legislation which imply similar terms depending on the type of contract formed. The references given are for the Sale of Goods Act 1979. The common terms which are implied into consumer contracts are that the goods, including food, will be fit for their purpose (s.14(3)) (*Frost v Aylesbury Dairy Co* mentioned earlier), will be of satisfactory quality (s.14(2)), will conform to their description (s.13(1)) or sample (s.15(2)), and can be sold (s.12(2)). A further consumer protection measure is contained in the Unfair Contract Terms Act 1977, which prohibits the exclusion of these implied terms in consumer contracts by virtue of section 6(2).

Contracts for consumer services must be carried out with reasonable care and skill, within a reasonable time and for a reasonable price. These three terms are implied into consumer contracts by virtue of sections 13, 14, and 15 of the Supply of Goods and Services Act 1982.

Law of Negligence

This can be best explained by the case of *Donoghue v Stevenson (1932) AC 562*, which revolved around a decomposing snail found in a bottle of beer, not by the purchaser but by a friend for whom it had been

bought. There was therefore no contractual liability by the retailer to the ultimate consumer. The principle of law established, which can make the producer liable to the ultimate consumer, whether or not the purchaser, can be found in the well-quoted passage from Lord Atkin's speech:

> A manufacturer of products, which he sells in such a form as to show that he intends them to reach the ultimate consumer in the form in which they left him with no reasonable possibility of intermediate examination, and with the knowledge that the absence of reasonable care in the preparation or putting up of the products will result in an injury to the consumer's life or property, owes a duty to the consumer to take that reasonable care.

The consumer of course has the burden of proving the lack of care and also that the damage suffered was a result of the lack of care.

Product Liability

If goods are defective, they may now come under the remit of Part I of the Consumer Protection Act 1987. This makes a producer (s.1(2)) liable for the damage caused by a defective product (s.2(1)). Damage to the actual item cannot be claimed, although damage to other consumer items is recoverable, as is personal injury or loss, providing they are in excess of £275 (s.5). This legislation can be used to take action in relation to food-poisoning incidents, without the need to prove negligence and where the ultimate consumer was not the purchaser and therefore may not have contractual rights.

Conclusion

It can be seen that there is a significant amount of legislation which deals with consumer protection issues. Only the main areas have been indicated, and there are many more, e.g., the Misrepresentation Act 1967 and the Fair Trading Act 1973 Furthermore, none of the areas mentioned have been covered in any depth, and to appreciate the full application of the law and the way in which it is interpreted, it is necessary to read the actual legislation and cases pertaining to it as well as some texts which comment on it. It should be emphasized that prosecutions under the criminal provisions are often seen as a last resort. Officials are keen to prevent offenses being committed in the first place and therefore offer advice and guidance to traders to help them understand their obligations to consumers. Similarly, many potential civil problems can be sorted out by negotiation, mediation, and arbitration without the need to sue a trader. It is important to note that the achievement of consumer protection aims can often be met, in both criminal and civil areas, without recourse to the courts.

CONTAMINATION OF FOOD

E Todd, Michigan State University, East Lansing, MI, USA

Introduction

Contaminants in foods can be grouped according to their origin and nature. Essentially, these are microbiological (bacteria, viruses, parasites), extraneous matter (biological, chemical, physical), natural toxins (seafood toxins, mycotoxins), other chemical compounds (pesticides, toxic metals, lubricants, veterinary drug residues, undesirable fermentation products, radionuclides), packaging materials, and poisons introduced through tampering. Most of the agents found in food are natural contaminants from environmental sources, but some are deliberate additives, including those used for tampering. Cooking can increase or decrease the toxicity of some of these contaminants but has little effect on most chemicals. Consumers have specific concerns about food contaminants but often lack the means to make appropriate judgments on what is high risk and what is not. Additives were at one time a major concern, but today, microbiological issues are the greatest, followed by pesticide and animal drug residues and antimicrobial drug resistance.

Microorganisms

Foodborne Disease Bacteria

Bacteria that cause foodborne disease occur worldwide, the most common being *Salmonella, Staphylococcus aureus, Clostridium perfringens*, and *Bacillus cereus*. These bacteria can multiply rapidly in moist, warm, protein-rich foods, such as meat, poultry, fish, shellfish, milk, eggs, and most food after it has been processed. Infectious organisms such as *Salmonella* and *C. perfingens* can multiply in the digestive tract and cause illness by invasion of the cell lining, production of toxins, or both. Other organisms produce enterotoxins, e.g., *S. aureus* and *B. cereus*, or neurotoxins, e.g., *C. botulinum*, in the food during their growth and metabolism. The staphylococcal and *Bacillus* enterotoxins are heat-resistant, as are the spores of *Clostridium* and *Bacillus* species. Spores, therefore, can survive cooking and germinate into vegetative cells which can grow in the food if it is left at room temperature. Three other pathogens, *Listeria monocytogenes, Vibrio vulnificus* and *Escherichia coli* O157:H7, have caused severe illnesses leading to deaths. *Listeria* is widespread in the environment and is associated with processed food that has become contaminated. Most illnesses have resulted from consumption of contaminated smoked fish, delicatessen meat products, milk and soft cheese. *Escherichia coli* O157:H7 has been responsible for meat (mainly hamburger)-associated outbreaks, sometimes causing hemorrhagic colitis and hemolytic uremic syndrome. Cattle appear to be a major source of this organism. However, illnesses have resulted from contaminated sprouts, lettuce, unpasteurized apple juice, unpasteurized milk, yogurt, cheese, and water. In the last decade, *Salmonella enteritidis* has been the source of many outbreaks involving egg products through transovarian infection from hen to egg. In the last few years, *S. typhimurium* DT 104 and other antibiotic-resistant salmonellae have also recently become a concern. *Vibrio* spp. naturally occur in seawater, and outbreaks have been associated with molluscan shellfish, especially when the ambient temperatures have been high enough in the water to allow rapid growth of the organisms within the molluscs. More foodborne illnesses are caused by bacteria than any other group of agents. There are several specific qualitative detection methods for most pathogens, but their detection in food is usually more difficult than in clinical specimens. Quantitative methods exist for only some pathogens. Refer to individual organisms; Food Poisoning, Tracing Origins and Testing; Food Poisoning, Statistics. (*See* **Gums**: Food Uses; Dietary Importance.)

Viruses and Prions

Viruses are difficult to detect in food, and historically, few viral foodborne diseases have been confirmed, but these agents are probably major causes of foodborne and waterborne disease from epidemiological investigations. Hepatitis A virus and Norwalk-like agents (within the small round structured virus group) are typical foodborne enteric viruses. Enteric viruses typically arise from infected food handlers or sewage. Shellfish can accumulate viral particles if they are present in the water and cause infections following their ingestion. Although the foot-and-mouth disease virus is not a human pathogen, it can be transmitted through food to animals, as is believed to have occurred in the large UK outbreak in 2001. (*See* **Viruses**.) Another area of concern is the transmissible spongiform encephalopathies caused by

prions, notably the bovine form, which has been responsible for over 100 deaths in the UK. Since there is no control of the disease, eradication of infected animals, including sheep with scrapie, and removal of bovine brain and spinal tissues from the food chain are currently being pursued in Europe.

Parasites

A limited number of parasites are foodborne (waterborne or person-to-person spread is more frequent), and illnesses are usually mild. *Trichinella* is found in garbage-fed pork and wild carnivores, including bears and walruses, which are eaten by hunters. *Taenia saginata* and *T. solium* are widespread in beef or pigs, respectively, and up to one-third of human infections of *Toxoplasma gondii* arise from contaminated meat. Since *Cryptosporidium* can cause infections in humans and animals, and the parasite can be spread through sewage and cattle feces into water systems. It is resistant to standard chlorination procedures and needs to be filtered out during water treatment. Over half of the tested public water supplies that use surface water have been found to have small amounts of *Cryptosporidium* in the potable water supply. Produce sprayed or washed with contaminated water or ice made with it are potential vehicles for this agent. People at risk for severe cryptosporidiosis include people with weakened immune systems, including AIDS patients and those who take drugs that suppress the immune system. *Cyclospora* is another coccidian parasite associated with consumption of water, but also produce such as raspberries, basil, and lettuce. Other parasites, such as *Anisakis, Pseudoterranova*, and *Diphyllobothrium* are relatively frequent in fish but rarely invade gastrointestinal tissues to cause serious illnesses. All parasites can be destroyed by thorough cooking of raw meat or fish, or freezing for several weeks. (*See* **Parasites**: Occurrence and Detection; Illness and Treatment.)

Natural Toxicants

Seafood Toxins

Seafood may contain natural toxins that are of concern in many parts of the world. These are paralytic shellfish poison (saxitoxins), diarrhetic shellfish poison (okadaic acid and related compounds), neurotoxic shellfish poison (brevetoxin), amnesic shellfish poison (domoic acid), pufferfish poison (tetrodotoxin), ciguatera poison (ciguatoxin and other toxins), and scombroid poison (histamine). All but the last are accumulated in shellfish or fish through the food chain from dinoflagellates, diatoms, or bacteria. All these organisms are phytoplanktonic or benthic forms of life, naturally occurring in specific areas of the marine environment. Scombroid poison is produced through the decarboxylation of the histidine to histamine in certain fish, notably tuna, mackerel, mahi mahi, and marlin, through bacterial spoilage. All these seafood toxins are resistant to normal cooking practices and are not detectable by organoleptic means. Shellfish in potentially toxic areas can be controlled by preventing harvesting until the causative dinoflagellate and diatom blooms have diminished. However, because of their sporadic occurrence and difficulty in detection, it is more difficult to prevent toxic fish from reaching the consumer. Except for histamine, there are few chemical analytical tests for regulatory purposes, and for most toxins bioassays are used. (*See* **Shellfish**: Contamination and Spoilage of Molluscs and Crustaceans.)

Mycotoxins

Mycotoxins are widely produced on moist crops by a variety of fungi. Poultry and livestock have been poisoned, with both acute and chronic toxic effects. However, acute poisonings, including deaths, have rarely been documented for human beings; examples of potential problems include ergotism from *Claviceps* growth on rye, alimentary toxic aleukia from *Fusarium* on cereal grains, and aflatoxicosis from *Aspergillus* contamination of maize and other grains. Less conclusive are links to chronic illness from aflatoxins in peanuts, other nuts and grain crops, citreoviridin in moldy rice, fumonisins, ochratoxin, and zearalenone in grain, trichothecenes (vomitoxin) from winter wheat, and patulin from apple juice, although epidemiological data would support a link between liver cancer and aflatoxin in parts of China. Milk and meat from animals feeding on moldy crops may contain mycotoxins and are potential sources of carcinogens and teratogens. There are chemical and analytical methods for most mold toxins, and some crops are monitored and advisory levels set for specific toxins. There is also an indication that mild gastroenteritis can arise from beer and soft drinks in containers contaminated with adventitious molds penetrating through small holes, e.g., punctured cans and faulty bottle tops. These have not been thoroughly investigated. (*See* **Mycotoxins**: Occurrence and Determination.)

Plant Toxins

Several naturally occurring secondary metabolites from plants can cause illness, e.g., neurolathryism from α-aminoproprionic acid in *Lathyrus* species (wild peas), cyanide poisoning from cyanogenic glycosides in almonds, cherries, etc., solanine poisoning from α-solanine in potatoes. Novel foods used from

plant species that have not been used for food before need to be evaluated carefully to avoid the potential for adverse effects. (*See* **Plant Antinutritional Factors**: Detoxification.)

Extraneous Matter

Extraneous matter is foreign material entering a food during its production, storage or distribution, and can be (1) biological matter, such as insect parts, rodent excreta, animal hair, mites, nematodes, and mold, (2) chemical compounds, such as oil or tar, or (3) physical materials, such as glass, metal, and stones. These are undesirable from an esthetic point of view, but injuries and gastroenteritis after their consumption have also been reported. In addition, psychosomatic illnesses have been documented from people observing disgusting objects in their food. Manufacturers receive more complaints about extraneous matter than all other food-related problems combined, and usually install metal or glass detectors on plant lines to minimize these types of contamination.

Other Chemical Compounds

Environmental contaminants of food-safety concern to both scientists and consumers include trace elements, organometallic compounds, and organic substances such as halogenated hydrocarbon pesticides. These compounds have several characteristics in common: (1) they tend to be stable and persistent in the environment; (2) they tend to accumulate in the food chain; and (3) they can be biotransformed with increased toxicity. Analytical chemistry has made us aware of the presence of agents in foods that have the potential to cause chronic illness, but the adverse effects generally cannot be directly demonstrated in human populations. However, the causes of most cancers are not known, and the number of cases of stomach, colon, bladder, and kidney cancers that might be expected to reflect exposure to environmental chemicals are not increasing. Testicular cancer and brain cancer, however, may be on the rise but are not necessarily related to chemical contaminants in foods. Some chemicals, including pesticides, have been shown in animal studies to disrupt the endocrine system and affect reproductive development in the fetus; however, it is not known whether consumption of food containing small amounts of chemical contaminants has any effect on the human population.

Pesticides

Pesticides include insecticides, herbicides, fungicides, rodenticides, insect repellants, weed killers, antimicrobials, and algaecides, that are designed to prevent, destroy, repel, or reduce pests (animal, plant, and microbial). Some are selective, impacting only target organisms, whereas others have a broad-range toxicity. These may be applied in solid, liquid, aerosol, or gaseous form. Spraying in one area may result not only in contamination locally but, depending on weather conditions and patterns, contamination up to thousands of kilometers away because particles can be carried into the upper atmosphere. Some residues may remain in both fresh produce and processed foods. Metabolically stable lipophilic pesticides tend to accumulate in fat deposits in exposed farm animals, and this can lead to biomagnification in animals higher up the food chain, including humans, but today, with better control of the use of chemicals in the environment, this is a diminishing concern in developed countries.

Disorders of the nervous system, liver, and kidney and various types of cancer typically have a long latency period. The critical parameters which determine whether or not a pesticide will cause any adverse effect are (1) the intrinsic biochemical properties of the chemical, (2) the level of exposure to the chemical, and (3) the duration of exposure to the chemical. The severity of illness ranges over a wide spectrum of effects, depending on the duration and extent of exposure and on the susceptibility of the person exposed. Chronic pesticide exposures in the parts per billion and trillion range through the diet are thought to pose at most a very low risk. However, there are many organochlorine, organophosphate, carbamate, pyrethrin, and arsenical pesticides that alter the immune system in wildlife and laboratory animals. More recently, more selective chemical and biological pesticides have been developed, e.g., spores of *Bacillus thuringiensis*; these are not known to have any adverse affects against humans or domestic animals. (*See* **Pesticides and Herbicides**: Toxicology.)

Organochlorine Pesticides

Organochlorine insecticides were widely used, and many persist in the environment today. Dichlorodiphenyltrichloroethane (DDT) and cyclodienes, such as aldrin, endrin, and heptachlor, have been used worldwide for over four decades against insects of public and veterinary health significance. Because of their stability, metabolites of these and other organochlorine compounds have now reached all parts of the world's surface. The most toxic insecticides, such as endrin, have also caused acute human illness from contaminated food products, e.g., tortillas, and even deaths from consumption of flour in contact with the insecticide during transportation in Pakistan. (*See* **Pesticides and Herbicides**: Types of Pesticide.)

Although many countries have banned the use of DDT, it is still of value in controlling diseases such as malaria. Milk from cattle reared in areas where DDT was used in agriculture can be heavily contaminated (e.g., over 500 p.p.m.). High levels can also be found in mild products, e.g., ghee, butter, cheese, and infant formula. Hexachlorocyclohexanes, e.g., lindane, have also been identified in milk after feed prepared from sprayed crops had been given to cattle, or insecticidal ointment had been applied directly to their skin. Some organochlorine compounds originally unconnected to agricultural use have accumulated in foods because of their long-term persistence, e.g., fish containing mirex, an ant poison and also a fire retardant in household materials. Dioxin, a byproduct of defoliant Agent Orange, waste incineration, and industrial processes is found widely in the environment, although usually at low concentrations. As a result of an industrial accident 25 years ago in Italy, the long-term impact of dioxin is being examined; one effect is a reduction in the number of male births. In 1999 in Belgium, chickens and other food-producing animals ingesting dioxin-contaminated feed cost the Belgian economy more than $750 million. Motor oil containing the dioxin entered the food chain after being mixed with vegetable oils used in the feed manufacture.

Many organochlorine pesticides have been linked to hormone disruption and reproductive problems in aquatic invertebrates, fish, birds, and mammals. They degrade slowly and, being fat-soluble, accumulate in the food chain, eventually ending up in body fat. The long-term effects of organochlorine compounds on human beings are not yet known.

Organophosphates

Organophosphates are irreversible cholinesterase inhibitors and can cause changes in the immune system. Some are highly toxic and are responsible for more accidental pesticide poisonings than any other class of pesticides. Symptoms may be reversed with atropine treatment. They are relatively inexpensive and control a variety of insects. Examples are parathion, malathion, and diazinon. They are widely used on food crops, in residential and commercial buildings and for ornamental plants and lawn care, which means that many people may be regularly exposed to them. Although they do not persist in the environment, residues have been found in fruits and vegetables. There is no known health risk from consumption of this kind of uncooked food containing low residues over a long period of time.

Carbamates

Carbamates are insecticides, fungicides, herbicides, and nematocides. These act in a similar manner to the organophosphates for insecticides and nematocides by inhibiting acetylcholinesterase, except that the action is more rapidly reversible. The toxicity is generally low, with the exception of a few compounds, particularly aldicarb. They are considered to be nonresidual and generally break down more rapidly than chlorinated hydrocarbons. Aldicarb has been absorbed from the soil by plants with leaves and fruit accumulating the chemical. Watermelons grown on previously contaminated soil, and hydroponically grown cucumbers treated with aldicarb have caused anticholinesterase symptoms in several hundred persons in outbreaks in North America. Symptoms of acute carbamate poisoning are the same as for organophosphate poisoning; abdominal pain, nausea and/or vomiting, diarrhea, muscular weakness, twitching, blurred vision, watery eyes, pinpoint pupils, excess salivation, sweating, seizures, disorientation, and excitation.

Pyrethrins and other Botanicals

Botanicals are substances that are naturally produced by plants that are poisonous to pests that prey on those plants. Pyrethrins are derived from plants and, together with their synthetic analogs, are used as insecticides. Pyrethroids affect the nervous system and are neurotoxic. Insects become disoriented, and body functions fail, but pyrethroids do not affect mammals because they do not penetrate mammalian skin, and they have esterases than can detoxify the chemical. Although these are generally safe for mammals, they can be toxic to aquatic life. Strychnine, neem, and rotenone are examples of other botanicals that can be used against pests.

Other Pesticides

Alkyl mercury salts, used as fungicides on seed grain, have caused human illness either through direct consumption of the grain or through meat from pigs eating the contaminated grain but are no longer used in most countries. Other chemicals considered too dangerous today and banned in many countries are the thallium salts formerly used as rodenticides. Bromide fumigants, such as methylbromide, are used against insects, nematodes, viruses, weeds, and fungi and are applied directly to the soil. Crops planted on these soils, particularly lettuce, celery, tomatoes, cucumbers, and strawberries, may accumulate bromine. When dibromoethane was found in flour and cake mixes arising from fumigation of wheat during storage, its use was banned because of its mutagenic, carcinogenic, and teratogenic properties. Other fumigants are methylene chloride, carbon tetrachloride, chloropicrin, phosphine, and ethylene dibromide

(banned). (*See* **Fumigants**.) Alar, a plant-growth regulator, penetrates fruits, cannot be removed by washing or peeling, and can be converted to products that may be carcinogenic in cooked fruit or products. Controversy that arose regarding its potential carcinogenicity led to its removal from use by the manufacturer.

Pesticide Contaminants

In addition to pesticides themselves, certain impurities in formulations can be toxic. Acute delayed toxic effects, including weight loss and pneumonia, have developed from exposure to trimethylphosphorothioate present in malathion sprays. The potential carcinogen nitrosodimethylamine has been found as a contaminant in certain pesticides. Improved pesticide production practices have since reduced the level of these toxic impurities. (*See* **Nitrosamines**.)

Herbicides

After 50 years of use, 2,4-D of the phenoxy family of herbicides, is the most widely used herbicide worldwide. Its major uses in agriculture are on wheat and small grains, sorghum, corn, rice, sugar cane, soybeans, low-till rangeland, and pasture. It is also used on rights of way, roadsides, noncrop areas, forestry, lawns, turfs, and aquatic weeds. There are moves to restrict its applications, even though no scientifically documented health risks, either acute or chronic, exist from approved uses. Atrazine, a triazine herbicide used to control broadleaf and grassy weeds in corn, sorghum, soybeans, sugarcane, pineapple, Christmas trees, and other crops, also has a low toxicity, but animal studies indicate its potential for endocrine disruption and carcinogenicity. In contrast to most herbicides, paraquat, a bipyridyl contact herbicide, is highly toxic through dermal exposure and ingestion, and must be handled with care. Some weeds are developing herbicide resistance, and either new compounds or new approaches may be required for use of herbicides in the future.

Summary

Several pesticides are considered potentially carcinogenic or teratogenic based on various tests including animal studies. However, human data are limited (except for arsenic and perhaps for the use of the defoliant Agent Orange in Vietnam), and there is no epidemiological evidence that any pesticide is a human mutagen, carcinogen, or teratogen at normal exposure levels. Future work needs to concentrate on mechanisms of pesticide toxicity and metabolism, reevaluation of acceptable limits, and their control in the environment. The use of pesticides will not be eliminated in the future, but their use may be reduced, and safer compounds will replace the more toxic and persistent compounds; unfortunately, DDT and other organochlorines will remain in the environment for many years.

Toxic Metals

The sources of toxic metals are atmospheric contamination, sewage sludge, trace contaminants in animal feed, fertilizers, or pesticides. Contamination may also occur during processing, home cooking, and storage in metal containers. Heat does not reduce the toxicity of these metals substantially.

Cadmium

Cadmium is naturally present at a very low level in the environment, but large concentrations are produced as waste byproducts of electroplating, rust proofing, color tints for paint, plastic stabilizers, and batteries. Effluents also arise from textile, porcelain, and enamel manufacturing. Crops grown in sludge containing cadmium can accumulate the metal up to 13 times the soil concentration. When cadmium salts are released into an aquatic environment, crustaceans and fish accumulate quantities large enough to be hazardous if they are a part of the regular diet. (*See* **Cadmium**: Toxicology.)

Lead

Lead present in rocks and soil may be accumulated in plants and transmitted to humans through the food chain. However, most lead comes from atmospheric aerosols and dust particles through industrial processes and automobile emissions, although lead is less used as a petroleum additive today. Urban areas therefore contain more lead particles than rural regions. These fall on soil and are absorbed by crops. Modern canning uses lacquer, side-seam welds, and seamless two-piece cans to replace lead solders. Acidic foods or beverages stored in ceramic vessels made with glazed lead salts or galvanized pans have accumulated lead. In addition, the alimentary tract can receive lead from potable water transported by lead piping or stored in lead-lined tanks, and through the compulsive nibbling by children of paint chips containing lead, with up to 550 μg per day being accumulated. Lead is a cumulative poison, and chronic exposure may lead to damage to the brain, liver, peripheral and central nervous system, and reproductive, renal, and immune systems. (*See* **Lead**: Toxicology.)

Arsenic

Arsenic is widely distributed throughout the earth and reaches food sources from water through the dissolution of minerals and ores, from industrial effluents, and from atmospheric deposition; concentrations in ground water in some areas are sometimes elevated as a result of erosion from natural sources. The average daily intake of inorganic arsenic in water is estimated to be similar to that from food. Arsenic is used commercially in the production of pharmaceuticals, metals, herbicides, wood preservatives, and sheep dips. Arsenic compounds have occurred in seafood, eggs, and cheese. Chronic poisoning from arsenic is unusual unless it occurs naturally in the water supply. However, inorganic arsenic is a documented human carcinogen, and a relatively high incidence of skin and possibly other cancers that increase with dose and age has been observed in populations ingesting water containing high concentrations of arsenic.

Mercury

Mercury is used in electrodes, the manufacture of plastics, slimecides in the pulp and paper industry, paints, and fungicides. In the environment, the toxic form is methyl mercury, which is a neurotoxin as well as a teratogen. The mercury content of crops may increase with the use of sewage sludge. It is found in fish and shellfish living in water contaminated from industrial wastes and in large lakes artificially created for hydroelectric power from drowned, decaying vegetation. Acid rain also helps to mobilize industrial aerosols into water supplies. People with a regular diet of fish containing high levels of organic mercury, or shellfish containing inorganic mercury, are at greatest risk. (*See* **Mercury**: Toxicology.)

Tin, Copper, and Antimony

Although tin can reach aquatic environments through natural sources, industrial pollution and antifouling paint on boat hulls, there is little evidence that it can cause chronic human illness. However, acid foods in tin-lined cans are able to dissolve enough metal to cause acute gastroenteritis. Both copper and antimony become toxic when they are in contact with acidic liquids. Copper pipes used in soft-drink vending machines, and antimony-lined bowls or cups have been implicated in acute illness. The speed of metal solubilization depends on the acidity of the liquids, temperature and time of exposure.

Fluoride

The beneficial effects of fluoride in drinking water on teeth have been demonstrated, but fluoride can be toxic, and intakes of more than 10 mg per day are not recommended. The total consumption of fluoride from both water and food prepared using water has to be considered in determining intake levels.

Lubricants

Polychlorinated biphenyls and polychlorinated naphthalenes were produced as lubricants and should not be brought into contact with food or feed, but cattle may ingest them by licking the oils from farm machinery or animal feed containing leaked oil. Affected animals develop a debilitating condition, and human ingestion of milk is considered hazardous. Because of their extreme persistence in the environment, PCBs are not only banned from future use but are being removed from aging equipment, e.g., transformers, and are destroyed by incineration. Polybrominated biphenyls have also been accidently fed to livestock with resultant human exposure through milk and meat.

Veterinary Drug Residues

Antibiotics are added to reduce disease and improve the growth of farm animals and aquaculture fish; these are of less concern for their chemical effect and more for their ability to increase antimicrobial resistance in strains that might subsequently infect humans. There is evidence that antimicrobial resistance is increasing worldwide but particularly in developing countries. Steroids and growth hormones are used to increase productivity, e.g., bovine somatotrophin for milk, synchronize breeding cycles, and act as tranquillizers. The human effect of consuming foods with these drugs is still being debated, but many countries refuse to accept products derived from animals given these drugs. Also, some drug residues may be allergenic, e.g., penicillin. The withdrawal times of such drugs are critical to keep the residues in food as low as possible.

Undesirable Fermentation Products

The carcinogen ethyl carbamate is a natural fermentation product in the production of wine, either through reaction of ammonia with the antimicrobial agent diethyl pyrocarbonate or through ethanol with carbamyl phosphate. Limits of 30 μg per kilogram of wine and 400 μg per kilogram of brandy have been set to reduce the level of carbamates for human exposure. There have been over 1500 cases and 20 deaths owing to eosinophilic myalgia syndrome in the USA from tryptophan dietary supplements contaminated with derivatives of L-tryptophan. These contaminants

were thought to have arisen during the fermentation process when a genetically modified strain of *Bacillus amyloliquefaciens* was used to produce the tryptophan. However, some purification steps were left out of the process at the same time, and no satisfactory explanation for the contamination has been made.

Radionuclides

Radionuclides are normally present in the environment at low levels from naturally radioactive rock but can also arise from atmospheric fallout from nuclear tests and gaseous emissions and spills from accidents at nuclear reactors. Food is one possible means of transmitting radionuclides to the human body, with a danger for long-term carcinogenic, teratogenic, or mutagenic effects. Higher doses may also affect reproductive capability and shorten the lifespan. Radium-226 and uranium-238 are naturally occurring radioactive elements that may be at high levels in certain locations because of the underlying rock structure. Cereals are the food items that contribute the most radium-226 to our diet. Fallout from tests or accidents persists longer in arctic zones, and persons eating an exclusive meat diet, such as Lapps and the Inuit, are at highest risk from lead-210 and polonium-210. Milk and meat supply most of the radionuclides, such as strontium-89, strontium-90, iodine-131, and cesium-137, to our bodies. The direct effects of the Chernobyl nuclear reactor explosion in Ukraine in the immediate area of the reactor were extreme, but worldwide contamination was not as high as was originally feared and had no lasting impact on the food supply. (*See* **Radioactivity in Food**.)

Packaging and Storage

Packaging can exist in various forms, from crates to wraps. Wood preservatives, such as phenols or copper arsenates, and insecticides against termites, used in crates, can contaminate food during shipping through direct contact or vapors. Wood shavings used for packing can also transfer these chemicals to foods, or to animals if the shavings are used for bedding. In addition, food stored in rooms with walls covered with insecticidal paint, or containing pest strips from which pesticides evaporate over a long period of time, may become exposed to the chemical.

Paper, cardboard, plastic wrap, or aluminum foil may not keep out lindane vapors if not properly wrapped. Phosphoric acid esters as flame retardants in paper, adhesives, and plastic wrappers, e.g., bread bags and margarine or butter wraps, can reach food. Diffusion through these is dependent on the time of contact and type of food wrapped (lipid-rich or moist foods absorb better than other foods). Hermetically sealed containers protect food from all chemical and microbial contaminants if the process is carried out correctly.

Tampering Problems

For centuries, food has been adulterated for fraudulent purposes or deliberately contaminated for injuring or killing specific persons. Recently, commercially produced food has been tampered with for a variety of reasons, including product extortion to obtain money from a company or life insurance firm, attempts to ruin a company by a dissatisfied customer or disgruntled employee, attention in the media for a political cause, or as a joke to observe the reaction of those affected. In dioxin contamination of feed, there may be some situations where this is deliberately done to use waste oils mixed with vegetable oils. Tamper-resistant and tamper-evident packaging has reduced, but not eliminated, these problems. Nowadays the possibility of contamination of the food chain, water supplies or even retail food is a real threat of bio terrorism. CONTRACEPTIVES: NUTRITIONAL ASPECTS

F Ford, University of Sheffield, Section of Reproductive Medicine, Sheffield, UK

Background

In 1998, the Royal College of General Practitioners (RCGP) celebrated the 30th anniversary of its unique and world-renowned study into the safety and effects of the oral contraceptive (OC) pill on women's health. The study recruited 1400 GPs and 47 000 volunteer women throughout the UK, half of whom were using OCs, the other half of whom had never done so. It has become one of the largest detailed investigations into the pill worldwide and has highlighted many important and significant links and risk factors between the oral contraceptive and a variety of medical conditions.

Diet, Oral Contraceptives, and Cardiovascular Disease

The RCGP study was among the first to show that the risk of cardiovascular disease among pill users is concentrated mainly in users who smoke, especially in older women. The study was also the first to demonstrate a link between the risk of hypertension or arterial disease and the progestogen content of the pill. Most excess cardiovascular disease among users of OCs is due to thrombosis (not atherosclerosis); studies indicate that the lower the OC estrogen dose, the lower this risk. OCs containing the third-generation progestins desogestrel and gestodene have been associated with greater risks of venous thromboembolism than are associated with older progestins, although there is some controversy surrounding these findings.

OC users have lower dietary carotenoid intakes than nonusers. Since OC users smoke and drink more than nonusers, and both factors are associated with lower carotenoid intakes, OC users form a potential high-risk group for disease.

Conflicting reports regarding the possible effect of OCs on folate status prompted researchers to evaluate the relationship between dietary folate intake and the concentration of folate in serum and erythrocytes among users and nonusers of OCs. The authors concluded that the use of OCs produces significantly lower serum folate levels during the first week of the menstrual cycle in spite of adequate folate intake.

Recent epidemiologic studies have shown an increased mortality from cardiovascular diseases in people with higher serum copper levels. Even though a higher serum copper concentration in women using OCs is well known, there is still uncertainty about the influence of newer progestin compounds in OCs on serum copper concentration. This issue is of particular interest in the light of recent findings of an increased risk of venous thromboembolism in users of OCs containing newer progestins like desogestrel compared to users of other OCs. While an elevated serum copper concentration was found in users of all types of OCs, the elevation was more pronounced among women taking OCs with antiandrogen effective progestins such as third-generation OCs containing desogestrel. Further investigation is required to shed light on the possible role of high serum copper concentration in increasing the cardiovascular or thrombotic risk of women using OCs.

Oral Contraceptives and Weight Gain

Although weight gain is frequently reported, as a side-effect of OC use, there is little empirical evidence that such weight gain actually occurs. Published studies on the effects of OCs have shown that long-term use is not associated with increases in weight. Despite these findings, it is a common perception among women that oral and other hormonal contraceptives cause weight gain. In 1995, more than one million American women used Depo-Provera, and more than 500 000 used Norplant. Clearly, it is important to determine whether the use of these drugs can be expected to promote weight gain in women.

Preliminary reports suggested that users' perceptions of weight gain may be justified for some newer contraceptive drugs. Implanted (Norplant) and injected (Depo-Provera) forms of progestin have been found to lead to increases in appetite and body weight.

The mechanisms by which contraceptive hormones may affect body weight are not known. Numerous studies have shown that energy intake and expenditure are altered across phases of the menstrual cycle. Few researchers have examined how these cyclic changes are affected when a contraceptive drug suppresses ovulation. A placebo-controlled experiment showed that, although the phase of the menstrual cycle affected both energy intake and resting energy expenditure, suppression of the cycle with depot medroxyprogesterone acetate did not cause short-term changes in energy intake or expenditure, or cause weight gain, in young healthy women. Further research is needed to determine whether similar effects occur with different contraceptive hormones, over longer periods of time, and in other populations, such as overweight or obese women.

H Gourama, Pennsylvania State University, Reading, PA, USA
S L Cuppett and L B Bullerman, University of Nebraska-Lincoln, Lincoln, NE, USA

Background

Planting and harvesting of fruits and vegetables are determined by many factors including season of the year, the cultivars, climatological conditions, and the type of soil. In addition, since the majority of fruit and vegetable consumers are often located far from growing areas, most crops must be stored then transported to marketplaces if demand for them is to be satisfied throughout the year and throughout the world. Because fruits and vegetables are essential sources of vitamins, minerals, fiber, and other nutrients, consumers are demanding a larger and more consistent supply of these products. Controlled atmosphere (CA) storage of fruits and vegetables not only increases the shelf-life of these products and maintains good quality but also allows for a consistent year-round supply in the marketplace. CA storage has been shown to lengthen the shelf-life of fruits and vegetables by controlling their levels of transpiration, respiration, and diseases.

Control of Undesirable Plant Processes

The quality of fruits and vegetables after harvest depends upon whether they were harvested at the right maturity stage, and if the metabolic activities after harvest are controlled. Some of the physiological activities of fruits and vegetables such as respiration and transpiration continue after harvest. However, other metabolic activities of these plant products such as photosynthesis and water absorption through the roots stop at harvest. All of these changes create metabolic stresses on fruits and vegetables that shorten the storage life of these crops and reduce the nutritional and organoleptic quality. Optimal storage conditions after harvest can control the loss of quality of these products by maintaining metabolic homeostasis and by minimizing processes like transpiration, respiration, sprouting, and elongation of existing structures, seed germination, and greening.

Control of Transpiration

The loss of moisture after harvest can lead to many changes in the texture and structure of plant products such as shriveling, shrinkage, and product loss. Thus, minimizing the amount of water loss during the post-harvest period is critical for maintaining good quality and freshness of these products. Transpiration rates depend not only on the type of plant product but also on the humidity and temperature of the external environment. Reduction of the rate of transpiration in these food products can be achieved by maintaining low temperatures, high relative humidities, and small vapor pressure differences during storage.

Control of Respiration

Respiration in plant products is defined as a physiological process by which plant tissues exchange gases with the surrounding environment. The principal outcome of this physiological process is the metabolic transformation of carbohydrates such as starch and oxygen to carbon dioxide and water through glycolysis, the Krebs cycle, and the electron transport chain. Respiration, if allowed to occur to any extent, produces heat, thus affecting the temperature of the product. Generally it is known that fruits and vegetables with high respiration rates such as broccoli, sweet corn, mushroom, and asparagus are perishable, whereas products with low respiration rates are stable during storage. The respiration rate of fruits and vegetables is influenced by oxygen level, temperature, carbon dioxide, ethylene, and physical stress. Control of temperature by refrigeration is critical in reducing the rate of respiration. However, many products, such as melons, peppers, cucumbers, etc., cannot be stored for a long time under refrigeration because of their susceptibility to chill injury. Additional control measures such as appropriate packaging and transportation, modified atmosphere (MA) storage, and CA storage of fruits and vegetables should be implemented.

Pioneering work has led to the development of CA storage, an effective process that can extend the shelf-life of fruits and vegetables by controlling the gases within the storage environment. CA and MA are basically processes that change the normal composition of the air (78% N_2, 21% O_2, 0.03% CO_2) surrounding fruits and vegetables. CA storage is usually used in conjunction with refrigeration. The first studies regarding fruit preservation in a gaseous medium were carried out in an atmosphere consisting of more carbon dioxide and less oxygen than is normally present in the air. The benefits of CA and MA include slowing down the respiration rate, sensitivity to ethylene, and, consequently, the ripening process, inhibition of microbial growth, and control of insects. The exact gas composition will depend on the type of product, temperature, and length of treatment. CA and MA have been proven to be beneficial for vegetables such as cauliflower, asparagus, brussels sprouts, celery, mushrooms, cabbage, lettuce, peppers, broccoli, and other vegetables. Among vegetables, artichokes may be held in 2–3% carbon dioxide and 2–3% oxygen, asparagus in 5–10% carbon dioxide and atmospheric oxygen (air), broccoli in 5–10% carbon dioxide and 1–2% oxygen, cabbage in 3–6% carbon dioxide and 2–3% oxygen, okra in 3–5% oxygen and 0% carbon dioxide at 8–12 °C, radishes in 1–2% oxygen, 0% carbon dioxide at 0–5 °C, mature tomatoes in 0–3% carbon dioxide and 3–5% oxygen at 12–20 °C, and partially ripe tomatoes in 0–5% carbon dioxide and 3–5% oxygen at 8–12 °C. Generally, the relative humidity for the CA of vegetables varies from 90 to 98%. CA storage was also found to reduce chilling injuries to cucumbers.

CA storage has also been proven to be good for maintaining the quality and extending the shelf-life of fruits. CA storage has been shown to improve the chilling sensitivity, retarding the ripening and senescence and controlling microbial and insect attacks. One of the principal commercial fruits with which CA storage has been used successfully is apples. Generally, apples are stored in 1–3% oxygen and 1–5% carbon dioxide at 0–5 °C, depending on the variety. These apples are typically harvested before or at the beginning of the increase in the respiration rate. During CA storage, apples can go through many chemical and physiological disorders, such as development of bitter pit, corky lesions, and superficial

scald. CA storage of Golden Delicious apples at low temperatures and low oxygen atmospheres produces the highest amounts of volatile aroma compounds such as branched-chain esters. Low-oxygen atmospheres have also been found to be beneficial for fruit firmness, acidity, and color. It has been reported that there are many advantages in storing apples in CA for a long period of time (up to 3 years) over normal air storage. These advantages include maintenance of firmer fruits, good skin color, higher soluble solids, and low pH. It has also been found that the development of flesh browning after short exposure of 'Fuji' apples to 20-kPa carbon dioxide is a good prediction of CA-induced flesh browning. CA storage has also been shown to extend the shelf-life of green bananas by storing them in 2–5% oxygen and 2–5% carbon dioxide at an optimal temperature of 13 °C. It has been reported that equal amounts of oxygen and carbon dioxide (5%) at 11.7 °C are suitable for Gros Michel bananas held for 20 days. Lacatan and Dwarf Cavendish bananas have been effectively stored for 3 weeks using CA storage conditions of 6–8% carbon dioxide and 2% oxygen at 15–15.5 °C. A mixture of 5–10% oxygen and 0–5% carbon dioxide is generally effective for oranges, 5–10% oxygen and 0–10% carbon dioxide for lemons, 1–2% oxygen and 3–5% carbon dioxide for peaches, 1–2% oxygen and 0–5% carbon dioxide for plums and prunes, 5–10% oxygen, 15–20% carbon dioxide for strawberries, and 3–5% oxygen and 5–10% carbon dioxide for mangos. The temperature range for CA storage of fruits varies from 0 to 5 °C, and for tropical fruits, the temperatures are higher, from 5 to 15 °C.

Control of Ripening

Prior to senescence, fruits go through a ripening stage, which consists of biochemical reactions that transform fruits into sweet, soft products with good aromas. The color also changes from green to yellow, orange, and/or red. Fruits can be divided into categories, based on their ripening physiology. Some fruits, such as apples, tomatoes and bananas, are referred to as climacteric, whereas other fruits, such as oranges, grapes and pineapples, are nonclimacteric. Kidd and West were the first to establish the relationship between decreasing oxygen and raising carbon dioxide and the onset of climacteric changes in apples and pears. These two types of fruits are distinguished by their response to the gas ethylene. Climacteric fruits, when exposed to ethylene, exhibit a respiration surge/climax, which is coincident with their ripening, whereas nonclimacteric fruits do not have a respiration climax and show no ripening changes. Also, during ripening, climacteric fruits produce and release ethylene into the atmosphere. Ripening in climacteric fruits hastens their transition into senescence and, therefore, shortens their storage life. Thus, control of the level of ethylene in the environment is very important for extending the storage life of climacteric fruits. (*See* **Ripening of Fruit**.)

Ethylene production in climacteric fruits has an important physiological role in seed germination, leaf abscission, ripening of fruits and vegetables, and the yellowing of leaves. Methionine is the primary precursor of ethylene biosynthesis. Methionine in the presence of ATP transforms into *S*-adenosylmethionine, which then transforms into aminocylpropane carboxylate (ACC) and ethylene. ACC synthase and ACC oxidase are key regulatory enzymes involved in the biosynthesis of ethylene. Ethylene's biosynthesis and physiological function depend on the oxygen concentration. Apples stored at 3% oxygen generate up to three times less ethylene than the apples stored in the air. Golden Delicious apples stored at low oxygen and at low temperature receive the highest sensory score after 5 months of storage. Maintenance of ethylene concentration of less than $1\,\mu l\,l^{-1}$ in CA storage delays fruit softening and other ripening changes, including the development of disorders, such as superficial scald and bitter pit in apples, both of which are also markedly influenced by preharvest factors and maturity. It is clear that the potential for disorder development, which would be readily manifest in air or refrigerated storage, can be modified significantly by storage in conditions that induce significantly reduced ethylene production rates and/or prevent build-up of ethylene in the storage atmosphere.

High concentrations of carbon dioxide suppress the production of ethylene. A number of investigations have shown that treatment of fruits with elevated levels of carbon dioxide leads to an accumulation of ACC. The inhibition of ethylene formation may be due to the inactivation of ACC oxidase, the enzyme that catalyzes the reaction of ACC to ethylene. However, small concentrations of carbon dioxide (0.1% or lower) have been found to be stimulatory to the production of ethylene. Reducing oxygen levels from 2 to 1%, with 1% carbon dioxide at 1 °C, leads to a decrease in the respiration rate of Red Delicious apples by one-third. Storing apricots at low concentrations of oxygen and high carbon dioxide levels (12–15%) for 30 days or less improves the quality of Perfection and Rival apricots.

Carbon monoxide has also been used in CA storage. Carbon monoxide is an air pollutant that is hazardous to humans and can affect vegetables detrimentally before and after harvest, because of its ethylene-mimicking capabilities. In a study, carbon

monoxide added to air, or 2% oxygen, reduced the respiration rate of head lettuce during storage at 2–5 °C. Carbon monoxide can stimulate carbon dioxide and ethylene production by climacteric fruits but has little effect on respiration rates on nonclimacteric fruits, such as strawberries. However, it has been reported that a combination of 4% oxygen, 2% carbon dioxide, and 5% carbon monoxide may be optimal for delaying maturation and ripening, maintaining good quality and retarding decay during storage of mature green tomatoes at 12.7 °C. It has also been found that packaging precut vegetables, i.e., lettuce, cabbage, celery, broccoli, cauliflower, parsley, and green onions, in 1.5 mil (a mil is a full unit used for thickness) polyethylene bags and modifying the atmosphere within these packages to include 25–50% oxygen and 3–10% carbon monoxide retard brown discoloration. Carbon monoxide has also been shown to prevent browning of mushrooms by inhibiting polyphenol oxidase activity.

Many investigations have shown that preserving foods by atmosphere modification has more advantages than disadvantages, depending on the commodity, variety, atmospheric composition, and temperature. The advantages of preserving fruits and vegetables are as follows:

- reduction of low-temperature diseases, such as chill injury during refrigeration;
- control of insect and microbial attacks;
- better preservation of organoleptic characteristics such as taste and aroma;
- retardation of ripening; and
- the period of preservation is significantly longer than when fruits and vegetables are stored in an uncontrolled atmosphere.

Potential problems with these processes, especially MA storage, include the following: storage under low levels of oxygen may lead to the development of off-flavors owing to anaerobic respiration; certain types of defects, such as brown stains on lettuce and blackheart in potatoes, can be initiated at low levels of oxygen; and at high levels of carbon dioxide, the ripening of some fruits can be irregular.

Control of Microorganisms

Fruits and vegetables contain water and other solutes, which are utilized by microorganisms deposited on their surfaces during the growing season. Most of the microorganisms are opportunistic, invading the tissue as it matures, particularly if the crops are stored under conditions of high temperatures and humidity. Although fungi and bacteria cause substantial losses in vegetables and soft fruits, most losses are caused by molds, since the inherent acid conditions of the product delay bacterial growth. (*See* **Spoilage**: Bacterial Spoilage; Molds in Spoilage.)

It is difficult to determine the full extent of postharvest losses caused by microorganisms; however, conservative estimates place US losses at around 24% of the harvested crops of fruits and vegetables. Postharvest losses have been estimated to be 50% of the harvested crop, and much of this is due to rot caused by microbes, especially fungi. Fruits and vegetables are frequently washed with recirculating water after harvest. This water is often contaminated with soft-rot bacteria and fungi, because of the recirculation, and these can contaminate fresh commodities. Therefore, an effective concentration of a broad-spectrum antimicrobial agent should be maintained in water used for handling fruits and vegetables in order to kill potential pathogens and spoilage microorganisms. Chlorine and sodium orthophenylphenol (SOPP) have been used for this purpose. Bananas are generally surface-contaminated with several fungi, i.e., *Cephalosporium, Gloeosporium, Fusarium*, and *Verticillium* species, which may cause crown rot during marketing. These fungi can be killed by exposure for 1 min to 2 ppm chlorine in water.

Care must also be taken in properly maintaining the storage environment of fruits as a means of controlling microbial losses. Rooms used for ripening bananas, degreening citrus fruits, and refrigerated storage can become heavily infested with spores of pathogenic fungi. These rooms may be disinfected easily and economically by atomizing a water solution containing 1% formaldehyde or 5% sodium hypochlorite into the atmosphere and closing the room for a few hours. Gaseous nitrogen trichloride and sulfur dioxide have also been used to disinfect lemon and grape storage rooms, respectively. Brief heat treatment has been shown to be most successful in eradicating latent or incipient fungal infections in several fruits. Hot water is the best heat-transfer medium because of the availability, heat capacity, and lack of residues on the fruits. Hot water has been advocated for control of *Penicillium* and *Diplodia* species on oranges, *Colletotrichum* species on papaya and mango, and crown rot of banana.

Irradiation has also been investigated as an alternative to chemical means to control insect and fungal contaminants. Irradiation has also been shown to extend the shelf-life of fruits and vegetables by delaying the ripening process. The use of gamma irradiation has shown promising results in controlling specific infections in apples. Ionizing radiation doses for up to 100 krad has been approved for the treatment of produce. Infection may also be prevented by the use of fungicides before harvest or before storage.

Many weak acids, such as benzoic, sorbic, propionic, acetic, nitrous or sulfuric acid, are used to control molds in foods and stored products. (*See* **Fungicides**.)

Biological control of postharvest diseases is an emerging area that has has been widely investigated, owing to increased concern over the safety of these chemicals and to development of resistance of number of plant pathogens to these chemicals. A number of biological controls have been tried, including antagonistic microorganisms, induced resistance, and the use of natural antimicrobial substances. *Trichoderma viride* has been applied to strawberry plants to partially control gray mold caused by *Botrytis cinerea* on strawberry fruits after harvest. Brown rot on peaches has been controlled by *Bacillus subtilis*. Many investigators are trying to enhance the natural defense mechanisms of fruits and vegetables such as the reinforcement of plant cell wall, phytoalexins, PR proteins, and constitutive inhibitors such as monoterpene aldehyde. Other potential nonchemical control mechanisms include the use of ultraviolet light, heat treatment, calcium chloride, and chitosan.

A storage atmosphere that has been modified by reducing the oxygen level and increasing the carbon dioxide level can influence the development of postharvest diseases either by direct inhibition of the pathogen or by altering the resistance of the host. It has been found that 30–40% carbon dioxide in the storage atmosphere inhibits the development of several pathogenic fungi on temperate zone fruits. Tropical fruits may be less tolerant to high levels of carbon dioxide. The following are recommendations for some tropical fruits: avocado in 2–5% oxygen and 3–10% carbon dioxide, banana in 2.5% oxygen and 2.5% carbon dioxide, mango in 3–5% oxygen and 5–10% carbon dioxide, papaya in 2–5% oxygen and 5–8% carbon dioxide, and pineapple in 2–5% oxygen and 5–10% carbon dioxide.

The most commonly used gas combination is 5% carbon dioxide and 3% oxygen, a mixture that provides good storage conditions, along with low temperatures (0–4.4 °C). Dry ice can be used to increase the carbon dioxide content to 10–45% during transit or short-time storage. Such treatment is beneficial for sweet cherries, strawberries, raspberries, and several other products. Among vapor treatments, sulfuric fumigation is a standard practice for control of decay of grapes in storage, but it is injurious to most other fruits and vegetables. Biphenyl pads have been used to control decay in packages of some citrus fruits. (*See* **Fumigants**.)

Another potential disinfectant for fruits and vegetables is ozone. This has been extensively investigated over the last few years. Ozone dissolved in water has been shown to be effective in sanitizing the surface of fruits and vegetables. Sodium orthophenylphenate is frequently used as an antiseptic wash or in a wax on several crops including citrus fruits, pears, sweet cherries, and sweet potatoes.

Control of Insect Pests

Insect pests, along with microbial diseases and spoilage, are responsible for much storage loss that causes extensive economic losses. Various control methods are available for these pests, including hygiene and cultural control, physical control, physical barrier, and chemical and biological control. Treatment by hot water or hot air has been used to control insects and increase the shelf-life of fruits and vegetables. Postharvest has also been found to affect the senescence of fruits by influencing the rate of respiration and ethylene synthesis. (*See* **Insect Pests**: Insects and Related Pests; Problems Caused by Insects and Mites.)

Use of Fumigants

Typical fumigation procedures expose the fruit, at ambient or near ambient temperatures, for several hours to methyl bromide or ethylene dibromide at concentrations of 45 g to a few kilograms per 1000 m^3 of air space in air-tight chambers. The fumigants are highly toxic, and their residues can pose an additional problem in the use of chemical fumigants. For the safety of operators and consumers, applications of fumigants should follow the standards set by the proper regulatory agencies.

Use of Gas Control

Strict control of storage atmospheres has many advantages such as delay of maturation, ripening, senescence, insects, and microorganisms. Treatment of European red mite on Delicious and Spartan apples with close to 100% carbon dioxide or nitrogen at 21–24 °C provides a 100% kill in 2 days. A mixture of 60% carbon dioxide with air provides no mite mortality, even after 7 days of exposure. This indicates that the biocidal effect resulted from low oxygen. The effects of carbon dioxide are also more or less the same on a number of other insects of economic importance. The codling moth is also sensitive to high carbon dioxide and low oxygen levels. The possible phytotoxicity caused by such an atmosphere indicates a potential for using high levels of carbon dioxide on some apple cultivars. Laboratory tests have shown the effects of high carbon dioxide (60%) and low-oxygen (0.5%) atmospheres, applied at 25 °C and at relative humidities of 60 and 95%, as reducing the amount of time required for codling moth mortality.

Design of Storage Areas

Fruits and vegetables can be stored in a CA most effectively in special chambers. These chambers are equipped with a cooling system, devices for creating the necessary gas composition, and devices for controlling and regulating relative humidity. A number of factors should be considered carefully before the construction of any storage facility. These factors include: site selection, integrity of the structure, insulation, vapor barriers, an appropriate refrigeration system, adequate temperature- and gas-monitoring system, and good storage facility layout.

Volume Planning Decisions

The requirements that should be kept in mind before planning for storage chambers are the level of produce loading that can be expected, the distribution of temperature and gases in the mass of produce, and the geometry and parameters of the chambers. If the chambers have very high loads, it will be difficult to obtain a gas mixture of the required composition to maintain CA. It has been shown that produce must be loaded in a continuous stack with a minimum gap between them and the walls. For instance, in the UK, the standard distance between boxes in the stack is 0.5 cm. When loading containers in the chambers, the gap between them is 2.5 cm; in the case of boxes on racks, the gap between them is 5 cm. In all cases, the gap between the stack of produce and the enclosure wall is 2.5 cm. At the same time, it must be considered that these chambers should be economical. Studies in the former USSR have shown that from the viewpoint of minimum costs of enclosures, chambers with a height up to 5.4 m are considered economical. In other countries, this value is 4.0–4.8 m (UK) and 5.6–6.6 m (USA, Italy, France).

Modern CA fruit storage areas consist of individual chambers with load capacities of 50–150 tonnes, or more. Volume planning designs regarding these chambers are generally made on the basis of various considerations, which are summarized in Table 1.

Table 1 Considerations for chamber designs

Chamber design	*Measurements*
Volume	4–5 m^3 $tonne^{-1}$
Size	Vary with the size of boxes
Net height	4.8–5.4 m
Gap	1–2 cm for boxes; 5–10 cm for trays
Minimum capacity	30–50 tonnes
Dimensions of chambers	6 × 6 m, 6 × 12 m, and 12 × 12 m; with a net height of 4.8–5.4 m

Hermetic Sealing and Gas Insulation

To maintain the desired gas mixtures, chambers should be airtight, and because of the cost of airtight insulation of partition walls, these chambers should not be very high. One of the most common materials used for sealing is foamed-in-place polyurethane, which should be protected by a fire-resistant thermal barrier. Another important factor is the selection of the gas-impermeable material used for the construction of the chambers. The most reliable gas insulation materials are galvanized iron sheets, aluminum foil covered with asphalt on one or both sides, vinyl-based resins, polyester and epoxy resins, reinforced fiber glass, and asphalt matriced with rubber. Besides these, plastic sheets, gas-impermeable varnish, paints, etc. have also been used. Galvanized iron sheets and aluminum foil covered with asphalt are the materials that are used most widely in Italy, the USA, and the UK. These barriers should prevent the build-up of moisture within walls and ceiling.

The most difficult places to design in chambers with a CA are the joints between walls, ceiling and floors, and inlets and outlets of pipelines in the building. One of the techniques to maintain the seal between walls and floors is the use of continuous monolithic foamed-in-place polyurethane. Doors lined with galvanized iron sheets on both the inner and outer sides have been used. Wood doors that are sealed with epoxy coatings have also been used. Urethane foam is usually used to insulate doors. The cost of these insulated doors is about 11–14% of the total cost of construction of the storage facility. Other considerations in the design of CA storage facilities include the installation of an observation window, pressure relief system, and continuous leakage testing. Research is in progress to make cold storages airtight and more flexible. A plastic tent has been developed for the CA storage of small quantities of fresh commodities. These CA tents are airtight and can be set up easily, allowing flexibility in the use of this storage space.

Effects on Fruit and Vegetables

M V Rama and P Narasimham, Formerly of Central Food Technological Research Institute, Mysore, India

Introduction

Controlled-atmosphere storage (CAS) is one of the most important innovations in fruit and vegetable storage systems as the composition of gas in the storage affects their storage life. The CAS technology involves reduction of oxygen (O_2) and increasing carbon dioxide (CO_2) as compared to the ambient atmosphere. Sometimes it also involves removal of ethylene and addition of carbon monoxide. CAS implies continuous monitoring and precise adjustment of these gases within the storage container, to a predetermined level. On the other hand, in modified-atmosphere storage (MAS), gas composition is not actively controlled; gas atmosphere within the package is created by the respiratory activity of the fresh produce. Several types of whole and minimally processed fruits and vegetables have been successfully stored in modified-atmosphere packages. Kidd and West originally established the scientific basis of CAS in the early twentieth century. It has been shown to be effective in extending the postharvest life and quality of a wide range of fruits and vegetables.

Increasing commercial use of this technology over recent years in both the short and long term has been in response to market demand for the supply of all types of fresh fruits and vegetables at all times. This article reviews the uses of pre-CAS treatments, physiological changes related to ripening and respiration, sensory and storage quality, and poststorage life of fresh fruits and vegetables stored in controlled atmosphere.

Gaseous Atmosphere in Commercial Use

Although the original idea was to replace refrigeration by CAS, observations show that CAS is most effective in combination with refrigeration, providing additional benefits. Responses to modification in the atmosphere vary considerably among species, organ types, developmental stage, crop temperature, growing conditions, and the degree of ripeness before harvest and include both undesirable and beneficial physiological responses. Recommended controlled-atmosphere conditions during storage for various fruits (**Table 1**) and vegetables (**Table 2**) have been given. Except for apple and pear, for most other fruits and vegetables the typical controlled-atmosphere conditions suggested have no, little, or only some commercial use.

Most fruits and vegetables tolerate as low as 2% O_2 and as high as 5–10% CO_2. The commercial adoption of CAS for a given kind of produce depends on the balance between cost and benefits, because control of gas composition is expensive. **Table 3** gives the general effects of low O_2 and high CO_2 concentrations on fruits and vegetables.

In general, the lower the O_2 and the higher the CO_2 levels, the better will be the controlled-atmosphere effects such as retardation of ripening and senescence. However, the extent to which O_2 level can be reduced and the CO_2 level can be elevated is limited due to the shift from aerobic to anaerobic metabolism, which leads to off-flavors. The incorrect application of CAS may have detrimental effects on the crop being stored. Sprouting and rooting problems may be triggered under certain CAS conditions, as in carrot, onion, and potato. Apple and pear are the main fruit

types stored commercially under CAS at present. Studies on other fruits and vegetables have proved promising for its wider application.

Precontrolled Atmosphere Storage Treatment

Subjecting fruits and vegetables to various types of preCAS treatments can enhance the effectiveness of CAS. Cooling kiwi fruit to $-0.5\,^{\circ}C$ immediately after harvest reduces the incidence of rot caused by *Botrytis cinerea* and increases the shelf-life during CAS. Curing crops like potatoes, yam, sweet potato, garlic, and onion at high temperature before they are stored in controlled atmosphere is beneficial to enhance their storage life. A prestorage heat treatment effectively controlled 'telescoping' of cut green onions. Several types of pre-CAS treatments have been suggested, especially to improve the quality of apple varieties. Keeping Granny Smith apples at a higher temperature of $46\,^{\circ}C$ for 12 h before CAS resulted in firmer fruits with higher soluble solids-to-acid ratio and lower incidence of superficial scald than fruits which were not preheat-treated. Hypobaric ventilation prevents the accumulation of scald-related volatiles in the epicuticular wax of apples, thus preventing scald development.

Exposing apple, pear, and avocado fruits to high levels of CO_2 shock treatment prior to CAS is shown to be beneficial; such a treatment to golden delicious apples resulted in better green color of the skin and firmer flesh, with no change in titratable acidity. It also reduced the incidence of physiological disorders such as internal browning and mesocarp discoloration in pears and avocado respectively. An initial low O_2 stress (ILOS) reduces superficial scald incidence during CAS of apple varieties like Law Rome and Granny Smith. Scald development is related to the accumulation of 6-methyl-5-hepten-2-one (MHO) in fruits. ILOS inhibits both productions of alpha-farnesene and its breakdown product, MHO. ILOS is suggested to be a potential alternative for chemical scald inhibitors.

Therefore, besides the application of controlled-atmosphere technology to preserve the quality of certain fresh fruits and vegetables, a cold and high temperature, chemicals, low O_2, or high CO_2 pretreatment for a short duration would give additional beneficial effects in extending the storage life. Given below are some of the significant effects of CAS on fruits and vegetables.

Effect on Fruit Ripening

Studies have shown that controlled atmosphere has its most beneficial effects on climacteric fruits at the preclimacteric stage by prolonging this period. The effect is less marked in climacteric fruits at the ripening stage. The climacteric fruits are much

Table 3 General effects of low oxygen and high carbon dioxide concentrations on fruits and vegetables

Effects of low oxygen	*Effects of high carbon dioxide*
Reduced respiration rate and substrate oxidation	Decreased synthetic reactions in climacteric fruit
Delayed ripening of climacteric fruit and breakdown of chlorophyl	Delaying the initiation of ripening and inhibition of chlorophyl breakdown
Prolonged storage life	Inhibition of some enzymatic reactions
Reduced rate of ethylene production and degradation of soluble pectins	Altered metabolism of some organic acids; production of off-flavors
Formation of undesirable flavor and odors with altered texture	Induction of physiological disorders and reduced fungal growth on the crop
Development of physiological disorder	Inhibition of the effect of ethylene
	Retention of tenderness and decreased discoloration levels
	Changes in sugar content and effects on sprouting, as in potatoes

sensitive to ethylene (C_2H_4), hence its removal is particularly recommended for long-term storage. CAS inhibits the production of C_2H_4 by the fruit, which is due to the absence of sufficient oxygen. In Jonathan and Elstar apples, increased CO_2 concentration reduced the activity of ethylene; similar reduced ethylene activity is reported in kiwi fruits and mission figs. The activity of several oxygen-requiring enzymes related to fruit ripening is reduced in CAS. In bananas, although low oxygen levels (1–15%) in store induce ripening, the degreening process of the peel is inhibited. The fruit in which the ripening process is initiated is slowed down in a low-oxygen atmosphere. Holding mature green tomatoes in low O_2 atmosphere delayed the decrease in cell wall galactosyl residues and increased soluble galactose levels, thus causing delayed loss of fruit firmness; this change was associated with increased development of red color, respiration, and ethylene production. So it is suggested that cell wall-related ripening processes are either ethylene-dependent or require only low baseline ethylene levels to occur.

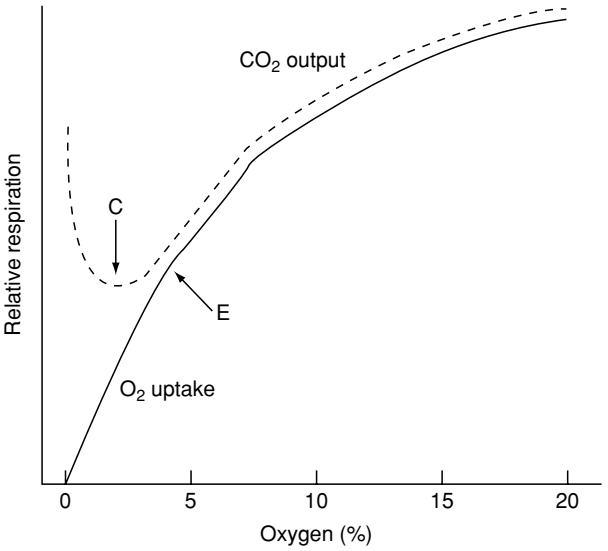

Figure 1 Schematic diagram showing the effect of O_2 concentration on the uptake of O_2 and evolution of CO_2 in fruits and vegetables. E, Extinction point (the lowest O_2 concentration at which aerobic respiration stops); C, critical O_2 concentration (the concentration of O_2 at which CO_2 produced is lowest).

Effect on Respiration

Effect of Low O_2

For some fruits and vegetables, depending on the temperature, the respiration rate is lowered during storage in 3% O_2. When the O_2 concentration of the storage atmosphere is reduced below 8% in particular, the respiration rate decreases as a function of the O_2 concentration (Figure 1). Anaerobic respiration is initiated in the tissue as the O_2 concentration drops to the extinction point. Anaerobic respiration becomes predominant, with a further decrease in the concentration of O_2, and the CO_2 output starts to increase after it reaches its lowest value at the critical O_2 concentration. Further reduction in O_2 concentration below the critical point brings a shift in the respiratory metabolism; pyruvic acid, the end product of glycolysis, is no longer oxidized through Kreb's cycle, but is converted into acetaldehyde, CO_2, and finally ethanol. This causes tissue breakdown and development of off-flavor. Thus the minimum concentration of O_2 necessary to continue aerobic respiration and prevent fermentation will be optimum for the storage atmosphere. This concentration is usually 2–5%, and depends on the kind of produce, temperature, and the duration of storage. Carrot shreds under low O_2 atmosphere exhibited an increase in respiratory quotient (RQ), an accumulation of fructose 1,6-biphosphate, coupled with an increase in the activity of phosphofructokinase (PFK). This suggests the involvement of PFK in the regulation of glycolysis under low O_2 atmosphere.

The decrease in O_2 uptake under reduced levels of O_2 in the atmosphere is due to the decrease in the

activity of oxidases like polyphenol oxidase, ascorbic acid oxidase, and glycolic acid oxidase, and not due to the reduction in the activity of cytochrome oxidase. The storage atmosphere must contain less than 2% O_2 for cytochrome oxidase to be affected; on the other hand, the affinity for other oxidases to O_2 is 20 times more than that of cytochrome oxidase. The increased activity of enzymes like pyruvate decarboxylase and alcohol dehydrogenase is not responsible for the initiation of the fermentation process; these enzymes are mostly active even before exposure to low O_2 levels.

The beneficial effects of low-O_2 atmosphere are also related to the biosynthesis and action of C_2H_4 under the established controlled atmosphere, as it is directly related to ripening and senescence processes. C_2H_4 is produced by the oxidation of 1-aminocyclopropane-1-carboxylic acid (ACC) by ACC oxidase (Eqn (**1**)):

$$\text{1-aminocyclopropane-l-carboxylic acid} + \frac{1}{2}O_2 \rightarrow C_2H_4 + CO_2 + HCN + H_2O \quad (1)$$

The concentration of O_2 that gives half the maximum C_2H_4 production rate ranges between 5% and 7% in various tissues, so that 2–5% atmosphere, usually used in CAS, directly interferes with C_2H_4 synthesis. The action of C_2H_4 on plant tissues at 3% O_2 is only about 50% of that in the air.

Effect of High CO_2

High CO_2 atmosphere affects several processes, including respiration rate, ethylene production, ripening and senescence, and acidity of the produce.

Respiration rate The respiration response to high levels of CO_2 depends upon the crop, cultivar, and the stage of development. Under similar CAS conditions the suppression of respiration was more in golden delicious apples than in Cox's orange pippin apples. In a study on the effect of elevated levels of CO_2 on respiration and ethylene production, changes in respiration seldom coincided with changes in C_2H_4 production. Respiration rate decreased in ripening banana, pink tomato, and pickling cucumber, while it increased up to 30% in potatoes and carrots, and had no effect on the respiration in guava, orange, and onion bulbs. Ethylene evolution was substantially reduced at all levels of CO_2 in guavas and tomatoes, while it was accelerated in bananas, carrots, cucumbers, onions and potatoes, which is possibly due to an early injury response.

Studies in pears have shown that high CO_2 atmosphere affects the glycolytic intermediates and enzymes; inhibition in the activity of phosphofructokinase, a key enzyme of glycolysis, resulted in the accumulation of fructose-6-phosphate and decrease in fructose-1,6-diphosphate, in contrast to the effect of low O_2. Accumulation of succinic acid, an intermediate of Kreb's cycle, has been observed in several crops, such as apples, pears, lettuce, podded pea, and activity of succinic dehydrogenase in peas under high CO_2 levels. The oxidation of several intermediates of the Kreb's cycle is suppressed, as revealed in studies of isolated mitochondria from apples. Formation of ethanol and aldehyde is common in many crops, under high CO_2 atmosphere, despite the presence of sufficient O_2; this phenomenon is called CO_2 zymasis.

Ethylene production A reduction in the O_2 uptake in climacteric fruits such as banana and avocado, without affecting the respiration activity before climacteric, has been observed under high CO_2 atmosphere; also the onset of climacteric rise, which is triggered by endogenous ethylene, is delayed. These results suggest that a high CO_2 atmosphere delays the burst of ethylene (C_2H_4). In most vegetables and nonclimacteric fruits like citrus, grapes, and Japanese pears, O_2 uptake is not affected under high CO_2 atmosphere. However a depression in the O_2 uptake occurs in ripening climacteric fruits and broccoli, accompanied by inhibition of C_2H_4 synthesis. On the other hand, 10% or more CO_2 in the storage atmosphere, in crops like lettuce, cucumber, and lemon, which are susceptible to high CO_2 level, resulted in the elevation of O_2 uptake with induction of C_2H_4 synthesis. These observations indicate that the respiratory response of crops to high CO_2 levels might be mediated mainly by the effect of CO_2 on the synthesis or action, or both, of C_2H_4. In other words, retardation of ripening or senescence and the associated biochemical and physiological changes are caused by concentrations on action or synthesis of C_2H_4 rather than on any direct effect on the respiratory metabolism. Tomatoes at breaker stage under CAS showed a reduced natural ethylene production rate and delayed increase in galactosidase activity. Such effects remained unchanged by the addition of exogenous ethylene. These results suggest that ethylene-mediated responses are impaired by low O_2 and high CO_2 and that exogenous ethylene and low O_2/high CO_2 concentrations are acting antagonistically.

Results of a study on ethylene biosynthesis in Jonathan apple fruits immediately after removal from CAS conditions (0–2% CO_2 with O_2 of 3% or 15% concentrations at 0 ° C) included inhibition of C_2H_4 production, decrease in the concentration of ACC, increased accumulation of ACC under low O_2, but

only in the absence of CO_2, and decrease in the activity of C_2H_4 forming enzyme at 20% CO_2 at both the O_2 concentrations. By these results, inhibition of ethylene production has been attributed to the inhibitory effect of CO_2 on ACC synthase activity.

Similar results are reported on other apple cultivars like Barnack and Beauty. In kiwi fruits, high CO_2 reduced ethylene production and ACC oxidase activity. Added to this, several responses of crops to ethylene such as fruit ripening, abscission, growth inhibition, floral senescence, and the induction of some enzymes, are delayed or prevented in high CO_2 atmosphere.

A comprehensive study of the effect of CO_2 in reversing the action of C_2H_4 in growth of pea segments has suggested that CO_2 competes with C_2H_4 for binding site, and the relative affinity of the site for 15% CO_2 is equivalent to that for 1 p.p.m. C_2H_4. However, the calculation of the binding site with radioactive C_2H_4 suggests that the inhibition of C_2H_4 binding is indirect or due to secondary effects such as pH changes.

Acidity and pH CO_2 dissolves easily in plant tissues, forming carbonic acid, which dissociates into bicarbonate and hydrogen ions. Hence the general assumption is that tissues exposed to high CO_2 levels would have low pH. However, the reported measurements of pH changes in several plant tissues stored in high CO_2 atmosphere have been contradictory. Intact lettuce tissues exposed to 15% CO_2 for 6 days showed a drop of about 0.4–0.1 pH in the cytoplasm and vacuoles respectively. Juice extracted from a crop exposed to high CO_2 has shown increased pH. As alterations in the pH of plant cells might affect the metabolic activities, the change in pH due to CO_2 could be treated as both beneficial and harmful effects of high CO_2 condition for the harvested crops.

Effects on Sensory Quality

Flavor and volatile compounds

Factors like volatile compounds, organic acids, carbohydrates, and phenolics affect the flavor of fruits and vegetables. Flavor determines the eating quality of the produce. Controlled-atmosphere-stored fruits are known to retain good flavor longer than fruits just cold or air-stored, as in kiwi fruits, Russian pears, and tomatoes. For golden delicious apples, CAS has proved best in terms of flavor maintenance. The controlled-atmosphere-stored white cabbages had a fresh peppery flavor and rated higher in flavor quality than corresponding air-stored samples. On the other hand, the flavor quality was inferior in limes and apricots stored in controlled atmosphere. The low O_2 of 3 kPa is reported to be enough to induce reduction in pear aroma compounds; the decadienote moiety appeared to have been more affected than methyl or ethyl moieties. The accumulation of amino acids and reduction in fatty acids and aroma compounds in Fuji apples stored under low O_2 atmosphere indicates that a change in the aroma production involves altering fatty acid and amino acid metabolisms.

Controlled atmosphere will affect the production of characteristic volatile compounds, which give flavor and aroma to fruit and vegetables. The production of volatile compounds is not only suppressed during CAS, as in several apple varieties, but the fruits fail to synthesize normal amounts even after removal from the CAS. The highest volatile emission from Granny Smith apples was after 5 months of CAS and it was highest under low-oxygen (LO) and ultra-low-oxygen (ULO) atmospheres. LO and ULO form valuable technologies for maintaining the sensorial quality of apple.

Development of Off-Flavor

The unfavorable concentrations of O_2 and CO_2 in the storage atmosphere, especially for a long time, result in the development of off-flavors and off-tastes in fruits and vegetables and are generally attributed to shift from aerobic to anaerobic respiration. In intact lettuce heads exposed to 20% CO_2, the development of off-flavor is related to the production of ethanol and acetaldehyde. More than 15% CO_2 induces odors in broccoli and cauliflower. In fruits like Granny Smith, yellow Newton apples, twentieth-century pear, and Angellena plums and peaches, ULO of 0.02–0.25% resulted in the development of alcoholic of-flavor. Sweet potatoes stored in 2% O_2 develop off-flavor with reduced sweet-potato flavor. Controlled-atmosphere-stored strawberries do not develop visible injury: the juice develops off-flavors, which are correlated to the accumulation of ethanol and ethyl acetate and acetaldehyde.

In contrast, avocados stored in air had higher ethanol and acetaldehyde content than those stored in CAS. One of the findings on the biogenesis of off-odor in broccoli under LO atmosphere suggests that broccoli has the enzymic capacity to convert free sulfur-containing amino acids into volatile sulfur compounds, which contribute to the objectionable odor. The precursors of such volatiles, free sulfur-containing amino acids, are synthesized, preferably in broccoli that is stored under LO atmosphere.

Ascorbic Acid and Acidity

The concentration of ascorbic acid in fruits and vegetables can be affected by storage conditions and is

important from the nutritional point of view. The loss of ascorbic acid is hastened in tomatoes when stored in high CO_2 atmosphere. Similar effects are reported in strawberries and blackberries, where the loss of ascorbic acid increases with increase in CO_2. In Chinese cabbage loss of ascorbic acid took place at 30–40% CO_2 levels. Though in general higher CO_2 (> 5%) content has the tendency to reduce ascorbic acid levels, it depends on the type of produce, storage temperature, and the concentration of CO_2. For example, the degradation of ascorbic acid in parsley leaves is retarded with storage in 4.2% O_2 and 1% CO_2 compared with air storage, but it is accelerated with storage in 4.2% O_2 and 6% CO_2. A LO atmosphere is favorable to the retention of ascorbic acid because of the low affinity of ascorbic acid oxidase to O_2. Pineapple stored in atmosphere containing less than 5.4% O_2 retained higher ascorbic acid content, with no effect on total soluble solids (Figure 2). The storage temperature during CAS affects the ascorbic acid content; CAS treatment at 12 °C resulted in lower ascorbic acid retention, while there was no effect at 1 °C in okra. Pears showed a decline in ascorbic acid concentration at enhanced levels of CO_2.

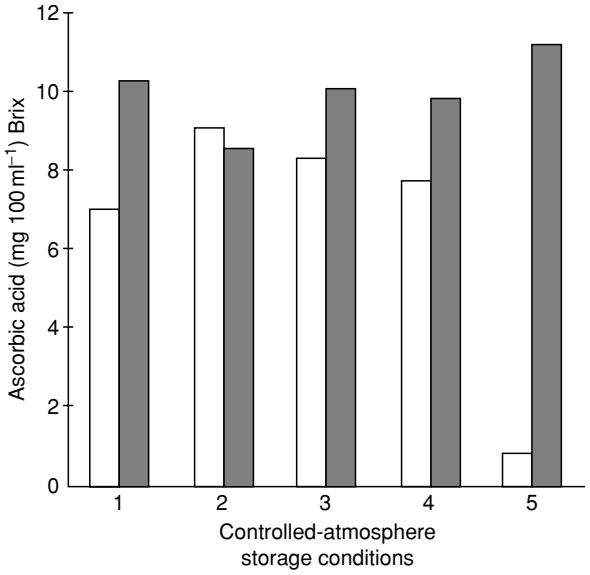

Figure 2 Effect of various controlled-atmosphere storage conditions on ascorbic acid (open columns) and total soluble solids (filled columns) of pineapple stored at 8 °C for 3 weeks and for 5 days at 20 °C. 1, 1.3% O_2 + 0% CO_2; 2, 1.4% O_2 + 11.2% CO_2; 3, 2.2% O_2 + 0% CO_2; 4, 2.3% O_2 + 11.2% CO_2; 5, 5.4% O_2 + 0% CO_2. Adapted from Haruenkit R and Thompson AK (1996) Effect of O_2 and CO_2 levels on the internal browning and composition of pineapples Smooth Cayenne. In: *Proceedings of the International Conference on Tropical Fruits*, pp. 343–350. Kuala Lumpur, Malaysia.

The organic acids, especially malic acid, of apples are retained better if favorable controlled-atmosphere conditions are reached quickly. However, if the CO_2 level reaches 3%, loss of acidity is sometimes stimulated in these fruits. A significant amount of acidity is lost in Valencia oranges stored in controlled atmosphere. In tomatoes the titratable acidity increased during the first 20 days of CAS at 13 °C and it tended to decrease during further storage (Figure 3). Vegetables such as lettuce, spinach, and broccoli always contain higher amounts of titratable acid after storage in air than after storage in controlled atmosphere.

Texture and Color

Due to delay in ripening under CAS, normally a desirable texture is maintained for several fruit types like apple, pears, peaches, apricots, and tomatoes. Retention of firmness is one of the most important advantages of the commercial CAS of apples. Though both high CO_2 and low O_2 contribute to the retention of flesh firmness, the effect of high CO_2 is more prominent than that of low O_2. Induction of enzyme polygalacturonase, which degrades pectic substances, is prevented when mature green tomatoes are stored in 5% CO_2 and 5% O_2 for up to 8 weeks at 12.5 °C: on removal of tomatoes from such an atmosphere to air, fruit softening is resumed due to the synthesis of polygalacturonase. In kiwi fruit, retention of fruit firmness is better in CAS, but presence of even low concentrations of C_2H_4 would counteract this positive effect. The texture of most other fruits and

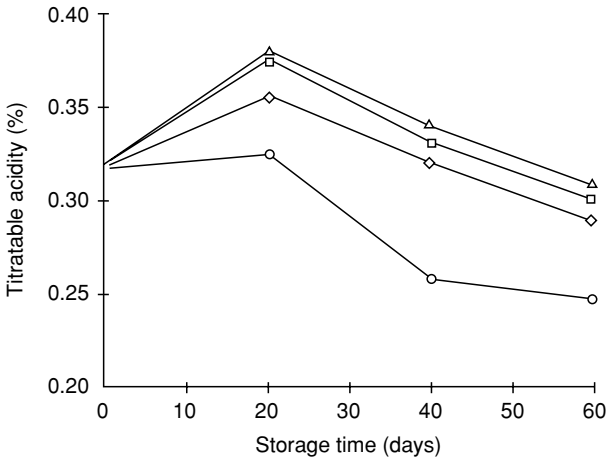

Figure 3 Changes in the titratable acidity of mature green tomatoes stored under different controlled-atmosphere storage conditions for 60 days at 13 °C (all treatments with 5.5% O_2). Circles, control; squares, 3.2% CO_2; triangles, 6.4% CO_2; diamonds, 9.1% CO_2. Adapted from Batu A (1995) *Controlled Atmosphere Storage of Tomatoes*. PhD thesis. Cranfield University, UK.

vegetables is little influenced by LO conditions. The positive effects of high CO_2 conditions reported include delay in the softening rate of strawberries and bush-type berries, reduced splitting in bitter gourd, and the retardation of the toughening of asparagus spears, cauliflower, and snap beans, and retention of bright yellow color and firmness in star fruits.

The reduced rate of chlorophyl breakdown under controlled-atmosphere conditions improves the retention of green color of the produce. High CO_2 concentration in particular preserves the chlorophyl content. Such an effect is obvious in green vegetables like spinach, asparagus spears, broccoli, snap beans, green limes, and cabbage. Some of the winter white cabbage cultivars retained better green color and crisp texture when stored at 0–2 °C under controlled atmosphere, consisting of 5–6% CO_2 and 3% O_2. The degradation of chlorophyl and the synthesis of pigment such as lycopene, carotene, and xanthophyl are suppressed when tomatoes are stored in 5% O_2 and a 5% CO_2 mixture; biosynthesis of anthocyanin is slowed down in plums under controlled-atmosphere conditions. Bitter gourd fruits stored for 3 weeks in controlled atmosphere (2–5% O_2 with 3.5–5% CO_2) had greater retention of green color. In spinach stored under low O_2 atmosphere (0.8%), the color and chlorophyl content were not affected. The extinction point of spinach is found to be > 0.4% but < 0.2% O_2, indicating that spinach can also be stored under LO atmosphere without quality loss due to anoxia. Bell peppers stored under LO showed slower rate of decrease in green color.

Controlled Atmosphere and Storage Disorders

Diseases and Pests

The process of ripening and senescence in climacteric fruits renders them susceptible to infections by pathogens. The delayed ripening and senescence in such fruits by storing them in controlled atmosphere allows them to retain greater resistance to postharvest diseases; thus CAS can reduce disease development in crops by improving their physiological conditions. When exposure time is short, some horticultural crops might be tolerant of more extreme controlled-atmosphere conditions such as <1% O_2 and > 20% CO_2 than are normally used. Such ULO and high CO_2 levels are fungistatic, directly suppressing fungal growth and spore germination. High CO_2 retards fungal decay incidence on cherry, blackberry, raspberry, strawberry, fig, nectarine, and grape. The reduction in disease levels in tomatoes is chiefly due to LO levels with a little additional effect from increased CO_2 levels. LO and high CO_2 levels, at temperatures less than 10 °C, reduce the infection of potatoes by *Erwinia caratovora*. On the other hand, anaerobic conditions created around freshly harvested or uncured potatoes during storage or transport prevent the formation of wound periderm and the oxidation of phenolic compounds, both of which are involved in the defense mechanism against bacterial infections; the depletion of O_2 rather than increase in CO_2 in the atmosphere would increase the roting by both *Erwinia* and *Clostridium*.

The postharvest pathogen of apple fruits *Penicillium expansum* can be better controlled in controlled-atmosphere conditions; its biocontrol agent *Candida sake* has the better ability to colonize under controlled-atmosphere conditions, on the apple fruit surface and in wound tissues, thus protecting apples completely from damage by the growth of *P. expansum*. The incidence of rots caused by *Botrytis cinerea* in white cabbages was reduced to a greater extent under storage atmosphere containing 5–6% CO_2 and 3% O_2; it also reduced or eliminated the incidence of pepper-spotting, a type of nonmicrobial leaf necrotic disorder common to cabbages.

Extreme controlled-atmosphere conditions are insecticidal too. For example, CAS is commonly used in Mexico to reduce the incidence of insect infestation of Manila mango fruits; these fruits can tolerate controlled-atmosphere treatment at temperatures < 44 °C. Fig moth (*Cadra cautella*) could be controlled when dried figs were stored under controlled-atmosphere conditions (1% O_2 with 10–15% CO_2). A short-term insecticidal controlled atmosphere (ICA) containing 40% CO_2 and 0.25% O_2 is shown to be a promising alternative to methyl bromide fumigation for Fuyu persimmons without affecting the marketability of fruits. A CO_2 concentration of 50% is shown to control insects in other tropical fruits like avocado, papaya, and mango.

Physiological Disorders

It is necessary to achieve and maintain precise gas mixtures during CAS, which otherwise may cause irrevocable damages to fruits and vegetables in the form of physiological disorders and injuries (Table 4). The preharvest factors like maturity at harvest, storage season and locality, and size of the fruit are also the factors determining the incidence of CAS disorders. The flesh breakdown injury and internal browning in pear fruits under CAS are associated with the production of acetaldehyde, ethanol, and ethyl acetate and stimulation of free radicals respectively, in the stored fruits. ULO of 0.5% induced a reddish discoloration in Brussels sprouts and an

Table 4 Threshold level of O_2 and CO_2 required for causing injury to some fruits and vegetables and typical injury symptoms

Crop and cultivar	*CO_2 injury level*	*CO_2 injury symptoms*	*O_2 injury level*	*O_2 injury symptoms*
Apple, cox's orange pippin	> 1%	Core browning	< 1%	Alcoholic taste
Apple, golden delicious	> 5%	CO_2 injury	< 1%	Alcoholic taint
Apple, Elstar	> 2%	CO_2 injury	< 2%	Core flush
Apple, Jonathan	> 5%	Flesh browning	< 1%	Alcoholic taint, core browning
Apricot	> 5%	Loss of flavor, flesh browning	< 1%	Off-flavor
Avocado	> 15%	Skin browning, off-flavor	< 1%	Internal flesh breakdown
Broccoli	> 15%	Off-odor	< 0.5%	Off-odor
Cabbage	> 10%	Discoloration of inner leaves	< 2%	Off-flavor
Cucumber	> 5%	Increased softening	< 1%	Off-odors
Lettuce	> 2%	Brown stain	< 1%	Breakdown at center
Kiwi fruit	> 7%	Internal breakdown	< 1%	Off-flavor
Mango	> 10%	Softening, off-flavor	< 2%	Grayish flesh, skin discoloration
Pepper, bell	> 5%	Internal browning and softening	< 2%	Off-odors and breakdown
Strawberry	> 25%	Off-flavor, brown discoloration	< 2%	Off-flavor
Tomato, mature green	> 2%	Discoloration, uneven ripening	< 2%	Off-flavor

extremely bitter flavor in nongreen portions of the sprouts.

The browning of core tissue that is triggered in conference pears is related to decreased ascorbic acid concentration under enhanced CO_2 levels. Pears that show browning produce ethane, which is said to be probably a result of membrane peroxidation.

Some recent tests have shown that apples, when stored under controlled-atmosphere conditions early after harvest, are more susceptible to CO_2 injury like internal browning, flesh softening, and core browning. Incidence of Braebun browning disorder (BBD), a type of CO_2 injury in late-harvested Braebun apples, increases with decrease in the level of O_2 in the storage atmosphere. Small-sized Fuji apples were less susceptible to CAS disorder than large fruits. Delaying storing apple fruits in controlled atmosphere or CO_2 accumulation is recommended as it may reduce the incidence and severity of all the above-mentioned physiological disorders.

The appearance of CO_2 injury symptoms is shown to be a function of concentration, exposure time, and temperature, while injury under low O_2 levels is due to anaerobic respiration which results in the accumulation of toxic byproducts like alcohol and acetaldehyde. On the other hand, certain types of physiological disorders can be curtailed under CAS. For example, a LO of > 5% reduces the brown discoloration of beans which usually develops during harvesting and handling. High CO_2 is reported to inhibit browning in snap beans at the site of mechanical injury and skin browning in lichee fruit.

A hypothesis to explain the mode of action of LO and high CO_2 on the incidence of physiological disorder, such as browning, has been proposed based on a recent study on the effects of CAS conditions on adenosine triphosphate (ATP) and adenosine diphosphate (ADP) levels and the concentrations of NAD(H) and NADP(H) in apple varieties stored. The reduced ATP level and increase in the accumulation of fermentative products might indirectly change the mitochondrial membrane permeability and the electrochemical potential. Alterations in the membrane permeability leads to leakage of ions, protons, acids, and phenolics from vacuoles, causing acidification and oxidation of phenols in the cytoplasm and finally the browning of tissues.

Residual Effects of CAS

Storing fruits and vegetables in CAS can affect their subsequent shelf-life. For example, bell pepper fruits exhibited suppressed CO_2 production and O_2 consumption for at least 24 h after transfer to air. The residual respiratory inhibition in bell peppers is found to be due to a reduction in the mitochondrial oxidative capacity and not due to changes in the ultrastructure of mitochondria. Black raspberry (cv. Bristol) showed greatest weight loss after removal from controlled atmosphere. Several potato cultivars showed complete sprout inhibition, low weight loss, and healthy skin post CAS. With regard to root quality during long-term storage and poststorage processing potential, CAS of LO and high CO_2 has been shown to be an effective method for Lance Asian bell roots. In controlled-atmosphere-stored cabbages, storage and trimming weight losses were lower; recoveries of trimmed cabbages suitable for marketing or processing were higher – up to 22% than in those stored in air.

Though the present literature is ambivalent as regards the quality and rate of deterioration of fruit and vegetables after they have been removed from

CAS, many reports indicate that the storage life is adequate for marketing, and sometimes the marketable life is even better than harvested produce.

Storage of Minimally Processed Fruits and Vegetables

The preference by consumers for vegetables in a 'ready-to-cook' and 'ready-to-eat' convenient form has resulted in the supply of fruits and vegetables in minimally processed form (peeled, sliced, diced, shredded, and topped vegetables) to the market. Such minimally processed (MP) produce has been successfully stored in modified-atmosphere packages (MAP) with little or no loss in their sensory, nutritional, and market quality. MAP using polypropylene bags with microperforations has been shown to be an effective method for storing MP fruits and vegetables. LO atmosphere is used to control spoilage microorganisms on cut spinach leaves for at least 7 days. A high level of O_2 inhibits undesirable fermentation reactions, delays browning during processing, and inhibits microbial growth during the storage of MP fruits and vegetables in sealed packs. MAP has been used commercially to extend the shelf-life of minimally processed mango and other salad vegetables and leaves.

CONVENIENCE FOODS

J E Tillotson, Tufts University, Medford, MA, USA

History

Today, convenience foods supply much of the food requirements of the world's population in the industrial countries. Their prominence in the modern diet is the result of the urbanization of society during the nineteenth and twentieth centuries. The universal consumption of convenience foods has arisen from the demands of modern lifestyles in the industrial countries requiring, for the majority of people, that their daily nourishment be supplied by commercial enterprises rather than by their own food-producing endeavors.

Ever-growing, global urban populations, increasingly without direct access, ability, desire, or time for growing and preparing food, but with rising financial means, have increasingly wanted the convenience, availability, and taste of commercially processed foods. This market demand has motivated the growth of a global network of food-processing and distribution industries, supplying all manner of convenience foods that, by 1999, had an estimated world retail sale value of US$4000 billion. Today, at any given time, tens of thousands of various types of convenience foods are offered for sale to consumers throughout the world. All of them offer consumers the advantages of food that is readily available, convenient, inexpensive, and often of surprisingly pleasing organoleptic quality, requiring only minimal or no preparation before consumption.

Convenience foods can be looked at in several ways. These foods can be narrowly classified by the type of processing technology employed: canning, freezing, dehydration, chilling, chemical preserving, etc., or by the type of food: frozen and canned vegetables; cake mixes and bakery products; soups, sauces, and condiments; processed meats and fish; chilled and frozen dairy-based products; ready-to-eat and shelf-stable dishes; plus many other types.

Convenience foods can also be further interpreted in a broader sense, beyond the specific production technology or product type, as a vehicle of explaining the dynamics and development of our food supply in recent times, and as an aid in envisioning the future nature of people's nourishment. History teaches us that what constitutes convenience food has changed a number of times to meet the changing food needs of society.

As it has been observed that, 'an army travels on its belly,' so it is equally true that, 'modern society survives on convenience foods.' Today, convenience foods are not simply add-on, optional products, but have now become central to supplying society's nourishment. How do we explain this growth of commercialization of our food supply?

While the availability today of the plethora of convenience foods is the result of brilliant technological innovation and scientific discovery, their current prominence in the diets of the world's industrialized countries cannot be fully explained solely by the application of food technology to the food supply. Food technology has been more of an enabling factor than a motivating force. Other types of technology, including transportation and communications, have also been significant in assisting the market growth of convenience foods.

Above and beyond the diverse technical forces involved, the phenomenon of convenience foods is best understood in the broader context of the social, economic, and political forces that are also responsible for their wide acceptance. During the last century, these diverse forces have shaped and motivated the central role that convenience foods have come to play today in the modern diet. The following interprets the economic, social, technical and political dynamics that have led to the central role of convenience foods in the modern diet. Processing technology descriptions as well as detailed accounts of specific types of convenience food are treated in other sections of this encyclopedia.

Early Convenience Foods

In the mid-nineteenth century, a food-supply revolution began that has continued to the present. This revolution would result in fundamental changes in the forms of food that people in the industrial countries would depend on for their daily nourishment. While food had been preserved as early as 4000 BC by methods such as drying, salting, smoking, and pickling, the nineteenth century urbanization brought the need for a better organized, comprehensive, and dependable system of food processing and distribution.

In this era, the industrial revolution was beginning; the new factories and the accompanying commerce of the period required large new labor forces in the industrial cities of Europe and America. Many

people left rural life in agriculture to work and live in the new industrial centers. In new urban jobs, these workers required food that was both readily available and affordable. A new food-supply system sprang up to meet the new urban population's needs. This initiated the trend that resulted over time in an ever-increasing percentage of the population depending on fewer and fewer others to supply their food. These social and economic changes set in motion the industrialization of the food supply, and with it, the development of convenience foods.

As the industrial era of the nineteenth century was enabled by the application of multiple technologies, the industrialization of the food supply was similarly based on the simultaneous application of multiple technologies. The movement of vast numbers to the new large cities, removed from their own participation in agriculture, created a food-logistics problem that the growth of new railroad systems in Europe and North America would help to alleviate.

Supplying the ever-increasing demand in the new urban centers required transporting food from ever-larger geographical growing areas. Because of the economics involved in the procuring and handling of raw agricultural commodities (e.g., wheat, cattle, vegetables, sugar, milk), the basic processing of these commodities became attractive in new, dedicated processing plants in the growing and producing areas, often located far from the growing cities. The railroads were essential in transporting these processed basic food ingredients to the cities.

The urban populations were able to buy staples (e.g., flour, white sugar, meats, and dairy products) in the newly appearing local grocery stores. Urban workers used their industrial wages to pay for the basic food ingredients required in preparing their daily meals. Their wages also paid for the convenience of letting others grow, process, transport, and sell, as well as for the availability of these basic food ingredients. This established the economic model that became the foundation of convenience foods to this day, whereby money was exchanged not only for the basic agricultural commodity, but also for the labor and other services associated with the food or ingredient offered.

Historically, the majority of early preserved foods used primitive preserving methods (e.g., drying, salting, etc.) that had been developed over centuries of trial-and-error, and were designed solely for the purpose of storing present food surplus of agricultural products against future needs. The quality of these primitive 'convenience foods' was often questionable. During the mid-1800s, the developing new commercial food supply system produced the first products that would conform to the modern definition of convenience foods. With the commercial introduction in the nineteenth century of canning – the heat preservation of food in glass or metal containers – convenience foods assumed new identities, quality and importance. Consumers of this era would become ready buyers of these first mass-produced convenience foods.

In England, Brian Dookin established one of the first industrial canning factories. By 1812, he had started his canning factory and 6 years later was producing cured beef, boiled beef, carrots, mutton-and-vegetable stew, and soups of various types in tinned iron containers. However, due to their high cost, only travelers, explorers, and the military used these initial canned foods.

By 1868, the earlier handmade cans were replaced by machine-cut, assembly-line-produced containers, with a concomitant reduction in production cost and improved quality. In the late 1870s, new methods of processing under steam pressure reduced processing times and made large-scale production possible. By 1910, a single can-making machine could produce up to 35 000 containers a day. These technological advancements, combined with the use of integrated food-handling equipment to peel, shell, clean, slice, chop, and cook various foods, made canned products inexpensive to produce and, as a result, affordable and acceptable as convenience foods by millions of people. The production model developed at this time that yielded low unit costs and reliable quality would be the basis of the manufacturing strategy for convenience foods in the future.

In 1910, American processors, employing more than 68 000 factory workers, were producing over 3 billion cans of food. The large capital investments necessary for a modern cannery of the period favored the formation of large processing companies, many of American origin (e.g., *Heinz, Campbell's*). The large-scale production of these new convenience foods required large and expanded markets for their sale. Aided by the transportation and communication revolution occurring at this time, the United States market was developing from regional to national scope, which, fueled by the country's economic growth and rising incomes, offered the necessary commercial outlets for fast-increasing, canned-food production.

Food processors at this time came to realize that their future market success depended on more than technological, logistical, and manufacturing abilities. In order to build competitive and sustainable distribution, businesses would require an understanding of the factors influencing the demand side of their businesses. They realized that attracting and retaining consumers were critical to their future commercial success.

Beginning in the 1860s, progressive processors started to commit the time, energy, and resources necessary to acquire a better understanding of the consumers' needs. Leading food canners used this information to craft attractive national reputations for their companies and their products. Their marketing response was to build consumer-recognized and trusted brands through effective packaging, advertising and promotion. After the 1880s, rapidly growing food companies began branding their products for national distribution. As the scope, scale, and reputation of their nationally distributed brands expanded, shoppers now, unlike in the past where they depended on a local retailer for buying advice, came to know, trust, and purchase national brands for the quality they embodied. This brand marketing innovation would become the future business model for the success of convenience foods to this day.

Initial development of convenience foods during this period was not limited to canned foods. Other types of convenience foods produced with different technologies and packaged in other types of containers became nationally available during this period through then-proliferating neighborhood stores, beginning to organize into grocery chains. Most famous and enduring among these were convenience entries in the (then) new category of breakfast cereals. Early leaders in packaged cereals were *Kellogg's* 'Corn Flakes' and *Post's* 'Grape-Nuts,' which became most successful in encouraging Americans to substitute these products for their former breakfast choices.

By the 1880s, several rapidly growing companies were packaging and branding a wide range of other food products – *Procter & Gamble, Pillsbury, Nabisco, Borden's* – that are still prominent brands. The immediate and sustained market success of these new-to-consumers forms of convenience foods predicted the major role that these foods and their promotion would play in shaping the future diets in the industrial countries. The consumer attraction and durability of these leading brands also presaged the importance of product innovation, advertising and promotion, and wide distribution to which the market success of convenience foods owed so much.

In addition to the technological, social, and economic factors responsible for the early successful development of convenience foods, political factors also would be significant. Increasingly during the nineteenth century, the safety and quality of various processed foodstuffs were a growing concern with the public, and not without justification. Progressive canners, such as Henry J. Heinz and others, came to realize that because of the sharp practices of some processors, consumers were often suspicious of processed foods: this concern had the potential to adversely affect the industry's future. Government-imposed standards were necessary to prevent mislabeling and food adulteration, occurring all too often in this era.

During the period of the 1880s up to the successful passage of the US Pure Food and Drug Act in 1906, various state and federal legislators, government and academic food experts, civic and professional organizations (American Medical Association, National Consumers' League, General Federation of Women's clubs), and a number of food processors lobbied for government oversight. The passage of this Act and the resulting government agency oversight of the industry gave the public the necessary faith in processed foods to further enhance their wide acceptance. Earlier similar food laws had been passed and implemented in other industrial countries with parallel results. The first British Food and Drugs Act was passed in 1860 and then extensively revised and strengthened in 1872.

Packaged and Branded Convenience Foods

In the period between the last quarter of the nineteenth and the first quarter of the twentieth century, commercially produced convenience foods became established in the diets of the industrial countries. The nascent food-processing industries of that era, producing these early convenience foods, were still learning the skills of economically mass-producing products. Of equal importance, the companies were learning how to brand, distribute and effectively market these early convenience foods on a more national scale.

Consumers not only accepted, but also had an apparent great desire and need for, more and more of these convenient products that fitted their new urban lifestyles so well. The food-processing industries responded aggressively to this growing consumer demand during the early part of the century. The social, technical, economic, and political foundations had been established for the next phase – the 1930s through 1980s – for the rapid growth and proliferation as well as improvement of convenience foods with their 'built-in-chef service.' These second-generation packaged foods would be an integral part of this new era with its lifestyle that would become known as 'the golden age of consumer products.'

New advances in convenience foods would depend on a greater scientific understanding of food processing and handling. While canning had been practiced

since the eighteenth century, it was not until the end of the nineteenth century that canning was established on a firm scientific basis by research at the Massachusetts Institute of Technology. While urban populations were becoming accustomed to early mass-processed convenience foods, the scientific foundation for the myriad advanced convenience foods, which would be introduced in the 1930s and later, was being established in the research laboratories of government institutes, universities and food companies.

A notable achievement of this new science-based food innovation era was the first market introduction in the 1920s of packaged frozen foods by a company founded by Clarence Birdseye, generally considered to be the initial patent-holder and first commercial developer of frozen foods. Frozen foods offered stored processed foods with a markedly improved texture, color, and taste over equivalent canned foods. The availability of frozen foods, with their improved eating quality versus canned foods presaged a trend that would continue during the nineteenth century: a newly developed processing technology, yielding an improved convenience food, would replace products manufactured with an older technology. Consumer markets would respond favorably to the 'new and improved' marketing claims of these new consumer products.

The first part of the twentieth century would prove to be a very productive era for food science and technology. Notable commercial convenience-food successes resulting from new knowledge would be: *Crisco*, hydrogenated vegetable shortening by *Procter & Gamble* in 1911; strained baby food in individual glass jars by *Gerber* in 1927; *Wonder Bread*, packaged, sliced white bread in 1930 by *Continental Baking*; frozen June peas and frozen spinach by *Birds Eye* in 1930; *Ritz* Crackers by *National Biscuit Co.* (*Nabisco*) in 1933, which, in 3 years, would become the world's largest selling crackers; soluble (instant) coffee, first produced by Nestlé in 1938 as the *Nescafé* brand, using countercurrent roast-coffee water extraction, followed by spray drying, and later improved by *General Foods* in 1964 by a freeze-drying technology, marketed as *Maxim* freeze-dried instant coffee; *Minute Maid*, frozen orange juice concentrate by the *Minute Maid Corp.* in 1947; packaged, prepared cake-mixes by *General Mills* and *Pillsbury* in 1948; Frozen TV dinners by *C.A. Swanson's & Sons* in 1953, using flash-freezing technology; and many other famous, convenience foods consumed to this day.

Through the period of the 1950s to the 1980s, there seemed to be no end to the growth of these new branded, packaged foods. This was especially true for the leading brands in the various supermarket categories. The consumer food industry, with the help of sophisticated input suppliers – packaging companies, process equipment manufacturers, and numerous suppliers of food ingredients, flavorings, and food additives – formed industrial clusters that served as sources of product innovation. This resulted in 'new products' introductions entering American supermarkets in the thousands of items per year. New methods of consumer research vastly improved the commerical development process by identifying potential consumer needs and desires prior to the actual physical development efforts. Nevertheless, new product failure rates were always high, but the great profitability of successful market winners justified the cost of both continuous product development efforts and the high advertising and promotion expenses of introducing new products.

These second-generation convenience foods were a perfect fit for the era, and they captured the contemporary consumer tastes and lifestyles. Consumers – having survived the Great Depression of the 1930s and the Second World War – were eager for the benefits of the new consumer society that followed, providing new products often previously unavailable. These new, and improved, consumer products fitted their rising incomes and new social aspirations. New home appliances, such as refrigerators with frozen food compartments and microwave ovens, as well as second family cars and new television sets were all necessary stimuli to the growth of the new branded, packaged convenience foods. The large volumes of these new mass-marketed foods – required for supporting their relative low cost – spurred the transformation of food retailing, giving rise to new large, shopper-friendly, self-serve supermarkets offering and selling thousands of new, attractive food items.

Housewives, often living in new suburban surroundings, driving second family cars and now having the time, desire, income, and shopping interest became avid purchasers of the new convenience foods. The increasing prevalence of then-new TVs in their homes gave marketers of convenience foods an economically effective means of introducing and marketing their products. As a result, the packaged convenience food industry experienced an unparalleled era of great prosperity. While there were safety questions raised concerning the increasing use of food additives, chemicals and new packaging in convenience foods, new laws addressed the majority of these safety concerns but did not restrict their increasing use in food manufacturing as well as the market growth of new convenience foods.

Ready-prepared Convenience Foods

In the middle of the golden era of consumer products, while mass-marketed, supermarket-sold, branded, packaged convenience foods were setting new consumption records, a new type of convenience food was rushing into the market place: ready-prepared foods that offered consumers the ultimate in utility and convenience, food requiring no preparation, complete and ready for consumption. Foods, both as hand-held snacks or full meals that can be purchased in fast-food outlets and restaurants, as well as in supermarkets and stores of all other kinds, and eaten at the site of purchase, in the home, or on the move. While the convenience of ready-prepared food has, in a sense, been available in many forms since the time of the Roman Empire and their cookshops, the rapid and extensive growth plus the commercial origin of these modern ready-prepared foods was without parallel.

By the 1990s, this new wave of convenience ready-prepared foods would largely blunt the phenomenal growth experienced by packaged, branded convenience foods in the US supermarkets since the 1940s. By the early 1990s, total consumer retail spending on foods of all types at all sales outlets had reached approximately US$700 billion annually equally divided by shoppers between traditional processed foods and new ready-to-eat foods. These new convenience foods became available everywhere: in restaurants of all types, catering, and institutional outlets (schools, universities, hospitals, government, and industrial cafeterias). Even supermarkets and stores of many kinds joined the new trend to offer also take-out, ready-prepared foods. By late 1990s, applying the successful marketing and branding techniques developed earlier by the packaged food industry, the annual growth of ready-prepared foods was outdistancing traditional foods sales by approximately four-to-one (4% versus 1–2%) annually. In other industrial countries, a similar trend was occurring, but not yet to the same extent as in North America.

The ever-changing concept of convenience foods was taking on still another identity, driven by a new set of social, economic, and technical factors. Socio-economic factors, in particular, were largely responsible for the success of these new ready-prepared convenience foods. Americans were experiencing unprecedented economic growth, affluence was molding their expectations, and ready-prepared foods became 'affordable luxuries' for all. A major factor in the changing economy was increasing participation by women in the work force; the number of women working outside the home doubled from fewer than one in three in the 1950s to nearly two in three in the 1990s. Overworked, time-constrained consumers, often in dual-income or single-parent households, not having the time, energy, or desire to cook, moved from the traditional never-changing meal schedules of the past to unstructured and fast-paced feeding schedules. Furthering this trend was the number of married households with children in the USA, which declined from 40% in 1970 to 24% in 2000.

Ready-prepared convenience foods were ideally suited, in both form and price, to the new eating patterns. Americans, both young and older, experiencing new lifestyles, increasingly prefer the easy availability, immediate service, and fresher taste of ready-prepared foods, as opposed to highly processed, packaged foods requiring supermarket purchase, tiring transfer to the home, and then preparation and clean-up. Food also became more than just daily nourishment, but often entertainment, too, as people were experiencing new tastes, foods of new ethnic varieties, and new types of restaurants. By the 1990s, Americans appeared to be eating convenience foods continuously and everywhere; concurrently, their away-from-home eating places were changing, as well as the types of food they were eating.

Between 1970 and 1990, the number of full-service restaurants per 100 000 people fell by one-quarter, and the number of bars and luncheonettes by half. New eating spots – fast-food outlets – were taking their place; during the same period, the number of fast-food outlets doubled. The majority of these were part of huge national and even international chains that been started in the 1950s and 1960s (*McDonald's, Burger King, Kentucky Fried Chicken*, now known as *KFC*). These fast-food chains, with their hamburgers, French fries, fried chicken, and soft drinks, combined with new moderate-priced, family-style restaurants (*Denny's, Red Lobster*), pizza shops (*Domino's, Pizza Hut*), and coffee outlets (*Dunkin' Donuts, Starbucks*) and assorted other types, would come to dominate America's new convenience food industry, with an estimated 40 million people per day eating at, or meals from, fast-food outlets in the 1990s. By 1998, the 20 largest fast-food chains would have 79 922 outlets, with annual sales of US$56 billion, accounting for 23% of total US restaurant sales, often located side-by-side, convenient by automobile, in or by major shopping malls and highways.

In order to compete, supermarkets would start to offer ready-prepared items, as did many other types of food shops. Traditional food companies also started to offer chilled, ready-prepared convenience foods. The same economic and social trends that favored the growth of the fast-food outlets also favored an equally strong growth of all types of institutional foodservice. These new convenience foods

with the often pervasive use of their brand names, have led to brand-name, fast-food outlets now prevalent in food courts of shopping malls and as mini-units in corporate, institutional, and governmental food settings.

As the nature of convenience foods has changed, so have the technologies to deliver the new ready-prepared consumer items. The traditional food industry practices the technologies of product formulation, processing, and packaging designed for product stability, often at ambient temperatures or deep-frozen, and months-long storage times, plus potential distribution over long distances. Ready-prepared convenience food technology has other objectives: freshness, short shelf-life, and capability of being prepared on demand for waiting customers in minimum time, by nonskilled labor. Often the fast-food outlet is merely the final stage in a vast, highly complex system of mass production that gathers the necessary agricultural products and ingredients, partially prepares and processes them – often in central commissaries – for final and speedy, minimal preparation at consumer store level. This new segment of the food industry has industrialized the final preparation of food that occurred in the past in the home kitchen.

The nature of ready-prepared food production, often with short-shelf-life products, requires organizations with great skill handling timely logistics and exacting, day-to-day market-demand forecasting. As a result of the significant differences in the necessary business skills required for ready-prepared foods as compared with traditional processed foods, the leading marketers of these new convenience foods are predominantly business organizations quite different from the traditional food processors.

While the major fast-food chains have acquired such market dominance and apparent invincibility in supplying modern consumers' diet at the start of the twenty-first century, political forces are building that could prove to be problems for their further growth. Concern about the narrow dietary composition and high fat content of fast-food menus is growing, and questions are being raised by medical professionals and government health policymakers, especially given their high rate of consumption by the young.

Summary

Over the last 150 years, populations of the industrial countries, as well as those of the recently developing countries, increasingly favor convenience foods as diet mainstays. Convenience foods cleverly meet the nourishment needs of modern life. World-wide shoppers want the advantages these foods offer: taste, quality, variety, economy, availability, nutrition, safety, and – above all – their labor-saving functions. Today, these foods offer the advantage of minimum, or even nil, preparation effort, and they are available everywhere at attractive prices. Their consumer prices are being determined more by the 'added-value' services offered than by the cost of ingredients used in their production. Convenience foods have changed the diet for many, while enhancing our modern, quick-paced lifestyle. They again confirm that 'food is never just something to eat.' (From *Much Depends on Dinner*, by Margaret Visser, 1986).

New food science and technology, combined with associated packaging and processing technologies as well as advances in communication, distribution, and marketing, have enabled the development of a series of convenience foods and added to ever-increasing consumer satisfaction. However, basic to their phenomenal growth are the changing social, economic, and political factors responsible for their wide everyday consumption. As the nature of these environmental factors has changed over the past century, so has the basic identity of convenience foods. As we have seen in the three major past transformations of convenience foods – early, brand and packaged, and now ready-prepared forms – outlined above, so it is likely that the nature of convenience foods will change again in reaction to new social, technical, economic, and political forces.

COOKING

Contents

Domestic Techniques

A J Rosenthal, Oxford Brookes University, Headington, Oxford, UK

Introduction

As with all forms of cooking, domestic cooking is intended to improve the palatability of the food, making it more appetizing. Unlike industrial food preparation and catering or food service, domestic cooking is carried out in the end user's home, by people who may not have any technical knowledge of what is happening from an engineering or biochemical point of view. By definition, cooking raises the temperature of the food. This results in a number of simultaneous and interrelated processes which influence the flavor, texture, appearance, nutrient content, and safety of the food. The different techniques of domestic cooking reflect the way in which the temperature of the food is raised (**Figure 1**).

Clearly, there are two basic ways in which energy can be applied to a foodstuff, resulting in a rise in temperature. The traditional route is by contact with a heated medium which causes heat to flow to the surface of the food and then on to the center by conduction. An alternative route is to apply electromagnetic radiation. Of the two types of electromagnetic radiation commonly used in domestic cooking, infrared, radiant heating (grilling) employs short-wavelength radiation which is only able to penetrate a couple of millimetres below the surface of the food. The inner regions of the food heat by conduction. Microwaves have longer wavelengths which are able to penetrate deep into foods, generating heat *in situ*.

In many cases energy transfer during cooking is not by a single mechanism. For example, ovens absorb and emit infrared energy and baked food heat by a combination of convection and radiation. Similarly, barbecues emit infrared radiation as well as generating hot combustion gases, which flow around the food, heating it by convection.

General Considerations

Surface Heat Transfer

The crucial difference between the different techniques of heating by contact with a heated material is what happens at the surface of the food.

When a solid food is placed in a hot fluid, there is a stagnant layer of fluid around the food. This boundary layer acts as an insulating barrier which slows the flow of heat from the fluid to the food.

Air is a good insulator (thermal conductivity, $0.024\,W\,m^{-1}\,K^{-1}$); therefore a boundary layer consisting of air greatly slows the flow of heat from an oven to the food (**Figure 2a**). One way of reducing the thickness of this boundary layer is to agitate the heating medium. In the case of fan-assisted ovens, the air is forced to circulate, thereby impinging on the

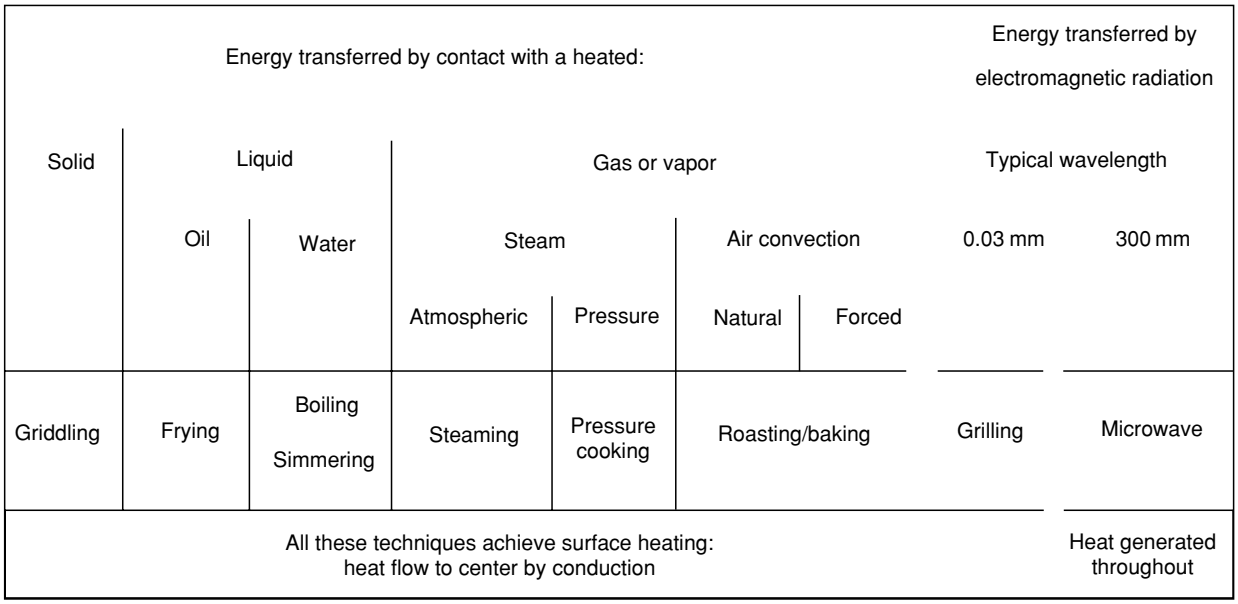

Figure 1 Classification of domestic cooking techniques.

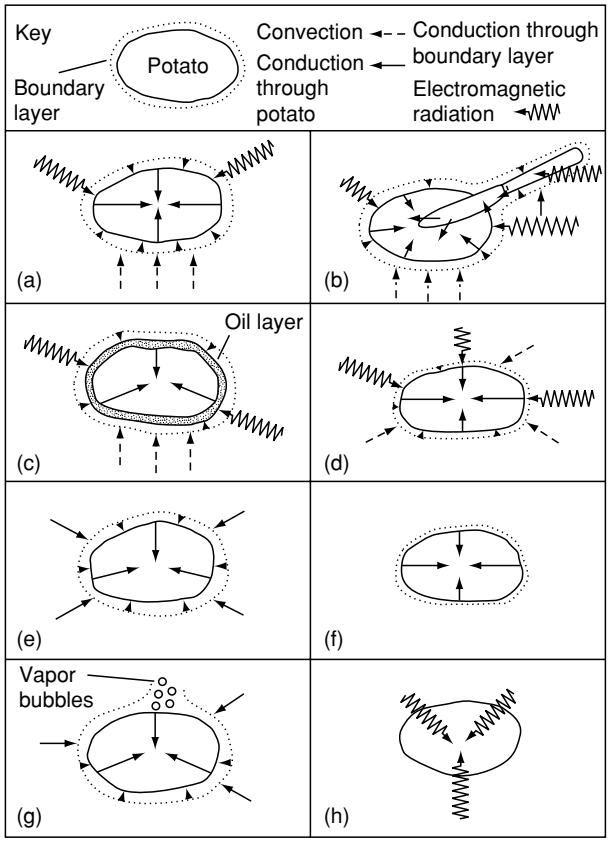

Figure 2 Eight ways to cook a potato: (a) bake; (b) bake with a good conductor (e.g. knife) inserted; (c) roast; (d) forced convection (fan-assisted oven); (e) boil; (f) steam or pressure-cook; (g) fry (chipped); (h) microwave.

surface of the food and physically reducing the thickness of the boundary layer (Figure 2d). The surface heat transfer coefficient in a fan-assisted oven is about 10 times greater than in a conventional oven.

Heat travels by conduction through static boundary layers. Heating media which are better conductors of heat than air will increase the rate of heat flow to the surface of the food. Water has a thermal conductivity of $0.573\,W\,m^{-1}\,K^{-1}$, and the rates of convective heat transfer during boiling and simmering are therefore considerably faster than in ovens at the same temperature (Figure 2e). However, the maximum temperature attainable with water is limited by its boiling point. Alternative liquid heating media, such as oil, have thermal conductivities in the same region and can operate at temperatures around 180 °C. Hence rates of heat flow to the surface in frying are considerably greater than in boiling. This is also partly attributable to physical agitation of the boundary layer caused by the generation of water vapor at the surface of the food in contact with the hot oil (Figure 2g).

When saturated steam is used as the heating medium, heat flow to the surface of the food is accompanied by simultaneous condensing of the steam. The dramatic volume change during condensation results in fresh steam flowing to occupy the void, thereby maintaining a virtually negligible boundary layer (Figure 2). However, if the steam is not saturated, then the noncondensing air accumulates at the surface of the food, forming an insulating layer. In fact, as little as 6% air in steam reduces the surface heat transfer by 90%.

Rate of Heating

During heating the rate at which heat flows into any food depends on the shape and size of the food, the temperature difference between the food and the heating medium, as well as the rate of heat transfer between the food and the heating medium.

Shape and size influence the rate of heating. Large surface areas obviously allow more heat to flow than small surfaces. Shapes with more surface-to-bulk ratio such as spherical foods will heat quicker than other shapes such as slabs. Consequently, if we consider how fast it takes heat to penetrate to the center of two 'spherical' potatoes of different size we see that it takes longer for heat to penetrate to the centre of a large potato compared with a small one. There are two reasons for this: the large potato has a greater distance for the heat to flow to reach the centre and the ratio of the heating surface area to mass is smaller for a large potato.

The driving force in any heating operation is the difference in temperature between the food and the heating medium. The greater the difference, the higher the rate of heat transfer. In the case of domestic cooking, foods heat by what is referred to as unsteady-state heat transfer. That is to say that the temperature difference reduces as the temperature of the food rises and hence the driving force lessens as the process ensues.

The physical properties of the food and the heating system contribute to the heating rate. Factors such as how easily the heat is able to flow through the insulating surface boundary layer and then on through the bulk of the food by conduction towards the center are influential.

Engineers who study heating processes have methods of predicting rates of heating based on the physical properties of materials and heating systems. In order to illustrate the factors which influence the rate of heating, Figure 3 has been produced. As a measure of the heating rate, the time taken for a food of fixed shape and size to reach a particular temperature has been used. In this figure, 2-cm-diameter spherical potatoes starting at 5 °C have been used. The identical potatoes are placed into different heating media at designated temperatures and the time taken for the centre temperature to reach 80 °C has been predicted. The temperature of 80 °C has been chosen as a realistic center cooking temperature for many meats and vegetables, and one which will certainly achieve gelatinization of starch in a food like a potato.

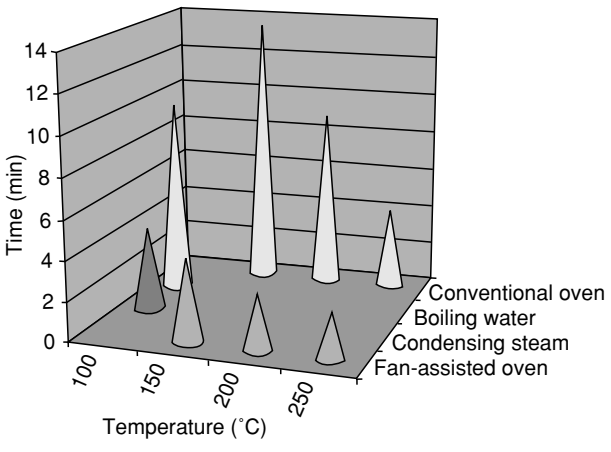

Figure 3 Predicted time for the center of 2-cm-diameter potatoes to reach 80 °C.

Clearly, short cooking times can be achieved in a number of ways. Working at higher temperature achieves more rapid cooking, as does selecting a cooking process with a high surface heat transfer coefficient. Hence, working with a fan-assisted oven is faster at cooking than conventional ovens because they reduce the thickness of the insulating surface boundary layer around the food.

Cooking by Electromagnetic Radiation

Infrared

As with the other traditional forms of cooking, grilling (broiling) causes the surface of the food to heat, and the center then heats by conduction. Absorption of infrared radiation at the surface is proportional to the difference of the fourth power of the temperature of the radiation source and the surface of the food. However, various foods absorb infrared radiation to differing extents depending on their absorptivity (e.g., black body, 1; perfect reflector, 0; water, 0.96).

Conventional grilling and barbecuing are restricted by the fact that radiant energy is supplied from one direction; cooking of all sides is only achieved by frequently turning the food, e.g., on a spit.

In practice, infrared heating is involved in many cooking techniques, such as baking and roasting. In these cases the oven walls heat up by convective heat transfer and then emit infrared radiation.

Microwaves

Microwaves penetrate deep into most foods; their sinusoidal electromagnetic waveform causes dipoles (e.g., water) to oscillate, which in turn causes heat (Figure 2h). As microwaves pass through a food material their energy is lost; although heating does occur within the food, it is greatest at the surface. The actual temperature achieved within the food depends on several factors, including the frequency of the radiation, the strength of the field, the dielectric loss factor of the food, the free moisture present, and the shape of the food.

Quality Changes during Cooking

General Considerations

Mrs Beeton tells us that there are only two basic cooking methods: wet and dry. Wet cooking includes boiling, simmering, steaming, pressure cooking, stewing, and poaching. During wet cooking the surface temperature of the food does not exceed the boiling point of water (usually 100 °C, but up to about 120 °C in domestic pressure cookers); consequently, the surface remains moist. Dry cooking includes frying (deep and shallow), baking, roasting (in an oven with natural or added fat), grilling (broiling), barbecuing, and griddling. The surface temperature during dry cooking may well exceed 100 °C, leading to evaporation of moisture and a dry or crisp surface.

Whatever is being cooked, it is worth bearing in mind that most foods are biological in origin and many are still respiring up to the time of cooking. The rise in temperature during cooking can result in a severe disruption of structural integrity and the termination of normal metabolic activity.

We eat a diverse range of foods, each with its own criteria of quality. Since the changes that occur during cooking are dependent on both the temperature achieved in the product and the time at which the food is held at each temperature, the quality of the product is constantly changing. Most of the quality changes that take place during domestic cooking can be described by first-order Arrhenius kinetics (i.e., after a finite activation energy is reached, the rate of change is proportional to a rate constant, which is itself exponentially affected by temperature). The activation energy and rate constant vary for different quality factors; moreover, any particular factor may behave differently in each food (e.g., thiamin is destroyed more rapidly during cooking of rainbow trout than in a buffered solution with the same temperature–time profile). This means that if a food is cooked on the basis of one quality characteristic (e.g., color in meat, or texture in cakes) and if the time–temperature treatment is varied from an established procedure, then the other quality parameters may be suboptimal. For example, microwaved meat may not develop the same flavor as conventionally roasted meats.

Textural Changes

No single mechanism is responsible for the texture of foods, yet changes in protein structure and solubilization of polysaccharides (and some proteins) are the two primary phenomena involved.

Heat causes proteins to unwind their tertiary structure. Heating for long periods or high temperatures frequently results in irreversible changes in tertiary structure, termed denaturation, which causes changes in functional properties. If the protein is highly charged, the uncoiled amino acid chains tend to repel each other and the protein increases its affinity for water, leading to an enhanced solubility. (*See* **Protein**: Interactions and Reactions Involved in Food Processing; Functional Properties.)

If the protein molecules are reasonably close to their isoelectric point, the amino acid chains tend to attract each other with hydrophobic interactions and hydrogen bonds, forming a network of chains. This association of molecules results in a reduction in the amount of water which is associated with protein, and hence the following consequences: a loss of protein solubility; precipitation of the protein from solution, giving rise to a solid structure (such a change is responsible for the thermal setting or gelation); loss of water-holding capacity accompanied by an aqueous exudate from the product (often observed when cooking meats); shrinkage of the product as both the above occur; and increase in the opacity of the food (e.g., egg white).

Some proteins undergo reversible thermal transitions when heated. For example, collagen (and its partially hydrolyzed derivative, gelatin) is solubilized when heated. Owing to its prevalence in connective tissue, this has important implications in tenderness of cooked meat and is partly responsible for the softening action of long-duration stewing.

Solubilization is also a process which affects polysaccharide material between the cell walls of plants. Dissolution of these pectins results in softening of the plant tissues. Addition of sodium bicarbonate enhances solubilization of pectin by producing the sodium salt and displacing the calcium ions which are naturally chelated in the structure. (*See* **Carbohydrates**: Interactions with Other Food Components.)

Another mechanism commonly involved in providing rigidity in plant tissues is turgor. Denaturation of the proteins present in the cell membranes causes a termination of osmoregulation and a subsequent softening of the tissues. Deliberate protein denaturation is the aim of blanching, a brief exposure to temperatures around 85 °C, with the intention of destroying flavor-modifying enzymes prior to home freezing.

Starch is present in many plant foods. Heating starch with an ample supply of water leads to gelatinization. The granules swell as they absorb water and the crystalline regions are disrupted. This has both a softening and a thickening effect, which is why gelatinized starch provides the viscosity of many sauces. (*See* **Starch**: Structure, Properties, and Determination.)

The light, open texture of baked flour products is due to the presence of gas or air cells in the prebaked dough or batter. During heating the gases expand; this expansion is aided by the generation of additional gas from chemical leavening agents (e.g., sodium bicarbonate) and from an increase in the vapor pressure of the water present. Finally, the liquid matrix is heat-set by denaturation of proteins and starch gelatinization. In the case of popcorn the impervious grain coat acts as the wall of pressure vessel. As the grain is heated the water vapor pressure increases until the wall ruptures. The vapor then flashes off, opening out the endosperm which then heat-sets.

A crisp outer surface is often associated with dry cooking. The temperature in excess of 100 °C results in moisture being lost from the surface.

Color and Flavor Changes

With the exception of added colors sometimes used in domestic cooking (e.g., saffron or cochineal), two types of color change result from domestic cooking: modification of natural pigments present in the raw materials, and browning reactions. Most natural colors tend to be relatively unstable when cooked. In addition to these chemical reactions, in wet cooking loss of natural color may result from leaching of water-soluble pigments into the cooking medium.

Metalloporphyrin colors are found in foods of both animal and plant origin. Myoglobin, the pigment found in muscle, undergoes color change from red-purple to brown when heated; this is a result of certain amino acids in the globin protein constituent of the molecule becoming coordinated with the central iron atom. Chlorophylls are also prone to lose their color when heated in acid conditions. The change from bright green to a greyish green is the result of demineralization of the central magnesium atom from the molecule. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Sensitivity to pH is exhibited by other natural pigments. Anthocyanins, for example, change from red (in acid conditions), through colorless (when neutral) to blue (when alkaline). This can result in color changes when heat disrupts cells and allows these water-soluble pigments to mix with the cooking water.

Browning reactions tend to occur at low levels of available water. They are therefore common in dry cooking where the surface layers may dry out. Caramelization occurs when concentrated sugars are heated, particularly in the presence of acids or alkalis. Caramelization is of importance in both sugar and flour confectionery. The most famous of these reactions is Maillard browning, which involves the reaction between carbonyl groups (as found in reducing sugars) and amino groups. The reaction gives rise to a variety of brown compounds and characteristic aromas. Simple mixtures of one amino acid and one reducing sugar have been shown to produce distinctive aromas, reminiscent of particular foods (e.g., glucose and cysteine heated at 180 °C for 30 s smells of puffed wheat, yet after 3 min it smells of overroasted meat). (*See* **Browning**: Nonenzymatic.)

Generally speaking, volatile components are lost during cooking, and this can result in a loss of the uncooked flavor. Since domestic cooking is carried out by the end user, loss of volatiles is not completely wasted and may act as an appetizer.

Sustained heating of dry surfaces can result in carbonization, usually accompanied by the generation of smoke. In such circumstances the surface browns, then blackens as it burns; such products are usually regarded as spoiled.

Nutritional Changes

Although the act of cooking involves raising the temperature of the food, the term is frequently undifferentiated from other food preparation procedures, many of which commonly precede cooking. Peeling and trimming are two such operations which can lead to substantial loss of available nutrients, by cutting unsightly portions off the food and throwing them away!

Nutrient loss during cooking is attributable to two basic routes: thermally induced chemical reactions, and leaching of nutrients into the cooking medium.

Many nutrients are thermally unstable and when heated their concentration falls exponentially with time. Obviously, different nutrients have their own rates of destruction. The most sensitive vitamins are ascorbic acid (vitamin C) and folic acid, both of which can be completely destroyed by domestic cooking. Of the essential amino acids, lysine is the least stable to heat and up to 40% may be lost by domestic cooking practices. In general, rapid cooking methods, using high temperature for short times, or microwaves cause less nutrient destruction than long-duration, low-temperature cooking methods such as stewing. (*See* **Amino Acids**: Properties and Occurrence; **Ascorbic Acid**: Properties and Determination; **Folic Acid**: Properties and Determination.) High-temperature short time processes such as frying can result in similar levels of vitamin C, as in raw potatoes.

In addition to thermal decomposition, nutrients can be lost by reacting with each other. For example, proteins will participate in Maillard reactions, particularly when ϵ-amino groups are present.

Sodium bicarbonate is sometimes added to vegetables for its softening effect. Unfortunately, its

addition leads to the destruction of vitamin C, as well as chemically modifying proteins, lowering their biological value.

Cooking processes are not entirely detrimental from a nutritional point of view. For example, frying can result in an uptake of oil, resulting in an increased energy density in foods.

Safety Aspects

A common misconception is that domestic cooking is performed purely to improve the gastronomic experience at the detriment of the food's biological value. In fact, domestic cooking can make safe products which would otherwise contain harmful or toxic components.

Harmful components in food arise in the form of naturally present toxins (e.g., cyanides in kidney beans and cassava), or compounds that interfere with digestion, effectively making the food less nutritious (e.g., trypsin inhibitors found in many legumes). The presence of pathogenic microorganisms may lead to infections, while other microorganisms produce toxins, both of which result in food poisoning. (*See* **Hemagglutinins (Haemagglutinins)**; **Plant Antinutritional Factors**: Detoxification; **Trypsin Inhibitors**.)

Cooking is effective at destroying or removing many of these harmful components. However, some toxins are relatively heat-stable (e.g., the toxin produced by *Staphylococcus aureus*) and may not be destroyed by the temperatures and times incurred during domestic cooking. It is of course likely that untrained domestic cooks will be oblivious to the risks involved in eating particular foods, or to the neutralizing effect of cooking. A further risk arises from cross-contamination of cooked food by raw ingredients, resulting in a potential for fresh growth of pathogenic microorganisms.

Domestic Use of Microwave Ovens

T Ohlsson, SIK – The Swedish Institute for Food and Biotechnology, Gothenburg, Sweden

Microwave Ovens

Towards the end of the 1970s, sales of domestic microwave ovens started to grow rapidly in Japan, a couple of years later in the USA, and at the end of the 1980s also in western Europe. The domestic microwave oven industry has now grown into a world-wide multibillion dollar business, with about 24 million ovens being sold annually. On many markets, the microwave oven is the home appliance with the largest sales volume. It is estimated that there are about 225 million microwave ovens in the homes in Japan, the USA and western Europe. User studies have shown that it is predominantly the affluent, 'middle-aged parents with kids' families that own microwave ovens.

This population of microwave oven owners represents a large potential market for food products that can be microwave-heated. The food industry has quickly responded to these market possibilities. The number of new product introductions for the microwave food segment has grown rapidly on many markets; e.g. in the USA during the middle and later part of the 1980s.

Microwave and microwaveable food today constitute an important segment of the food market in Japan, the USA and, increasingly, western Europe. The microwave food segment comprises not only prepared food items, such as meals and side dishes, but also products specially made for microwave heating, the most striking example being the microwave popcorn bag, developed by Golden Valley Microwave Foods in the early 1980s. It is today a billion-dollar market, alone. The presence of microwave ovens in the homes affects the preparation or cooking instruction for more or less all packed food products, even those not traditionally associated with microwave heating.

The growing number of microwave ovens and microwave foods has also greatly influenced the food packaging industry. Requirements of microwave compatibility have greatly changed the way in which the food industry selects food packaging. For prepared foods, microwave-transparent plastic and paperboard packaging has grown at the expense of aluminum packaging. A vast number of packaging designs, specific to microwave heating, have been developed.

The most striking example is the so-called susceptor package, in which an extremely thin metallized film on a PET film is heated by the microwaves to temperatures sufficient to crisp or brown pizza or pie crusts, or to pop popcorn.

The food technology differences between microwave and conventional heating are manifested by differences in development of food flavor and aroma and of food texture and appearance. Thus, modified recipes and special 'microwave-adapted' food ingredients have been developed by the industry to overcome at least in part some of the quality problems of microwave-heated foods.

This very substantial development of foods, packaging, and ingredients for microwave heating has given an increased general knowledge about microwave heating in the industry. Much of this knowledge is empirical, but a clear trend towards more scientifically based R&D has been seen in later years.

Heating Mechanism

What are Microwaves and How Do They Heat Foods?

Microwaves are electromagnetic waves in the frequency range from 300 to 300 000 MHz, corresponding to wavelengths from 1 m to 1 mm. For domestic food applications we are, however, limited to the ISM (Industrial, Scientific, Medical) band of 2450 $\pm$ 50 MHz.

The heating of foods by microwave energy is accomplished both by the absorption of microwave energy by rotation of the dipolar water molecules and by translation of the ionic components of the food. This energy is converted into heat. Thus, both the water content and the dissolved ion content (often salt) are dominating factors in the microwave heating of foods. When the dipolar water molecule is subjected to a microwave field that rapidly changes direction, the dipole tries to align itself with the field direction. There is a time lag, as some response time is required for the water molecule to overcome the inertia and the intermolecular forces in the water. The electric field thus provides energy for the water molecule to rotate into alignment. The energy is then lost to the random thermal motion of the water and equivalent to a temperature rise.

The energy-transfer mechanism will be efficient only if the time between the changes of direction of the electric field is so short that the dipolar molecule aggregates can barely follow the changes. If the time is long (frequency low), the alignment will be good and the energy transfer low. If the time is short (frequency high), the aggregates will not move much between field reversals, and the energy-transfer rate will again be low. Since the statistical number of water molecules that are bound together by hydrogen bonding will decrease with increasing temperature, so the inertia and energy release will be reduced. As the frequency in dielectric heating equipment will be maintained constant and below the energy transfer efficiency optimum, the efficiency will decrease with increasing temperature.

Hydrated ions, such as sodium and chloride from table salt, try to move in the direction of the electrical field, and an electric resistance heating effect is accomplished. The ions are surrounded by water molecules and will, in the movement, transfer energy randomly to the water molecules. These are more mobile at higher temperature and not so tightly bound to ions. The ions can then move more freely and absorb and dissipate more energy. The conductive heating due to dissolved ions increases with increasing temperature.

When a microwave impinges on a food surface, some of it will be reflected, and some will be transmitted and penetrate into the food and gradually be absorbed, while generating heat. Materials can be classified into reflecting, absorbing, and transparent, according to their interaction with the dielectric field. Reflecting materials are mostly metals, where the electric field creates surface currents that only penetrate a few microns into the material. Transparent materials, however, do not absorb the energy to any significant extent. Glass and most plastic materials are typical examples of this. Materials that will absorb microwave energy, according to the heating mechanism explained above, are those containing polar constituents, predominantly water.

The penetration depth (as calculated from dielectric data) for water and three food materials is shown in Figure 1 as a function of temperature. It can be seen that microwave penetration in water rapidly increases with temperature. For beef, the penetration depth is very high in the frozen state, rapidly decreasing during defrosting and leveling out with further temperature increases, whereas the penetration depth continues to decrease with rising temperature for salty ham.

Frozen foods show much lower dielectric properties as compared with thawed foods. Most of the water in frozen foods is present as ice crystals inside the food, and pure ice has very low dielectric properties. However, approximately 10% of the water remains unfrozen as a strong salt solution in the food, thus explaining why frozen foods absorb microwave energy. There is a marked jump in dielectric loss in the melting region, which partly explains the tendency towards so-called run-away heating in microwave thawing of foods, where already thawed parts

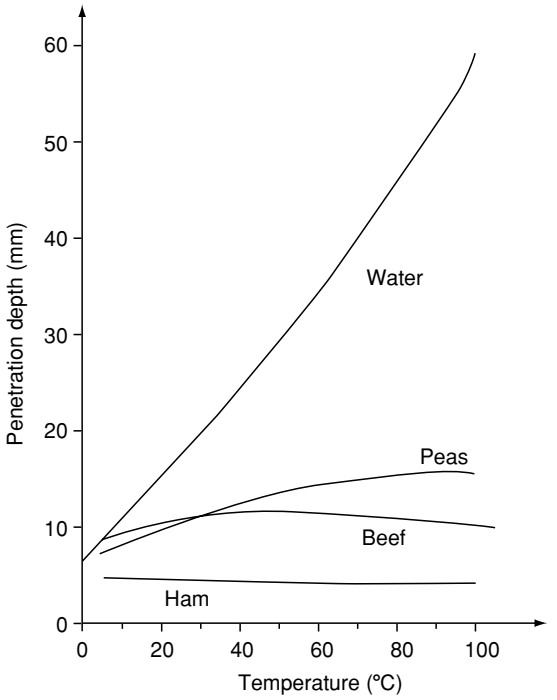

Figure 1 Penetration depth of foods at 2450 MHz.

absorb most of the available microwave energy because of their higher loss factor.

For nonfrozen foods, dielectric loss tends to decrease with increasing temperature, more pronounced so, the higher the water content and the lower the ionic content. This will tend to slow down runaway heating in thawing such foods. Salty foods, however, demonstrate a pronounced increase in dielectric loss with increasing temperature due to conductive losses. Since most foods contain some ionic material, the reduction in dipolar absorption with increasing temperature tends to be partly balanced by increasing conductive losses.

The actual temperature rise in microwave heating depends not only on the energy released in the food but also on its thermal properties, as apparent from the following energy balance:

$$Pt = mc_p\Delta T \text{ or } Pt = m\Delta H,$$

where P is power in watts; t is time in seconds; c_p is specific heat; m is mass in grams; ΔT is temperature increase in degrees Celsius; and ΔH is the change in enthalpy corresponding to the temperature rise.This means that low microwave absorption can still lead to a considerable temperature rise in foods of low specific heat, such as fats and oils.

The release of microwave energy in foods is largely dependent on both the microwave oven field and the microwave penetration pattern in the particular food material. The field distribution is a function of both the type of microwave oven and the manner of introducing the microwaves into it, as well as the type, shape, and distribution of the food inside.

In a rectangular slab of food of even thickness, the power level will gradually decrease inwards to an insignificant level if the slab thickness is large, in comparison with the calculated penetration depth.

For layered materials of different dielectric properties, microwaves will be reflected and refracted also at the interface between these materials, for example between meat and an outer layer of fat. Depending on the thickness and dielectric properties of the layers, standing wave patterns may develop, with maxima and minima. The result can be that the fat layer will be overheated, in spite of its lower dielectric loss factor. A contributing factor will then be the much lower specific heat of the fat material.

In a slab with sharp corners and edges protruding into the microwave field, energy concentrations will occur there, causing selective heating, especially at the corners. A sharp edge or corner will act as an antenna and attract more energy than surrounding areas.

When microwaves impinge on to a food surface at different angles, part of the energy is reflected, part refracted. Refracted energy will be partially absorbed. Most of the remaining energy will be reflected back at the other food surface and so on. Depending on the food geometry, the result can be focusing of energy to certain areas, which may be part of the explanation for concentration heating effects.

For spherical or cylindrical shapes, the result can be a concentration of energy to the center of the food, depending both on the food diameter and on its dielectric properties. This central heating effect occurs for diameters approximately one to three times the penetration depth in the material. For cylinders, concentration effects occur when the electrical field is parallel to the cylinder axis. The effect is stronger for foods with high values for its dielectric properties. At 2450 MHz, central heating usually happens at diameters between 25 and 55 mm, a common food size.

Heating Effects

Microbial Effects

The basis for the application of microwaves to food is the thermal heating effects caused by a combination of dipole rotation and electrical resistance heating. Over the years, there has been considerable discussion about the possibility of additional, nonthermal or *per se*, effects, from the exposure of the food to microwave fields.

In what ways, if any, will the effects on microorganisms of microwave heating differ from that of conventional heating methods?

The problems of insufficient microbiological inactivation in microwave reheating of chilled foods were highlighted by a study on survival of *Listeria* in ready meals heated according to recommended cooking instructions in the UK.

The study gave rise to much concern about the microbiological safety of foods heated in microwave ovens. The requirements that all parts of the food must reach 70 °C have been made clear to all parties involved, as a result of the UK microwave oven safety concerns.

It had already been claimed in the early 1960s by some researchers that microwave heating may have special, nonthermal effects on microorganisms, permitting sterility to be reached at considerably lower temperatures and with shorter treatment times than by other means of heat processing.

A number of comprehensive studies on microorganisms have been reported, which demonstrate the absence of any other effects than purely thermal.

The conclusion reached in 1989 by an IFT expert panel on Food Safety and Nutrition was that it is generally recognized that microwave interactions are solely due to thermal effects.

In 1989, results were published on exposure of milk, claiming the formation of unacceptable levels of D-proline and *cis*-hydroxyproline, involving a risk of brain damage in infants. However, the experimental conditions were subject to grave doubts, and efforts by other research groups to duplicate his results have been futile, even under the very excessive microwave heating conditions used.

Nutritional Effects

There are several good reviews available on the nutritional effects of microwave exposure. The general conclusion is that no significant nutritional differences exist between foods prepared conventionally or by microwave heating.

As regards the nutritional quality after comparable degrees of conventional and microwave heating, it was concluded that protein quality is retained in microwave heating of animal foods and improved in vegetables. Since no crust is formed in microwave cooking, the availability of amino acids, especially of lysine, is high. The content of fat in fatty details of meat and pork may decrease. Minerals and vitamins such as potassium and vitamins B_1 and C, are better retained in microwave heating as the cooking is done in a minimum amount of water – provided excessive heating is avoided.

Sensory Effects

Microwave-heated foods demonstrate more or less pronounced differences in appearance, flavor, and texture from conventionally heated foods. This is a result of the differences in temperature, moisture, and pressure gradients already discussed, and the related changes in structure and binding properties. Absence of surface color can be avoided only by combining microwave heating with other surface heating by hot air or by the use of susceptors.

In conventional cooking, a combination of enzymatic and chemical reactions is given time to develop. These reactions cause textural changes such as softening, firming, and tenderizing, and the formation and/or breakdown of flavor substances to give the combined flavor that is traditionally regarded as the normal or optimal. The absence of surface drying and Maillard browning reactions in microwave heating will also mean the absence of flavor notes that are very important to meat and bread.

The Microwave Oven

It is estimated that there are more than 225 million microwave ovens in homes in the industrialized world today. Penetration into households has reached above 100% in the USA, Japan, and Australia and above 80% in the UK and the Nordic countries in Europe. There are hundreds of models on the market in a wide range of design, control features, sophistication, and price. The basic oven shape and components are illustrated in Figure 2.

Alternating current from the mains is transformed to around 4 kV and rectified to direct current in the power pack. This is fed to the magnetron tube, in which the electric energy is transformed into microwave energy. This, in turn, is transferred through a waveguide to the rectangular oven space, the so-called microwave cavity. The cavity is a closed metal box, designed to prevent any external leakage of microwave energy. It is fitted with a door with microwave seals and often has a microwave tight metal screen for visibility of the oven interior during heating. The food to be heated is positioned on a bottom plate of microwave transparent material or on a rotating plate, or turntable.

Differences can be considerable between the multitude of oven makes and models on the market today, both in generated microwave power and in field distribution. Commonly, microwave output power lies between 500 and 1000 W for domestic ovens. Control features range from a simple timer and a start–stop button to weight and temperature sensors and microchip-based programing. The

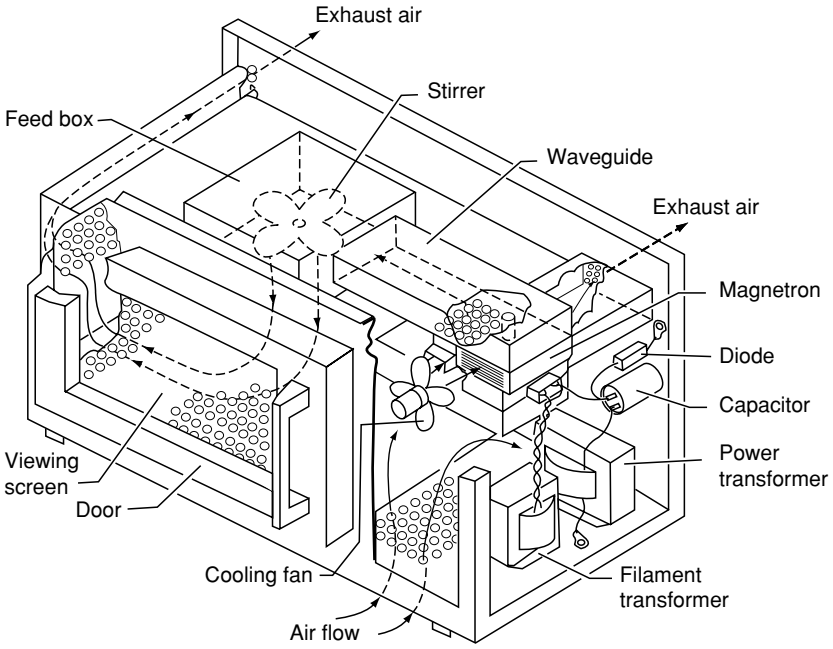

Figure 2 The microwave oven.

dimensions of domestic ovens are normally $30 \times 30 \times 25$ cm, dimensions that are of comparable magnitude to the wavelength in air at 2450 MHz (12 cm), which is the only frequency in use today for domestic microwave ovens. There is a growing trend to combine microwaves with a conventional heat source, such as hot air convection heating. Similar combination ovens already enjoy a substantial share of the domestic oven market on the European continent.

Energy is fed into the cavity by means of some kind of waveguide and antenna arrangement or opening slot in the roof or upper side wall of the cavity. The arrangement is designed to distribute the energy efficiently and evenly inside the cavity to enable rapid and uniform heating of a wide range of food loads.

In the oven space, a limited number of standing wave patterns can be generated as a result of multiple reflections at the metal cavity walls, usually not more than three to five different patterns. This means that the field is not entirely evenly distributed in the three dimensions, but demonstrates a pattern of maxima and minima. At the metal surfaces, the field strength is always zero. The field pattern is continuously modified by using a mode stirrer, a rotating propeller-like device, that will help a number of the possible modes to exist in the oven for certain time intervals. Alternatively, field differences can be compensated for by moving the food through the field on a rotating turntable at the bottom of the oven space. Most ovens use a combination of direct microwave radiation from the in-feed region and a multimode standing wave pattern in the oven.

In addition, ovens are often designed to contain devices that to some extent direct microwaves into the central area of the oven shelf, where foods are placed for heating. These so-called confined modes between the food and the oven bottom have been shown recently to be of great importance for developing ovens with more uniform heating patterns. The major reason for this is a promotion of bottom heating through promotion of the propagation of waves with an exceptionally long horizontal wavelength.

When food material is introduced into the oven cavity, the food composition, geometry of the food and package, and the positioning of the food in the oven will affect the field distribution compared with that in an empty oven.

Computer simulations of the microwave field and food temperature distribution have been used to evaluate the influence of the large number of product and oven factors since 1971, when a one-dimensional temperature profile simulation was presented. In recent years, thanks to the vast improvements in computer calculation power, numerical simulations of the three-dimensional microwave field pattern are possible, even on PCs. Both the FEM (Finite Element Method) and the FDTD (Finite Diference Time Domain) method is used. The FDTD method offers advantages of lower computer requirements and the simplicity of understanding the method and of 'building' models. However, the uniform grid (element) size

gives unnecessarily large matrices. The simulations give primarily the normalized electric field distribution. The translation to temperature patterns will also require modeling of the power dissipation of the oven.

Computer simulations will be an important field for research in the future, for improving the understanding of the complex interaction of the variables influencing the microwave field during heating, as well as for the optimization of oven design and microwave foods.

The rate of heating for a single food component in a microwave oven is primarily a function of the available microwave power, but the sample weight and the dielectric properties of the sample will to some extent affect this available power. Normally, available power will diminish with decreasing sample weight. Another factor that influences the available oven power is the line voltage.

The recognized standard procedure today for determining oven power output is the International Electrotechnical Commission (IEC) standard, which is based on heating a 1000 g water load, from 10 to 20 °C under precisely controlled conditions. The IEC has also issued an internationally recognized standard performance test for microwave ovens.

Microwave Foods and Packaging

Taking into account that microwave ovens are designed to give as even a field distribution as possible in the loaded oven with minimal corner and edge overheating, then food composition, geometry, and positioning as well as packaging will constitute the main remaining factors that determine the heating performance and resulting food quality.

For slab-shaped foods, the product thickness should be even, and preferably limited to less than 2.5 times its microwave penetration depth. Rounded edges and corners will limit preferential corner and edge heating tendencies. The temperature variations over large, flat surfaces of food, in terms of hot and cold spots, are normally larger than the in-depth temperature variation, and may have a greater influence on the overall heating results.

When heating food components of different dielectric and thermal properties together, such as in meals on a tray or a plate with different compartments, care must be taken in selecting the shape and relative arrangement of the components so as to optimize the heating uniformity. In this context, advantage can be taken of the central focusing tendencies of rounded (cylindrical or semispherical) geometry for thick food samples of limited penetration depth. Food components with a high dielectric loss, such as meat stew, can be partially shielded by components of lower loss (such as mashed potato) to even out the temperature distribution. Material with a low dielectric loss is less susceptible to corner and edge overheating, etc. By adjusting the thickness of the material with a low dielectric loss, the formation of variable standing wave patterns inside the food can be kept to a minimum.

In microwave heating, packaging is an integral part of the food product. Packaging composition, shape, and incorporated active functions all contribute to the heating result, in direct interaction with the composition, properties, geometry, and positioning of the food inside.

The packaging material should permit temperatures of at least 120 °C without affecting the handling stability or food protective properties. For low-moisture foods high in oil or sugar, the temperature stability may have to be extended up to 150 °C, because these foods will easily overheat in a microwave field. To permit reheating also in a conventional oven (dual ovenable), a temperature resistance of up to 200 °C is required.

The main packaging alternatives are:

- polymer-coated paperboard;
- mono- or multilayer polymers, laminated or coextruded;
- aluminum foil or foil- and polymer-laminated board;
- glass.

Of the polymer materials in use, PP (polypropylene) will meet the minimum temperature stability requirement, whereas APET (polyester) can be used up to 200–250 °C.

The ideal food package shape is round or oval with vertical sides and rounded edges to limit sharp corners and edges to a minimum. Rectangular containers may be required for practical reasons but should have rounded corners and edges to reduce preferential heating tendencies.

Metals reflect microwaves completely, and food areas close to a metal surface will not be microwave-heated at all. Also, the presence of metal in the package or other metal objects in the microwave oven will markedly influence the microwave field distribution.

Previously, recommendations have been to avoid metal trays or foil laminated packages in microwave heating, because they were likely to cause damage to the magnetron, due to excessive reflection of energy. Since modern magnetrons are considerably less sensitive, aluminum containers, with transparent covers may now be used safely, provided they are not positioned so close ($\leq$ 2 mm) to the oven wall that electrical discharges or sparks can occur.

The metal changes the mode pattern in the oven and thus influences the heating result. This may even be improved compared with heating in a transparent package. Because microwaves can now penetrate only from the top and not from the sides, corner and edge overheating is eliminated, even to the extent that these parts may remain cooler than the central parts of the food.

The product thickness will be limited to about half the penetration depth of the food material, to permit sufficient heating of the bottom layer. The property of metal to completely reflect microwaves can be utilized in the design of packages, which minimize heating differences between food components of different physical properties, shape or thickness. A pattern of aluminum foil can be applied on the package to screen areas that would otherwise overheat, but permit full penetration into areas that would otherwise remain cooler.

The use of susceptors was briefly mentioned earlier in this article. Susceptors, or receptors as they have also been called, are extremely thin films of metal, vacuum-deposited on PET film with paperboard backing. At a metal film thickness of only 25–50 nm, part of the impinging microwave energy is transmitted, part reflected, and a substantial part absorbed generating heat and leading to high temperature in the metal film. When such a susceptor film is applied a few millimeters from the food surface, the generated heat will transfer rapidly to the food and heat the food surface. The surface temperature reached will be sufficient to reverse the temperature and moisture profile in the food and to crisp and brown the food surface, like in conventional grilling. Susceptor temperatures will usually not exceed 115–130 °C when in close contact with the food, but may otherwise reach temperatures up to and above 250 °C. At such high temperatures, there will be some risk of migration of substances into the food from the plastic film and paperboard backing. Therefore, susceptors are being developed that have a built-in temperature-limiting function.

There has been much concern for migration of hazardous chemical components from susceptor packaging material. Extensive research in the USA, UK, Germany, The Netherlands, and Sweden have demonstrated, however, that microwave heating itself does not increase migration rates.

Future Outlook

The market for *domestic microwave ovens* will continue to grow world-wide, even though a near-saturation point has already been reached in a few countries, like the USA and Japan, where all households already have one or more ovens.

The *heating performance* and consistency of microwave ovens will improve gradually as a result of the ongoing international standardization of performance and output power testing methods. At the same time, the growth in fundamental knowledge on field distribution and the interactions between oven design, microwave field, and food will lead to improved oven performance.

Packaging development continues in materials, shape, shielding, susceptors, and other forms of active packaging, in combination with a product development that increasingly takes into account dielectric and thermal properties of foods and their interaction with the microwave field.

There will also be important improvements in oven components, such as solid-state components, which will substantially lower both oven weight, size, and production costs. In Europe, at least, the proportion of combination ovens, combining microwaves with heat by convection or radiation, will continue to grow.

Physical and Chemical Properties

Copper is a tough, soft, ductile, reddish metal, with an atomic number of 29, a relative atomic mass of 63.54 amu, an electronic configuration $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3p^6\ 3d^{10}\ 4s^1$ and a relative density of 8.95. The melting and boiling points are 1083 and 2595 °C, respectively.

Copper is the 25th most abundant element in the earth's crust, comprising about 0.01%, and has two natural isotopes, ^{63}Cu and ^{65}Cu, with isotopic abundances of 68.94 and 31.06%, respectively. In total, 11 isotopes are known. Copper is found in its native state and also as a component of sulfides, oxides, and carbonates. Copper is used in alloys such as brasses and is completely miscible with gold (Au). It can be only superficially oxidized in air, sometimes acquiring a green coating of hydroxo carbonate and hydroxo sulfate.

The principal states of copper oxidation are +1 and +2. However, Cu(I) is not stable in solution, since the disproportionation reaction has an equilibrium constant of $1.1 \times 10^6\ 1\,mol^{-1}$. The complex formation can stabilize Cu(I) with the complex formed with cyanide presenting a high stability. Most Cu(I) compounds are fairly easily oxidized to Cu(II) compounds, but further oxidation to Cu(III) is more difficult.

The most common oxidation state, especially in aqueous solution, is +2. In diluted acid solution, Cu(II) precipitates as the sulfide (solubility product $10^{-35}\ mol^2\,l^{-2}$) with hydrogen sulfide or ammonium sulfide. Copper dissolves readily in HNO_3 and H_2SO_4 in the presence of O_2, and it is soluble in NH_4OH, ammonium carbonate, or KCN solution. Most Cu(II) salts dissolve readily in water.

Cu(I) compounds are diamagnetic and, except where color results from the anion or charge-transfer band, colorless. Cu(II) complexes and compounds are blue or green, except for red or brown species. The blue or green colors are due to the presence of an absorption band in the 600–900-nm region of the spectrum.

Determination in Foods and Beverages

The copper content in foods and beverages is in the order of micrograms per gram ($\mu g\,g^{-1}$).

Atomic absorption spectrometry (AAS) is probably the most commonly used technique of the wide range available for the analysis of copper in foods and beverages. When the contents are sufficiently high, flame atomic absorption spectrometry (FAAS) is used, and when they are low, electrothermal atomic absorption spectrometry (ETAAS) is employed. Whenever possible, FAAS is the technique of choice, since it is less time consuming and less sensitive to interference (background absorption).

The widespread distribution of copper is a source of problems of contamination, and as a result, special care must be taken when dealing with samples containing very low levels, as occurs with some foods, bearing in mind that the lower the concentration, the higher the risk of contamination. Wherever possible, plastic instruments should be used to prepare biological samples whose copper contents are low. In order to prevent contamination of samples, all the glass- and plastic-ware used must be thoroughly washed with diluted nitric acid. Blanks should be used to check the absence of contamination. To ensure the quality of the results, certified reference materials of a similar nature to the material being analyzed should be used. This also allows any suspicion of contamination to be eliminated.

Sample Digestion

Samples of most types of food and beverage require a prior preparation in order to convert the sample into solution before analysis. The choice of the procedure depends on the element to be determined, the complexity of the matrix, and the analytical technique to be applied.

This preparation can be omitted in some samples, especially in beverages, such as tap water or wine, where, in the latter, a simple dilution of the sample can be sufficient. Nevertheless, in most food and beverage samples, the destruction of the organic matter is necessary to a greater or lesser degree, depending on the technique of analysis to be applied.

The sample preparation is a critical step in trace-element analysis. The classic standard methods for organic-matter destruction are: wet digestion by conductive heating (hot plate, digestion block) or dry ashing (muffle furnace) at a defined temperature. Wet-digestion methods are generally more rapid than dry digestion methods. The disadvantages are that only fairly small samples can be used and also that the digests normally have to be heavily diluted before the analysis, resulting in poor detection limits. These techniques usually use mineral acids, oxidants, and ashing aids. Wet digestions can be carried out with a concentrated acid or mixture of acids, in open or closed systems. Since 1975, microwave-assisted sample digestion has been increasingly used for sample preparation in trace-element determination in food samples.

The advantages of microwave digestion over conventional sample preparation techniques are: a reduction in the time needed for the sample preparation and also of the amounts of acids used for digestion, and the possibility of controlling pressure/temperature, automation, and flexibility in sample preparation. Two types of microwave digestion systems are now available for wet digestions: closed-vessel microwave and open-vessel focused microwave.

Each of these techniques offers specific advantages. Closed systems can be used to prepare samples under controlled digestion conditions with a minimal volume of acid and a reduced risk of contamination. Nitric, hydrochloric, and hydrofluoric acids and their mixtures are the most widely used with closed digestion vessels. Nitric acid is usually added due to its antioxidant properties, and hydrofluoric acid is used when siliceous matter is present. The addition of hydrogen peroxide to nitric acid is also recommended.

Automated focused open-vessel microwave systems operate at ambient pressure and offer flexibility in digestion conditions, with vessels and reflux columns available in borosilicate glass, Teflon perfluoralkoxy, and quartz. These systems can be used to prepare samples sequentially with minimal attended operation, since digestion reagents are added automatically in programmed volumes and dispensing rates. To minimize analyte losses, a ramped, multistage heating program can be used in addition to reflux columns with the digestion vessels. When compared with the closed vessel system, the open-vessel system can process large samples, which leads to lower detection limits. High-pressure and high-temperature conditions are not required to obtain a complete digestion when an instrumental technique such as ETAAS is used for trace-element analysis.

Precautions should be adopted in all wet-digestion procedures when strong acids and strong oxidizing agents are used. The formation of explosive nitro compounds has been reported when fat-rich samples have been digested with nitric acid. Whichever wet digestion procedure is applied, the digests are left to cool and diluted with water.

Dry digestion or ashing procedures are also widely used to destroy organic matter. The main problems with these procedures are the possible losses of analyte by volatilization or by retention on crucible walls during dry ashing. Although several studies strongly indicate that ashing at temperatures up to 450 °C is free of losses by volatilization or retention, it is recommended that the temperature be increased gradually up to 400–500 °C and maintained until white ashes are obtained. Dry ashing is time-consuming, usually taking a day or more, although it requires very little attention from the analyst. The resulting ash can be dissolved in a small amount of solvent, and contamination through reagents is scarce.

To eliminate potential losses and/or to speed up the ashing procedure, ashing aids and matrix modifiers can be used. This, however, always increases the risk of contamination and worsens detection limits. Ashes are usually dissolved in diluted HCl or HNO_3 and it is sometimes necessary to heat them with concentrated HNO_3 and $HClO_4$ until no more fumes are produced, in order to complete the destruction of the organic matter. In some cases, organic-matter destruction can be replaced by acid extractions of the food product. Hydrochloric acid, nitric acid, or a mixture is used as the extractant, and the use of an ultrasonic bath facilitates the extraction.

Some analytical techniques that are useful for copper determination, such as ETAAS, do not require organic-matter destruction in some kinds of food. Nevertheless, even when this is not the case, a complete digestion, minimizing residual carbon content, is not required. The suppression of the digestion step will reduce the time needed for the analysis and the risk of losses and contaminations. Organic-matter destruction and dilution or dissolution of the residue can be replaced by:

- direct injection of the sample (water) or after the appropriate dilution (wine);
- dissolution of the sample in an adequate solvent, e.g., butter in the mixture composed of butylamin/water/tetrahydrofuran (48/12/40);

- addition of a chemical modifier $Mg(NO_3)$ and an emulsifying agent Triton X-100 (0.2% w/v), e.g., to whole milk, nonfat milk, and whey milk;
- preparation of a slurry of finely pulverized sample (slurry) in acidic diluents and subsequently treated by sonication.

The advantages of the slurries are a decrease in the time needed for the analysis and a reduced risk of external contamination due to reduced sample manipulation. Using slurries, copper detection limits lower than $0.2\,\mu g\,g^{-1}$ can be achieved in biological samples.

An alternative to slurry sampling and microwave-assisted acid digestion is ultrasound-assisted extraction. The main advantage of this over slurry sampling is a doubling of the tube lifetime, most likely because the matrix is not introduced into the atomizer, thus avoiding the buildup of carbonaceous residues or silicates on the graphite platform. In comparison with microwave-assisted digestion, it gives a twofold better precision and better detection limits.

Determination

Molecular Absorption Spectroscopy

A large number of reagents have been proposed for the spectrophotometric determination of copper, but only a few, such as pyridil-azo derivatives chloroazoantipyrine, 4-(2-pyridylazo) resorcinol, cuprizone (oxalic acid bis(cyclohexylidene) hydrazine) and diphenylcarbazone, diethyldithiocarbamate are of any real practical use. Cuprizone, one of the reagents used, reacts with Cu(II) to produce a blue, water-soluble complex with a molar absorptivity of $1.6 \times 10^4\,l\,mol^{-1}\,cm^{-1}$ at 600 nm.

Visible spectrophotometric methods have been applied mainly for determining the copper content of water, a matrix that does not require prior digestion. In general, these methods should only be considered as an alternative when atomic absorption or plasma emission techniques are not available. The main limitation of molecular absorption spectroscopy methods is their lack of sensitivity to determine copper at the low content levels of foods and beverages.

A preconcentration using pretreated silica columns or a chelation solvent extraction prior to applying a visible spectrophotometric method will yield sensitivities similar to those obtained with AAS measurements. A concrete example of precolumn derivatization uses a preconcentration column of C_2-bonded silica and pretreated with ammonium 1-pyrrolidinecarbodithioate – hexadecyltrimethylammonium bromide(I) ion-pair in mobile phase buffer (50 mM Na acetate–20 mM $NaNO_3$ adjusted to pH 6.0 with dilute HCl) (4:1). The metal–dithiocarbamate complexes are then backflushed on to an analytical column Spherisorb ODS2 (5 μm). Elution with acetonitrile–buffer (17:8) containing I (15 mM, respectively) and detection at 430 nm (Cu). The detection limits are $0.5\,\mu g\,l^{-1}$, and the results are comparable to those obtained by a conventional method involving chelation, solvent extraction, and AAS.

As an example of postcolumn derivatization, there is an ion chromatographic method that uses derivatization with 2-(2-benzoxazolylazo)-1-naphthol (α-BOAN) detection at 565 nm in a nonionic surfactant solution of Brij35 used for the separation and determination of copper(II). The detection limit is 16 μg of Cu per liter. This method has been used with good results in the separation and determination of Cu(II) in certified reference materials (rice flour and bovine liver).

Moreover, some of the reactions between copper and different organic reagents, such as cuprizone, diethyldithiocarbamate, or 1,5-diphenylcarbazide, have been adapted to flow injection analysis (FIA). This analytical technique has become very popular and has been used to determine the copper content of water and different biological matrixes (cow milk, milk-based infant formulas) or their digests (plants). Detection limits of copper ranging from 0.02 to $0.3\,\mu g\,ml^{-1}$ have been reported in water and about $5\ \mu g\,l^{-1}$ in plant digests after liquid–liquid extraction. These values can be improved with purification or separation after organic-matter destruction and prior to determination.

Fluorescence

Several fluorescent reagents can be used to determine copper in food extracts and digests, the most frequently reported being: 5-(2-carboxybenzenazo) rhodanine and 5-(4-chloro-2-carboxyphenylazo) rhodanine. The intensity of fluorescence is measured at 400–408 nm (excitation at 310 nm), with detection limits ranging from 0.01 to 0.05 μg of Cu(II) per milliliter.

Atomic Absorption Spectrometry

FAAS FAAS is the technique of choice for measuring copper in food-sample digests. The most sensitive line is 324.8 nm using a lean air acetylene flame, the measurement is almost independent of the stoichiometry of the flame, and the interferences are scarce, though large amounts of some transition elements in the presence of mineral acids can depress the response; e.g., $10\,000\,\mu g\,ml^{-1}$ depresses 10 μg of copper per milliliter by 10%. At 324.8 nm, a detection limit of $0.0015\,\mu g\ ml^{-1}$, which is sufficient for many

routine determinations, can be achieved under optimal conditions.

Flame emission can be used at a wavelength of 324.8 nm with a lean nitrous oxide acetylene flame. To improve the sensitivity of FAAS when trace amounts of copper have to be measured, separation and preconcentration/enrichment procedures based on adsorption, chelation, or precipitation processes can be used.

ETAAS ETAAS is recommended when copper contents are very low or the sample volume is very small. The 324.8 nm line is used. Copper is easily atomized from the wall or the platform of a graphite tube, and only minor interferences have been reported, as a result of which no chemical modifier is usually necessary in the ashing step. Temperatures of 800 and 2000 °C are used for ashing and atomization, respectively. The rate-limiting step for the atomization of copper is the reduction of Cu_2O by graphite that precedes atomization.

Chloride interferes in the determination of copper by ETAAS, so chloride should be removed from the sample before electrothermal atomization, a small excess of an oxyacid (sulfuric or nitric) added before the drying or ashing steps, or the method of standard additions should be used for quantification. To suppress chloride interferences, NH_4NO_3 has been used together with pyrolytically coated tubes, which are more sensitive but less robust than uncoated tubes. A 1% ascorbic acid solution has been found to reduce the interference of seawater upon the determination of copper.

Background corrections can be made by using a deuterium lamp or a Zeeman correction, although copper is one of the few elements to suffer from sensitivity loss when the Zeeman correction is used. The 324.7-nm line has an anomalous Zeeman pattern, and several isotopes split the line. The 327.4-nm line may be preferable and should be chosen. The characteristic mass for copper at the 327.4-nm line with Zeeman background correction is about half that with deuterium background correction. The reproducibility of the results with Zeeman background correction is improved when a transverse-heated graphite furnace is used instead of a longitudinal heated one.

One of the advantages in using ETAAS in trace-element analysis is that a complete digestion, minimizing residual carbon content, is not required. This elimination or reduction of sample digestion reduces the time needed for the analysis. Among the proposed methods are direct injection of the sample, dissolution of the sample in an adequate solvent, the use of a chemical modifier together with an emulsifying agent, and the use of slurries.

One of the facts to take into account in the direct analysis of a solid sample by ETAAS graphite furnace, is the sample weight. The use of too little or too much sample may lead to erroneous results, even if the analyte content lies within the linear dynamic range. Masses smaller than 0.3 mg or larger than 1.1 mg lead to overestimated and underestimated results, respectively.

Inductively coupled plasma-atomic emission spectrometry Inductively coupled plasma-atomic emission spectrometry (ICP-AES) provides, under optimal conditions, an approximate limit of detection of $1\,\mu g\,l^{-1}$. Although the cost of ICP-AES instrumentation has fallen considerably, AAS still remains the most widely available atomic technique for most laboratories.

ICP-AES can be used to measure copper ($\lambda = 324.7$ nm) in diluted biological fluids. In the case of water, a prior preconcentration by chelate formation and solvent extraction, or by adsorption on a column may be necessary. Detection limits of $0.07\,\mu g\,l^{-1}$ can be achieved when an ultrasonic nebulizer is used.

In the case of foods, samples have to be digested and preconcentrated or purified, or, in the case of solid samples such as cereals, samples are ground and mixed with graphite powder as buffer in a ratio of 2:3, after which an aliquot of the mixture is transferred to the powder sampler for introduction into the sealed ICP-arc system. The limit of detection is $0.02\,\mu g\,g^{-1}$.

The destruction of the matrix with one or more acids (e.g., HCl, $HClO_4$, and H_2SO_4) increases the possibility of spectral overlap. Therefore, whenever possible, only HNO_3 should be used in sample preparation, because H, N, and O do not add any additional spectral interferences to those already existing in a pure water spectrum.

Inductively coupled plasma-mass spectrometry Inductively coupled plasma-mass spectrometry (ICP-MS) is a powerful technique for trace multielement and isotopic analysis, because of its high sensitivity and ability to determine the isotope composition of a sample using less cumbersome pretreatment procedures than other mass spectrometry techniques.

However, ICP-MS is prone to interferences caused by sample matrix components. The interferences may be caused by polyatomic ions having the same nominal mass as the analyte, signal suppression or enhancement due to nonspectroscopic matrix effects and blockage of the nebulizer and sampler. Therefore, in order to achieve accurate and reliable results, matrix separation is needed when the matrix elements

in the prepared solution interfere with the determination. A detection limit of 4.8 $\mu g\,l^{-1}$ can be obtained.

Chemiluminiscence

FIA systems have been developed to determine micro-amounts of copper in well, rain, lake, and waste waters by using chemiluminiscence reactions. The systems luminol–CN^-–Cu(II) and luminol–$KMnO_4$–Cu(II) permit detection limits ranging from 10 $ng\,l^{-1}$ to 8.5 $\mu g\,l^{-1}$ to be achieved.

Potentiometric Methods

Electroanalytical techniques can be considered as an alternative to AAS or plasma techniques for measuring elements at trace levels. The main advantages of these techniques are an excellent sensitivity and the possibility of the simultaneous determination of different elements. Potentiometric methods also permit the speciation of the analyte, an important point from a nutritional and toxicological point of view.

The application of potentiometric techniques to the determination of an element content in foods requires complete organic-matter destruction. Once the sample has been converted into a solution, a sufficient amount of a base electrolyte should be added, and the oxygen has to be removed, since metals deposited on the electrode in the form of an amalgam or a film are usually very sensitive to oxidation, and oxygen interferes in the determination through its double-wave reduction.

The high sensitivity of the electrochemical methods requires the use of high-purity reagents and the adoption of measures to prevent sample contamination. Copper can be determined in food digests by differential pulse polarography with a stationary Hg-drop or a stick Au-base Hg film working electrode, a Pt counter-electrode and an Ag–AgCl reference electrode. The limits of detection of Cu are 0.45 μM, and the corresponding peak potentials are -0.71 V/-0.74 V/-0.65 V, depending on the supporting electrolyte used.

Anodic stripping voltammetry (ASV) is probably one of most suitable methods for determining copper in biological matrixes. In ASV, copper is selectively deposited out of the sample matrix on to a working electrode at a suitable working potential. After a selected period of deposition, the analytes collected on the working electrode are stripped back into the solution phase, and the oxidation currents are measured.

Different electrodes are available:

- Working electrode: hanging mercury drop electrode or a Hg film deposited on a 3-mm-diameter glassy-carbon rotating electrode;
- Reference electrodes Ag–AgCl or saturated calomel electrode (SCE); and
- Auxiliary/counter-electrode electrode: platinum (Pt) electrode.

The reference and auxiliary electrodes are connected with the sample solution via a liquid bridge filled with a solution of suprapure potassium chloride (KCl). The supporting electrolytes are: 1 M KCl, 2 M NH_4Ac/HAc, 1 M NH_3/NH_4Cl, 0.075 M $HClO_4$.

To determine copper by ASV, copper can be electrodeposited on a hanging/stationary mercury drop working electrode at -1.1 and -1.2 V vs. Ag–AgCl or SCE (with a platinum auxiliary electrode) for times ranging from 100 s to 4 min. The deposited metal can be determined by differential pulse ASV at $+0.04$ V. Detection limits at the $ng\,l^{-1}$ or $ng\,g^{-1}$ level have been reported.

The use of a selective electrode allows copper to be measured over a wide range of concentrations with an approximate practical detection limit of 10^{-8} $mol\,l^{-1}$. Copper ions in aqueous solution can be determined with an ion-selective membrane electrode containing a mixture of copper and silver sulfides. A supporting electrolyte, such as 2.5 M $NaNO_3$ is needed. The electrode response is linear from 1 μM to 1 mM Cu. The presence of Ag, Hg, Fe, and strong reducing agents (hydrazine 20–200 $\mu g\,l^{-1}$ does not affect the potential but reduces the life of the electrode.

Neutron Activation Analysis

Neutron activation analysis (NAA) is a nondestructive method that has been used for copper determination in biological material and bioavailability studies. The values obtained applying NAA correlate well with those obtained by AAS or ICP. NAA is not in common use, being restricted to specialized laboratories.

X-ray Fluorescence

X-ray fluorescence (XRF) techniques allow the determination of copper in very small samples (microsamples) of biological matrixes (e.g., blood serum, a hair, a cell). Samples have to be dried, milled, homogenized and compacted into disks. The destruction of the organic matter is not required. Copper content can be determined by direct XRF using a wavelength dispersive XRF spectrophotometer and a synthetic standard prepared by incorporating the analyte into cellulose. The detection limit is 5 μg of Cu per gram. There is a good agreement between the results obtained by XRF and NAA.

Speciation

ICP-AES and ICP-MS are element-specific detectors for high-performance liquid chromatography (HPLC) that have been used for copper speciation. With this aim, they can be coupled to size-exclusion chromatography for simultaneous monitoring of molecular weight fractions and their associated elements. HPLC coupled with ICP-AES has been used in copper speciation in foods such as soy bean flour extracts. Using size-exclusion chromatography coupled to ICP-AES in human milk, the distribution of copper between the different protein and non-protein fractions can be estimated.

Conclusions

AAS techniques are still the most widely used techniques to determine the copper content of foods and beverages. The most difficult and risky (because of contamination or analyte losses) step in copper determination in foods is sample preparation prior to the element measurement, a fact that is reflected in the numerous sample treatments found in the literature. ETAAS offers the advantage of not requiring complete organic-matter destruction, thus permitting the direct introduction of a sample, slurry, or acid extract.

However, ICP-AES offers the advantage of simultaneous element determination in a sample, as do potentiometric techniques, which also permit the differentiation between oxidation states, although, in the latter, complete organic-matter destruction is required. The use of appropriate reference materials is essential to check analytical accuracy. Currently, NAA remains useful as a reference method. The hyphenated techniques based on the coupling of a separation technique such as HPLC with an element detection will contribute to copper speciation in foods and beverages.

Physiology

M A Johnson, The University of Georgia, Athens, GA, USA

Introduction

Copper was identified as an essential nutrient early in the twentieth century. Today, research focuses on the molecular biology of copper metabolism and the role of copper in the heart, blood vessels, nervous system, immune function, formation of red blood cells, and bone health. A major challenge is the lack of a copper protein in blood that can reliably assess the copper status of humans. Although copper has been added to infant formulas for decades, copper is rarely added to enriched or fortified cereals consumed by older children and adults. An easily absorbed form of copper, such as copper sulfate, is added to only a few multiple vitamin/mineral supplements.

Body Content

Adult humans contain about 50–120 mg of copper, with the highest concentrations found in the liver, brain, heart, skeleton, hair, and nails (Table 1). Because of its size, muscle contains the largest percentage of body copper. Copper in liver, kidney, and intestine is strongly related to copper intake.

Table 1 Copper in human fluids, excretions, and tissues

Fluids and excretions	*Level*
Serum	0.5–1.5 mg l^{-1}
Sweat	20–100 μg l^{-1}
Urine	4–66 μg l^{-1}
	5–50 μg day^{-1}
Feces	0.5–2.5 mg day^{-1}
	20–100 mg kg^{-1} dry weight
Menstruation	0.5 mg per period
Hair	10–50 mg kg^{-1} dry weight

Tissues	*Concentration (mg kg^{-1} wet weight)*	*Estimated % of total body copper*
Bone marrow	5–7	15
Liver	5–7	8
Brain	5–7	8
Bone	2–3	19
Skin	2–3	15
Lung, heart, kidney	2–3	< 5
Muscle	< 2	25
Blood	< 2	5
Spleen	< 2	< 1

Reproduced from Johnson MA (1998) Copper: physiology, dietary sources and requirements. In: *Encyclopedia of Human Nutrition*. Academic Press, with permission.

Serum is the most widely used indicator of copper status, but it is not strongly related to the body stores of copper and becomes low only when the stores of copper are nearly exhausted. Similarly, copper in hair is not strongly related to the body levels of copper. Although sweat contains copper, it is difficult to collect and the relationship between body stores and sweat levels of copper has not been established. Sweat is not considered a major excretory route, unless sweat loss is extremely high. Losses of copper in the feces are proportional to intake, while urinary excretion is less than 5% of intake. Unlike for iron, menstrual losses do not deplete the body of copper.

Absorption, Transport, Storage, Excretion

Copper absorption in humans is usually estimated from copper intake minus copper excretion in the urine and feces. However, more accurate estimates of copper absorption and excretion are made by using a stable isotope of copper.

The primary site of copper absorption in humans and other animals is in the intestine in the duodenum. When fed a typical diet, human adults generally absorb about 50–75% of the copper ingested from food. The percentage absorption decreases as the amount of copper ingested increases. In adults, advanced age and gender do not influence copper absorption.

At the lower levels of copper intake, absorption is probably regulated by a saturable active transport mechanism, while at high levels of copper intake passive diffusion plays a role. Metallothionein is a metal-binding protein found in the intestine and other tissues that may also regulate copper absorption. Copper bound to metallothionein in the mucosal cell will be lost when these cells slough off the intestine. As will be discussed in more detail, copper absorption is negatively influenced by numerous dietary factors, including zinc, iron, molybdenum, ascorbic acid, fructose, and sucrose.

Copper is transported in the circulation bound primarily to albumin and to a lesser extent to transcuprein and low-molecular-weight compounds. Newly absorbed copper is transported to the liver and rapidly incorporated into ceruloplasmin. Ceruloplasmin is the transport protein from the liver to other organs. Some liver copper will also be incorporated into metallothionein, especially when copper intake is high. Metallothionein may help detoxify copper when copper exposure is high.

Gestation is a very important period of life for storage of copper. At birth the human liver has 5–10 times the adult concentration of copper. Liver copper gradually decreases during the first year of life as the infant uses liver copper for other functions in the

body. Premature infants are at high risk for copper deficiency unless they receive breast milk or copper-fortified formula.

Copper is lost from the body primarily through the bile and the feces, and retention of copper in the body is controlled primarily through regulation of copper absorption at the intestinal cells and excretion through the bile. Very little of the copper excreted into the bile is reabsorbed. Copper loss from the urine, skin, nails, and hair is very small, and, unlike some other minerals, the kidney does not regulate copper homeostasis.

Functions and Essentiality

Most of what we know about copper comes from livestock or from experimental animals fed diets deficient in copper. Some information is available from infants fed diets low in copper, healthy adults fed low amounts of copper, and adults given total parenteral nutrition without copper. Copper clearly is required for the immune system, the nervous system, the cardiovascular system, skeletal health, for iron metabolism, and for formation of red blood cells. However, the roles of copper in other functions such as the regulation of cholesterol, glucose, and blood clotting are not well understood. Some disorders of the vascular and nervous systems induced by copper deficiency during prenatal development in animals cannot be reversed by copper supplementation after birth. Thus, copper must be provided during pregnancy. Copper's role in cardiovascular and skeletal health also has important implications for major public health problems seen in industrialized nations, namely heart disease and osteoporosis.

Copper functions in several enzymes and proteins in the human body. Table 2 lists copper enzymes found in mammals. Cytochrome c oxidase is essential

Table 2 Human enzymes and proteins that contain copper

Enzyme or protein	*Function*
Cytochrome c oxidase	Mitochondrial enzyme involved in the electron transport chain; reduces oxygen to water and allows formation of adenosine triphosphate; activity is highest in the heart and also high in the brain, liver, and kidney
Ceruloplasmin (ferroxidase I)	Glycoprotein with 6–7 copper atoms; 4 copper atoms involved in oxidation/reduction reactions; role of other copper atoms not fully known; scavenges free radicals; oxidizes some aromatic amines and phenols; catalyzes oxidation of ferrous iron to ferric iron; assists with iron transport from storage to sites of hemoglobin synthesis; about 60% of plasma copper bound to ceruloplasmin; primarily extracellular; activity will be low during severe copper restriction
Ferroxidase II	Catalyzes oxidation of iron; no other functions known; in human plasma is only about 5% of ferroxidase activity
Monoamine oxidase	Inactivates catecholamines; reacts with serotonin, norepinephrine (noradrenaline), tyramine, and dopamine; activity inhibited by some antidepressant medications
Diamine oxidase	Inactivates histamine and polyamines; highest activity in small intestine; also high activity in kidney and placenta
Lysyl oxidase	Acts on lysine and hydroxylysine found in immature collagen and elastin; important for integrity of skeletal and vascular tissue; use of estrogen increases activity
Dopamine beta-hydroxylase	Catalyzes conversion of dopamine to norepinephrine, a neurotransmitter; contains 2–8 copper atoms; important in brain and adrenal glands
Copper, zinc superoxide dismutase	Contains 2 copper atoms; primarily in cytosol; protects against oxidative damage by converting superoxide ion to hydrogen peroxide; erythrocyte levels are somewhat responsive to changes in copper intake
Extracellular superoxide dismutase	Protects against oxidative damage by scavenging superoxide ion radicals and converting them to hydrogen peroxide; small amounts in plasma; larger amounts in lungs, thyroid, and uterus
Tyrosinase	Involved in melanin synthesis; deficiency of this enzyme in skin leads to albinism; catalyzes conversion of tyrosine to dopamine and oxidation of dopamine to dopaquinone. Present in eye and skin and forms color in hair, skin, and eyes
Metallothionein	Cysteine-rich protein that binds zinc, cadmium, and copper; important for sequestering metal ions and preventing toxicity
Albumin	Binds and transports copper in plasma and interstitial fluids; about 10–15% of copper in plasma is bound to albumin
Transcuprein	Binds copper in human plasma; may transport copper
Blood-clotting factors V and VIII	Role in clotting and thrombogenesis not well understood; part of structure homologous with ceruloplasmin

Reproduced from Johnson MA (1998) Copper: physiology, dietary sources and requirements. In: *Encyclopedia of Human Nutrition*. Academic Press, with permission.

for energy production in mitochondria. Ferroxidases such as ceruloplasmin (ferroxidase I) and ferroxidase II are copper enzymes. Many amine and diamine oxidases contain copper. Lysyl oxidase catalyzes the cross-linking of collagen and elastin; thus, copper deficiency causes bone and vascular abnormalities in many species. Superoxide dismutases are antioxidants. Copper deficiency in animals with dark hair can cause dark hair to lighten because of decreased activity of tyrosinase. Copper-binding proteins include metallothionein, albumin, transcuprein, and blood-clotting factors V and VIII. Copper also binds to low-molecular-weight ligands such as amino acids and small peptides.

Assessment of Copper Status

Severe copper deficiency is verified by low serum or plasma copper or ceruloplasmin, low red cell superoxide dismutase activity, anemia, and neutropenia. A major problem with using low ceruloplasmin as an index of copper status in people with chronic diseases such as cardiovascular disease, cancer, or inflammatory diseases is that ceruloplasmin synthesis is elevated during disease states and hence reflects disease state rather than copper status. Therefore, patients at risk for copper deficiency, such as those receiving total parenteral nutrition without copper, should have their serum copper routinely assessed.

Marginal copper deficiency is very difficult to detect and limits our ability to identify the role of copper in human health. Many copper proteins are easily measured in the blood, but their concentrations do not change very much when copper intake is increased or decreased. Studies at the US Department of Agriculture Human Nutrition Research Centers have identified the dietary intakes associated with decreases in copper proteins and other indices. Elderly women fed 0.57 mg copper per day for 105 days had low red cell superoxide dismutase activity, low platelet cytochrome c oxidase activity, low red cell glutathione peroxidase activity, and elevated plasma factor VII, but had no changes in plasma copper or ceruloplasmin. In contrast, young men fed 0.38 mg copper day^{-1} for 42 days had decreased plasma copper and ceruloplasmin concentration and activity. Thus, it appears that copper intakes must be below 0.6 mg copper day^{-1} for copper proteins to be decreased. Also, the magnitude of these decreases is not large enough to be used for routine assessment of healthy adults.

Ceruloplasmin and serum and plasma copper are increased by cigarette smoking, oral contraceptives, estrogen status, pregnancy, infectious disease, hematological diseases, diabetes, coronary and cardiovascular diseases, uremia, cancer, inflammation, and after surgery. Ceruloplasmin is an acute-phase reactant which accounts for its rise during numerous disorders and therefore limits the use of ceruloplasmin as a copper status marker, especially during illness.

Copper Deficiency in Infants

In infants, severe copper deficiency can be diagnosed by assessing plasma or serum copper, ceruloplasmin, and neutrophils. Sometimes copper deficiency is mistaken for iron deficiency because both mineral deficiencies are associated with anemia and low hemoglobin concentrations. However, only the anemia of copper deficiency responds to iron supplements.

Infants are more susceptible to severe copper deficiency than are children and adults. Risk factors for copper deficiency were identified in 52 copper-deficient infants (Table 3). Copper accumulates in the liver late during gestation. These liver stores are used in the first few months of life, because milk contains little copper. The highest risk for copper deficiency is in infants who are malnourished, premature, or of low birth weight. When these physiological conditions are combined with feeding practices such as cows' milk or total parenteral nutrition, the risk for copper deficiency can increase. Breast-feeding helps protect against copper deficiency because the copper in human milk is well utilized by infants.

Copper deficiency is rare among infants in developed countries because infant formulas are supplemented with copper. Also, it is recommended that copper be added to total parenteral nutrition solutions for infants as well as adults. However, where malnutrition is prevalent, copper deficiency may continue to be a

Table 3 Copper deficiency in infants

	% of cases
Predisposing factors	
< 18 months of age	96
Low birth weight (< 2500 g)	40
Fed exclusively or predominantly cows' milk	54
Received total parenteral nutrition	23
Formula-fed	12
Antecedent malnutrition	25
Physical features	
Hypotonia (loss of muscle tone)	43
Hypopigmentation	29
Psychomotor retardation	21
Skin rash	21
Dilated veins	15
Hepatosplenomegaly (complication of anemia)	15
Bone fractures	11

Median age at presentation was 8.3 months for full-term infants and 3.0 months for low-birth-weight infants. Reproduced from Johnson MA (1998) Copper: physiology, dietary sources and requirements. In: *Encyclopedia of Human Nutrition*. Academic Press, with permission.

problem. For example, clinicians in Chile reported that copper deficiency was more common than zinc deficiency and that supplements of copper improved the growth of 11 infants with malnutrition complicated by copper deficiency. It is believed that the cows' milk-based diet used during recovery from malnutrition in many developing countries does not provide enough copper for optimal growth and development.

Nutrient Interactions Influencing Copper Bioavailability

The bioavailability of copper is decreased by high intakes of several nutrients, including zinc, iron, molybdenum, ascorbic acid, sucrose, and fructose. It is well documented that high intakes of zinc interfere with copper absorption in humans and animals. The mechanism appears to involve the induction by zinc of metallothionein synthesis in the intestine and copper becomes 'trapped' in this protein and is not available for transport into the circulation. Zinc probably has little influence on copper status when the zinc to copper ratio is 15:1 or less. However, 50 mg of zinc day^{-1} has decreased some indices of blood copper status in humans. It is recommended that healthy adults limit their supplemental intake of zinc to less than 20 mg day^{-1}. The current recommended dietary allowance in the USA for zinc is 8 mg for women and 11 mg for men.

Although studies in animals have shown that high iron intakes interfere with copper status, there are not enough studies to determine if supplements of iron impair the copper status of people. Interactions between copper and molybdenum are well documented in ruminant animals, but little information is available for humans. High intakes of ascorbic acid induce copper deficiency in many species, but there is very little information in humans. In one study, 600 mg ascorbic acid day^{-1} did not decrease copper absorption, but in another study, 1500 mg ascorbic acid day^{-1} decreased the activity of ceruloplasmin. Supplemental intakes of ascorbic acid in excess of 1000 mg day^{-1} are common in North America, but the long-term impact of excess ascorbic acid on copper status is unknown.

Rats fed copper-deficient diets that contain 50% or more by weight fructose or sucrose develop more severe copper deficiency than when they are fed starch as the source of dietary carbohydrate. It is believed that in other species, including humans, the type of carbohydrate may not markedly influence the copper status of people. For example, in one human study, high intakes of fructose caused an increase in copper absorption but a decrease in red blood cell copper, zinc superoxide dismutase.

Combinations of copper antagonists interfere with copper status in animals. For example, high concentrations of sucrose exacerbate the effects of iron, zinc, and ascorbic acid on copper deficiency in rats. These type of relationships have not been evaluated in humans.

Genetic Diseases

Menkes disease, Wilson disease, and aceruloplasminemia are genetic disorders involving the regulation of copper and/or ceruloplasmin (Table 4). These

Table 4 Genetic disorders of copper metabolism

	Menkes disease	*Wilson disease*	*Aceruloplasminemia*
Genetics	Xq13.3 X-linked 1 in 300 000	13q14.3 Autosomal recessive, 1 in 30 000	3q 23–35 (ceruloplasmin), Autosomal recessive Frequency unknown
Clinical	Onset before birth, gray-matter degeneration, abnormal hair, hypothermia, hypopigmentation, tortuous arteries, early death (< 3 years)	Onset late in childhood, abnormal basal ganglia, liver disease, Kayser–Fleischer rings in eyes, psychiatric disorders	Adult onset, dementia, dystonia, diabetes, retinal degeneration
Laboratory	Low serum copper and ceruloplasmin, low liver copper	Low serum copper and ceruloplasmin, elevated liver copper	Low serum copper and ceruloplasmin, normal liver copper, elevated liver iron
Defect	Impaired copper transport in intestine and placenta	Impaired biliary excretion of copper	Impaired export of iron from reticuloendotheilial cells
Treatment	No effective treatment	Chelation very effective to remove body copper; zinc supplements help prevent further copper accumulation	Unknown
Animal models	Mottled mouse	LEC rat	None

Reproduced from Johnson MA (1998) Copper: physiology, dietary sources and requirements. In: *Encyclopedia of Human Nutrition*. Academic Press, with permission.

disorders are advancing the understanding of the cellular and molecular regulation of copper homeostasis. All three disorders are characterized by low serum copper and low serum ceruloplasmin; however, Menkes disease results in copper deficiency, Wilson disease leads to copper overload, and aceruloplasminemia causes iron overload in certain tissues.

Menkes disease is an X-linked disorder that causes mental deterioration, hypothermia, failure to thrive, connective tissue disorders, and death in early childhood. The advanced neuronal degeneration at birth suggests that the disease begins *in utero* and that copper is needed for fetal development of the nervous system. Copper uptake into cells is normal but copper-dependent enzyme activity is deficient. Placental and intestinal transport of copper is decreased. Neither oral supplements nor injections of copper will reverse this copper-deficient state. There may also be a milder type of Menkes disease that was formerly known as X-linked cutix laxa. Most patients reach adulthood, but have impaired physical and mental function.

Wilson disease is an autosomal recessive disorder that usually presents in adolescence with liver cirrhosis and neuronal degeneration. Copper accumulation in the liver and basal ganglia appears to account for tissue damage but the mechanism of toxicity is unknown. Copper chelation therapy is beneficial if the disease is diagnosed early. Supplements of zinc help limit copper absorption and subsequent accumulation. However, the neurologic symptoms are often irreversible and liver disease may be quite advanced at the time of diagnosis. The metabolic defect appears to be decreased biliary copper excretion and impaired incorporation of copper into newly synthesized ceruloplasmin.

Aceruloplasminemia is an autosomal recessive disorder of iron metabolism that was discovered in some people who were thought to have Wilson disease but did not follow the strict clinical criteria for the disease and did not have mutations in the Wilson P-type adenosine triphosphatase (ATPase). Their symptoms were somewhat similar to the dementia of Parkinson disease, combined with retinal degeneration and elevated liver iron, but normal liver copper. Basal ganglia had high iron concentrations as shown during magnetic resonance imaging of the brain. Mutations in the ceruloplasmin gene resulting in truncations of the open reading frame were found in these patients. Thus, it appears that abnormalities in the ceruloplasmin gene and its protein products cause disordered iron homeostasis.

The genes responsible for Menkes and Wilson disease do not involve ceruloplasmin. Rather, the genetic disorder appears to involve a transmembrane protein with homology to cation-transport P-type ATPases. There is 65% homology between the Wilson and Menkes P-type ATPases. Both contain an area proposed to bind copper. The Wilson gene appears to be expressed predominantly in the liver while the Menkes gene is expressed in most tissues other than the liver. The phenotypic differences in Wilson and Menkes disease are probably due to the tissue-specific expression of the genes. Evolutionary conservation of these types of proteins in bacteria, yeast, plants, and mammals indicates that a unique protein structure necessary for copper transport is preserved throughout the animal and plant kingdom.

Requirements and Recommended Intakes

The lack of a biochemical index of marginal copper status has made it very difficult to determine copper requirements in humans. When recommended dietary allowances in the USA were revised in 1989, there were insufficient data to make a firm recommendation for copper. However, in 2001 Dietary Reference Intakes in the USA were estabilished (Table 5). For adults, the Recommended Dietary Allowance for adults is $0.9\,mg\,day^{-1}$ and the upper level is $10\,mg\,day^{-1}$. Liver damage was the endpoint used to estimate the upper level. The European Commission has also established population references for several nutrients, including copper.

Dietary Sources

The amount of copper in various foods varies by about 100-fold and depends on where a given food was produced and how it was processed (Table 6).

Table 5 Dietary reference intakes for copper

Age (years)	*Recommended dietary allowance (mg day^{-1})*	*Upper intake level (mg day^{-1})*
0–0.5	0.20[a]	–
> 0.5–1	0.22[a]	–
1–3	0.34	1

Table 6 Copper in foods

Food	*Copper content (mg kg^{-1})*
Dairy	
Cheese	0.4–0.8
Chocolate milk	0.2–0.3
Cottage cheese	0.1–0.2
Cows' milk (skim, 2%, whole, buttermilk)	0.02–0.08
Human milk	0.02–0.08
Yogurt	0.01–0.09
Eggs (fried, scrambled, or soft-boiled)	0.4–0.8
Fish and shellfish (cooked)	
Cod, fish sticks, haddock, salmon, sardines, tuna	0.3–0.8
Shrimp	2–3
Oysters	0.3–16
Fruits	
Apples (red, with peel, raw)	0.1–0.4
Apple juice (canned)	0.02–0.2
Banana (raw)	1–2
Grapes (raw, purple, or green)	0.4–1.4
Grape juice (canned)	0.01–0.13
Orange (raw, all varieties)	0.1–1
Orange juice	0.1–0.3
Dried fruits (currants, dates, figs, prunes, or raisins)	1–5
Grains and cereals (cooked or processed)	
Barley, pearl	0.4
Bread	
White (loaf, rolls, biscuits)	1–2.6
Whole wheat	2–3
Rye	1.6–2.8
Corn (fresh, frozen, cream-style, grits)	0.1–0.4
Flour	
Whole grain	2–8
White	1–3
Macaroni (cooked)	0.6–1
Oatmeal (cooked)	0.3–1.2
Wheat bran	10–20
Wheat cereals (shredded, bran flakes, puffed wheat, raisin bran)	4.5–5.5
Legumes	
Beans (boiled or baked; cowpeas, kidney, lima, navy or pinto)	1–4
Beans (dry; cowpeas, kidney or lima)	5–10
Peanuts (fresh, roasted or butter)	3–10
Meats (cooked: beef, pork and poultry)	
Muscle meat	0.7–1.4
Liver	20–180
Nuts and seeds (almonds, brazil nuts, hazelnuts, pecans, pistachios, sesame seeds, sunflower seeds, or walnuts)	8–18
Vegetables	
Broccoli (fresh, frozen, or boiled)	0.1–0.9
Cabbage (fresh, boiled, or coleslaw)	0.1–0.2
Carrots (raw or boiled)	0.5–1
Cauliflower (fresh, frozen, or boiled)	0.2–1
Onions (raw or cooked)	0.2–1
Peas (green, canned, cooked)	1–1.5
Potatoes	
Baked (with peel)	0.6–1.8
Boiled (without peel)	0.3–1
Spinach (canned, fresh, frozen, or boiled)	0.6–1.2
Sweet potatoes (boiled or baked)	1.6–2.0
Tomatoes (raw, canned or juice)	0.3–1.4

Variation in copper content may be the result of soil conditions, type of fertilizer or other agricultural chemicals, weather, time of harvesting, and processing. The amount of copper in a typical serving can be approximated by using portion sizes of 250 g for fluid milk and juices, 120 g for small servings of fish or meat, 100 g for fruits, vegetables, and legumes and 30 g for a slice of bread, small bowl of cereal, or slice of cheese. Copper concentrations are highest in legumes, nuts, and shellfish, and lowest in dairy foods such as cows' milk. Removal of the germ and bran during refining of flour decreases the copper content of grain foods. Copper in drinking water is quite variable and depends on the natural mineral content, the pH of the water, and the use of copper water pipes. Acidic water that flows through copper pipes will pick up some copper. Estimates of the contribution of water to copper intake range from less than 10% to over 50% of the recommended intakes.

In the USA, copper is added to some, but not all, multiple-vitamin/mineral supplements. Cupric oxide is one of the most common sources of copper used in multiple-vitamin/mineral supplements; however, its solubility and bioavailability are probably very poor for humans (but quite good for ruminants). It is recommended that copper sulfate be used in these multinutrient preparations. Most infant formulas are supplemented with copper in the form of copper sulfate. Copper is not routinely added to ready-to-eat breakfast cereals intended for older children and adults.

Copper Toxicity

Tolerance to high intakes of copper varies considerably among species. For example, rats tolerate high amounts of copper, while sheep are intolerant of high intakes of copper. Soluble salts of copper (carbonates, sulfates, and chlorides) are more toxic than the less soluble forms (nitrates, acetates, and oxides). High intake of zinc protects again copper toxicity in many species.

Acute toxicity from copper is rare in humans and usually occurs from accidental or intentional ingestion of copper salts. Acute symptoms include salivation, nausea, vomiting, epigastric pain, and diarrhea. Ingestion of about 100 g or more of copper sulfate can produce hemolytic anemia, liver failure, renal failure, shock, coma, or death.

Data are quite limited to make a scientifically based safe upper limit of copper intake for humans.

Table 7 Regulations regarding total intakes of copper and copper content of drinking water

Agency	*Upper limit*	*Rationale*
Water content		
World Health Organization (WHO)	2.0 mg l^{-1}	Attempt to keep contribution of water to no more than 10% of total copper intake
European Commission (EC)	None	Suggested guide of 0.1 mg l^{-1} at water treatment plant, and 3 mg l^{-1} after water has stood in pipes for 12 h
US Environmental Protection Agency (EPA)	1.3 mg l^{-1}	Based on a 'lowest observed adverse-effect level' of 5.3 mg in humans (nurses, study), consumption of 2 l water daily, and addition of safety factors
	1.0 mg l^{-1}	Nonenforcible concentration of 1 mg l^{-1} based on taste considerations
Total intake		
Food and Agricultural Organization/World Health Organization (FAO)/WHO)	0.5 mg kg^{-1}	Based on no-observed-effect level of 5 mg kg^{-1} in dogs
US National Academy of Science	10 mg day^{-1}	
European Commission	10 mg day^{-1}	Risk of nausea and vomiting increases when this dose is exceeded

Reproduced from Johnson MA (1998) Copper: physiology, dietary sources and requirements. In: *Encyclopedia of Human Nutrition*. Academic Press, with permission.

The copper intake of nurses was roughly estimated at between 5.3 and 32 mg copper, and the dose of 5.3 mg copper day^{-1} has been adopted by some authorities as the 'lowest observed no-effect level'. Other authorities have suggested 0.21–0.5 mg kg^{-1}, or up to 30 mg of copper in a 60-kg person, as the maximum tolerable daily total intake for copper. Proposals for the maximal allowable amount of copper in drinking water are in the range of 1–2 mg l^{-1}, but based on copper poisoning in children, the safe amount for children may be as low as 0.2 mg l^{-1}. This wide range of estimates is attributed to insufficient data, lack of understanding by toxicologists and regulatory authorities that copper is an essential nutrient, lack of awareness that humans are exposed to copper from both foods and beverages, and concern about copper toxicosis syndromes such as childhood cirrhosis. Regulations for copper intakes and copper in drinking water are summarized in Table 7.

Indian childhood cirrhosis was a common killer until the early 1990s when it became preventable and treatable. The disease generally occurs between the ages of 6 months and 5 years, and is characterized by increased hepatic, urinary, and serum copper concentrations. Symptoms include nonspecific complaints such as abdominal distension, irregular fever, excessive crying, and altered appetite. Jaundice is usually a late feature. If left untreated, the illness progresses rapidly within a few months and is associated with liver failure and possibly death. The source of the dietary copper appears to be milk boiled in copper or brass (an alloy with about 70% copper and 30% zinc) vessels that have been used extensively in India, particularly by traditional Hindu families. Some investigators also believe that a genetic disorder enhances susceptibility to this toxicity syndrome associated with excessive dietary exposure to copper. Public health campaigns in India designed to discontinue the use of copper-containing vessels markedly reduced the incidence of this disease.

Contamination of drinking from copper plumbing has emerged as a public health concern. Copper-associated liver diseases in infants and children, similar to the condition seen in India, have now appeared in parts of Europe. The source of copper appears to be drinking water. Treatment for this liver disease involved D-pencillamine (a copper chelator) and in a few cases a liver transplant was conducted. In an investigation in Wisconsin (USA), one water system involved had an alkaline pH of 7.2–7.4 that would not be expected to be corrosive. However, phosphate was added to sequester iron, and this may have prevented calcium and magensium from depositing on the inner surface of the copper pipes and providing a protective coating. Thus, copper was more easily leached into the water from the pipes. Homes built or remodeled within the past 10 years had the highest concentrations of copper in the water. In a second location, symptoms began after installation of new copper pipes in a mobile-home park and the water was naturally corrosive and very low in mineral content. In both areas, the symptoms were nausea, diarrhea, abdominal cramps, and headaches. The copper concentration of the water associated with toxicity was up to 3.6 mg l^{-1}. Flushing the faucet for 1 min decreased the copper content to below 0.25 mg l^{-1}. The authors suggested that owners of homes with new copper pipes should be informed about the risks of copper-contaminated drinking water and have their water tested. They also recommended that copper intoxication be included in the differential diagnosis for those presenting with chronic or intermittent

gastrointestinal upsets, particularly when these symptoms can be linked with a change in the water supply. Infants may be particularly sensitive to high intakes of copper and some investigators have recommended that drinking water contain no more than $0.2\,mg\,l^{-1}$.

CORONARY HEART DISEASE

Contents

Etiology and Risk Factor

F G Huffman, S Koutoubi and S Nath, Florida International University, Miami, FL, USA

Background

Our understanding of the biology and pathophysiology of cardiovascular medicine and pathogenesis of coronary heart disease (CHD), a multifactorial disease with a complex pathophysiology, continues to expand as new horizons in epidemiological, experimental, clinical, and genetic research are required. Even so, CHD remains the leading cause of death, accounting for more than 7 million of all cases of mortality, and is responsible for chronic disability and much of the healthcare costs worldwide. The World Health Organization predicts that CHD will prevail as the primary cause of morbidity and mortality worldwide until the year 2020.

No single risk factor consummates the 'cause and effect' relationship. That the presence of any one isolated risk factor cannot predict which individual will develop CHD. To date, data from myriad

Nonmodifiable risk factors
Age and gender (men $\geq$ 45 years; women $\geq$ 55 years)
Family history of premature CHD (CHD in male first-degree relative < 55 years; CHD in female first-degree relative < 65 years)
Modifiable risk factors
Cigarette smoking
Atherogenic diet
Physical inactivity
High blood pressure ($\geq$ 140/90 mmHg)
Obesity
Diabetes mellitus
High blood total cholesterol ($\geq 200\,mg\,dl^{-1}$)
High blood low-density lipoprotein cholesterol ($\geq 130\,mg\,dl^{-1}$)
Low blood high-density lipoprotein cholesterol ($< 40\,mg\,dl^{-1}$)
High blood triglycerides ($\geq 150\,mg\,dl^{-1}$)
Thrombogenic factors
Inflammation or infection
Cytomegalovirus
Chlamydia pneumoniae
Helicobacter pylori
Herpes simplex
C-reactive protein
Serum amyloid A protein
Others
High blood homocysteine
Angiotensin II

research have documented several hundred risk factors that are statistically associated with the development of CHD. Experts in cardiovascular research often agree to classify these etiological factors as major and minor risk factors or modifiable and nonmodifiable risk factors (Table 1). The majority of the CHD epidemic in developed countries are associated with the presence of smoking, high blood pressure, high blood cholesterol, and impaired glucose tolerance. Most often, these common risk factors tend to cluster in individuals who eventually develop CHD events.

Atherosclerosis, hardening of the arterial wall, commences in childhood and, after decade-long cellular, molecular, and biochemical changes, culminates in a heart attack, a well-known indication of CHD. In 1973, the 'response-to-injury' hypothesis of atherosclerosis was first outlined, underlining that the atherosclerosis results from an arterial response to chronic injury. Commonly chronic endothelial cell injury is initiated by tobacco toxins (smoking), high blood pressure, diabetes, oxidized low-density-lipoprotein (LDL) cholesterol, as well as free radicals resulting from oxidation of homocysteine (Hcy), and infection (e.g., chlamydia). In response to an injury to endothelial cells, there is a downregulation of protective mechanisms and upregulation of several factors leading to atherosclerosis. For example, at the site of endothelial injury, there is downregulation of the potent endogenous vasodilator nitric oxide (NO), tissue plasminogen activator (tPA), and prostacycline, leading to a hyperprothrombic environment characterized by upregulation of platelet aggregation and leukocyte adhesion. At the initial stage, circulating monocytes are attracted to the vascular intima, the battleground of the atherosclerotic process. It is worth mentioning that vascular cell adhesion molecule, usually expressed on the surface of endothelial cells due to an inflammatory process, always precedes the binding of monocytes. Monocytes then squeeze through the tight junctions of the endothelial cells, enter the subendothelial layer of the intima and are transformed to phagocytic state macrophage. Macrophages engulf oxidized LDL cholesterol and form the foam cells, the integral part of the 'fatty streak.' At one stage, smooth muscles cells from the tunica media migrate to the intima and release an extracellular matrix. Monocytes, lymphocytes, platelets, endothelial cells, and smooth muscle cells liberate numerous factors, such as platelet-derived growth factors (α, β), fibroblast growth factor, insulin-like growth factor-1, interleukins (IL)-1, -2, -6, and -8, tissue necrosis factor (TNF), which influence further cellular migration and proliferation. The size of the fatty streak increases with the accumulation of different types of cells and lipids. Eventually, calcium is deposited and forms an atherosclerotic plaque (Figures 1 and 2).

The following subsections detail each risk factor as it relates to CHD.

Age, Gender, and Menopausal Status

The absolute risk of CHD increases with age, as there is a progressive accumulation of coronary atherosclerosis with aging. Coronary heart disease is most common after the age of 65 years, irrespective of gender. Men however have a greater risk of CHD than women; with men developing atherosclerotic lesions 20 years earlier than women. Behavioral and physiological differences between men and women such as prolonged exposure to smoking, dislipidemia and hormonal differences may partly explain the gender difference. Among premenopausal women, CHD is rare (except among smokers and oral contraceptive users). However, the CHD risk is precipitous among postmenopausal women, approaching that for men.

Family History

Based on genetic data, twin studies, and phenotypes (measurable traits) linked by inheritance, a positive family history of CHD is one of the most potent etiological influences on CHD independent of other major risk factors such as smoking, high blood

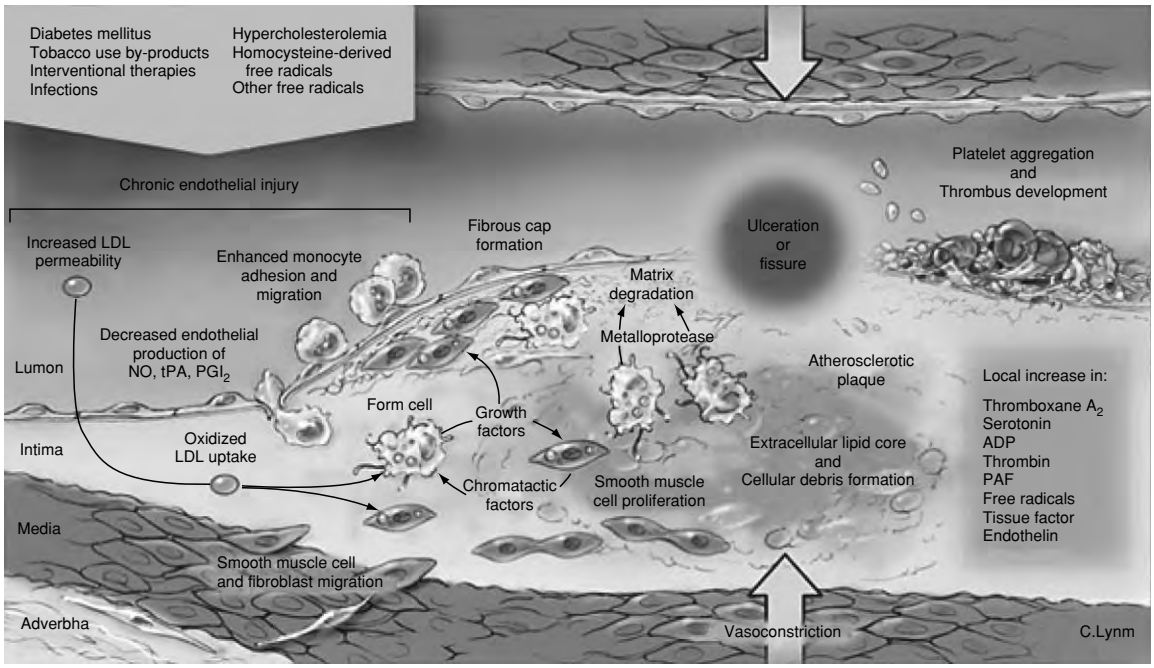

Figure 1 (see color plate 39) Mechanisms in the initiation and progression of atherosclerosis. Endothelial injury results from a variety of factors such as smoking, high blood cholesterol and homocysteine, and ulceration of atherosclerotic plaques, etc. (see text). At the site of endothelial injury, there is a downregulation of endothelial-derived nitric oxide (NO), tissue plasminogen activator (tPA), and prostacyclin (PGI_2) with increased adhesion of platelets and leukocytes, increased permeability to lipoproteins, and vasoconstriction. ADP, adenosine diphosphate; LDL, low-density lipoprotein; PAF, platelet activating factor. From Lefkowitz RJ and Willerson JT (2001) Prospects for cardiovascular research. *Journal of the American Medical Association* 285: 581–587 with permission.

pressure, diabetes, and high LDL cholesterol. For example, a single gene mutation (genetic variation) in lipid metabolism is well documented in the development of CHD. Plasma lipoprotein(a), Lp(a), is a new risk factor for CHD. In normal population, the variability of the *apo(a)* gene accounts for 90% of the variability of plasma Lp(a). African Americans have a higher levels of Lp(a) than white Americans. French Canadians also have a higher level than expected due to relative genetic homogeneity, also known as 'founder effects.' Familial combined hyperlipidemia, another well-known lipid disorder, may cause CHD before the age of 60 years, with a prevalence of about 2%.

The risk of CHD increases in an individual with a history of CHD in a first-degree relative (parent, brother, sister, son, or daughter). The family history is considered positive if clinical CHD or sudden death can be documented in first-degree male relatives before the age of 55 or in first-degree female relatives before the age of 65.

Smoking

Cigarette smoking is one of the most important risk factors for the development and progression of CHD. It has been estimated that smoking is responsible for about 30% of CHD-related deaths. Coronary heart disease events and deaths are attributable to cigarette smoking in both a dose- and duration-dependent fashion. Coronary heart disease risk is two to four times higher in smokers than in non-smokers. Inhaled cigarette smoke contains thousands of substances, many of which are toxic to cells. For example, the extensively studied chemical nicotine appears to be involved in endothelial cell death, diminished endothelial cell mitosis rate, and inhibition of NO synthesis. Detrimental effects of smoking on the cardiovascular system include an acute increase in vascular resistance and blood pressure, impaired oxygen transport, constriction of coronary vessel walls, acceleration of LDL cholesterol oxidation, decreased HDL cholesterol, increased platelet aggregation, and increased fibrinogen production. Smoking also acts synergistically with other etiological factors for CHD, thereby substantially increasing the risk. Passive smoking or environmental exposure also carries a substantial risk in the development of CHD. Like first-hand smoke, environmental smoke contains many toxins, such as carbon monoxide, benzopyrene, and hundreds of other chemicals. Many of these substances are toxic to arterial walls and may cause endothelial dysfunction and substantially reduce coronary microcirculation, an early process of atherosclerosis.

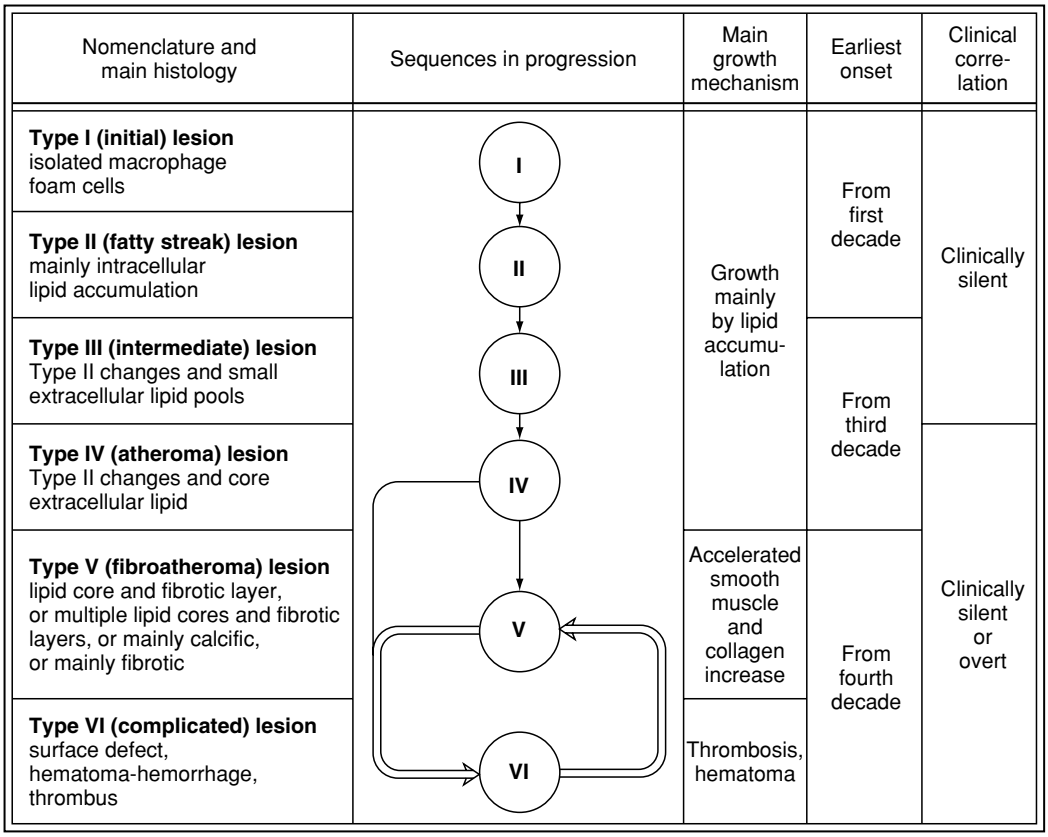

Figure 2 Flow diagram of the progression of atherogenesis. Roman numerals indicate histological characteristics of lesions. Loop I to loop IV illustrates the morphological changes in the lesion due to lipid accumulation. The loop between V and VI illustrates how lesions increase in thickness when thrombotic deposits form on their surface. From Stary HC *et al*. (1995) A definition of advanced types of atherosclerotic lesions and a histological classification of atherosclerosis. *Arteriosclerosis, Thrombosis, and Vascular Biology* 15: 1512–1531 with permission.

Psychosocial Risk Factors

There is mounting evidence that exposure to environmental stressors and psychological reactions to stress, an individual's personality prototype (type A), lack of social support, depression, and low socioeconomic condition are associated with increased CHD risk. Type A behavior is of special interest since it is associated with a two- to threefold higher risk for acute myocardial infarction, as documented by substantial prospective and case-control studies. A comprehensive explanation of the effects of psychosocial factors on CHD risk factors (e.g., high blood pressure) has not yet been established. Psychosocial factors may act in different ways. For example, they may be related to risky behaviors or lifestyle factors such as smoking, poor diet, physical inactivity, or excessive alcohol consumption, which in turn influence the development of CHD. However, the essential role of the psychosocial factors in developing CHD event is mediated by a neuroendocrine mechanism that alters catecholamine levels. Excessive adrenergic (sympathetic) activity may cause platelet aggregation, leading to occlusive arterial thrombus formation. It is also hypothesized that psychosocial stress may also increase circulating IL-6, which in turn acts on the hypothalamic–pituitary–adrenal axis, releasing many hormones that eventually result in abdominal obesity, insulin resistance, and various lipid disorders, the risk factors for CHD.

Atherogenic Diet

Many decades of research have established that diet plays a key role in atherosclerosis and subsequent events such as myocardial infarction. The rates of CHD are strongly associated with atherogenic diets, which influence other biological factors such as high blood pressure, LDL cholesterol, HDL cholesterol, thrombogenic factors, and obesity. The diet also affects CHD in other ways: high-calorie, high-saturated-fat (especially 12–16 carbon atoms) diets, combined with physical inactivity or a sedentary lifestyle, may lead to obesity, diabetes, and high blood pressure. Experimental models have proved that dietary saturated fat may cause atherosclerotic changes even in the absence of other classical etiological

factors for CHD. In contrast, substitution of saturated fat with isocaloric unsaturated fatty acids and complex carbohydrates, especially soluble fiber, lowers LDL cholesterol. Partial hydrogenation of polyunsaturated fatty acids (e.g., margarine) increases LDL cholesterol. Dietary cholesterol has a small effect on elevating LDL cholesterol. A diet high in protein can substantially limit carbohydrate intakes. Proteins from animal sources are generally higher in fat, saturated fat, and cholesterol and are considered atherogenic. Excessive salt intake is associated with high blood pressure in susceptible persons. Dietary supplementation of β-carotene (20 mg per day), a precursor of vitamin A, may increase cardiovascular mortality by 12–26%, especially among male smokers. Many epidemiological studies have shown a J- or U-shaped relationship between alcohol consumption and all-cause mortality. Excessive alcohol consumption is associated with increased CHD, possibly because of an increase in blood pressure and cardiac arrhythmias. In contrast, light to moderate alcohol consumption is cardioprotective, since it increases HDL cholesterol and apolipoprotein A1, and has favorable effects on markers of inflammation (e.g., C-reactive protein and IL-6).

Physical Inactivity

Prospective epidemiological studies have shown that both physical inactivity and a sedentary lifestyle are independent etiological factors and predictive of increased CHD risk. It is, however, difficult to quantify the association between the amount of physical activity and CHD. Results from meta-analyses have concluded that physical activity may lower the rate of CHD events by 50%. The positive benefits of physical activity on CHD outcomes may be partially mediated by lowering high blood pressure, decreasing triglycerides and LDL cholesterol, increasing HDL cholesterol, and increasing insulin sensitivity by lowering blood glucose levels.

High Blood Pressure

Although high blood pressure or hypertension is defined as a systolic blood pressure of 140 mmHg or greater and a diastolic blood pressure of 90 mmHg or greater, this definition is arbitrary. Several large-scale epidemiological studies have consistently demonstrated a positive, strong, continuous, graded, and independent relationship between high blood pressure and the etiology of CHD. The prevalence of high blood pressure is approximately 50% in the persons aged 65 years or older in many countries. High blood pressure promotes the atherogenesis process by several mechanisms: increased endothelin production, increased leukocyte adherence, impaired endothelium-derived relaxant factor production, increased endothelium-derived contractile substances, and increased vascular permeability to lipoproteins. It has been shown that in essential hypertension, endothelial damage inhibits NO production, and there is production of endothelin a potent vasoconstrictor from the activated endothelium. In addition, high blood pressure may also cause structural remodeling of vascular walls (cell proliferation) and accumulation of smooth muscle cells in the tunica intima, which in turn initiates a series of cascades leading to atherogenesis.

Obesity

Obesity, particularly central or abdominal obesity, is considered one of the prime etiological risk factors for CHD, since the adverse effects of obesity on CHD risk factors (blood pressure, lipid profiles, and glucose tolerance) are numerous. Central obesity is defined as a waist-to-hip ratio of > 102 cm in men and > 88 cm in women. Among the several adverse effects of obesity in mediating CHD, the most profound effect is high blood pressure. It has been estimated that more than 75% of high blood pressure is directly attributed to obesity. It is well documented in medical literature that blood pressure increases with weight gain and decreases with weight loss. Another significant negative effect of obesity is on lipid metabolism; obesity increases triglycerides and LDL cholesterol, and decreases HDL cholesterol. Although it is difficult to establish the exact contribution of obesity to glucose intolerance or insulin resistance, the role of excess body fat, particularly abdominal fat, is positively correlated with insulin resistance.

Diabetes Mellitus

Individuals with either type 1 (insulin-dependent diabetes mellitus) and type 2 (noninsulin-dependent diabetes mellitus) are at higher risk for CHD than nondiabetic individuals. Atherosclerosis is responsible for more than 75% of all mortality among diabetics. Silent myocardial ischemia commonly occurs in patients with diabetes. Data from longitudinal epidemiological studies suggest that diabetes or hyperglycemia (random plasma glucose concentration $\geq 200\ \mathrm{mg\,dl^{-1}}$ or fasting plasma glucose concentration $\geq 125\ \mathrm{mg\,dl^{-1}}$) is an independent and well-established etiological factor for CHD. Diabetes, especially type 2 diabetes, is a strong CHD risk factor in women which increases CHD-related mortality by 400%.

The relationship between diabetes and CHD risk is complex, poorly understood, and yet to be elucidated. Diabetes alters endothelial cell function by contributing several mechanisms such as smooth muscle cell proliferation and extracellular matrix production, elevation of endothelin and angiotensin II, enhance platelet adhesion, and decrease in tPA. All these changes

result in the progression of atherosclerosis. In the case of type 2 diabetes, the hyperinsulinemic state exerts mitogenic effects on the smooth muscle cells, leading to an alteration of endothelial structure. In addition, in the pathogenesis of atherosclerosis process, hyperglycemia and other CHD risk factors such as smoking, high blood pressure, hyperlipidemia, obesity, physical inactivity, and insulin resistance are interrelated and intertwined and continue to act independently in patients with diabetes. The majority of patients with type 2 diabetes have insulin resistance, which indeed predisposes then to CHD. There are other factors such as abdominal obesity, elevated triglycerides and LDL cholesterol, low HDL cholesterol, high blood pressure, and alterations in coagulation mechanisms that tend to cluster among type 2 diabetics, collectively known as metabolic syndrome. Elevated plasminogen activator inhibitor-1 (PAI-1) concentration, a novel risk factor of CHD, is another potentially important thrombogenic factor in this syndrome.

Blood Lipids

The essential roles of blood cholesterol and triglycerides in the etiology of CHD are well established. There is a continuous and graded risk between total blood cholesterol and CHD in population-based studies. However, on an individual basis, total cholesterol may be used as a risk factor in determining CHD. In fact, most of the lipid-related risk is explained by the LDL cholesterol levels, and the positive association between high LDL cholesterol ($\geq 160\,\mathrm{mg\,dl^{-1}}$) and the risk of CHD is applicable to individuals with or without established CHD, in both men and women. In epidemiological studies, LDL cholesterol increases as total cholesterol increases. Low-density lipoproteins increase with age, weight gain, and atherogenic diets. Genetic factors such as the heterozygous form of familial hypercholesterolemia further increase LDL cholesterol in the general population. The oxidized form of LDL is the main culprit in atherogenesis. Scavenging macrophages engulf oxidized LDL particles, resulting in the formation of lipid-laden foam cells. Subsequently, in combination with smooth muscle proliferation, the lipid-laden foam cells are transformed to a fatty streak, as mentioned earlier. Oxidized LDL cholesterol also inhibits relaxation factors and promotes contraction factors leading to modification of vascular tone, which eventually leads to vasospasm and thrombus formation.

A low level of HDL cholesterol is a strong independent etiological factor for CHD. Low HDL cholesterol is defined as a level of $<40\,\mathrm{mg\,dl^{-1}}$ (Table 2). High-density lipoprotein cholesterol levels are negatively influenced by cigarette smoking, overweight/obesity, physical inactivity, and type 2 diabetes. It has been hypothesized that cholesterol efflux from atherosclerotic lesions is promoted by HDL cholesterol via a receptor-mediated mechanism.

A meta-analysis of prospective studies has indicated that elevated triglycerides, or hypertriglyceridemia ($\geq 200\,\mathrm{mg\,dl^{-1}}$), is an independent risk factor for CHD after controlling for LDL and HDL cholesterol. Several factors contribute to the development of high triglyceride levels such as cigarette smoking, obesity and overweight, physical inactivity, type 2 diabetes, excess alcohol consumption, and genetic disorders (e.g., familial hypertriglyceridemia). The proposed potential mechanisms by which elevated triglycerides contribute to CHD include increased thrombogenicity, increased chylomicron and very low-density lipoprotein (VLDL) remnant particles, increased LDL and decreased HDL cholesterol, and altered metabolic processes involved in triglyceride transport.

Lp(a) is a cholesterol ester- and apolipoprotein B-containing particle with the presence of glycoprotein apo(a) that can promote atherogenesis by enhancing oxidation of LDL cholesterol, promoting cholesterol deposition in tunica intima, and interfering with fibrinolysis. The level of Lp(a) appears to be genetically determined.

Thrombogenic Risk Factors and Homeostasis

Both case-control and prospective studies have shown that thrombogenic factors (fibrinogen, blood clotting factor VII, tPA and, PAI-1) independently and

Table 2 Classification of total, LDL, HDL cholesterol, and triglycerides ($\mathrm{mg\,dl^{-1}}$)

Lipid fraction	*Classification*
Total cholesterol	
< 200	Low

consistently increase the risk of CHD. Coronary thrombosis is generally present in most cases of acute myocardial infarction. Increased platelet counts and platelet aggregation are also associated with recurrent CHD. PAI-1 activity or antigen inhibits fibrinolysis, and increased concentrations of fibrinogen promote platelet aggregation, which in turn induces blood clotting. Several factors elevate fibrinogen, notably increasing age, smoking, obesity and diabetes, use of oral contraceptive pills, and genetic polymorphism. Blood clotting factor VII plays a pivotal role in coagulation initiation and may also be predictive of myocardial infarction. Plasma concentrations of factor VII again are influenced by both environmental and genetic polymorphism. PAl-1 regulates the rate of tPA synthesis by the endothelial cells. Several studies have shown that the levels of PAl-1 and tPA mass concentrations are predictive of initial and subsequent myocardial infarction. Elevated plasma fibrinogen, a consistent procoagulant risk factor for CHD, has several mechanisms; notably, it increases fibrin formation, platelet aggregation, and plasma viscosity. Other markers such as the D-dimer, plasmin-α-antiplasmin complex, are indicators of activation of the fibrinolytic system.

Inflammation and Infectious Agents

There is a considerable body of evidence indicating that inflammation and infection are responsible in the pathogenesis of CHD as potential etiological factors. C-reactive protein (CRP) is of special interest. Both experimental and clinical studies have documented that elevation of plasma CRP, a marker of low-grade inflammation, can predict an increased risk of CHD event in healthy persons independent of other risk factors. Although the definitive mechanism of actions of CRP that triggers low-grade inflammatory response in atherosclerosis is still under further investigation, possible indirect roles have been as follows: (1) CRP may act as a procoagulant, (2) it binds avidly with neutrophils, (3) it facilitates uptake of oxidized LDL cholesterol by macrophages, (4) it induces complement activation, (5) it is chemotactic for monocytes, and (6) it impairs endothelial functions and enhances tissue injury. Other low-grade markers of inflammation, notably amyloid A protein, albumin, IL-6, TNF-α, transforming growth factor β1, and leukocytes may also be involved in the atherogenesis process. In the development of coronary event, the proposed mechanisms of IL-6 include alterations in insulin sensitivity, increased hepatic release of fibrinogen, procoagulant effects on platelets, and increased release of adhesion molecules. TNF-α inhibits lipoprotein lipase, stimulates lipolysis, and influences endothelial function leading to a procoagulant state. Recently, chronic infections by several microorganisms, especially herpes simplex viruses, cytomegalovirus, *Chlamydia pneumoniae*, and *Helicobacter pylori*, have attracted interest in the potential roles in the pathogenesis of atherosclerosis leading to CHD.

Homocysteine

There is substantial evidence supporting elevated plasma levels of Hcy (> 15 μmol l^{-1}) as an independent etiological factor for premature atherosclerotic lesions. Hcy is a metabolite of methionine as a product of many *S*-adenosylmethionine-dependent transmethylation reactions that require several enzymes (cystathionine β-synthase, γ-cystathionase, betaine-homocysteine methyltransferase, methionine synthase, 5,10-methyltetrahydeofolate reductase) and vitamins (folic acid, B_{12}, B_6). Enzymatic defects or vitamin deficiencies cause Hcy accumulation, which causes (1) direct toxic effects to the endothelium, (2) increased adhesiveness of platelets, (3) oxidation of LDL cholesterol, (4) proliferation of smooth muscle, (5) inhibition of nitric oxide formation, and (6) increased thromboxane formation. Meta-analyses document that as much as 10% of the CHD risk may be attributable to elevated Hcy, and each 5 μmol l^{-1} increment of Hcy is associated with a 60–80% increase in CHD. Homocystinuria is a rare autosomal recessive genetic disorder that is associated with a 10-fold increase of blood Hcy levels.

Emerging Risk Factors

Accumulating evidence suggests that the renin–angiotensin II system plays an integral role in the multiple processes critically implicated in the pathogenesis of atherosclerosis. The inflammatory response of angio-

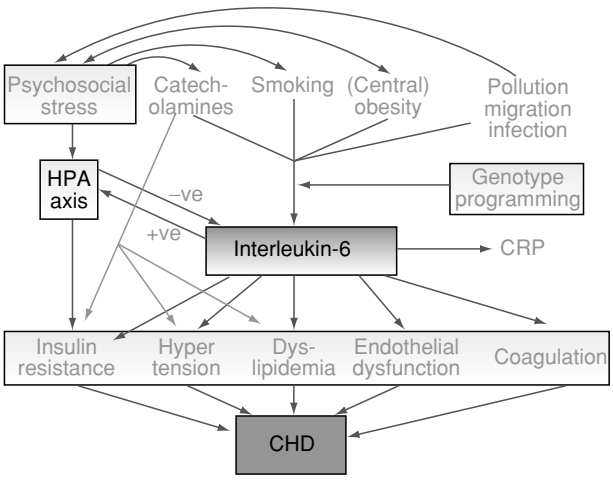

Figure 3 Possible mechanisms of action of IL-6 in the pathogenesis of CHD. From *Atherosclerosis* 148(2): 209–214 with permission.

tensin II on endothelium is mediated by the release of platelet-derived growth factor, insulin-like growth factor, IL-1, IL-6, and IL-8. Angiotensin II may also alter the structural integrity of endothelium, antagonize NO synthesis, increase the growth and migration of smooth muscle cells and fibroblasts, and promote LDL cholesterol oxidation and deposition in the intimal layer. IL-6 may also initiate the atherosclerotic process by changing metabolic, endothelial, and coagulant mechanisms. The possible mechanisms of action of IL-6 in CHD pathogenesis are illustrated in Figure 3.

The multifactorial etiology of CHD and the contribution of these factors, individually or in combination, to the risk of developing a CHD event in future is of prime importance in terms of both primary and secondary prevention.

Antioxidant Status

D S P Abdalla, Universidade de São Paulo, Cidade Universitátia, São Paulo, Brazil

Introduction

Coronary heart disease (CHD) is still the major component of total cardiovascular disease (CVD) mortality. The possibility that antioxidant substances might safely prevent oxidative stress and antagonize the atherosclerotic process has raised great interest in scientific and public communities. Epidemiological studies have demonstrated that those who consume higher amounts of fruits and vegetables have lower rates of CVD events. A possible explanation for this protective effect is the content of antioxidant micronutrients of fruits and vegetables. This section briefly summarizes the basic concepts behind the hypothesis that antioxidants may be helpful to prevent or retard the progression of CVD.

Oxidative Stress in Atherosclerosis

Atherosclerosis is a multifactorial disease of the arterial wall that has been considered to be the primary cause of most cardiovascular diseases, including CHD. The so-called oxidative theory of atherosclerosis has received great attention in the past 15 years, and a large body of experimental evidence has been accumulated. Free radicals may directly damage arterial endothelium, promote thrombosis, and interfere with normal vasomotor regulation. Oxidation-related events have been claimed to be involved in several steps possibly related to atherosclerosis: (1) the activation of endothelial cells to express adhesion molecules; (2) recruitment of monocytes in the subendothelial space and their differentiation into macrophages; (3) formation of foam cells;

(4) differentiation, proliferation, and migration of smooth muscle cells; (5) activation of metalloproteinases; and (6) alterations of vasorelaxation. Oxidative stress, particularly oxidation of low-density lipoprotein (LDL), has been considered to be a crucial event in atherogenesis. Free radicals derived from arterial wall cells can induce oxidative damage to LDL protein and lipids, which significantly increases its atherogenicity. Oxidatively modified LDL (oxLDL) can start the chronic inflammatory reactions of atherosclerosis. OxLDL elicits local vascular cells to produce monocyte chemotactic protein 1 and granulocyte and macrophage colony-stimulating factors promoting monocyte recruitment and differentiation to macrophages in the subendothelial area of arterial walls. As oxLDL is more negatively charged, it is recognized and internalized by the scavenger receptor pathway on macrophages, which is not regulated by negative feedback mechanisms, resulting in a massive uptake of oxLDL leading to foam cell formation. Furthermore, oxLDL is also cytotoxic to vascular cells, thus causing the release of lipids and lysosomal enzymes into the extracellular space of the arterial wall, perpetuating the inflammatory stimulus and enhancing the progression of the atherosclerotic lesion (Figure 1). OxLDL also seems to be involved in the immune response. Ox-LDL and its immune complexes have been found in atherosclerotic lesions. In addition, plasma of rabbits and humans contains autoantibodies that react with several forms of oxLDL. Moreover, a positive correlation between progression of carotid atherosclerosis and the titer of antibodies against oxLDL has been found. OxLDL can also impair endothelial function by inhibiting the release of endothelium-derived nitric oxide ($^{\bullet}$NO). Disturbances of G protein-dependent stimulation of $^{\bullet}$NO release, as well as direct inactivation of $^{\bullet}$NO, may be involved in this effect, resulting in enhanced vasospasm and platelet and monocyte adhesion to endothelium. OxLDL increases endothelial cell tissue factor and decreases protein C activation and may thus increase procoagulation at the endothelial surface. The oxidative hypothesis of atherosclerosis has been validated by a series of *in vivo* studies performed in animal models where the initial development of the atherosclerotic disease was effectively inhibited by supplementation of selected antioxidants.

Diet and Antioxidant Status

Diet has a profound effect on antioxidant status. The overall antioxidant effect of diet is determined by its components and other factors, such as:

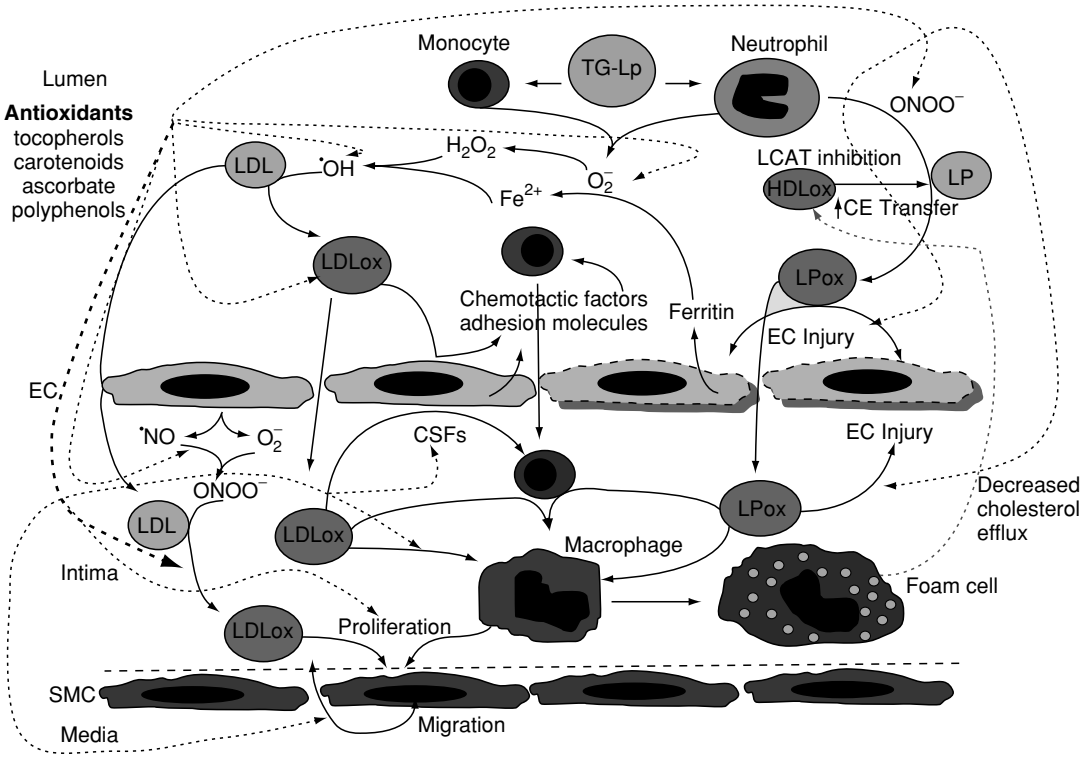

Figure 1 (see color plate 40) Possible effects of antioxidants in the atherogenic process. CE, cholesteryl ester; CSFs, colony-stimulating factors; HDLox, oxidized HDL; LCAT, lecithin: cholesterol acyl transferase; LDLox, oxidized LDL; LPox, oxidized lipoproteins; TG-Lp, triacylglicerol-rich lipoproteins; EC, endothelial cells; SMC, smooth muscle cells.

(1) antioxidant nutrient components; (2) absorption and bioavailability; (3) food processing and storage; (4) food additives and nutritional supplements; (5) chiral form and other chemical characteristics of nutrients. A dietary antioxidant is a substance that significantly decreases the adverse effects of reactive oxygen species, reactive nitrogen species, or both on normal physiological functions in humans. The diet contains antioxidants recognized as essential nutrients or nonnutrients, and such nutrient antioxidants include: vitamin E (tocopherols and tocotrienols), vitamin A, ascorbic acid, and nutrients essential for the normal function of endogenous enzymatic antioxidant systems, such as Cu, Mn, Zn (cofactors of superoxide dismutase), Se (cofactor of glutathione peroxidase) and Fe (cofactor of catalase and peroxidases). The diet also contains nonnutrient antioxidants, including a large number of phytochemicals.

Dietary Antioxidants

Mechanisms of Antioxidant Action and Relation with CHD Pathophysiology

Vitamin E (tocopherols and tocotrienols) Vitamin E is the generic term used to describe at least eight naturally occurring compounds that exhibit the biological activity of α-tocopherol. It includes α-, β-, γ-, and δ-tocopherol and α-, β-, γ-, and δ-tocotrienol. The naturally occurring *RRR* stereoisomer and the synthetic *all-rac*-α-tocopherol are equally well absorbed, yet levels of α-tocopherol in the blood and tissues increase significantly more than *all-rac*. In the liver, the α-tocopherol transfer protein preferentially selects *RRR*-α-tocopherol over γ- and other tocopherols for incorporating into very-low-density lipoprotein (VLDL), which then enters into systemic circulation. Tocotrienols appear in the blood and tissues at significantly lower levels than tocopherols, even when ingested at equivalent or higher amounts.

The antioxidant activity of the tocopherols and tocotrienols is mainly due to their ability to donate their phenolic hydrogens to lipid free radicals. α-Tocopherol acts as a chain-breaking antioxidant by donating its phenolic hydrogen to the chain-propagating lipid peroxyl radical ($LOO^{\bullet}$) in membranes and lipoproteins and replacing the latter with the less reactive α-tocopheroxyl radical (α-$TO^{\bullet}$). Alternatively, α-tocopherol may react directly with the initiating radical to prevent $LOO^{\bullet}$ formation. $LOO^{\bullet}$ may also be eliminated via a radical–radical reaction with α-$TO^{\bullet}$. Ascorbate, ubiquinone 10 and other co-antioxidants, donates electrons to the α-$TO^{\bullet}$ reducing it back to α-tocopherol. Both, α- and γ-tocopherol, the principal forms of vitamin E in the diets of Europe and the USA, respectively, protect against peroxynitrite-induced lipid peroxidation. This process is inhibited more effectively by γ-tocopherol than α-tocopherol. These results suggest that γ-tocopherol can act as a trap for membrane-soluble electrophilic nitrogen oxides, forming stable carbon-centered adducts through its nucleophilic 5-position, which is blocked in α-tocopherol. Besides the reactions with free radicals, tocopherols also react with singlet oxygen either by physical quenching or by chemical reactions. In physical quenching, excited state singlet oxygen ($O_2{}^1\Delta_g$) is deactivated to ground-state triplet oxygen ($O_2{}^3\Sigma_g$) through a charge-transfer mechanism. The tocopherols also react chemically with singlet oxygen and become destroyed after the reaction.

LDL particles may contain approximately 12 mol of vitamin E per mol of LDL. The oxidative resistance of LDL is increased in vitamin E-supplemented individuals, especially at intakes $\geq$ 269–336 mg of α-tocopherol equivalents, and there are strong correlations between oxidative resistance and LDL-α-tocopherol concentrations in these subjects. In vitamin E-supplemented subjects, the rate of oxidation was significantly decreased at 269 and 537 mg of α-tocopherol equivalents per day, leading to the conclusion that vitamin E was the most important variable that determined oxidative resistance of LDL. However, this relationship becomes weaker in unsupplemented subjects. In contrast, some studies on LDL oxidation have suggested that α-tocopherol accelerates the peroxidation of LDL lipids under mild free-radical generation and in the absence of co-antioxidants, such as ascorbate and coenzyme Q_{10}.

The bioactivity of $^{\bullet}NO$ is particularly sensitive to oxidative stress. The superoxide radical combines readily with $^{\bullet}NO$ in a diffusion-limited reaction to form peroxynitrite. In atherosclerosis, hypercholesterolemia, hypertension, and diabetes, the superoxide flux in the arterial wall is increased, leading to reduced $^{\bullet}NO$ bioavailability/activity. α-Tocopherol localizes mainly in lipoproteins and membranes, where it serves to scavenge lipid peroxyl radicals. Despite this action, atherosclerosis is characterized by lipid peroxidation within the arterial wall, even in the presence of α-tocopherol. Experimental studies have shown that arteries deficient in α-tocopherol showed a dose-dependent impairment of $^{\bullet}NO$-mediated arterial relaxation upon exposure to oxLDL. In contrast, vessels containing a high amount of α-tocopherol were resistant to this effect of oxLDL. This effect may be accounted for by inhibition of protein kinase C-α phosphorylation by α-tocopherol, which will prevent protein kinase C stimulation by oxLDL. One hallmark of atherosclerotic plaque is

proliferarion of vascular smooth muscle. Considerable *in-vitro* data indicate that α-tocopherol inhibits the proliferation of smooth muscle cells. This effect was also associated with the inhibitory effect of α-tocopherol on protein kinase C. Thrombus formation within the vessel lumen, an important event in pathophysiology of cardiovascular disease, is often precipitated by the adhesion and aggregation of platelets to a ruptured atherosclerotic plaque. It has been reported that platelet α-tocopherol content is an important determinant in platelet responsiveness toward protein kinase C-dependent stimuli leading to inhibition of platelet aggregation. Moreover, platelet α-tocopherol status appears to be important in regulating $^{\bullet}NO$ and superoxide radical production, which could also contribute to inhibit platelet aggregation. Recent data indicating that patients treated with vitamin E showed a high risk for hemorrhagic stroke could be related to its modulation on platelet function.

The antioxidant efficacy of tocotrienols in membranes is higher than that of tocopherols, in spite of their uptake and biodistribution after oral ingestion being lower than that of α-tocopherol. Cell-culture studies indicate that tocotrienols inhibit cholesterol synthesis by directly regulating the expression of 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGR), through a posttranscriptional process involving accelerated degradation of the reductase protein. The molecular mechanism for this suppression by tocotrienols was ascribed to their side-chain's unique ability to increase cellular farnesol, a mevalonate-derived product, which signals the proteolytic degradation of HMGR. Some studies in humans have shown that tocotrienol supplements decreased LDL-cholesterol, apolipoprotein B (apoB), lipoprotein (a) (Lp(a)), thromboxane B_2, and platelet factor 4, suggesting hypolipidemic and antithrombotic effects. However, supplementation studies with α-tocotrienyl acetate, which is hydrolyzed, absorbed, and detectable in human plasma, did not lower cholesterol in hypercholesterolemic subjects, although it was potent in decreasing LDL oxidizability. *In-vitro* studies with HepG2 cells suggest that α-tocotrienol is effective at levels of $10\,\mu mol\,l^{-1}$. Interestingly, γ- and δ-tocotrienol, which lack the 5-methyl substituents present in α-tocotrienol, show a higher HMGR suppression. This structure–activity relationship indicates that in addition to the requirements of the prenyl side-chain for HMGR supression, changes in the methyl substitution on the chromanol ring may also lead to a divergent effect on HMGR activity. The conflicting results obtained in human studies might also be related to differences in the effective concentrations in cells necessary to inhibit HMGR. Moreover, it has recently been found that humans do not respond uniformily to the cholesterol-lowering action of tocotrienols, particularly when cholesterol and alcohol intakes are not controlled. Tocotrienols, as well as other HMGR inhibitors, lower apoB levels partly by upregulating LDL receptors in the liver. This facilitates the liver uptake of circulating apoB-LDL. In addition, tocotrienol has been shown to increase the intracellular proteolytic degradation of apoB and alter the assembly process of VLDL. Thus, it seems that the ability of tocotrienol to reduce apoB levels in blood plasma depends on both the clearance rate of LDL and the production of VLDL. A novel tocotrienol fraction from specially processed rice bran oil enriched with didesmethyl-tocotrienol (with no methyl group on the chromanol ring) has been shown to decrease plasma Lp(a). Additionally, long-term prevention studies in humans are needed to validate this effect, which may have important implications in the prevention of atherosclerosis and thromboembolism.

Carotenoids Carotenoids are pigments found only in plants and microorganisms. Most carotenoids in the diet are provided by deeply pigmented vegetables and fruits. Nearly 600 of these compounds have been identified in nature. Less than 10% of the carotenoids can be metabolized to retinol and act as vitamin A precursors. The predominant carotenoids found in blood plasma (i.e., about 90%) are β-carotene, lycopene, lutein, β-cryptoxanthin and α-carotene. The structure of carotenoids is a key determinant of their physical properties, chemical reactivity, and biological functions. The unique chemical features of each carotenoid, such as size, shape, hydrophobicity, and polarity, determine its ability to be incorporated into the molecular microenvironment and its biological function. Thus, when carotenoids are consumed by humans from the diet, these structural properties influence the absorption, bioavailability, and biodistribution, and may affect their actions at the subcellular level and on biochemical pathways. Carotenoids exist in different geometric forms (*cis*- and *trans*-isomers), which can be interconverted by light, thermal energy, or chemical reactions. After passive absorption by the enterocyte, unmetabolized carotenoids are incorporated into chylomicra followed by the uptake of remnants by liver. *Cis*-β-carotene appears in blood and tissues at significantly lower concentrations than the corresponding *trans* form, even when ingested at equivalent or higher amounts. After absorption, the *cis* form of β-carotene is converted to the *trans* form. This conversion seems to increase the bioavailability of the *trans* form at the expense of the *cis* form. The more nonpolar carotenoids (e.g., β-carotene, α-carotene, lycopene) are predominatly within LDL. The more polar

carotenoids (e.g., lutein) are associated with high-density lipoprotein (HDL). Approximately four carotenoid molecules are associated with each VLDL and one with each LDL particle, whereas for every 1000 HDL particles, only one contains carotenoids. An inverse relation between body mass and plasma concentrations of carotenoids, irrespective of dietary carotenoid intake, has been found in both epidemiological and clinical studies. High concentrations of carotenoids are found in tissues that are rich in LDL receptors, such as the corpus luteum, adrenal gland, and testes.

Carotenoids are efficient quenchers of singlet oxygen and directly scavenge free radicals. In comparison, vitamin A is a poor antioxidant. Lycopene exhibits a better antioxidant capability than β-carotene and lutein. The *in-vivo* antioxidant actions of carotenoids is mainly due to inhibition of lipid peroxidation. Moreover, cell-culture studies and very small clinical trials suggest that lycopene may inhibit macrophage cholesterol synthesis, secondary to the inhibition of HMGR, and increases macrophage LDL receptors. It is worth noting that lipid-lowering pharmacological agents can reduce serum concentrations of lycopene, via a reduction in lipoprotein particle size and competition between the drug and carotenoids for incorporation into VLDL. The biological link between high levels of carotenoids and a reduced risk of cardiovascular diseases has been suggested to be the antioxidant effect of carotenoids in LDL. Moreover, carotenoids have been detected in lipid-rich atherosclerotic plaques, although concentrations are very low. The serum concentrations of β-carotene achieved with supplementation are much higher than those achieved with the consumption of a carotenoid-rich diet. This fact may have contributed to the adverse effects observed in some intervention trials (ATBC, Table 1). Thus, a diet intervention strategy is advantageous considering that: (1) it is risk-free because, until now, no adverse effects have been associated with consuming more carotenoids from food; and (2) benefits may be gained, even if other biologically active compounds, other than carotenoids, are the truly active agents or act in synergism with carotenoids.

Ascorbic acid Ascorbic acid (vitamin C) is an essential micronutrient required for normal metabolic functions in the organism. Like other primates, humans lost the ability to synthesize ascorbic acid, as a result of a mutation in the gene coding for L-gulonolactone oxidase, required for the biosynthesis of ascorbic acid via the glucuronic acid pathway. A lack of ascorbic acid in the diet causes the disease scurvy, which can be prevented with 10 mg per day, an amount easily obtained by consumption of fruit and vegetables. Tissue saturation in healthy men occurs at ascorbic acid intakes of approximately 0.1 g per day. Thus, further increases over this intake may have minimal or no additional effect on tissue ascorbic acid concentration, and hence disease risk. Ascorbic acid is a cofactor for several enzymes involved in the biosynthesis of neurotransmitters, collagen, and carnitine. Ascorbic acid has also been implicated in the catabolism of cholesterol to bile acids by the enzyme cholesterol 7α-monooxygenase and in the steroid metabolism in the adrenals. The role of ascorbic acid in these metabolic pathways is basically to reduce the central metal ion of the mono- and dioxygenases, acting as a cosubstrate in these reactions. Ascorbic acid is an important water-soluble antioxidant in biological fluids. Ascorbic acid scavenges reactive oxygen and nitrogen species, such as superoxide, hydroxyl, nitroxide and aqueous peroxyl radicals, singlet oxygen, ozone, peroxynitrite, nitrogen dioxide, and hypochlorous acid. Two major properties of ascorbic acid make it a strong antioxidant: (1) the low one-electron reduction potentials of both ascorbate and its one-electron oxidation product, the ascorbyl radical, which allows both forms to react with and reduce basically all physiologically relevant oxidants; (2) stability and low reactivity of the ascorbyl radical. The latter readily dismutates to form ascorbate and dehydroascorbic acid, or is reduced back to ascorbate by an NADH-dependent semidehydroascorbate reductase. Ascorbic acid can also act as a co-antioxidant by regenerating α-tocopherol from α-TO$^{\bullet}$, although *in vivo*, this interaction is not clear.

The effect of ascorbic acid on hypercholesterolemia has been investigated in numerous studies, although results are still controversial. In one supplementation study, consumption of 1.0 g of ascorbic acid per day for 4 weeks resulted in a reduction in total cholesterol, whereas in another study, supplementation with (0.060–6.0) g per day for 2 weeks had no effect. The positive effect of ascorbate may be related to its role as a cofactor for cholesterol 7α-monooxygenase, or, its modulating effect on HMGR. Several observational studies have found a significant association between elevated plasma ascorbic acid and increased concentrations of HDL-cholesterol and reduced concentrations of LDL-cholesterol. In relation to thrombosis, two studies found an inverse association between serum ascorbate concentrations and coagulation factors, as well as a positive association between low serum ascorbate and elevated coagulation activation markers. However, these effects were not confirmed by further studies. *In-vitro* studies have shown that physiologic concentrations of ascorbic acid increase PGE_1 (protaglandin E_1) and PGI_1

Table 1 Randomized trials of antioxidants in CHD

Study	Participants	Follow-up (years)	Antioxidants	Results
Primary prevention trials				
ATBC	29 000 male smokers (50–60 years)	5–8	VE (50 mg per day) β-Carotene (20 mg per day)	No effect on coronary mortality (increased incidence of lung cancer)
PHS	22 071 healthy males (40–84 years)	12	β-Carotene (50 mg every other day)	Supplementation confers neither benefit nor harm with respect to CHD or cancer
CARET	18 314 men and women heavy smokers/asbestos workers	4	β-Carotene (30 mg per day) Retinol (25 000 IU per day)	Trend towards excess cardiovascular deaths (relative risk = 1,26; 95% CI = 0.99–1.61)
Women's Health Study	40 000 healthy US health professionals (40–84 years)	Ongoing	VE (600 mg every other day) β-Carotene (50 mg every other day)	Cancer and cardiovascular endpoints
Su. Vi.MAX	12 735 healthy men and women	Ongoing	VC (120mg per day) VE (30 mg per day) β-Carotene (6 mg per day) Selenium (100 μg per day) Zinc (20 mg per day)	Premature deaths, cancers, cardiovascular diseases end points

(prostacyclin) production, reducing platelet aggregation and thrombus formation. Low concentrations of ascorbate have also been associated with increased concentration of plasminogen activator inhibitor 1, a protein that inhibits fibrinolysis. High doses of ascorbate, administered either orally or by intra-arterial infusion, have shown beneficial effects on vasodilation. Four studies investigated vasodilation in patients with CVD and found increases of 45–220% in vasodilation after administration of ascorbate (1.0–2.0 g oral or 0.025 g min^{-1} infusion). A 100% reversal of epicardial artery vasoconstriction was observed in coronary spastic angina patients infused with 0.010 g of ascorbate per minute. In the studies reporting an inverse association between plasma ascorbate and angina pectoris and CHD, the association was reduced after adjusting for smoking, suggesting that smokers may need additional ascorbic acid intakes. The possible mechanisms to explain the positive effect of ascorbate on vasodilation are related to its antioxidant activity and are suggested as the following: (1) ascorbate may spare $^{\bullet}NO$ by scavenging superoxide radicals or preventing the formation of oxLDL; (2) maintenance of intracellular concentrations of glutathione by a sparing effect or regeneration of thiols from thyil radicals, which may enhance the bioavailability of $^{\bullet}NO$ or increase the stabilization of $^{\bullet}NO$ through the formation of *S*-nitrosothiols.

Phytochemicals (polyphenols) The secondary metabolism of plants (e.g., shikimate and acetate pathways) generates products that are grouped under the term phytochemicals or polyphenols. The term polyphenols includes several classes of compounds that share a common structure; among them, flavonoids constitute the most important group, including more than 5000 compounds already identified. Subclasses of flavonoids are flavonols, flavones, catechins, flavanones, anthocyanidins, and isoflavonoids. Phenolics are derivatives of benzene with one or more hydroxyl groups associated with the aromatic rings. Several *in-vitro* studies have shown that flavonoids can modulate a variety of mammalian enzyme systems. Some of these enzymes are involved in important pathways that regulate cell division and proliferation, platelet aggregation, and inflammatory and immune responses. Soybean isoflavones, in particular genistein and daidzein, have a weak proestrogenic or antiestrogenic activity, which enable them to interact with estrogen receptors and decrease serum cholesterol concentrations. *In vitro* studies

have shown that genistein, a specific inhibitor for tyrosine kinases, prevents the development of atheroma by inhibiting cell adhesion and proliferation, by inhibiting LDL oxidation and by altering growth factor activity. In addition, soy isoflavones improve coronary vascular reactivity in female nonhuman primates, as well as, the endothelium-dependent flow-mediated vasodilation and arterial compliance in postmenopausal women. The phenolic compounds found in tea (e.g., quercetin, kaempferol, myrecitin, and epigallocatechin gallate) may be protective against CHD. Some epidemiological studies have correlated a high tea flavonoid intake with a lower incidence of CHD (Table 2). Since the 'French paradox' was revealed, it has been demonstrated that red wine, as well as dark grapes, contains many phenolic antioxidant compounds. In particular, *trans*-resveratrol has been shown *in vitro* to act as: (1) a strong antioxidant, (2) a vasorelaxant, (3) a phytoestrogen, and (4) an inhibitor of platelet aggregation, cyclooxygenase-2, and polymorphonuclear leukocytes activity. However, human studies are still needed to confirm the effects of *trans*-resveratrol in the protection against CHD. The antioxidant properties of olive oil phenolics, particularly oleuropein and hydroxytyrosol, have also been demonstrated in cellular and animals models. Among biological activities demonstrated by olive oil phenolics, the following can be mentioned: inhibition of platelet aggregation and human neutrophil respiratory burst; reduced formation of thromboxane B_2 and leukotriene B_4 by human leukocytes; and increased production of $^{\bullet}NO$ by mouse macrophages. Cocoa (*Theobroma cacao* L.) also contains appreciable amounts of phenolic substances, and *in-vitro* and *ex-vivo* studies indicate that they are endowed with certain biological activities such as an antioxidant capacity and immunoregulatory effects.

Epidemiological Studies on Antioxidants and Coronary Heart Disease

In the last two decades, observational studies around the world have suggested an inverse association between the consumption of fresh fruits and vegetables, important sources of antioxidants, and the risk of

Table 3 Case-control studies relating antioxidants and CVD

Study	*Comparison groups*	*Comments*
Scotland, Finland, and Southern Italy men	Plasma VE, VC, β-carotene were determined in angina patients and healthy controls	The relative risk of angina between the lowest and highest quintiles of lipid-standardized VE levels was 2.98 (95% CI = 1.07–6.70); after adjustment for cigarette smoking, the relative risks for VC and β-carotene were, respectively, 1.63 (0.76–3.49) and 1.41 (0.63–3.13); antioxidants did not reflect regional CVD mortality rates
EURAMIC	Adipose tissue levels of α-tocopherol and β-carotene were obtained in men from 10 European countries with first acute MI and healthy controls	The multivariate odds ratio in the lowest quintile β-carotene level compared to the highest was 1.78 (95% CI = 1.17–2.71); the associations were strongest among current and former smokers. α-Tocopherol levels were not associated with an apparent increased risk, with an odds ratio of MI in the lowest compared to the highest category of 0.83 (95% CI = 0.57–1.21)

MI, myocardial infarction; VC, vitamin C; VE, vitamin E.

CHD. Several case-control studies (Table 3) and prospective cohort studies (Tables 2 and 4), comparing rates of CHD with different plasma levels or intake of antioxidants, have reported a significantly reduced CVD incidence and mortality in subjects or populations presenting a high intake or plasma levels of vitamin E, vitamin C, and β-carotene, while others have not supported these associations. However from the results of these studies, it was not possible to establish a causal relationship and several limitations. Some of the restrictions to the case-control studies are sample size, biases in cases and control selection, quality of information on exposures, and recall bias. Moreover, blood levels of antioxidants are assessed with a single measurement some time after the index event, thus precluding any distinctions between short- and long-term exposures. In addition, storage of samples for long periods may decrease the concentrations of antioxidants. The prospective cohort studies are also limited by several factors: (1) subjects taking vitamin supplements may also have a healthier lifestyle than nontakers, such as practice of physical activities, equilibrated diet, and no smoking; (2) lack of precision and reliability of nutrient intake

Table 4 Prospective cohort studies of dietary intake and CVD

Study	*Participants*	*Follow-up (years)*	*Comparison groups*	*Results (relative risk; 95% CI)*
Nurses' Health Survey (NHS)	121 000 female nurses (USA) (34–59 years)	8	Upper vs. lower quintiles of dietary and supplemental vitamin E, vitamin C or β-carotene intake	β-Carotene (0.78) Vitamin E (0.66) Vitamin C (0.80; nonsignificant after controlling for vitamin E intake)
Health Professional Follow-up Study (HPFS)	39 910 male health professionals (USA) (40–75 years)	4	Upper vs. lower quintiles of dietary and supplemental vitamin E, vitamin C or β-carotene intake	β-Carotene (0.71) Vitamin E (0.60) Vitamin C (1.29)
First National Health and Nutrition Examination Survey (NHANES-1)	11 349 adults (USA) (25–74 years)	10	Upper vs. lower dietary and supplemental vitamin C intake	Vitamin C (0.66) Intake of other vitamin supplements was not taken into account
Iowa Women Health Study	34 486 postmenopausal women (USA) (55–69 years)	7	Upper vs. lower quintiles of dietary and supplemental vitamin E, vitamin A, retinol, and carotenoid intake	Vitamin E (0.96) No benefit for Vitamin A, retinol, and carotenoids
	2 748 men (Finland) (30–69 years)	14	Upper vs. lower tertiles of dietary and supplemental vitamins or β-carotene intake	Vitamins (0.66) β-Carotene (1.02)
	2 385 women (Finland) (30–69 years)	14	Upper vs. lower tertiles of dietary and supplemental vitamins or β-carotene intake	Vitamins (0.35) β-Carotene (0.62)
	1 899 men with hyperlipidemia (USA) (40–59 years)	13	Upper vs. lower quartiles of serum β-carotene intake	β-Carotene (0.64)

ascertained by food-frequency questionnaires; and (3) confounding factors that were neither measured nor controlled for in multivariate analysis.

The randomized intervention trials (Tables 1 and 5) have been considered as the golden standard to test the hypothesis that antioxidant micronutrients effectively have a causal relationship with the decrease of CHD morbidity/mortality. Until now, the results of these trials have raised the possibility that some benefits from observational epidemiology may have been overestimated. β-Carotene and vitamin C appear to confer no overall benefit in the primary prevention of CVD among well-nourished subjects. However, whether risk can be reduced among those with disease or lower baseline levels of these micronutrients remains unclear. For vitamin E, the results are still controversial; while the results of the Cambridge Heart Antioxidant Study (CHAOS) show a

lower incidence of nonfatal infarction and major cardiovascular events in supplemented subjects, HOPE results indicate no benefit on chosen endpoints. There are also criticisms of the randomized trials. Supplementation of a diet with individual antioxidants could not exert optimal effects because the concerted mechanism of action of the antioxidant system (Figure 1) could require the availability of adequate and harmonized levels of several antioxidant components in the diverse microenvironments in the organism. Furthermore, it may be possible that the antioxidants chosen (vitamin C, vitamin E, and β-carotene) could only be markers for the intake of other, as yet unidentified, substance(s) with the true biological effect. The rationale behind the approach of antioxidant supplementation in order to prevent the development and progression of CVD has not yet been firmly established. More basic research is required to ascertain the appropriate antioxidant(s) and doses, oxidation biomarkers, intermediate and final end points, among other factors, before planning further large intervention trials. Thus, until the results of these studies produce the final answers, the consumption of fruits and vegetables and a healthy life style would be advisable.

Intervention Studies

P C Elwood, Llandough Hospital, Penarth, South Glamorgan, UK

Definition and Aims

In the section on epidemiology a number of research strategies are discussed. These fall into two obvious groups: observation and intervention. In general, observation studies seek to ascertain more about the natural course of a disease process, whereas intervention studies test the effect of a possible therapeutic or preventive measure. (*See* **Epidemiology.**)

There is a further division of intervention studies, and this division is of particular importance in nutrition research. First, there are trials in which a foodstuff or a nutrient is given to subjects, and the effect upon a mechanism or a metabolic process, or the effect on a biochemical or hematologic variant is observed. Measuring the change in blood lipids following changes in dietary fat intake, or measuring the blood pressure response to coffee prepared in different ways, illustrates this kind of study. In these, the numbers of subjects can be relatively small, because a measurement of the outcome variable (serum cholesterol, blood pressure, or platelet aggregation, etc.) is obtained for every subject. Furthermore, such trials can usually be relatively short-term, and often it is acceptable to use a cross-over design, in which each

patient has a period on the intervention diet or supplement being evaluated, and a period on a normal diet without the intervention, thus serving as his or her own control. This last can be a most efficient design, provided the order of the intervention and control periods is random for each subject, and provided an adequate washout time is allowed between the two periods.

In the second kind of intervention trial, the effect of a dietary change, or a nutritional supplement, on the incidence of a disease is studied. This might be the reduction in the mortality of patients who have had a heart attack and who are advised to eat fatty fish, or the effect of a magnesium supplement given to patients judged to be at risk of a heart attack or stroke. Trials such as these are very different in that the outcome is a disease event, and this is likely to occur in only a very small proportion of persons in the trial. As a consequence, the numbers involved have to be very large and/or the period of observation very prolonged.

Both kinds of trials involve intervention and the level of confidence that one can put on the results is, in general, much higher than in studies from which the evidence is purely observational. Most of the design features are the same in the two kinds of intervention trial, but the problems which arise in those which aim to change the progress or reduce the incidence of a disease are substantial and so most of the following discussion will focus on the second.

Design

The only design for intervention studies which is now acceptable, fulfills the basic criteria for randomized controlled trial (RCT). These criteria include the following:

1. The allocation of subjects to the group which will receive the intervention, or to the control group which will not, must be random. Only allocation at random is likely to insure that there are no systematic differences or bias between the groups, which might account for some of the effects found and which might wrongly be attributed to the intervention. In fact, the comparability between the groups should later be checked by comparing the distributions of age, social class, and perhaps smoking, etc. in the two groups to give some assurance that by chance some systematic difference or bias has not occurred.
2. The advice, handling, and monitoring of the two subgroups of subjects – those receiving the intervention and those not – must be identical in every respect other than the intervention being tested. As far as possible the subjects in the trial should be 'blind' with regard to whether or not they are receiving the intervention under test. While this last is easy in a drug trial by the use of placebo tablets, it is unlikely to be possible in a trial of a foodstuff.
3. The outcome, whether this is a change in a biochemical or other variant or a difference in disease incidence or disease progression, must be assessed by an observer who is blind as to whether or not the subject has or has not been receiving the intervention.

The setting-up and conduct of an RCT is a major undertaking, and this is particularly true of a dietary trial. It may be appropriate therefore to consider the use of a factorial design. In this, two or more interventions are separately randomized. Equal numbers of subjects therefore receive each possible combination of the interventions, with some receiving all and some none. This design is acceptable provided that there is no reason to expect strong interactions between the different interventions. It is highly efficient as the main effects are all tested simultaneously without loss of power. For example, a trial by Burr and colleagues evaluated the effects of three dietary changes on mortality after a heart attack: a reduction in saturated fat, an increase in fatty fish, and an increase in cereal fiber consumption. Advice on each of these dietary changes was given to half of the total patient group, selected for each intervention at random.

The compliance of subjects with the intervention being tested is of great importance and should be taken into account when drawing conclusions from a trial. In fact, it is important to monitor both the degree of compliance by those who have been given advice about the dietary factor being tested and the extent to which the control subjects may spontaneously change their consumption of that factor. Ideally, compliance should be monitored in an objective way; for example, the estimation of plasma eicosapentaenoic acid will indicate how much fatty fish has been consumed. If an appropriate objective measure is not available, then at intervals the subjects (both those advised and the controls) can be asked to keep a diary of the food they consume.

Every reasonable effort should be made to achieve and maintain a high level of compliance. At the same time, whether or not a subject complies with the intervention, and whether or not a control subject spontaneously adopts the measure under test, all the subjects must be retained within their originally randomized group, and their results analyzed accordingly. This leads to what is known as an 'intention to treat' analysis. Omission of patients from one or other group because of poor compliance or other reason can unbalance the comparability obtained by

the original randomization, and is highly likely to introduce bias and invalidate any conclusions drawn from the results of the trial.

In planning a trial, careful attention should always be given to the likely power of a study, that is, the likelihood that the planned trial will be large enough, and the outcome measures sensitive enough to detect a statistically significant beneficial effect, should one occur. A number of things affect the power of a study. The most obvious are the number of outcome events and the likely difference in this between the intervention and the control group. Clearly, this last will not be known, otherwise the trial would be unnecessary. An estimate usually has to be made. If the intervention involves the consumption of a foodstuff, such as fish, or fruit and vegetables, the reproducibility of measurement of consumption should be assessed, and any changes in the consumption of other foods or nutrients monitored.

All these estimates should be realistic. It is all too easy to overestimate the likely effect of advice. For example, dietary intakes are relatively fixed, particularly in older subjects, and advice to increase the consumption of, say, fruit and vegetables, or to reduce fat intakes, has relatively little effect.

Primary and Secondary Trials in Coronary Heart Disease

The terms 'primary' and 'secondary' are used to distinguish trials which test a preventive measure in patients who have not already had a clinical episode of a disease (primary) from those based on patients who have already had a myocardial infarct or other clinical event (secondary trials). A distinction of this kind is most often made in coronary heart disease (CHD).

In fact, the concept of primary and secondary trials is not helpful. The terms relate to past history, and not to future risk. In relation to risk of a future vascular event, subjects simply form a continuum, ranging from subjects at exceedingly low risk, such as young, healthy subjects, to patients who have recently had a vascular event. Ranged between these are subjects who smoke, who have raised blood pressure, raised cholesterol, etc., whose risk of a vascular event is somewhere between those of subjects at the two extremes. In the evaluation of the risk of any individual, the occurrence of a past vascular event is only one of a number of risk factors which determine the likelihood of a future event. Figure 1 displays the continuum of risk.

Ideally, all possible preventive measures should be tested in an RCT based upon younger healthy subjects. The numbers required for a trial in such individuals are however formidable. Further difficulties arise in persuading healthy subjects to comply with the intervention to a sufficient degree and for a sufficient time.

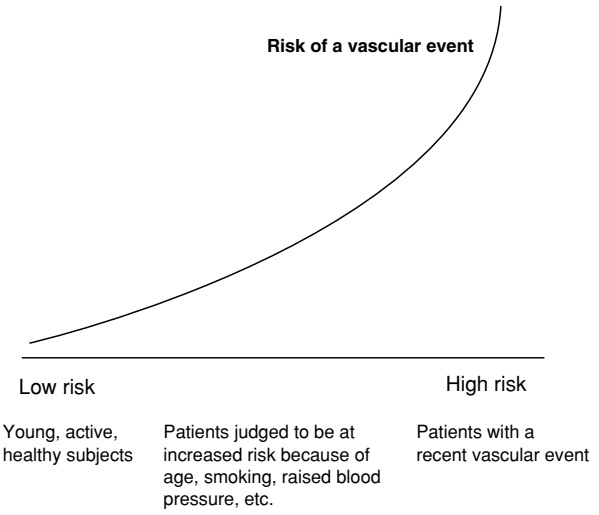

Figure 1 Low verus high risk of a vascular events

Intervention trials are therefore often conducted in subjects who have evidence of an increased risk, be it raised levels of risk factors, or some evidence of vascular disease, such as angina pectoris. Trials can even be based upon patients who have already had a CHD event, such as a myocardial infarct. All such patients know that they are at an increased risk of a further event, and they are likely to be more easily persuaded to comply with a dietary change for long periods. It can be argued that the underlying disease of survivors of a myocardial infarction is at an advanced stage and may not be reversible within the time span of a trial of a reasonable duration. There may well be some truth in this, particularly if the aim of the intervention is to reduce atherosclerosis.

Nevertheless, a myocardial or a cerebral infarct results when a thrombus develops on top of an atheromatous plaque on the wall of a blood vessel. Dietary factors are undoubtedly relevant to the risk of thrombosis. For example, the head of an intravascular thrombus is usually a mass of aggregated platelets, and alcohol reduces platelet activity. A myocardial infarct can precipitate ventricular fibrillation and death, and there is evidence that fish oil reduces the electrical stability of the myocardium. Free radicals from an ischemic lesion can damage the myocardium, and antioxidants from fruit and vegetables may reduce this damage to the heart muscle. There are therefore mechanisms in vascular disease, other than atherosclerotic disease in the vessel wall, which are affected by dietary items and which are appropriately tested in dietary intervention RCTs.

Hypotheses Tested by Dietary Intervention Trials

It would be a mistake to summarize the present situation on dietary trials in CHD, as results are constantly accumulating and the picture is changing. Rather, intervention trials in a few areas will be described briefly, largely in order to illustrate methodological aspects.

Dietary Fat Reduction

Undoubtedly, the relationship of saturated fat to fat reduction has been more investigated in the prevention of CHD than any other potential prophylactic. The early trials focused largely on the reduction of total fat in the diet; interest then focused on the P:S ratio (the ratio of polyunsaturated to saturated fats) and on monounsaturated fats. Almost all metaanalyses or overviews of dietary RCTs have failed to detect any significant reduction in mortality from dietary changes aimed at reducing cholesterol, though several overviews have reported a significant reduction of around 20% in the incidence of nonfatal myocardial infarctions. (*See* **Cholesterol**: Role of Cholesterol in Heart Disease; **Fats**: Requirements.)

An issue worth noting because of its wider relevance to the drawing of conclusions from trials is the degree to which successful trials are cited in preference to negative trials. A report of an overview of 22 RCTs in which the effect of a reduction in dietary fat intake had been examined went on to examine how often these trials had been cited in the general literature. It was found that the few trials in which a reduction in CHD had been observed had been cited six times more frequently than the trials which had failed to find such an effect. This positive bias in the reporting of trials is serious bias in any overview of the literature, whether this is based upon a formal metaanalysis, or simply an impression gained from reading the literature.

The relevance of cholesterol level to vascular disease has been very considerably reinforced by the results of recent RCTs of statin drugs. These drugs substantially reduce cholesterol level, and at the same time are associated with a reduction in vascular disease incidence and mortality. The reduction in disease appears however to commence virtually immediately, and this has led to the suggestion that some of the benefit from these drugs may arise because of effects that have been described on platelet function, on hemostasis and on immunological mechanisms.

Within the area of lipids and vascular disease, one trial stands out. This tested the effect of the so-called 'Mediterranean diet,' a dietary pattern modeled on the dietary pattern in Crete and other Mediterranean communities. The initial finding was a 70% reduction in all-cause mortality together with comparable reductions in nonfatal events, and these results have been sustained in a 4-year follow-up, reported in 1999. The diet advised in this trial was rich in fruit and vegetables, but the group responsible for the study considered that its most important feature was its richness in α-linolenic acid. In the trial this last was achieved by distributing a special margarine containing rapeseed oil to half the subjects. At present only one RCT of a Mediterranean type of diet has been reported. Clearly there is an urgent need for further trials.

Fatty Fish

The hypothesis that fatty fish, fish oil, or eicosapentaenoic acid might reduce the risk of CHD emerged from surveys of Inuit in Greenland in the 1930s. Later, historical studies showed that changes in fish consumption during World War II had been accompanied in The Netherlands and in Norway by decreases in heart disease mortality. Laboratory and animal studies then examined the effects of fish oil on various risk factors and certain mechanisms involved in CHD. This was the background to the setting-up of a major RCT of fish and mortality. A total of 2033 men were randomized factorially to three interventions, one of which was the consumption of fatty fish on at least 2 days each week. The consumption of fish was associated with a reduction in mortality of about 30% and a saving of lives of about 36 per 1000 men advised. Because these estimates of benefit are derived from the results of a single trial they carry a considerable uncertainty. Further trials are required, followed, hopefully, by a metaanalysis. It is notable, however, that this trial gave no evidence that nonfatal infarctions were reduced by the fish consumption. Indeed, there were rather more nonfatal infarctions in the men advised (4.8%) than in the other men (3.2%). It is therefore possible that the effect of fish is to reduce the risk of death after infarction rather than to reduce the incidence of infarction. Evidence consistent with this hypothesis comes from studies of the electrical stability of the myocardium in animals, following experimentally induced infarction.

Fruit and Vegetables

It is believed that the oxidation of lipids is an important step in the development of atherosclerosis. Oxidized low-density lipoprotein cholesterol is potentially highly atherogenic, while antioxidants prevent its oxidation and reduce the risk of other oxidative damage, thus retarding the development of atherosclerosis. There is therefore growing interest in the protective effect of both supplements of the

antioxidant vitamin supplements, including vitamins E, C, and β-carotene, and in fruit and vegetables which carry these and other antioxidants.

Numerous observational studies based on communities and on individuals give supporting evidence of benefit. In fact, the evidence is virtually totally consistent that subjects and groups with high consumptions of fruit and/or vegetables have a reduced incidence of both digestive cancers and of CHD. Despite their consistency, however, these observations are seriously open to confounding by related social and other dietary factors. Hence there is no substitute for RCTs.

A number of RCTs have been conducted to test the effects of supplements of vitamins E, C, and/or β-carotene. A recent overview of these has concluded that 'there is no clear indication for the use of these supplements . . . and the suggestion of potential harm associated with β-carotene in two clinical trials (indicates) that β-carotene in the form of additional vitamin supplements should be avoided.'

On the other hand, RCTs of fruit and vegetables necessitate increasing consumption of these foods by half the subjects studied, and even in a so-called secondary preventive trial the dietary increase has to be either large or prolonged, or both. This makes such trials very difficult. The diets of older subjects tend to be relatively fixed, and it is exceedingly difficult to persuade subjects – even patients who have already had a clinical CHD event – to increase their consumption of any food item. In our experience this is especially true for fruit and vegetables. (*See* **Antioxidants:** Natural Antioxidants.)

Dietary Fiber

For a very long time there has been interest in dietary fiber. At first this focused upon 'roughage,' or unabsorbed dietary material, and measures such as fecal bulk and bowel transit time were commonly used. Interest then focused on cereal fiber, the diseases of possible relevance being bowel cancer and CHD. Numerous observational studies have been reported, but one of the uncertainties in all of these is the effect of confounding factors. In fact, confounding is a major source of possible confusion in all dietary studies that are dependent upon observation. The diet of an individual is determined by a host of factors, including lifestyle, education, social standing and income level, educational and psychological factors. Furthermore, the consumption of any one food or diet factor is interrelated with a host of other foods, and cannot realistically be considered in isolation. For example, an increase in the consumption of wholemeal bread will probably lead to an increase in spreading fats; an increase in fish consumption will probably be balanced by a reduction in meat. It will be almost impossible to take account of all these confounding and interrelated factors in a study of disease incidence in relation to a single food item or nutrient. The final elucidation of relationships between diet and disease must therefore be ultimately dependent upon intervention studies, in which control over confounding is achieved by randomization, and different levels of dietary intake are achieved experimentally.

There has been only one RCT of dietary fiber and CHD. This was conducted by Burr and his colleagues in south Wales. Advice was given to 1017 men who had already had a myocardial infarct. This led to a mean intake of cereal fiber of 19 g per day, compared with 9 g in 1016 controls given no advice about fiber. After 2 years there was no significant difference in the deaths in those given the advice about fiber (12.1%) compared to those not so advised (9.9%).

Interest in fiber has however shifted again, and attention is now being focused on soluble fiber. This, too, is confounded and interrelated with numerous other food items and nondietary items and its importance will only be sorted out by RCTs.

Interpretation of the Results of RCTs

Relative and Absolute Risk Reduction

There are two important aspects of trials that should be understood. First, the results of a controlled trial can be expressed as 'relative' protection, or the 'relative' reduction in the outcome events, or they can be expressed in terms of the 'absolute' effect of the intervention. This can be very easily illustrated.

In the Diet and Reinfarction Trial (DART) 1015 post-myocardial infarction patients were given advice to eat fatty fish on at least 2 days per week. A group of 1018 other patients, selected at random, were given no such advice. During the next 2 years 127 (12.5%) of the men advised to take fish had a CHD event, while 149 (14.6%) given no such advice had an event. The difference between these incident figures implies a relative reduction in the risk of an event of 30%. On the other hand, the absolute reduction was 2% over the 2 years or one IHD event was prevented per year in every 100 patients advised to eat fatty fish.

Both these figures are correct, but each expresses rather different concepts. Thus the relative reduction, or relative benefit, is the proportionate extent to which the risk is reduced in a group in which there has been an intervention, compared to a control group with no such intervention. The absolute reduction, or absolute benefit, is the number of events prevented. Another way of expressing this last is the number needed to treat (NNT) to prevent one disease event. Clearly, for fatty fish, this is 100 patients for 1 year.

While figures of absolute benefit may at first sight appear disappointing, they carry a wealth of information. Thus, in the above example, one can say that, of every 100 patients advised to eat fatty fish, a CHD event will be prevented in one or two each year, but about six will still die from CHD each year. About 92 will derive no benefit because, judging from the experience of the subjects in the control group, they would have survived anyway. No worry! They will have enjoyed the fatty fish and will probably have saved money on meat!

Intervention with drugs has much the same protective effect (for example, antihypertensives achieve a relative reduction in CHD event of about 25%, that is, closely similar to the 30% achieved by fish consumption in DART). However the patients who are given drugs, and who would have survived anyway, will have been exposed to the undesirable side-effects of the drugs, and their therapy will have generated considerable costs. None of this is meant to imply that dietary intervention is a substitute for medication. Raised CHD risk factors should be treated appropriately, but considerations should also be given to dietary intervention. These are not in competition.

Overviews or Metaanalyses

In the nature of things, certainty is unobtainable and even the largest and most carefully conducted RCT can, by chance, give a wrong answer. Firm conclusions should only be based on evidence drawn from a number of trials. The play of chance can never be ruled out, whatever the level of statistical significance, and consistency in a number of studies is likely to be a better guide to truth than the results of any single study. Further to this, the results of any single trial cannot be extrapolated to the general population with certainty. Conclusions from a trial are limited by issues such as the selection of patients tested, the diagnostic criteria used, the way the intervention was achieved, and the possibility that the intervention may have affected other factors of relevance to the disease. Together, these uncertainties can make it inappropriate and perhaps misleading to generalize the results from any one study to patients in general and make them the basis of clinical recommendations.

Hence the importance of overviews of studies, or metaanalyses of data from a number of different studies. This approach is particularly appropriate with RCTs, but it is important that data from every relevant RCT are included.

In fact, even the most meticulous search of the literature followed by a formal overview of all the evidence from relevant RCTs still leaves uncertainties. There is publication bias, and reports which report an effect are generally more likely to be accepted by a journal than those which show no effect. But then this limitation affects judgments based simply on cumulative reading of the literature, however carefully done. Nevertheless, the approach in research that is likely to get closest to the truth is clearly drawing conclusions from all the available acceptable evidence. Cochrane, an epidemiologist, saw this and he commented in a Rock Carling lecture, later published as *Effectiveness and Efficiency*: 'It is surely a great criticism of our profession that we have not organised a critical summary, by speciality or sub-speciality, adapted periodically, of all relevant clinical trials.'

The Cochrane Collaboration

This urging by Cochrane led to the setting-up of the Cochrane Centre in Oxford, and then to the Cochrane Collaboration, a worldwide effort coordinated in 11 Cochrane Centres. The collaboration aims to identify every RCT ever done in medical care, to group these by clinical objective, and make them readily available as databases. These then constitute the basis for statistical overviews, or metaanalyses, which draw on all the acceptable trial evidence relevant to each clinical procedure.

Final Considerations

RCTs of dietary factors are immensely difficult and before one is mounted consideration should be given to a number of general considerations relevant to intervention in cardiovascular disease. In summary, there are unlikely to be any easy answers!

First, compliance with a dietary intervention is likely to be poor. Trials of the effect of dietary advice on cholesterol levels have generally shown very little effect, and to some extent – and probably a very large extent – this is because of the difficulties most people find in making a significant, let alone a large, reduction in dietary saturated fats. Likewise, attempts to increase the intake of dietary fiber or fruit and vegetable intake have achieved relatively little change. Results such as these have far-reaching implications for the acceptability of prophylactic strategies in symptomless subjects, or in the general population.

Second, effectiveness is likely to be low. Geoffrey Rose defined a paradox – population preventive strategies, even those with large overall potential benefit, are likely to confer little benefit on the individual – and he went on to describe the overall benefit/risk balance in strategies involving the general population as 'worrisome.' An overview by Davey-Smith and Ebrahim of nine major population-based RCTs of the effect of advice on diet, smoking, and blood

pressure led to the conclusion: 'The pooled effect of intervention on multiple risk-factors is insignificant.'

Third, the costs of intervention are likely to be high. The cost of an intervention strategy that really matters is not the cost of the change of diet, the cost of nutritional supplements of medication in a single subject. Rather, the cost that matters is that of treating a sufficient number of subjects, for a sufficient time to save one life, or prevent one disease event. While this approach has been well developed with drug therapy, the most relevant costs of a dietary intervention are those that arise from the need for subjects to accept a change in their diet, and for most of us, a possible small change in the long-term risk of a disease is far from the front of our minds when preparing a meal.

Prevention

F G Huffman and S Nath, Florida International University, Miami, FL, USA

Background

There has been a steady decline of coronary heart disease (CHD)-related mortality in most industrialized nations over the past few years. Despite this fact, CHD remains the leading cause of morbidity and mortality in adults of middle years and older (after age 65), leading to a loss of productivity and substantial healthcare costs in the industrialized countries. The World Health Organization estimates that by the year 2010, CHD would be the leading cause of death in the developing countries as well. Therefore, prevention (both primary and secondary) of CHD is extremely important from a public health point of view.

The preceding section in this chapter highlights the etiology of CHD that includes both modifiable and nonmodifiable risk factors. Among all CHD risk factors, cigarette smoking, unhealthy diet, overweight or obesity, physical inactivity, high blood lipids (high total cholesterol and elevated low-density lipoprotein cholesterol), high blood pressure or hypertension, and high blood glucose (also metabolic syndrome) are preventable or manageable. Several prophylactic therapies and screening of high-risk individuals also offer potential benefits for the prevention of CHD (**Table 1**).

Primary prevention of CHD is generally defined as the modification of risk factors or prevention of the development of these risk factors, with the aim of delaying or preventing a first coronary event (angina pectoris, myocardial infarction, or sudden death), offers the greatest opportunity for reducing the burden of CHD from a personal, economical, and global aspect. The prime objective of primary prevention is to reduce both short-term (< 10 years) and long-term (> 10 years) risk. However, secondary prevention includes therapy or measures to minimize recurrent coronary event (angina pectoris, history of myocardial infarction, history of bypass graft or angioplasty) and decrease mortality and morbidity in patients with established CHD, which is not cost-effective in most cases. The potential benefits of primary prevention exceed those of secondary prevention, since $\sim 30\%$ of patients with first myocardial infarction survive less than 3 months. The first CHD event may progress to prolong permanent morbidity. Both primary and secondary preventions share many common characteristics (**Figure 1**). Therefore, the elements of both

Table 1 Prevention of coronary heart disease

Lifestyle modification	*Goals*	
Smoking cessation	Encourage patient to stop smoking completely	
Healthy diet	25 g of fiber, > 400 g of fruits and vegetables; < 30% fat, < 10% saturated fat, poly- and monounsaturated fat 10% each, < 300 mg of cholesterol of daily calories; salt intake 6 g or less per day	
Weight control	Maintain a healthy BMI (18.9–24.9)	
Physical activity	30–60 min aerobic activity four to six times a week	
Risk factors	*Goal*	*Recommended drugs*
Blood lipid		Statins
LDL cholesterol	< 130 mg dl^{-1}	
Total cholesterol	< 200 mg dl^{-1}	
Blood pressure		Low-dose thiazide
Systolic	130–139 mmHg	Diuretics
Diastolic	85–89 mmHg	β-blockers
		ACE inhibitors
		Calcium antagonist
Prophylactic therapy	*Purpose*	
Aspirin (75–325 mg per day)	For secondary prevention and maybe for primary prevention	
ACE inhibitors	For secondary prevention	
Statins	For both primary and secondary prevention	
Folic acid	For primary prevention	

BMI, body mass index; LDL, low-density lipoprotein; ACE, angiotensin-converting enzyme.

primary and secondary preventions are addressed simultaneously. Combining both primary and secondary prevention, the overall objective of CHD prevention is to reduce the risk of initial or subsequent CHD events, thereby reducing premature CHD-related morbidity and mortality, and prolonging survival.

Primary and Secondary Preventive Measures for CHD

Smoking

Cigarette smoking is a convincing risk factor for CHD, and cessation of smoking (including all forms of tobacco) rapidly and significantly decreases the risk for the development of CHD and CHD-related mortality in a very cost-effective way. Smoking cessation is a complex, multifactorial, and difficult process. Simple brief counseling with a clear, firm, positive, encouraging, and sympathetic attitude is the first step in the management of smoking cessation. Persistent smokers may require extended counseling, more than one session preferably, by a skilled counselor or psychologist. Nicotine chewing gum or transdermal nicotine replacement patches with a progressively decreasing dosage can be helpful for heavily addictive persons as an adjunct to counseling.

Family support is very important in smoking cessation. Encouragement from a family or spouse is of great help. 'Smoke-free' environments at home, restaurants, work sites, public transport vehicles, and other public premises can greatly improve the atmosphere for smoking cessation attempts by smokers.

Diet

Diet is an important determinant for the development of CHD by affecting the obesity, blood pressure, and blood lipids. Therefore, it is crucial to maintain a 'healthy diet,' which constitutes (1) consumption of six or more servings of whole-grain products with ≥ 25 g of fiber, especially soluble fiber; (2) consumption of at least five servings of fruits and vegetables (> 400 g per day); (3) limiting consumption of saturated fat < 10% (preferably < 7%) of total daily calories, and cholesterol < 300 mg per day (preferably < 200 mg per day); (4) consumption of polyunsaturated fatty acids up to 10% of total daily calories; (5) limiting salt intake to 6 g per day, the equivalent of 100 mmol of sodium per day; and (6) limiting alcohol consumption to one or two standard drinks for men per day and not more than one drink for women (a pregnant woman should not drink) per day to prevent or delay the development of CHD risk.

Overweight and Obesity

Patients who are overweight (body mass index (BMI = kg m^{-2}) > 25 kg m^{-2}) or obese (BMI > 30 kg m^{-2}), or with excess truncal or abdominal fat (waist circumference > 102 cm in men and > 88 cm in women), are at increased risk for CHD, because of the adverse effects of fat on blood lipid levels, blood

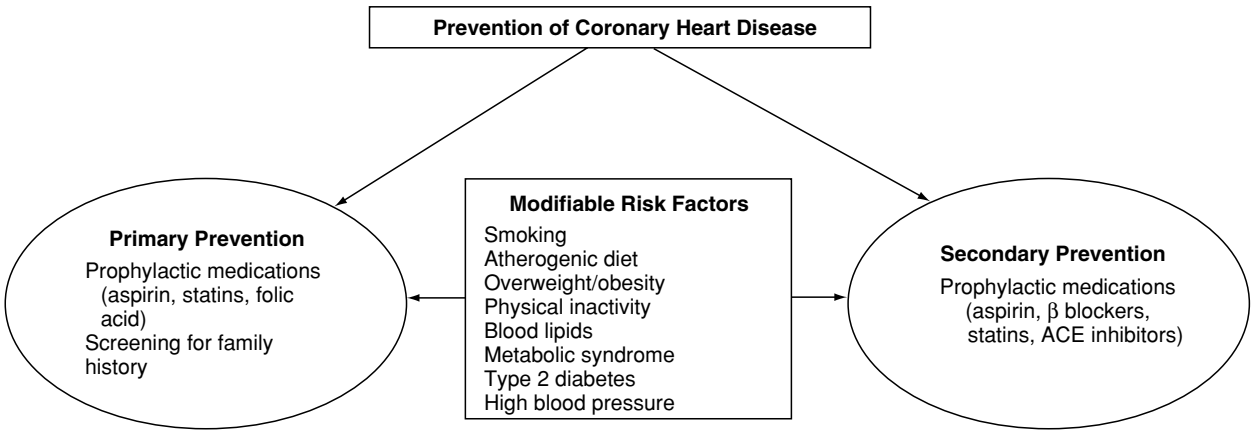

Figure 1 Shared preventable measures in primary and secondary prevention of coronary heart disease. ACE, angiotensin-converting enzyme.

pressure, and glucose tolerance. Prospective epidemiological studies have shown a J-shaped association between BMI and all-cause mortality among Western populations. High-risk populations require professional advice on weight reduction.

Successful weight reduction is not easy to manage, often requiring long-term professional support and encouragement, good motivation of the person, a calorie-restricted lipid-lowering diet, and a suitable physical activity program. Realistic weight-reduction goals should be based on short-term results and agreed between the physician and the patient. It is recommended that a weight reduction of 0.5–1 kg per week is a suitable rate until the target weight goal is achieved. The National Heart, Lung, and Blood Institute, USA has recommended that a person with BMI 27–35 should decrease their caloric intake by 300–500 kcal per day, and a person with BMI > 35 should decrease their caloric intake by 500–1000 kcal per day from their diet to achieve a 10% weight loss in 6 months.

There has been considerable concern about the usage of drugs and their possible side-effects for weight reduction. For example, sibutramine, a sympathomimetic, reduces food intake but may cause hypertension and tachycardia. Lipase inhibitor orlistat (Xenical) has significant effect on weight reduction but may cause severe gastrointestinal symptoms. Weight loss is usually observed within 2 weeks of initiation of therapy. However, researchers agree that a reduction in caloric intake combined with regular physical activity may be the most effective and safe method in reducing excess body fat.

Physical Activity

Prospective epidemiological studies have documented that sedentary lifestyle is a strong predictor of CHD risk, irrespective of other risk factors. Therefore, a regular, suitable exercise program is recommended for a sedentary person, since it has favorable effects on body weight, blood pressure, blood lipids, insulin sensitivity, and glucose tolerance. Epidemiological studies have demonstrated strong evidence that aerobic exercise reduces the risk of CHD. Brisk walking, jogging, cycling, mowing, swimming, aerobic dancing, skipping, and other recreational sports that require movement are good examples of aerobic exercise.

It is now recommended that everyone must perform at least 30–60 min of physical exercise four to six times a week. Generally, an exercise program includes a 5–10-min warm-up by stretching and other gentle activity followed by 20–30 min endurance or aerobic phase, and finally 5–10 min of a cool-down phase. Physical exercise prescription (intensity and duration) for patients with clinically established CHD must be based on comprehensive clinical evaluation and results of exercise testing. The Second Joint Task Force of European and other Societies on Coronary Prevention recommends that the intensity and duration of activity should initially be set low and gradually increased according to the limits imposed by exercise-induced symptoms. Patients recovering from myocardial infarction and other cardiac events should also be given advice about a suitable, gradually increasing exercise program. In these patients, exercise programs must be supervised, and ECG monitoring should be used in the early stages.

Blood Lipids

CHD risk is best evaluated by measuring plasma concentrations of total cholesterol, low-density lipoprotein (LDL) cholesterol, and high-density lipoprotein (HDL) cholesterol. Results from animal experiments, epidemiological, and other studies consistently demonstrate an independent, strong,

positive, and graded relationship between high total cholesterol and elevated LDL cholesterol and the risk of CHD development. Recently, several clinical trials consistently showed that LDL-lowering therapy reduces the total mortality, CHD-related mortality, major coronary events, and coronary artery procedures in persons with established CHD and persons with CHD risk equivalent (i.e., diabetes). Based on the results of prospective epidemiological and clinical trials with both angiographic and clinical end points, an LDL cholesterol level of $< 100\,mg\,dl^{-1}$ is set as the goal of therapy in secondary prevention. Two basic components of LDL-lowering therapy are 'therapeutic life changes' (Table 2) and drug therapy.

Therapeutic Life Changes (TLC) The Third Report of the National Cholesterol Education Program (NCEP) Expert Panel, USA, 2001, recommends a multifactoral life style approach that includes: (1) reduction of saturated fat intakes (< 7% of total calories) and cholesterol (< 200 mg per day), (2) consumption of plant sterols (2 g per day) and soluble fiber (10–25 g per day), (3) weight reduction, and (4) increased physical activity.

Drug Therapy In order to attain the goal of LDL cholesterol levels of $< 100\,mg\,dl^{-1}$, many persons with CHD and CHD risk equivalents will need LDL cholesterol-lowering drug therapy in addition to TLC. Low-density lipoprotein cholesterol should be measured on admission or within 24 h in order to decide the need for drug treatment. Currently, four major classes of drugs are widely used to lower LDL cholesterol effectively: hepatic hydroxymethylglutaryl coenzyme A (HMG CoA) reductase inhibitors (statins), bile acid-binding resins, fibric acid derivatives, and nicotinic acid. Recently, many comprehensive clinical trials with statins have robustly documented that this class of drugs is the most effective in lowering LDL cholesterol from angiographical and clinical end points. Statins also have a better safety profile compared with other classes of drugs. Therefore, at present, the statins are the first line of drugs used to lower total and LDL cholesterol levels. In some special conditions, like familial hypercholesterolemia, a combination of drugs (statin and resin or statin, resin, nicotinic acid) may be used.

Blood Pressure

A large number of epidemiological studies have demonstrated that elevated arterial blood pressure is a risk factor for CHD. The goal for blood pressure reduction is to maintain systolic blood pressure (SBP) < 140 mmHg and diastolic blood pressure (DBP) < 90 mmHg. The goal can be achieved by nonpharmacological treatment (lifestyle modification) alone or in combination with pharmacological therapy.

Table 2 Components of therapeutic life changes[a]

Weight reduction	Balance energy intake and expenditure to maintain a healthy weight (BMI 18.5–24.9)
Increased physical activity	30–60 min aerobic exercise most days of the week
Healthy diet	
Saturated fat	< 7% of total calories
Polyunsaturated fat	10% of total calories
Monounsaturated fat	20% of total calories
Total fat	25–35% of total calories
Carbohydrate	50–60% of total calories
Fiber	20–30 g per day
Protein	~ 15% of total calories
Cholesterol	< 200 mg per day

[a]Adapted from the Third Report of the National Cholesterol Education Program (NCEP), USA, 2001.
BMI, body mass index.

Lifestyle modifications Several randomized clinical trials have evaluated the effectiveness of lifestyle interventions on managing mildly elevated blood pressure in a cost-effective way. The essential features of lifestyle modifications are to: (1) maintain a healthy weight or reduction of excess body weight based on BMI; (2) achieve a moderate level of physical fitness by 30–45 min of aerobic physical activity in most days of the week; (3) reduce salt (sodium) intake moderately (100 mmol per day) and not to exceed total salt intake of 6 g per day (however, results from the meta-analysis of randomized clinical trials presently do not recommend a restriction of salt intake for the normotensive population); (4) increase the intakes of potassium (60–90 mmol per day) preferably from fruits and vegetables; and (5) limit alcohol consumption to no more than two standard drinks for men and one for women per day. Table 3 demonstrates the elements of lifestyle modification or nonpharmacological treatment for elevated blood pressure.

Pharmacological treatment Several large-scale, multicenter, randomized, controlled trials have credibly demonstrated that antihypertensive medications lower CHD-related morbidity and mortality and all-cause mortality. The decision to commence pharmacological treatment relies on the degree of blood pressure elevation, presence of target organ damage (e.g., heart disease, nephropathy, peripheral arterial disease, and retinopathy), presence of clinical cardiovascular disease and other risk factors, or conditions such as diabetes. A general agreement, however, is that an individual with a 'high normal BP' (130–139/85–89 mmHg) and with target organ disease and/or diabetes should be treated with

Table 3 Lifestyle modifications for high blood pressure

Lose weight if overweight or obese
Increase aerobic physical activity 30–45 min for most days of the week
Stop smoking completely
Limit sodium intake to 6 g or less per day
Maintain adequate intake of dietary potassium
Limit alcohol intake to one or two drinks per day

antihypertensive medication after a trial of lifestyle modification. Drug treatment begins with monotherapy, low doses followed by slow titration to achieve 24-h control with once-daily medication depending on the patient's age, needs, and response, as well as economic condition. The most commonly used antihypertensive agents: thiazide diuretics in low dosage, β-blockers (especially if angina is present), angiotensin-converting enzymes (ACE) inhibitors, calcium antagonists, α-blockers, and angiotensin II receptor blockers. Most experts prefer low-dose thiazide diuretics or β-blockers as a first line of antihypertensive agents, unless contraindicated. Other preferred choices for initial therapy are: β-blockers for hypertensives with uncomplicated myocardial infarction; ACE inhibitors for individuals with CHD and decreased ejection fraction, with left ventricular function, diabetes with proteinuria; and thiazide, β-blockers, or calcium antagonist (calcium channel blocker) for isolated systolic hypertension. Isolated systolic hypertension is a CHD risk factor, especially for the elderly, and should be managed properly.

The antihypertensive agents are not free of adverse effects. However, the use of combinations of low doses of two agents from different classes have been shown to potentiate the effect of other agents without incurring any adverse effects.

Blood Glucose

Data from large numbers of epidemiological and (including the Framingham Study) pathological studies document hyperglycemia as an independent risk factor for CHD. Persons with both type 1 and type 2 diabetes and diabetic women are at increased risk for developing CHD than nondiabetics and diabetic men, respectively. The underlying mechanisms for this remain to be answered. In addition to hyperglycemia, diabetics frequently have other classical risk factors for CHD – hypertension, lack of physical activity, low levels of HDL cholesterol, and hypertriglyceridemia– that intensify the risk of developing CHD events.

The effects of glycemic control among diabetics and alteration in CHD risk have not been appraised conclusively. Results from randomized controlled trials show that prudent insulin therapy retards the occurrence of microvascular events and a nonsignificant reduction of macrovascular events in patients with type 1 diabetes. To date, no clinical or epidemiological evidence of the role of blood glucose control in reducing CHD events significantly in patients with type 2 diabetes has been documented. However, there is general agreement that control of blood glucose (hemoglobin $A_{1c} < 7.0\%$) among type 2 diabetics may minimize CHD complications. In order to achieve an acceptable level of hemoglobin A_{1c}, type 2 diabetics often need professional dietary advice (reducing total calorie and fat intake), reduction of overweight or obesity (5–9 kg irrespective of starting weight), and increased level of physical activity as a first line of management. Frequent aerobic exercise (at least 30 min most days of the week) also facilitates blood glucose control and weight control. Oral hypoglycemic agents come as a second line of therapy when a desirable hemoglobin A_{1c} cannot be achieved with lifestyle modification alone.

Table 4 Guidelines to reduce coronary heart disease in patients with diabetes mellitus

Risk factors	*Recommendations*
Smoking	Complete cessation
Physical activity	At least 30 min three or four times per week
Weight reduction	5–9 kg irrespective of starting weight
Hemoglobin A_{1c}	Target: $< 7\%$
Fasting blood glucose	Target: 80–120 mg dl^{-1}
LDL cholesterol	Target: < 100 mg dl^{-1}
Calorie restriction	250–500 kcal less than average daily intake
Blood pressure	Target: $< 130/85$ mmHg

Control of blood glucose also maintains normal plasma lipid levels in patients with type 1 diabetes without nephropathy. Diabetic dyslipidemia (elevated triglycerides, low HDL cholesterol), which is more pronounced among type 2 diabetics, may be corrected by normalizing blood glucose using oral hypoglycemic agents. The primary goal of LDL cholesterol < 100 mg dl^{-1} can be achieved by moderate caloric restriction (250–500 cal less than the average daily intake), $\leq 30\%$ fat, $< 7\%$ saturated fat, and < 300 mg of cholesterol per day. Cholesterol-lowering therapy is recommended if dietary modification fails. The primary goal for blood pressure in diabetics is to maintain blood pressure $< 130/85$ mmHg. Moderate weight loss has also been shown to reduce dyslipidemia and hypertension among diabetics. Smoking cessation is obligatory. Guidelines to reduce CHD for diabetics are shown in Table 4.

Metabolic Syndrome

There is mounting recognition that many persons have a collection of multiple major risk factors and

emerging risk factors for CHD; a cluster of these conditions is known as a metabolic syndrome characterized by abdominal obesity, 'lipid triad' (elevated serum triglycerides, low HDL cholesterol, and high LDL cholesterol) hypertension, insulin resistance, and other thrombogenic risk factors. Primary prevention is mainly focused on reducing body weight through diet and by increasing physical activity. Dietary modification and physical activity also effectively normalize dyslipidemia.

Prophylactic Therapies

To prevent the aforementioned classical risk factors and other thrombogenic factors that play pivotal roles in the CHD events, a great deal of emphasis is placed using several prophylactic drug therapies. Likewise, increased consumption of polyunsaturated fatty acids (ω-3 and ω-6) may be used as antithrombic agents.

Aspirin Compelling evidence from randomized studies insinuates that a low dose of aspirin or acetylsalicylic acid (between 75 and 325 mg) daily may considerably reduce subsequent myocardial infarction and all-cause mortality among patients with postmyocardial infarction. With regard to primary prevention, the use of aspirin and the balance between benefits and hazards is not lucid. However, a recent meta-analysis has suggested that aspirin may be used as a primary prevention agent but requires formal accurate estimation of absolute CHD event risk. A maintenance dose of 75 mg of aspirin is recommended as a secondary prevention for all postmyocardial infarctive patients if not contraindicated.

β-blockers Results from the meta-analysis indicate that β-blockers substantially decrease all-cause mortality in patients following myocardial infarction. Therefore, like aspirin therapy, β-blockers should be reckoned for patients following myocardial infarction if not contraindicated.

ACE inhibitors ACE inhibitors significantly reduce all-cause mortality and the risk of progression of heart failure among patients following myocardial infarction and with chronic left ventricular systolic dysfunction.

Statins Although TLC is considered as the basis of prevention to lower the high total cholesterol and elevated LDL cholesterol, recently, several trials with statins have documented unambiguously that statins may be used as a method for primary prevention without any substantial side-effects. Recent pharmacoeconomic analyses indicate that statin therapy may be highly cost-effective in secondary prevention and moderately so in primary prevention. However, the cost-effectiveness of statins as a primary prevention needs to be evaluated from a global perspective.

Estrogen Abundant observational studies strongly and consistently attest that postmenopausal estrogen replacement therapy (ERT) may protect against CHD. However, recent, multicenter, randomized, placebo-controlled secondary prevention trials have negated this finding and documented that ERT may increase the risk of venous thromboembolism in postmenopausal women with CHD. Therefore, ERT is not recommended for secondary prevention of CHD for the postmenopausal women. The use of ERT may be effective as a primary prevention of CHD. None the less, ERT may be appropriate for postmenopausal women to continue when they are already receiving this treatment.

Folic acid A high level of total plasma homocysteine ($> 15\ \mu mol\ l^{-1}$) is considered as a notable risk factor for CHD based on epidemiological studies. High levels of homocysteine may be acquired, because of a deficiency of folic acid, or congenital, because of genetic mutation of a thermolabile variant of the methylenetetrahydrofolate reductase gene. Supplementation with folic acid (0.5–5.0 mg) reliably and effectively reverses the hyperhomocysteinemia.

Screening

First-degree relatives (parents, siblings, and descendants and other close relatives) of the patient suspected of having familial hypercholesterolemia, or other inherited genetic lipid disorder, or individual with premature CHD (men < 55 years and women < 65 years) should be regularly screened for risk factors as they are at increased risk for CHD.

Conclusion

Prevention of coronary heart disease is a global public health challenge. Given the unique and wide array of the determinants of health (access to quality healthcare, health policies and interventions, physical and social environments, and individual behavior and biology) in the different geographic areas of the world, the orderliness of preventive care for CHD will vary from one country to another. Therefore, it would not be pragmatic to define the aforementioned CHD prevention as a sole model; rather, the universal standards of prevention should be ensued and exercised. The implementation of these recommendations and emerging scientific knowledge in view of CHD prevention should be incorporated in a person's lifestyle as well as in a healthcare provider's professional care. In the near future, the Human Genome Project

will also be able to explicate the genetic factors that predispose to CHD.

CORROSION CHEMISTRY

P Marsal, Thionville, France

Background

For most people, the word 'corrosion' carries the image of rust specific to iron-containing metals, surmising that only iron is subject to this phenomenon. In fact, corrosion is the general term for the damage and destruction of most man-made metallic materials. This destructive force of corrosion has always existed but has grown in importance only in the modern era due to the advancement of civilization and technology.

Corrosion may be considered as the deterioration of metals and alloys made by humans, which tend to return to their original state; thus, 'rust' is the natural state of iron, as steel is obtained from iron oxides

found in the earth's crust. The same can be applied to many metals (such as aluminum, zinc, copper, and so on) which are unstable.

Thus, corrosion is an unavoidable problem, and the most important aim is to reduce its occurrence as much as possible. Annual damage due to corrosion in the world is very important. Every domain of industry is affected, including the food industry.

How Corrosion Starts

Prior to corrosion, a disparity or a heterogeneity can always be found, either physical or chemical. The most conspicuous physical disparity is obtained by the contact of two different metals (e.g., tinplate, galvanized steel) present in the same solution (e.g., salt water). Thereby, an electrochemical cell is formed.

Chemical heterogeneity may be represented by differences of ion concentration near identical electrodes or by the Evans cell, which results from differential aeration. The case of a salt water drop on a ferrous material is well known (see **Figure 4**). The anodic site (i.e., the area of corrosion) is always at the center of the drop where there is an oxygen deficit relative to the peripheral zone where aeration (and thus oxygen) is more extensive than in the center of the drop.

Microscopic disparities can also be found; there is no practical industrial process which yields metals with an absolutely homogenous surface, in the strict physical sense: a touch of the metal surface with the hand or simple machining with any tool may be sufficient to damage the surface. A cold-worked zone becomes less 'noble' that is more easily corroded than the surrounding zones as the atoms found in stressed crystals tend more easily to leave the metallic crystal lattice. The various chemical treatments sustained by the metallic material are other sources of heterogeneity.

Electrochemical Basis of Corrosion

A study of corrosion phenomena at a molecular level shows an electron exchange between donating and accepting sites. This is a reduction–oxidation or 'redox' reaction: the oxidizing part (which acts as a cathode) is reduced through electron capture, while electrons are donated by the reducing material (which acts as an anode), which becomes oxidized (**Figure 1**).

Some metal atoms lose electrons to form ions much more easily than others, depending on how strongly the metal's positive ion attracts electrons, and this depends on the nature of the metal. Reactive metals, such as sodium, are those that ionize very easily, whereas unreactive metals, such as platinum, are those that ionize only with difficulty.

- sodium atoms ionize very easily;
- zinc atoms ionize easily;
- iron atoms ionize fairly easily;
- copper atoms ionize with some difficulty;
- gold atoms ionize with great difficulty;
- platinum atoms ionize hardly at all.

Let us take an example: a bar of iron coupled to a bar of copper. A bar of iron builds up a greater concentration of electrons than a bar of copper when dipped in water. In the iron, the electrons are crowded more closely together and so repel each other more strongly. That is, the 'electron pressure' in the iron is greater than in the copper.

The electric potential is more negative (lower) for iron than for copper. (**Figure 2**). What can get the electrons flowing? Something is needed which consumes excess electrons and prevents them from accumulating in the copper bar. Hydrogen ions can do the job. Positive hydrogen ions, short of one electron, are strongly attracted to electrons and combine with them to form neutral hydrogen atoms. In acid water, they are plentiful. At the iron bar, ions continue to leave the surface and pass into the water, and the iron bar starts to corrode. The electrons released by the ionized iron atoms flow through the connecting wire to the copper bar and combine with the hydrogen ions to form gaseous hydrogen. The copper bar cannot corrode because it is protected by an excess of electrons coming from the corrosion of iron. The cathodic protection of iron (in the form of steel) by sacrificial anode (soluble anode) is usually obtained through a coating; galvanized steel is an important industrial example (**Figure 3**). Galvanized steel (zinc plating) on steel dustbins, iron rails, etc. is a very effective form of sacrificial anode protection. It works even when large areas of zinc have gone. As long as some zinc is left in contact with iron, the zinc corodes preferentially. Mildly acidic rain water is usually the electrolyte. The protection life through a metallic coating is roughly proportional to its thickness, as it dissolves progressively to protect base metal. Rust formation, too, is driven by electron exchange between an electron donor site and an electron acceptor site (in this case, oxygen; see **Figure 4**).

Moreover, electron exchange may take place in plain metal when some heterogeneities (physical or

chemical) are present in the metal structure. Microcells form and may cause in pitting (Figure 5).

Parameters Driving Electron Transfer

The most important factors governing electron transfer are potential and easiness.

The potential factor is governed by the electron affinity difference between the two transferring elements. The greater the difference, the faster the corrosion may develop. The potential factor is often called the dissolution potential. Consider, for example, a metal M in a solution containing M^+ ions. The potential of the metal is given by the Nernst formula

$$E = E_0 + \frac{RT}{nF}\log_e(a_{M^+}), \qquad (1)$$

where E_0 is a constant factor, independent of the solution concentration, a_{M^+} is the activity of the M^+ ions in the solution (activity is proportional to concentration), R is the gas constant ($8.31\,J\,K^{-1}\,mol^{-1}$), n is the number of moles of electrons driven by the cell potential E, F is the Faraday (96 500 coulombs), and T is the absolute temperature. The Nernst formula is commonly used as

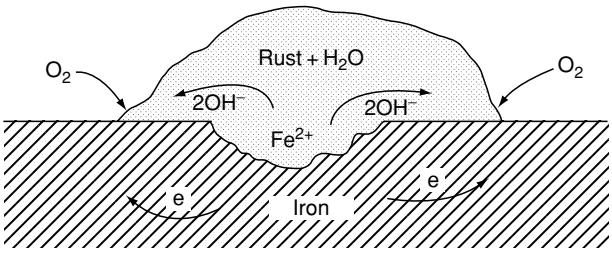

Figure 4 Formation of rust through the formation of a differential aeration (Evans) cell. Reproduced from Corrosion Chemistry, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

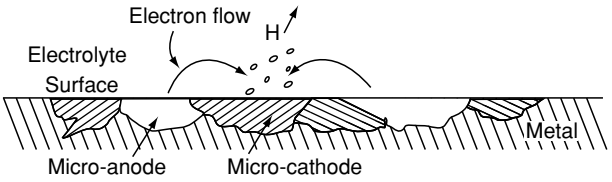

Figure 5 Microelectrochemical cell. Reproduced from Corrosion Chemistry, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

$$E = E_0 + \frac{0.06}{n}\log_{10}(a_{M^+}) \qquad (2)$$

for convenience. From measurements of differences in potential between a metal and a reference electrode, a series of dissolution voltages can be produced (Table 1). Elements that have a greater tendency than hydrogen to lose electrons are described as electropositive, while those that gain electrons are called electronegative, e.g., sodium is more electropositive than aluminum. From this series, it can be seen which of two metals, if placed in contact with each other, will become corroded. For example, in this series, zinc has a much greater dissolution voltage than iron; thus, if a piece of iron is coated with zinc and placed in water, the iron will not rust if the zinc coating is scratched, because zinc loses electrons in preference to iron. This is the principle behind the galvanizing of steel.

The easiness factor reflects any factors affecting the reaction arising from the conditions of the electrolytic media where the electron transfer takes place. If the electron donor (the anodic site) does not easily let electrons loose, the corrosion is said to be donor controlled, and there is an anodic overvoltage. In contrast, the corrosion is controlled by the electron acceptor if it cannot freely accept the electrons; a cathodic overpotential then exists.

Any corrosion cell can be studied through intensity voltage curves or polarization plots. In the laboratory,

special devices quantitatively measure the ease of electron transfer from an anodic site to a cathodic state. Evans diagrams are mostly favored as they are very simple; three examples are shown in Figure 6.

The ideal situation would be a corrosion battery with the lowest possible activity as a result of strong anodic and cathodic overvoltages.

The role of corrosion inhibitors is to increase the overvoltage on the anode, on the cathode, or on both electrodes simultaneously. They polarize the cell, thus reducing its electron flow, often through the formation of an insoluble compound on the surface of one electrode. The corrosion inhibitor behavior (especially the anodic inhibitors) is sometimes unpredictable as most of the compounds used, depending on their concentration and other environmental factors, may have a role as either an accelerator or inhibitor of corrosion. A corrosion accelerator is the reverse of an inhibitor. Every electroactive compound in the electrolyte which is able either to complex the positive ions coming from the anode or to use the electrons arriving at the cathode, either directly or through nascent hydrogen formation, must be considered as a corrosion accelerator.

Table 1 The electrochemical series

Metal	*Electrode reaction*	*Standard electrode potential (V)*
(Active end)		
Sodium	$Na \rightarrow Na^{+} + e$	− 2.712
Magnesium	$Mg \rightarrow Mg^{2+} + 2e$	− 2.34
Beryllium	$Be \rightarrow Be^{2+} + 2e$	− 1.70
Aluminum	$Al \rightarrow Al^{3+} + 3e$	− 1.67
Manganese	$Mn \rightarrow Mn^{2+} + 2e$	− 1.05
Zinc	$Zn \rightarrow Zn^{2+} + 2e$	− 0.762
Chromium	$Cr \rightarrow Cr^{3+} + 3e$	− 0.71
Iron	$Fe \rightarrow Fe^{3+} + 3e$	− 0.44
Cadmium	$Cd \rightarrow Cd^{2+} + 2e$	− 0.402
Cobalt	$Co \rightarrow Co^{2+} + 2e$	− 0.277
Nickel	$Ni \rightarrow Ni^{2+} + 2e$	− 0.250
Tin	$Sn \rightarrow Sn^{2+} + 2e$	− 0.136
Lead	$Pb \rightarrow Pb^{2+} + 2e$	− 0.126
Hydrogen	$H_2 \rightarrow 2H^{+} + 2e$	0.000 (reference)
Copper	$Cu \rightarrow Cu^{2+} + 2e$	+ 0.345
	$Cu \rightarrow Cu^{+} + e$	+ 0.522
Silver	$Ag \rightarrow Ag^{+} + e$	+ 0.800
Platinum	$Pt \rightarrow Pt^{2+} + 2e$	+ 1.2
Gold	$Au \rightarrow Au^{3+} + 3e$	+ 1.42
(Noble end)		

Appearance of Corrosion

Macroscopically, corrosion can appear in the following ways (Figure 7):

- Generalized or uniform corrosion, which appears at the same speed on the whole surface of the metal.
- Pitting corrosion, which appears on localized sites, e.g., at the interface between the metal and an inclusion, on the breaks of a passivation film or coatings. Current density is high in the vicinity of the defect as the anode is small, while the cathode is very large.
- Crevice corrosion, which appears in cracks mainly on stainless steels and under metallic coatings.
- Intergranular corrosion, which appears only on intergranular joints.
- Intragranular corrosion: arborescent corrosion cracks which appear in metallic crystals. Stress often initiates this type of corrosion.

Corrosion Reactions in the Food Industry

Most foodstuffs are in aqueous solution, they are thus conductors and, to some extent, active electrolytes.

Metals used in the food industry are found chiefly in two separate areas:

- metallic cans used for preservation of foodstuffs:

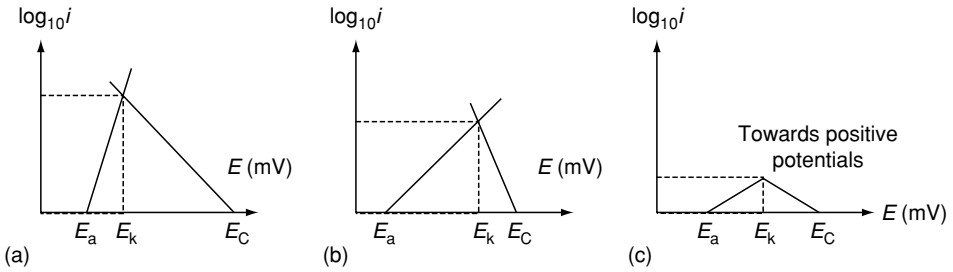

Figure 6 (a) Low anodic overvoltage, high cathodic overvoltage; the galvanic couple is under cathodic control. (b) High anodic overvoltage, low cathodic overvoltage; the galvanic couple is under anodic control. (c) High anodic and cathodic overvoltage; the galvanic couple is under mixed control. $\log_{10} i$, $\log_{10}$ of the corrosion current (or electrons), E_a, from the equilibrium potential: anodic polarization or overvoltage on the electrode supplying the electrons; E_k, mixed and common potential of both; E_c, from the equilibrium potential: cathodic polarization or overvoltage on the electrode capturing the electrons. Reproduced from Corrosion Chemistry, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

- processing equipment and storage vessels – aluminum alloys and stainless steels are most widely used for this application.

Corrosion of Metal Cans

Worldwide, over 200 billion cans are used every year to preserve and protect a very wide range of foods. Preservation of foodstuffs in closed cans by heat was proposed by the Frenchman Nicolas Appert at the beginning of the nineteenth century. A few years later, the first metallic cans were produced in England from tinplate, a material made from the tin/iron couple used since the Middle Ages for kitchenware. The preserved food industry developed most rapidly in the USA.

The shelf-life of cans should be several years, that is if the rate of corrosion is kept as low as possible. The metal canning of foodstuffs makes use of two base materials:

- Steel coated on both sides with a layer of tin of varying but uniform thickness (0.4 – 1.6 μm). For some 20 years, tin has been replaced, from time to time, by a layer of metallic, oxidized chromium not thicker than 0.015 μm. This composite is usually called 'tin-free steel.'
- Aluminum-based alloys, which have only been used extensively since World War II.

Tinplate is a very asymmetric material; the behavior of the tin/iron cell is shown schematically in Figure 8. Tin in the presence of most foodstuffs behaves as a sacrificial anode, and steel is thus cathodically protected. The anodic behavior of tin is due to the formation of many complexes with organic acids and phenolic compounds (tannins) found in fruits and vegetables. The uncomplexed fraction of tin in solution or in the foodstuff is very low. Following the Nernst equation, tin is more electronegative than it appears from the electrochemical series. (*See* **Tin**.)

Tinplate producers sell about 15 million tonnes per year, two-thirds of which is used for foodstuff canning. Tinplate is not a single product: many types can be manufactured, depending on the quality of the steel, the thickness of the tin coating and sometimes the quality of the lacquer.

Pure tin exhibits good resistance to the acid medium of foodstuffs without oxidizing agents. This corrosion is considered as normal. It even has a beneficial effect on the retention of several organoleptic qualities of foodstuffs. The most important corrosion accelerators (that is, electron acceptors) which may be found in foods are oxygen (air), sulfur dioxide (preservative), sulfur (pesticide), nitrates (water, fruit, vegetables) and trimethylamine oxide (fish). Farming techniques

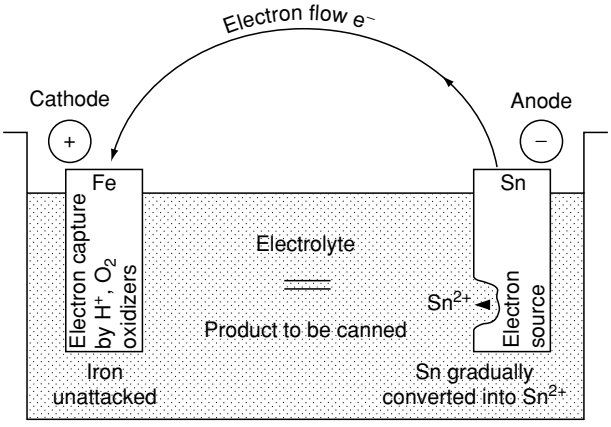

Figure 8 Schematic diagram of a tin/iron cell. Reproduced from Corrosion Chemistry, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

are always changing, and have an influence on the chemical composition of foodstuffs. Corrosion problems have multiplied during the last 20 years as a result of, for example, fast detinning by nitrates, which is even faster as the pH is lowered, and the preferential dissolution of iron due to the presence of pesticide residues such as dithiocarbamates. Contents of up to 40 mg per kilogram of foodstuff, which have no adverse effect on the consumer's health may, in some cases, lead to significant dissolution of tin through corrosion. Similarly, dithiocarbamate residues (a few milligrams per kilogram) are sufficient to invert the tin/iron cell and induce corrosion of the steel. When these additional corrosion risks appear, organic coatings inside the can are needed. For this purpose, lacquers (macromolecular compounds or high polymers) are used. They are insoluble and inert in aqueous media. On account of the nature of the foodstuffs and the various mechanical stresses these lacquers have to withstand, several different types are used. These are characterized either by their barrier behavior or by their degree of flexibility: oleoresinous, organosols, epoxyphenolics, epoxyesters, epoxyurea, and so on are commonly used. These organic films are deposited either on the flat sheet or after can manufacture. In both cases, they are cured thermally in an oven, usually at 200 °C for 10–15 min. Their thickness ranges between 5 and 15 μm, depending on the requirements for preservation of the can and/or the foodstuff. They must also withstand sterilization temperatures (125–130 °C).

Tin-free steels cannot be used alone as they are much more sensitive to acid corrosion, and an organic protective coating is thus essential.

Aluminum is widely used in the food industry, either as a canning material or in various equipment for preparation, storage, and transport of foodstuffs. For metallic canning, it is used much less than steel-based materials: only 2.5 million tonnes per year. In the USA, about 2 million tonnes per year are used due to the large market for beverage cans (beer, soft drinks). In foodstuff cans, aluminum is always used as an alloy (with magnesium or manganese), the exact composition depending on the required mechanical properties needed: for aerosol cans, 99.5% aluminum is used, and for collapsible tubes 99.7%. Aluminum is also used in composite packaging materials associated with polymer films (polyethylene, polypropylene, polyester, Pet, etc.). Theoretically, aluminum is a very passive metal as it can be easily covered with an alumina film (hydrated aluminum oxide). But being an amphoteric metal, it is still highly sensitive to corrosion in acid media (aluminum salts) or alkaline media (aluminates). Pure aluminum is subject to all the corrosion forms mentioned above (uniform, pitting, stress, inter- and intracrystal, galvanic). For this reason, aluminum is often chemically or electrochemically passivated (anodization or chroming) in sulfuric media. The surface treatments greatly improve the adhesion of organic coatings (or lacquers) always used for internal protection of metallic cans to achieve chemical inertness over several years. Epoxyphenolic, vinyl organosols or polyesters are usually used, in one or two layers, as the situation requires. Corrosion of aluminum cans is very rare with such protection. (*See* **Aluminum (Aluminium)**: Properties and Determination; Toxicology.)

Whether the can is in tinplate or aluminum, beer can only be stored in totally inert cans as it is extremely sensitive to contamination by iron or aluminum, resulting in cloudiness and taints.

Low density, high thermal conductivity, and low sensitivity to atmospheric corrosion are the three main specific advantages of aluminum over steel for cans.

Equipment Corrosion

Many aluminum alloys are still used in tanks and containers of all kinds (jars, cans, trolleys, tables, and so on). The meat, fish, milk, cheese, pastry, and confectionery industries all use such equipment. However, in the modern food industry, stainless steels are now more commonly used on account of their good mechanical properties and robustness to frequent cleaning. Similarly, glass and porcelain are now more commonly being used.

There are two main families of stainless steel which possess ferritic and austenitic structures. The first is mostly chromium and iron, while the second contains additional nickel. In both families, some molybdenum may be added to improve corrosion resistance. To prevent corrosion of welded zones, it is necessary

to reduce the carbon content of austenitic steels or to stabilize them by adding titanium and/or niobium. Corrosion resistance and also cost increase with the amounts of other elements used in alloys. It is thus essential to evaluate, as far as possible, the risks and the corrosion resistance properties of the steels used, to eliminate all technical problems, yet at the same time avoiding high costs of production and maintenance. Stainless steels can withstand different types of localized corrosion: intergranular corrosion, pitting, and cracking. Chloride solutions at high temperatures can be highly aggressive: any cracks in the passive layers may lead to rapid corrosion as they become anodic sites with regard to the remainder of the surface. Depassivation may have a mechanical origin (abrasion, wear), and the metal is then permanently depassivated or 'active.' It must be kept in mind that stainless steels have extensive but not universal corrosion resistance. Every use of stainless steel in corrosive media must be treated as a particular problem. The choice of the material must be made in conjunction with a metallurgist, the equipment builder, and the user in order to consider all aspects of the problem (both economic and technical).

Some food industries experience more corrosion problems than others, such as pork butchers and salt meat producers as a result of chlorine- and salt-containing vapor in plants (from brines).

For a long time, the dairy industry large quantities of austenitic stainless steel (18% chromium, 10% nickel) for tubes, heat exchangers, tanks, centrifugation bowls, etc. New varieties of ferritic steels, containing 17% chromium, a low percentage of carbon and some titanium, are now being successfully introduced for boilers.

Corrosion by Cleaning and Disinfecting Products

To obtain regular production of good-quality foodstuffs it is necessary to clean, disinfect, and descale surfaces in contact with food. The frequency of such treatments varies from one industry to another: two to four times a day in the milk industry to once a year in the sugar industry. These treatments require the use of chemical products, which may themselves exert a considerable corrosive action, generating microcavities which will, as the damage increases, be increasingly difficult to clean. (*See* **Cleaning Procedures in the Factory**: Types of Detergent; **Sanitization**.)

With regard to alkaline cleaning agents, stainless steels withstand corrosion well, while aluminium alloys are very sensitive, although corrosion may be reduced by the addition of silicates.

Corrosion of stainless steels in acidic media varies with the particular acid, pH, and oxidizing potential of the solution. In nitric acid solution, austenitic stainless steels face no generalized corrosion, being naturally autopassive. In some cases, slight pitting of the whole surface can be seen. However, aluminum alloys do not exhibit passivation in nitric acid, but here too, it is possible to reduce corrosion speed by adding organic acids such as malic or citric acids. Cleaning solutions based on sulfuric acid always contain corrosion inhibitors for stainless steels.

Chlorination is frequently used by many food industries, owing to its simultaneous strong and cheap disinfecting and bactericidal properties. Its effect is still not fully understood, but it is known that chlorine is effective between pH 7 and 9. As sodium hypochlorite, its effect is due to nascent oxygen, which is very effective against microbial germs. The problem with the use of chlorine is to determine the level of addition required. Resistance to chlorine varies widely between microbial species which are to be killed. In terms of corrosion, chlorine is a strong oxidizing agent. For metallic cans, chlorination of 0.5–2 mg of free chlorine per liter is sufficient to prevent their recontamination through suction via seams in the cans due to the increasing vacuum level developing inside. Higher chlorine levels may induce corrosion phenomena (detinning and rust on tinplate, pitting on aluminum cans).

With the very high chlorine concentrations (300–1500 $mg\,l^{-1}$) needed for thorough disinfection (in dairies, for example), the risk of pitting and crevice formation on stainless steel is higher as the temperature and contact durations increase. The lower the pH value, the higher the risk. Sometimes, corrosion inhibitors are also needed to improve the chemical inertness of stainless steels.

Iodine containing compounds are considered as having no action on stainless steels but should not be used for cleaning and disinfecting aluminum and aluminum alloys.

Solutions of peracetic acid (300 $mg\,l^{-1}$) made from acetic acid, hydrogen peroxide, and water, which have very good bactericidal properties, may be used at room temperature, for short durations (about 20 min) on austenitic steels and aluminum alloys.

Bacterial corrosion, although uncommon, may appear in some food industries, e.g., in buried tubing. Every material, even metals, may be attacked by microorganisms adhering to surfaces and, through their bioactivity, leading to the, accumulation of acids and dissolved gases. For example, we may quote ferrobacteria and sulfate-reducing bacteria. Ferrobacteria, acting on the anodic site, take their energy from the oxidation of ferrous ions to ferric ions, thus initiating the rapid formation of rust as they continuously modify the equilibrium by simultaneous anodic

and cathodic depolarization. Sulfate-reducing bacteria use hydrogen and induce cathodic depolarization: jelly-like vesicles appear, which are living bacterial colonies.

Ways to Prevent Corrosion

Some common ways of preventing corrosion of metals have already been mentioned:

- Organic coatings with inert macromolecular polymers used for cans and for steel-based equipment in food industry plants.
- When using unprotected metals (aluminum alloys and stainless steels), the following must be considered:
  – avoid as far as possible of the joining two metals;
  – choose the best suitable material;
  – modify aggressive media composition with inhibitors;
  – use cathodic protection by coupling a sacrificial anode metal to the material to be protected. The use of a metal as a sacrificial anode does not suppress corrosion and theoretically should not be used for materials in contact with food (unless the corroding metal is specifically authorized for contact with food (e.g., tinplate).

Regulations upon Materials in Contact with Foodstuffs

Corrosion may cause damage during food processing through steam or cooling fluid conveying tubes (perforations or breaks). Equipment failure as a result of corrosion may disrupt the processing of sensitive foodstuffs. If these are to be processed as soon as possible, significant losses may result.

In addition, certain foodstuffs may pick up certain metals. Although some metals may have no toxic effects, they may alter the organoleptic characteristics of the food. For example, beer can turn cloudy in the presence of even small amounts of iron. Also, iron has a deleterious influence on the color of some fruits and vegetables that are rich in phenolic compounds (tannic compounds). Gray or black complexes may form and change the foodstuff hue. For example, white coffee prepared with milk containing very small amounts of iron can take on a grayish appearance.

Sometimes, the presence of metals may have beneficial effects. For example, tin picked up by a foodstuff from the can may preserve the color of clear fruits and vegetables (such as mushrooms, pears, asparagus, and pineapple), owing to the reducing effect of stannous ions (Sn^{2+}).

Firm regulations are always based on a definite listing: any material or object that is not precisely authorized is forbidden. Some local regulations stipulate limits for global or specific migration levels. These vary from one country to another. On a worldwide basis, the *Codex Alimentarius* is the reference. (*See* **Legislation:** Codex.)

Traces of incompletely rinsed cleaning agents may pollute the foodstuff, although this operation is mandatory. The choice of corrosion inhibitors to be added to the cleaning products must always be done with reference to the list of compounds authorized for cleaning.

CREAM

Contents

Types of Cream

C Towler, P A E Cant and K R Palfreyman, Fonterra Research Centre, Palmerston North, New Zealand

Range of Products and Compositional Data

A variety of creams, with different compositions, functions, and types of packaging, can be obtained for consumption (**Figure 1**). Cream consists of emulsified globules of fat in a skim milk serum. A typical particle size distribution in cream is shown in **Figure 2**. Particles less than 1 μm in diameter represent mainly casein micelles; the fat globules are mostly in the 1–10 μm range. The fat provides flavor, and the emulsion form gives characteristic textural attributes and functional properties. The legal classification of products is generally based on fat content. As each country has different laws regarding the composition of different creams, this is not covered here, but **Table 1** gives typical values for the fat contents of different cream types. Other regulations may cover the heat treatment that might be applied to the cream – untreated, pasteurized, sterilized or ultrahigh temperature (UHT)-treated – as well as the limits on

Figure 1 Consumer creams.

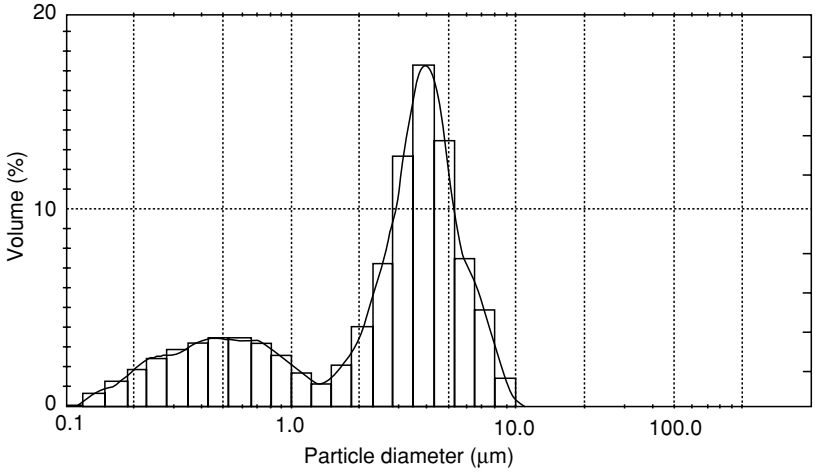

Figure 2 Particle size distribution in cream.

Table 1 Typical fat content of different types of cream

Cream type	*Fat content (%, w/w)*
Clotted	≥ 55
Double	≥ 45
Whipping	≥ 35
Aerosol whipping	≥ 32
In-can-sterilized	≥ 23
Single	≥ 18
Half	12–18

the permitted additives and the normal regulations relating to labelling. Several countries do not allow the sale of unpasteurized cream. Low-fat creams are used as pouring creams for desserts or for addition to coffee or tea. Creams with a higher fat content may be used as whipping creams. Permitted additives vary from country to country. Typical additives are sugar, stabilizers, emulsifiers, and stabilizing salts.

As the fat content increases, the viscosity of the cream increases, and creams with a fat content greater than 60% can be used as spreads. However, the fat content is not the only determining factor in consistency, and spreadable creams can be made with a

lower fat content by reducing the fat globule diameters (homogenization) and adding thickeners. Although cream is generally defined by its fat content, the suspending serum is also important. This serum consists largely of water (approximately 91%) containing lactose (approximately 5%), protein (approximately 2.8% casein and 0.8% whey protein) and other minor constituents such as minerals (0.7%) and vitamins. The levels of fat and milk solids-not-fat (MSNF) in milk are influenced by breed, nutrition of the cow, and lactational or seasonal factors. Another very important component of cream is the membrane that surrounds the fat globules, and this has been the subject of many scientific studies. The major components of this membrane are proteins (41%), phospholipids (27%), neutral glycerides (14%), water (13%), cerebrosides (3%), and cholesterol (2%). Many of the properties of cream are influenced by the membrane and its surface-active components as they affect the stability of the globules and their tendency to agglomerate. Vitamins, minerals, and enzymes are important minor components of the fat and the membrane.

Production and Packaging of Cream

Separation and Standardization

Cream is produced from whole milk by 'separation,' which relies on the density difference between the fat and the aqueous serum. The fat globules will rise in milk according to Stokes' law:

$$v_g = (d^2(\rho_f - \rho_l)g)/18\eta,$$

where v_g = velocity of globule (m s^{-1}); d = diameter of globule (m); ρ_f = density of globule (kg m^{-3}); ρ_l = density of serum (kg m^{-3}); g = acceleration due to gravity (m s^{-2}); η = viscosity of serum (kg m^{-1} s^{-1}). Note that v_g is negative as the equation represents a velocity of settling: $\rho_f < \rho_l$.

The rate of separation can be increased by applying a centrifugal force field, and this provides the basis of the milk separator:

$$v_g = (d^2(\rho_f - \rho_l)r\omega^2)/18\eta,$$

where r = radial distance of the globule from the axis of rotation (m); ω = angular velocity (rad s^{-1}).

The continuous separation of the fat-rich fraction (cream) and the serum (skim milk) is achieved through a stack of rotating disks into which the milk is distributed (Figure 3). Each gap between the disks acts as a zone of separation. Separation takes place in the gaps between the disks, where the denser aqueous phase moves outwards at a greater velocity than the fat globules and is channeled *via* the underside of the disks to the outside and the skim milk outlet. The fat globules concentrate toward the axis of the spinning disks and are channeled out via the upper surface of the disks to the cream outlet. The position of the rising channels is important in maximizing the separation efficiency, and their position on the disks should be in relation to the flows of the two products.

The rotational energy of the streams can be converted to hydrostatic pressure by paring disks (centripetal pumps) and used to pump the products away. Efficiency of separation is measured by the fat content in the skim milk, usually in the form of very small fat

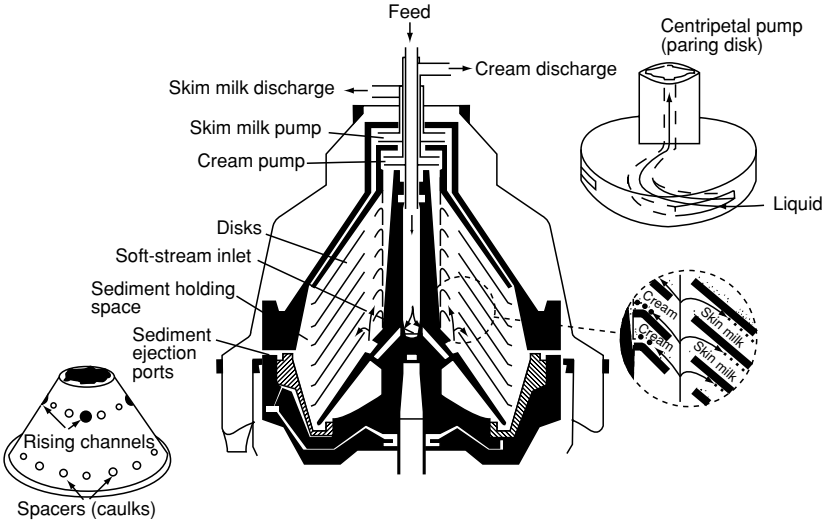

Figure 3 Elements of a milk separator. From Lehmann HR and Zettier K-H (1994) *Separators for the Dairy Industry, Technical Scientific Documentation No. 7*, 4th revised edn. Oelde, Germany: Westfalia Separator AG, with permission.

globules (less than 1 μm). Separation efficiency is influenced by the geometry of the disks (angle, diameter, etc.), their distance apart, and the rotational speed of the bowl. However, there are practical limits to these parameters, and little improvement is made even with very high rotational speeds. A commercial separator would normally work at between 4500 and 6000 rev min^{-1}, depending on size, to give cream with a fat content of approximately 40% and skim milk with a fat content of 0.06%. Incorporation of air markedly reduces the separation efficiency. Hermetic or hydrohermetic sealing systems are used to minimize air incorporation. Milk is fed into a hermetic separator through a hollow drive spindle. The cream and the skim milk are removed by rotating pumps in their respective chambers. The milk attains the rotational speed of the bowl more gradually in the hermetic separator when compared with the paring disk separator where the milk attains the rotational speed of the bowl almost instantaeously. The absence of air and the gentle action of the hermetic separator result in less free fat in the cream than with a paring disk separator.

The fat content of the cream is controlled by the relative flows of the outlet streams. If the flow of cream is restricted, the fat content will increase, but the separation efficiency will decrease if the fat content becomes very high. The separation temperature also influences the separation efficiency due to the effects on the cream viscosity and the relative densities of the fat and the serum. However, higher temperatures may disrupt the membrane, resulting in more free fat in the cream. Phospholipids migrate from the membrane into the serum as the temperature increases; this affects the functional properties of the cream, notably whipping, which may be adversely affected. Optimum separation of milk is normally achieved at 52–55 °C, but some separators are designed to separate milk at around 5 °C, the temperature at which it reaches the processing facility. Such separators have wider gaps between the disks than conventional separators to cope with the more viscous cream. Cold milk separators are always of fully hermetic design. The separation efficiency is not as good as with conventional separators, and there is a greater chance of damaging the fat globule membrane with a high proportion of solid fat in the cream.

Cream is normally standardized continuously by automatic control of the various streams. The fat content of the cream can be monitored through rapid instrumental analysis or by in-line density measurement, and the resultant signals may be used by process logic controllers (PLCs) to adjust the back pressures in the product lines automatically, in order to control the fat contents.

Pasteurization, Sterilization, and Packaging

Cream may be batch-pasteurized at a temperature of 63–65 °C and a holding time of approximately 30 min. Continuous pasteurization in a plate heat exchanger and holding tube is more common. Although 72 °C for 15 s is the legal minimum for milk pasteurization in most countries, the US Food and Drug Administration (FDA) recommends that equivalent heat treatment can be achieved for creams with fat contents >10% by increasing the pasteurization temperature by 3 °C at any given holding time. This recommendation has been incorporated into the New Zealand dairy industry pasteurization standard for cream, with the proviso that the minimum holding time at temperatures greater than 84.7 °C is set at 1 s to give an adequate safety margin. The time/temperature relationship for cream pasteurization at temperatures below 84.7 °C can be expressed as:

$$\log t = (14885/(T + 276.1)) - 41.97,$$

where t = minimum holding time (s); T = minimum temperature (°C).

Temperatures above 80 °C can shorten the shelf-life of the cream, possibly through the activation of bacterial spores. It is important that the cream is handled with care during any processing; positive pumps are recommended to avoid disruption of the fat globule membrane and the release of free fat. Pasteurized cream can be packed in glass, cartons, or plastic pots. Cartons require a water-tight barrier between the cardboard and the cream, and polyethylene is almost universally used, having replaced wax. Pots can be made of polystyrene or polypropylene, the latter being more popular. Covers can be aluminum foil/plastic laminates that are heat-sealed on to the top of the containers with a snap-on cover, or they can be screw-on plastic tops, normally with a tamper-proof plastic ring.

Alternatively, the cream can be in-can-sterilized for extended shelf-life. The cream, which must be of low bacterial count and low acidity, is standardized to a fat content close to 23%, which represents the legal minimum in many countries. Such cream is often called 'reduced cream.' The cream is preheated and homogenized. Homogenization breaks the large fat globules into smaller globules to reduce the tendency for the fat globules to rise (cream), at the same time creating a more stable fat globule membrane as protein is adsorbed from the serum to cover the new fat/serum interface. To obtain a final product without graininess, it may be necessary to add stabilizing salts, such as trisodium citrate, a sodium phosphate, or sodium carbonate, which increase the availability of serum casein due to calcium sequestration and/or

an increase in pH. Other stabilizers, such as carrageenan or sodium alginate, may also be added to enhance the stability and inhibit the separation and syneresis during storage of the processed cream. The cream is filled into lacquered cans that are sealed and sterilized in a suitable retort or continuous sterilizer. Conditions for sterilization are normally 115–120 °C for 10–20 min. Holding times depend on the size of the can and whether agitation is applied during retorting. The high viscosity of the cream reduces heat transfer, and the volume of a can is restricted (<300 ml) as the prolonged heat treatment necessary for larger volumes would increase Maillard browning reactions between protein and lactose, and adversely affect the color and flavor. The heat treatment does have an adverse effect on the stability of the cream, and some agglomeration of fat globules does occur (Figure 4).

Cream may be UHT-sterilized (≥140 °C for ≥2 s) and aseptically packed. The aseptic packaging material includes laminated cartons with plastic (e.g., polyethylene) on the inside, an intermediate aluminum foil barrier, and cardboard on the outside. The cartons may be preformed or formed continuously from a roll of laminate. The material must be first sterilized with hydrogen peroxide and the residual sterilant removed by draining and heating before filling. Pack sizes range from 100 ml to 1 l. Plastic pots may also be used, thermoformed continuously from a sheet before aseptic filling in a laminar filtered airflow and final heat sealing of an aluminum foil/plastic laminate on top of the pot. Pack sizes range from about 10 ml (single serve coffee cream) to 1 l. Lacquered metal cans are used for UHT aerosol cream.

Cream is packed in bulk in plastic pouches or plastic/foil laminate pouches contained in cartons or returnable plastic crates. UHT cream may be packed in bulk using special aseptic filling systems. Volumes up to 1000 l can be packaged, but bulk packaged cream would normally be retailed in packs of 5–25 l.

Cream is susceptible to deterioration because of microbial, enzymatic, and physicochemical changes. Pasteurized cream has a limited shelf-life of a few days and must be kept chilled (< 5 °C). Although microbial deterioration is the major hazard, lipases in the cream release fatty acids, which can result in rancid flavors. The fat globules will tend to rise to the surface and agglomerate unless the cream is homogenized. Homogenization is advantageous for low fat creams to increase the viscosity and inhibit creaming. Storage at a low temperature retards the 'plugging' of nonhomogenized cream as creaming is retarded due to the higher viscosity, and the lower proportion of liquid fat in the globules minimizes agglomeration. Cream in transparent containers should be kept in the dark, as light will cause photo-induced oxidative changes in the milkfat, with consequent deterioration in flavor. The shelf-life of sterilized cream is limited by chemical and physical changes. Spore-forming organisms may be a problem if not killed by preheating. In-can-sterilized cream has a long shelf-life at ambient temperature, although Maillard reactions, which are initiated in the sterilization process, and serum separation (syneresis) may occur during storage. The greatest problem with UHT cream is physical separation of the fat with subsequent agglomeration, although this can be minimized by homogenization. The addition of sodium caseinate or gum stabilizers, such as carrageenan or sodium alginate, will also inhibit the agglomeration of fat globules. Psychrotrophic bacteria in the milk may release heat-resistant proteolytic enzymes, which will result in coagulation and bitter flavors. The shelf-life of UHT cream is limited to some extent by

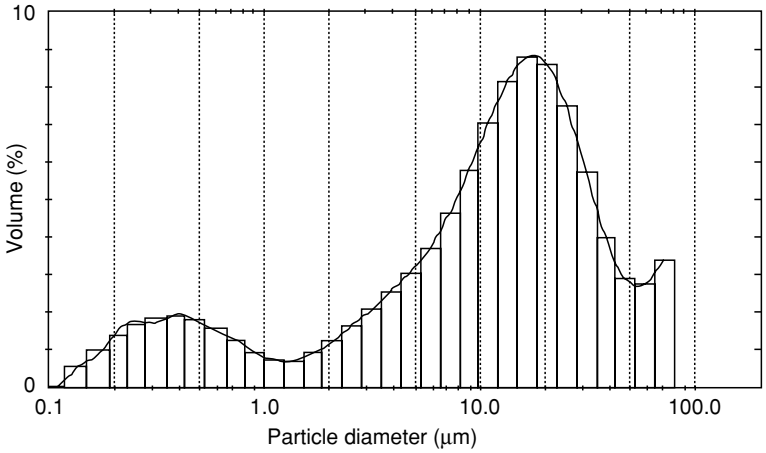

Figure 4 Particle size distribution in an in-can-sterilized cream.

its packaging. Plastics are permeable to air, and consequent oxidation adversely affects the flavor. A layer of aluminum foil in a laminate will prevent oxygen entry, but the flavor will still deteriorate due to non-oxidative reactions.

Freezing of Cream

Freezing of cream will provide protection against microbial deterioration. However, unless the freezing is very rapid, large ice crystals will disrupt the emulsion, resulting in separation on thawing. Bulk frozen cream is used for manufacturing purposes when phase separation is not important or a homogenization step is included. Sometimes, cream is frozen at times of the season when production is high. This cream can be used subsequently for butter production when stocks of fresh cream are insufficient to meet market demands. Bulk frozen cream may be used for the production of cream soups or ice cream.

If cream is frozen rapidly, small ice crystals that do not disrupt the emulsion are formed. One commercial process includes the use of a frozen novelty machine that forms thin rods of frozen cream. Another commercial process uses two continuous stainless steel belts that form a continuous film of frozen cream that breaks into flakes. Alternatively, cryogenic freezing with liquid nitrogen may be used. Frozen cream must be stored at less than −18 °C for a long shelf-life; temperature cycling must be avoided as this will result in the formation of large ice crystals that will damage the fat globule membranes.

Uses of Cream

Cultured (Sour) Cream

Cream can be cultured with suitable organisms that metabolize lactose to lactic acid and also provide other flavoring compounds. The reduction of pH coagulates the protein, which thickens the product and gives a somewhat extended shelf-life when kept under refrigeration. Pasteurized single cream (approximately 18% fat) is normally used as the starting material for culturing. Crème fraîche is a higher fat product that is lightly fermented. Sour cream is used as an ingredient in many savoury foods (e.g., stroganoff, vegetable dishes, dressings, snack dips, etc.).

Coffee Cream

Cream is a favorite 'whitening' agent for coffee as it provides a pleasant texture and flavor to complement the coffee flavor. Long-life coffee creamers can be produced by sterilization (UHT) or by drying. UHT coffee creamers are normally low-fat (10–15%) creams that are given an extensive homogenization

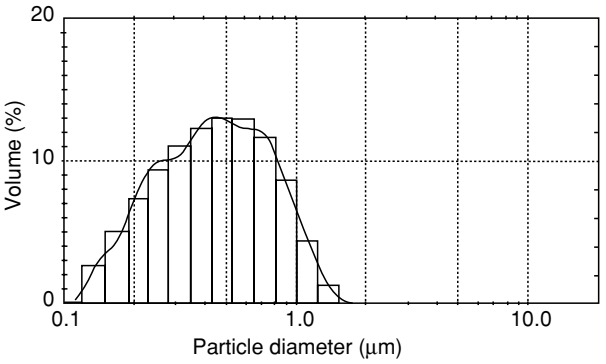

Figure 5 Particle size distribution in a UHT coffee cream.

(Figure 5). The particle size distribution shows a cream with all fat globules less than 2 μm in diameter. The heat and acidity of coffee provide a hostile environment for the cream, and destabilization of the emulsion can result in 'feathering,' with curdled cream forming a characteristic pattern on the surface of the coffee. The presence of calcium in the cream enhances the incidence of feathering, and the presence of calcium-sequestering agents, such as trisodium citrate or sodium phosphates, helps to alleviate this. Feathering may develop with time of storage of the coffee cream as calcium migrates from the serum to the fat globule membrane. Extra protein in the form of sodium caseinate will help to stabilize the cream against feathering. UHT coffee creams are most often packaged in single-serve form-fill-seal containers of about 15 ml.

Cream can be dried to form a powdered coffee creamer. Products available on the market are normally recombined products based on vegetable fat (coffee whiteners).

Whipped Cream

Mechanical agitation of cream will introduce air into the cream as dispersed bubbles. The protein in the cream provides stability for the formation of a foam. The fat globules concentrate at the air/serum interface, where the surface tension is believed to disrupt the fat globule membrane. As agitation continues, the air bubbles become smaller, and the globules interact to form a stable network (Figure 6). The interaction depends on several factors. The fat content has to be sufficiently high (approximately >28%) to give the necessary density of globules at the interface. The membrane around the fat must not be too stable, as some mechanical breakdown is necessary to develop the interaction and 'welding' of the globules. Homogenization has an inhibitory effect on whipping. The temperature and the aging of the cream are important. If the temperature is above 10 °C, excessive

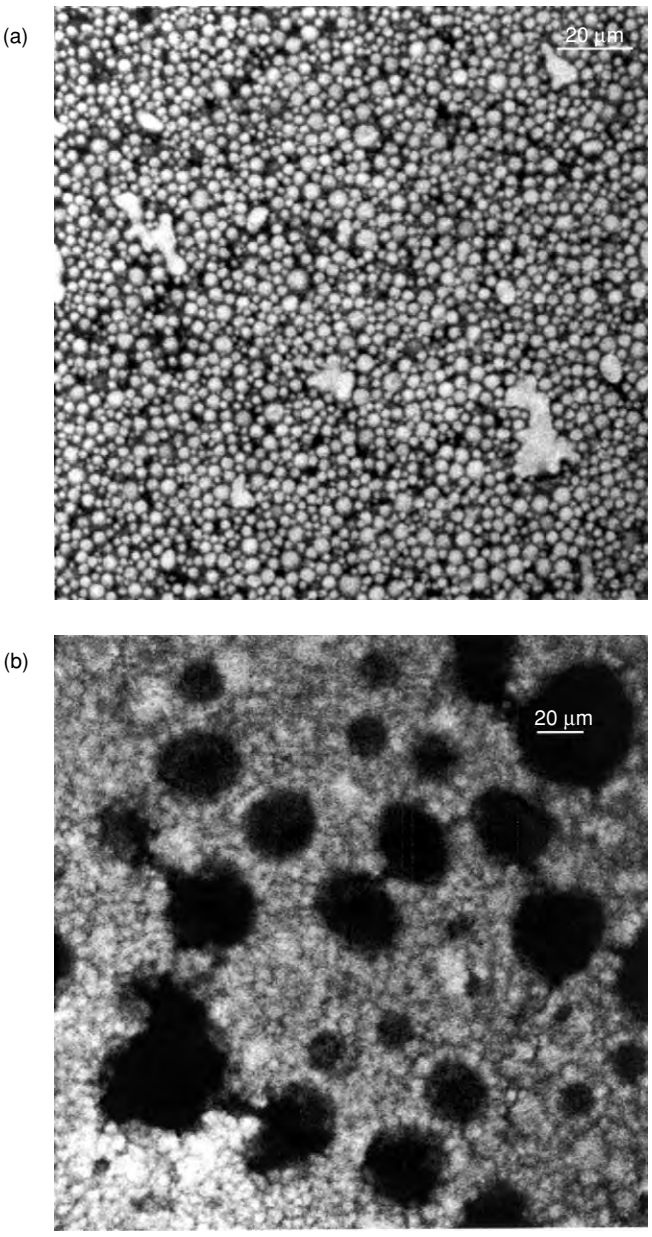

Figure 6 Confocal images of (a) unwhipped cream and (b) whipped cream (dark objects are air cells).

liquid fat will weaken the structure and act as a foam depressant. Cream should be stored refrigerated for at least 12 h before whipping to optimize fat crystallization and membrane destabilization. Long-life whipping cream can be produced by UHT treatment. Some homogenization is necessary to prevent 'creaming' and consequent superficial agglomeration of the cream. The whipping time of UHT cream is thus generally longer than that of normal non-homogenized cream. To give stability during storage, addition of gum stabilizers, such as carrageenan, helps to prevent the association and agglomeration of the fat globules. Whipping properties can be improved by the addition of emulsifiers. Emulsifiers can provide extra surface activity and increase overrun (percentage increase in the volume of the liquid cream when converted to whipped cream). Some emulsifiers (e.g., polysorbates) will increase fat globule interactions during whipping and consequently reduce the whip time and give a stiffer whip. The shelf-life of UHT whipping cream is considerably extended by refrigerated storage. Temperatures $> 25\,^{\circ}C$ and temperature cycling are particularly deleterious to the cream properties. Aerosol cream is packed under pressure with nitrous oxide gas. When the dispenser is activated, the cream is forced out of

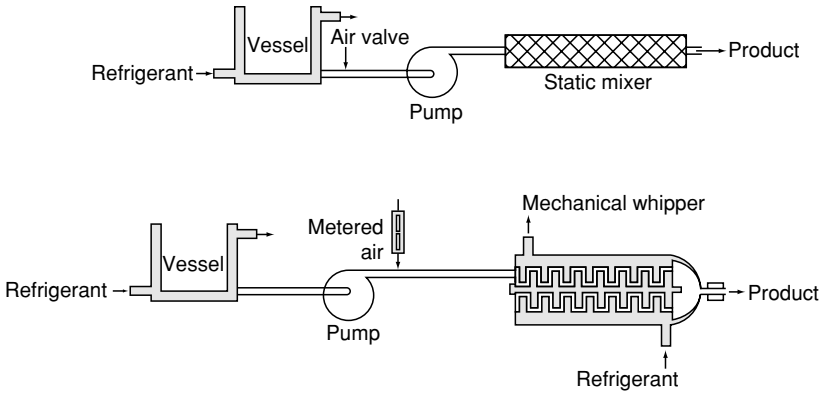

Figure 7 Continuous cream whippers.

the can by gas pressure, and the foam structure is then formed by the expanding gas that was dissolved in the cream. The percentage increase in volume (overrun) of aerosol cream (400–500%) is much greater than that of normal whipped cream (approximately 100%). As a result, the stability of the foamed aerosol cream is not as great as that of normal mechanically whipped cream, but the interaction of the fat globules is still important in providing stability.

The major industrial use of cream is as whipped cream in baking and confectionery to decorate cakes and desserts. Whipped cream can be produced commercially in large batch mixers or in continuous machines (Figure 7).

Control of cream whipping is very important as 'overwhipping' will result in the complete breakdown of the emulsion with 'churning' of the fat and release of free serum. 'Underwhipping' will give a soft foam without adequate structure to hold its shape. As whipped cream has a better freeze–thaw stability than the unwhipped product, it can be incorporated successfully in frozen confections. The addition of stabilizer, such as carrageenan or sodium alginate, will reduce the tendency of the whipped product to synerese.

Cream Liqueurs

Cream liqueurs are popular beverages that use the preservative powers of alcohol for a long shelf-life. Typically, the liqueurs contain 15% fat from the cream, 19% sucrose, and 14% alcohol. Higher-proof products contain 10% fat and 19% alcohol. Emulsification and emulsion stability are provided by sodium caseinate with a fat:caseinate ratio of 1:5, i.e., 3% caseinate in standard liqueurs and 2% caseinate in high-proof liqueurs. Other emulsifiers may be added (e.g., glycerol monostearate (GMS) at 0.34%) to give extra emulsion stability. The most common form of destabilization was found to be calcium-induced aggregation of fat globules, so sodium citrate was introduced into the formula at a level of approximately 0.16% to sequester free calcium in the serum of the liqueur. Some care is required in the use of the citrate as calcium citrate crystals may precipitate from the liqueur if used in excess. The liqueurs are manufactured by dispersing the sodium caseinate and sodium citrate in water, adding the cream and GMS to give a cream base. Ethanol and dissolved sucrose are then added to form a preemulsion that is homogenized to give the final product. The mixing and homogenization are conducted at approximately 55 °C. The ethanol can come from a variety of spirits, and flavors are added to differentiate individual brands of product. Extensive homogenization (e.g., twice at 17.5 MPa and twice at 4 MPa) assists in yielding a stable emulsion. Lack of sufficient homogenization can lead to formation of a 'neck plug' of aggregated fat during storage.

Other Uses of Cream

Cream is the raw material for the production of butter and anhydrous milkfat (AMF). In New Zealand, where cows are pasture-fed, cream for buttermaking is routinely steam-stripped and vacuum-treated during pasteurization. This reduces volatile flavor components from the pasture to desirable levels in the final products.

The Vacreator® (Figure 8) has long been the equipment of choice for cream treatment in New Zealand, but is now being superseded by the Flavourtech® spinning cone column (Figure 9). In both the Flavourtech® and the Vacreator®, steam is injected counter to the flow of cream, and then the vapors and liquid cream are separated under vacuum. The Flavourtech® has a series of fixed and spinning cones that expose the cream to the steam over a large surface area for more effective stripping of the volatile components.

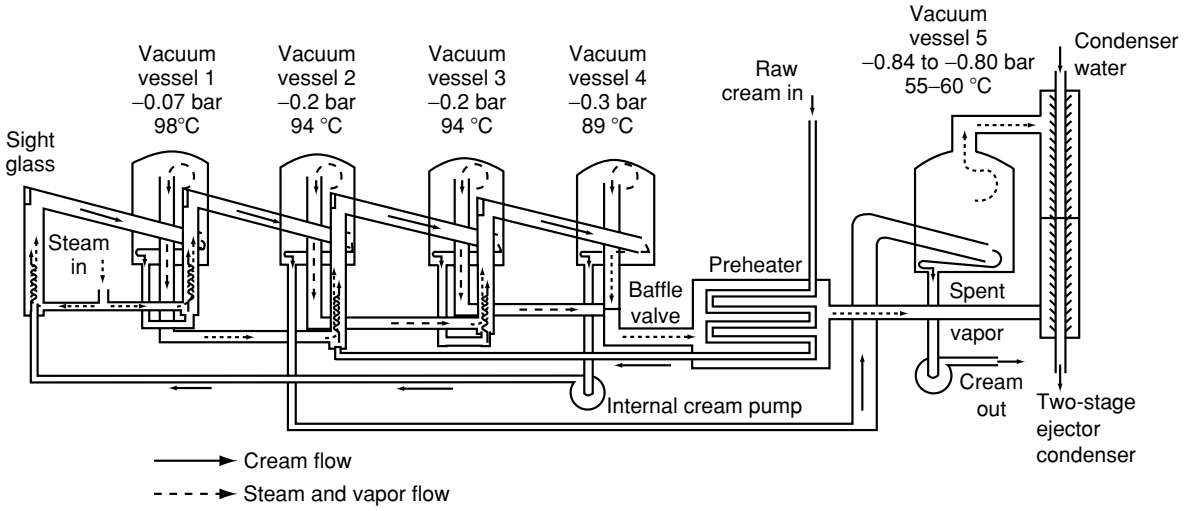

Figure 8 Vacreator®.

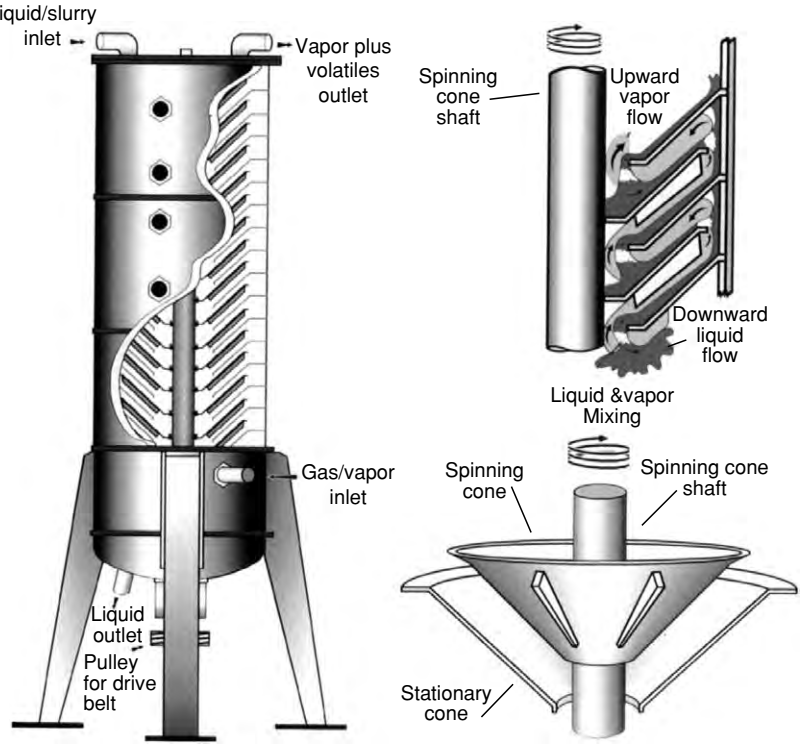

Figure 9 Flavourtech® spinning cone column. From Flavourtech Pty. Ltd., Sydney, Australia, with permission.

Cream can be used as a source of milkfat in foods. It contains more flavor components than butter or AMF. Fresh cream is generally regarded as being the optimum milkfat source for best-quality icecream.

Cream can be dried to produce high-fat powders that may be used as ingredients in foods and may be particularly useful for dry blends (e.g., cake mixes, soup mixes, or icecream powders). The spray drying of cream demands formulations to suit the end use and special driers are required to handle the high-fat product. Cream powders are not produced in large quantities because vegetable-fat-based products are much cheaper and easier to produce. Cream-based powders have the advantage of a superior flavor, but protection against lipid oxidation is required to give the product adequate shelf-life.

Clotted Cream

S Jolley, Otaihanga, Paraparaumu, New Zealand

History

Clotted, or scalded, cream is made principally in the West Country of England, in the counties of Devon, Cornwall, and Somerset. The process dates back a couple of centuries to a time when these counties were a long and difficult journey from the main consumers of milk in the cities, well before the invention of the mechanical cream separator. Clotted cream was made originally on farms rearing and fattening cattle, where it was found that skimmed milk was more easily digested by young calves than rich full-cream milk, and if the remaining cream was heated, it kept longer and had a pleasant flavor.

The predominant cattle breeds in the area at the time, Jersey, Guernsey, Devon, and South Devon, produced milk of a high fat percentage, with large fat globules that rose to the surface in a thick, firm cream layer. Milk was left to stand in shallow setting pans overnight, for up to 24 h, and heated slowly the next day for 2–3 h until the surface became wrinkled but unbroken, and bubbles appeared just below the surface. It is at this stage that the characteristic flavor developed. Originally, the cream was heated on a tripod over the fire in an open hearth and later on a kitchen range.

The pan was then moved to a cool place allowing the cream to cool slowly and form the deep yellow crust while the body of the cream thickened. The cream was then skimmed off using flat perforated skimmers.

The advent of small hand-driven mechanical separators for farm use simplified the whole process. Milk straight from the cow could be run through the separator, the warm milk at about 35 °C being the right temperature for efficient separation, and the cream scalded immediately. The separated cream was often floated on a small amount of skim for scalding on the stove, to avoid scorching the bottom of the cream layer.

At a later stage, scalding was more likely to take place in a piece of equipment like a *bain marie*. The setting pan containing the cream fitted into an aperture on the top of a water bath, allowing the base and sides of the pan to sit in the hot water circulating underneath.

The Product Today – Craft or Science

Clotted cream is still made on many farms in the West Country and on a commercial scale in several creameries, but little is made elsewhere. The area is a

well-known tourist destination, with Devonshire and Cornish clotted cream teas a specialty, famous throughout the world. One or two small manufacturers in New Zealand, Australia, the USA, and Canada cater for their local market.

Although there remain many Channel Island and Devon cattle in the West Country, much of the milk is now produced by Friesians and other breeds of cow the milk of which is whiter, with a lower fat percentage and smaller fat globules. This factor has an effect on both color and texture of the final product, as do the quality of pasture fed and the use of concentrated feeds. For those producing clotted cream all year round, there is the additional complication of seasonal differences in fat composition, requiring adjustments in the time/temperature combinations used in manufacture to achieve a consistent final product.

Clotted cream is a seasonal product, time-consuming and labor-intensive to make, so commercial enterprises are usually privately owned dairies making clotted cream on a small scale and having the capacity to increase production during the season. It is also a luxury product and will never have a very large market share, so expensive research time cannot be justified to improve manufacturing methods. Any developments in manufacture are largely individual to suit the milk supply of the operation, the experience of the manufacturer, and, ultimately, their customers. No two farm or factory operations are the same, and details of the process will vary in each case.

The traditional product has a sweet, nutty flavor, with a golden crust of grainy texture and a body of cream that is thick, smooth, and deep cream in color. Related products are made commercially for the confectionery trade. Apart from its use in the traditional Devonshire or Cornish cream tea, when it is served with scones or splits (light bread rolls) and strawberry jam, clotted cream can be used on raw fruit, particularly strawberries and raspberries; hot and cold desserts; in savory situations such as on quiches and with baked potatoes; and in many dishes such as sauces and curries, where it adds a rich, full flavor all its own. Although limited quantities are sent from the West Country to cities and catering establishments throughout the country, most is sold locally.

Methods of Manufacture

Farmhouse Production

Farmers who sell clotted cream as a lucrative sideline, usually separate the milk to a fat content of 55–60% as it leaves the parlor, using a small-scale centrifugal separator, either electrically or mechanically operated. The cream is poured into large stainless steel trays, usually rectangular in shape, for the heating process. If the cream is for sale to retail outlets, it can be poured directly into retail containers, provided that they are manufactured to withstand the heating process.

Heating is carried out by one of two methods. The following times and temperatures are only guides. Each operator will have to judge by the results until the most suitable combination is achieved.

1. Forced-air convection oven: The trays or retail containers are placed in the oven at 90 °C for 50–60 min. Initial cooling stages can be carried out in the oven by turning off the heat but allowing the fan to continue to run for up to an hour. Containers are then transferred to a cooling room or refrigerator to finish cooling, taking care not to shake the cream and disturb the crust. Some operators move the cream to a cold room or refrigerator immediately after heating, but if the cream is cooled too rapidly, the crust will collapse.
2. Scalding in a *bain marie*-type apparatus circulating hot water: The scalder usually consists of a shallow open-topped water container on a free-standing frame, in which hot water at 90–95 °C is circulated. The stainless steel top can be designed to take different sized trays or tubs for retailing. The trays containing the cream, or racks holding pots, are set into the covering top of the apparatus, so that hot water is in contact with the sides and bases of the containers. The cream is heated to 77–88 °C for 45–50 min. After heating, the trays are transferred to a cool room for cooling.

In either case, the essentials of the process are:

- cream should not be more than 50 mm deep in the container to ensure even heating;
- air must be able to circulate freely above the containers to allow evaporation to form the crust;
- the temperature/time combination must be high enough to kill milk-souring organisms and prevent off-flavors;
- the heating temperature and time must be sufficient to develop the flavor and texture, and form the crust;
- the cream should not be disturbed during processing to allow the crust to form;
- postheating contamination must be avoided;
- cooling must be done slowly to achieve flavor development, even thickening, and avoid the crust collapsing, particularly in retail containers.

The criteria on which to judge the results are:

- a rich, golden-colored crust that is wrinkled but not broken, with a grainy texture when cold;

- the body of cream that is smooth, thick, i.e. of spreadable consistency, but not solid, a deep creamy color, and with no separation of liquid at the bottom of the container;
- a full, rich, creamy flavor that is nutty, sweet, and lightly caramelized;
- a legal minimum fat percentage of 55%.

Commercial Manufacture

Commercial-scale manufacture has adopted and developed the traditional methods by employing modern technology. Milk destined for clotted cream is separated using a centrifugal separator at a temperature ranging from 35 to 40 °C, to a fat content of 55–60%. This fat percentage may have to be adjusted during the season as the composition of the butterfat varies, in order to achieve a consistent viscosity in the final product. Separation at this high fat percentage can result in the loss of fat in the skim if a higher separation temperature is used, which will drastically affect the yield of product. The yield will also be affected by evaporation from the cream surface during scalding. Evaporation is necessary for the formation of a good crust, but some operators may try to restrict evaporation and loss of yield at the expense of the crust.

Most commercial operations pasteurize the cream, many using plate-heat exchangers, but small dairies may still use batch pasteurizers. From the point of view of product safety, this step would seem to be unnecessary as the cream is heated to, and held at, a higher temperature than that required for pasteurization during the scalding or heating process. Also, the shear to which the cream is subjected could affect the setting time and thickness of the finished cream. Some operators compensate for this by adding a small percentage of homogenized cream prior to heating.

Commercial heating of the cream can be carried out in hot air using a convection oven, or by an extension of the hot-water scalding process. Some operators use a mixture of both methods, depending on the container and end result required. Either method can be automated to a limited extent.

Forced air convection ovens (see Figure 1) can be obtained in a range of sizes from bench-top models to large free-standing models, their capacities depending on the size of containers in the batch of cream being processed. They are convenient and safe, as they do not involve the use of very hot water, and steam is not emitted into the room. It is essentially a batch process, although it would be interesting to see if a bakery oven with a moving conveyor would work as well.

Ovens are convenient for heating cream in retail containers. Cream is poured into tubs or trays after separation and placed on to racks or wire mesh shelves. These can be either slotted directly into the oven or fitted into a large mobile unit that can be pushed into a freestanding oven. Heating times can vary from 65 °C for 40–45 min for the 21-g packs for airline catering, to 90 °C for 1 h for 227-g (8-oz.) tubs. The depth of crust formed on the airline portions is limited by their size, and there is a loss of flavor when using the lower heating temperature.

Figure 1 Free-standing hot-air convection oven showing overhead fans and a mobile rack on the left-hand side, which has shelves for retail containers.

A typical water scalding process (see Figure 2) involves running the cream into containers ranging from 113-g (4-oz.) tubs to large trays for catering purposes holding 4.53 kg. The containers fit into trays that are put into the scalding apparatus, as described for the farmhouse method. Water at 95 °C is circulated for up to 70 min, after which time the trays are lifted out for cooling (See Figure 3).

Some operators say they stir the cream for the first 10 min to ensure even heating, and variations in scalder design include gabled covers above the trays to avoid heat loss.

One operator has adopted a continuous method of scalding in which the cream is filled into pans holding 1.5–2.25 kg of cream. The pans are passed through

Figure 2 Large *bain marie*-style scalder, designed with a gabled cover to avoid heat loss.

Figure 3 Commercial operator transferring a tray of cream in retail tubs from the scalder to the cooling room.

the heated water bath on bars that move at a given speed to ensure the required scalding time, usually 1–1.5 h.

A recently formed company, which commenced a commercial clotted cream enterprise in 1998, produces three clotted cream products, using a combination of hot-water scalding, a convection oven and batch heating in a closed, jacketed vat. The company processes 600–750 kg daily, depending on the season and makes about 15 tonnes in the 2-week pre-Christmas period.

The company's traditional clotted cream is produced by hot-water scalding in four batches daily. Container sizes include 113-g, 227-g, 453-g and 906-g tubs, and 1.81-kg and 4.53-kg trays for catering establishments. A convection oven is used for small 21-g airline catering portions, because trays holding large numbers can be put into the oven on racks, making them easier to handle. The industrial-grade product is made in a batch pasteurizer using quite a different process.

Thickened Cream for Confectionery

Confectionery products, such as clotted cream fudge, toffee, and icecream, require a product that can be described as clotted cream but do not need the crust, the flavor, or the texture of true clotted cream.

Cream at 55% fat is homogenized at 1315–1754 gsc, heated to 65 °C for 45 min, then cooled to 30–35 °C when it has a thick blancmange-like consistency. This is poured into block molds and frozen. It is kept frozen until required by the confectionery manufacturer. The confectionery demand is increasing, and this outlet helps to even out seasonal requirements for the traditional product.

Cooling and Packing

To produce a good traditional clotted cream, whichever heating method is used, slow cooling is an important factor in achieving a firm even texture and the typical grainy crust. If the cream is cooled too rapidly by putting it into a cold store, at a temperature down to 4 °C, the cream loses its full flavor, and the texture becomes hard.

Containers are transferred from the heating area to a closed room at 12–14 °C, where the air is still, or preferably fitted with fans creating positive pressure, to avoid contamination at this vulnerable stage. The room can be fogged, i.e., the air sprayed, using peracetic acid at 25 p.p.m. to control molds and yeasts. It takes 4–5 h at this temperature for the fat to cool sufficiently to avoid crust collapse and loss of flavor. The containers can then be moved to a cold store maintained at 4 °C for a further 12–24 h before lidding and subsequent storage. Some commercial operations lid the retail pots after 5 h of cooling but run the risk of condensation forming inside the pots.

Steps should be taken to avoid contamination during transportation of cream to and between cooling areas, particularly from dust, the main source of mold and yeast infection. Many operators transfer the trays of cream on trolleys, which must be cleaned daily along with the rest of the equipment.

Farming enterprises and commercial operators who scald cream in large trays, either sell it in the returnable trays directly to catering establishments or pack it at a later stage into retail containers. Farmers may ladle the desired amount of cream into cartons or jars for individual customers, or pack it into lined tins for posting to regular consumers.

One commercial enterprise cools the cream briefly before filling into containers using filling machines while the cream is still liquid. Care must be taken with mechanical handling of the cream at this stage, from the point of view of damaging the texture and postheating contamination. If this practice is followed, the cream must be cooled further before the pots can be sealed. Cream processed in retail containers is best cooled for 24 h or overnight before lidding, but some operators seal the containers much sooner than this.

Lids may be of the snap-on variety, which can be applied by hand in small enterprises, with a hand-held applicator, or automatically in a lidding machine. The individual portions for airlines have a foil lid that is heat-sealed in place. This method would be used for larger retail tubs also.

Shelf-life and Problems

Raw cream of good bacteriological quality and hygienic production methods should give a traditional product with a shelf-life of at least 14 days. The most common problem is the appearance of molds on the surface, caused by postheating contamination during transfers in the cooling and packing operations. An entry air lock to avoid direct contact with outside air or an area with positive air pressure where these parts of the process can be carried out will do much to alleviate this problem.

The production of clotted cream is governed in the UK by Cream Regulations. Intending manufacturers should contact the Ministry of Agriculture, Fisheries, and Food or their local authority to find out the relevant details for their operation. If the product is labeled 'clotted cream,' it must contain no ingredients

other than cream, including flavoring or other added ingredients, whether or not that ingredient is a constituent of milk. Nisin is the only permitted preservative in clotted cream, but it is not used widely. If it is used, it must be declared on the label. (*See* **Cream**: Types of Cream; **Heat Treatment**: Ultra-high Temperature (UHT) Treatments; **Nisin**.)

CRYSTALLIZATION

Basic Principles

L Yu and S M Reutzel-Edens, Lilly Research Laboratories, Indianapolis, IN, USA

Background

Crystallization is the physical transformation (*phase transition*) of a liquid, solution, or gas to a crystal, which is a solid with an ordered internal arrangement of molecules, ions, or atoms. Many substances of scientific, technological, and commercial importance are crystalline, ranging from large-tonnage commodity materials to high-value specialty chemicals. Crystalline substances of importance to food sciences and nutrition include sugars, sugar alcohols, salts, fats, fatty acids, artificial sweeteners, etc. Crystallization is a means to isolate chemical substances in the solid form for long-term storage and downstream processing. As a purification technique, crystallization relies on the stringent structural requirement for crystal formation to exclude impurities. Crystallization performed under different conditions can yield crystals of different sizes and morphologies, thus providing a way of modifying particles to desired specifications. The growth of large single crystals is essential to the determination of the structures of molecules and crystals by crystallography and the fabrication of optical and electronic devices. The science of crystallization has been developed on the foundation of thermodynamics, kinetics, fluid dynamics, crystal structures, and interfacial sciences.

This article is divided into three sections. The first section, Principles of Crystallization, is concerned with the thermodynamic conditions of crystallization and the kinetics of crystal nucleation and growth. The second section, Molecular Aspects of Crystallization, discusses how the knowledge of molecular and crystal

structures provides mechanistic insights into crystallization and how elemental steps of crystallization can be manipulated at the molecular level to gain control over competing crystallization pathways. The third section, Techniques of Crystallization, describes the various ways in which crystallization can be performed.

Principles of Crystallization

Crystallization usually occurs through a *nucleation and growth mechanism*. Nucleation is the formation of stable molecular aggregates (*nuclei*) capable of growing into macroscopic crystals. Crystal growth is the actual development of the nuclei into visible dimensions. Both nucleation and growth require a thermodynamic driving force. In the case of solution crystallization, the thermodynamic driving force is *supersaturation*. Supersaturation is generated when the concentration of a solute exceeds its *equilibrium solubility*, the solute concentration in a solution that is in equilibrium with solute crystals. Supersaturation can be expressed as the difference between the concentration of a saturated solution c_{ss} and the equilibrium solubility c_{eq}^* or as the ratio between the two: $\Delta c = c_{ss} - c_{eq}^*$ or $S = c_{ss}/c_{eq}^*$. The thermodynamic driving force for crystallization from a melt is generated by lowering the temperature below the crystal melting point, or *undercooling*. For crystallization to occur from a gas, the vapor pressure of the crystallizing component must exceed its equilibrium vapor pressure, i.e., the vapor pressure attained when the gas is in equilibrium with the crystals.

Although any nonzero supersaturation can in principle cause crystallization from a solution, crystallization usually does not occur unless the supersaturation exceeds a certain threshold, or *metastable limit*. A diagram illustrating this phenomenon is shown in Figure 1. The solid line depicts the equilibrium solubility of a solute as a function of temperature. The region below the solid line is *undersaturated*, where crystallization is thermodynamically impossible. The region above the solid line is supersaturated, where crystallization is thermodynamically possible, and the solution is metastable. The metastable limit is indicated by the dashed line, and the region between the solid and dashed lines is called the *metastable zone*. A supersaturated solution free of crystal seeds can remain in the metastable zone indefinitely. For a solute to crystallize spontaneously, the solution concentration must be raised not only above the equilibrium solubility (solid line), but also above the metastable limit (dashed line) into the so-called *labile zone*. The width of the metastable zone depends on the nature of the solute and conditions of crystallization (e.g., stirring, solvent, temperature, pressure, the presence of impurities, and the surface characteristics of the crystallization vessel).

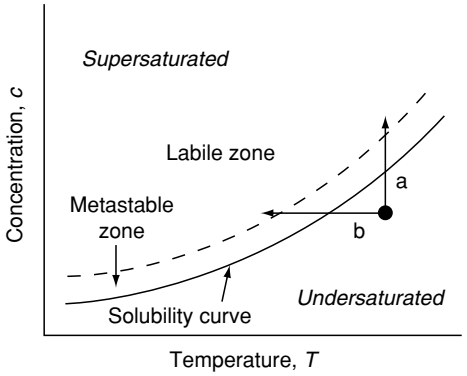

Figure 1 Equilibrium solubility, supersaturation, and metastable limit. An undersaturated solution can be induced to crystallize by solvent evaporation (path a), temperature change (path b), or both.

Crystal nucleation may be classified as primary or secondary. *Primary nucleation* refers to the formation of crystal nuclei from a solution that contained no preexisting crystals. Primary nucleation occurs through both homogeneous and heterogeneous mechanisms. *Homogeneous nucleation* is the formation of nuclei within a homogeneous fluid, and *heterogeneous nucleation* is initiated by contact with foreign particles and surfaces. The effectiveness of surfaces or interfaces as templates for nucleation frequently makes the heterogeneous mechanism the dominant mechanism when particulate contaminants are present. *Secondary nucleation* refers to the generation of crystal nuclei from preexisting crystals, such as those introduced through seeding.

The classical theory of homogeneous nucleation treats crystal nucleation as a thermally activated process whose activation energy is the free energy change (ΔG) for forming a microscopic crystal within a liquid. ΔG is further divided into a surface term (ΔG_s) and a volume term (ΔG_v). ΔG_s is the surface free energy change for creating a crystal–liquid interface, which is thermodynamically unfavorable ($\Delta G_s > 0$) owing to the generation of surface tension. ΔG_v is the volume free energy change for the liquid-to-crystal transformation, which is thermodynamically favorable ($\Delta G_v < 0$) owing to the greater thermodynamic stability of the crystalline product. Thus, the volume and surface terms represent the driving force and the obstacle of nucleation, respectively. The interplay of the two terms dictates whether or not a crystal nucleus is viable, i.e., capable of growing into larger sizes. Since both terms increase in magnitude with the crystal size r, but at different rates (ΔG_s proportional to the surface area and ΔG_v proportional to the volume of the

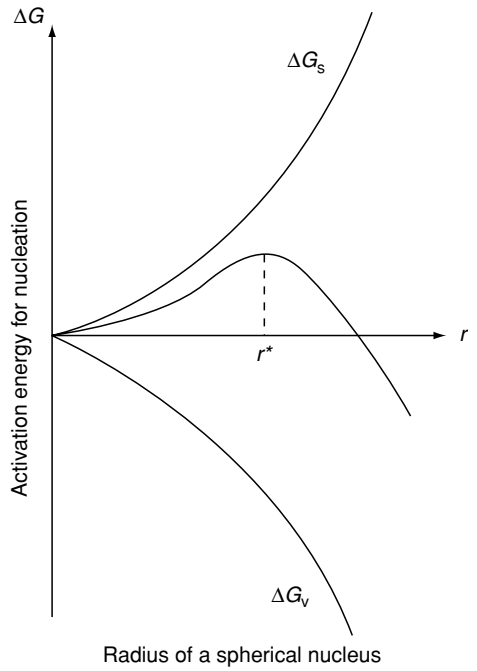

Figure 2 Classical theory of homogeneous nucleation. The free-energy change of crystal nucleation, ΔG, is divided into a surface term ΔG_s, representing the free energy increase for creating a crystal–liquid interface, and a volume term, ΔG_v, representing the free energy decrease for the liquid-to-crystal phase transition. The different dependence of ΔG_s and ΔG_v on the crystal size r leads to a maximum of ΔG at the critical nucleus size r^*. Nuclei dissolve if they are smaller than r^* and grow if they are larger than r^*.

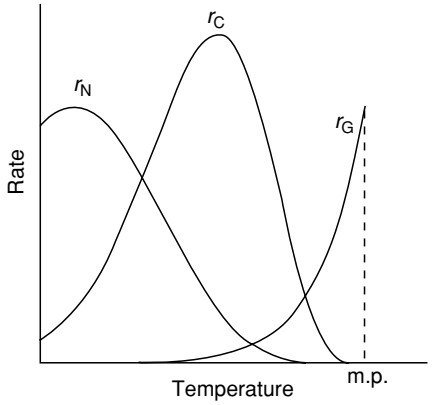

Figure 3 Typical temperature dependence of crystallization rate from a single-component melt. r_G, crystal growth rate; r_N, crystal nucleation rate; r_c, overall crystallization rate. The fastest crystallization rate is achieved at an intermediate temperature between the preferred temperatures for nucleation and growth.

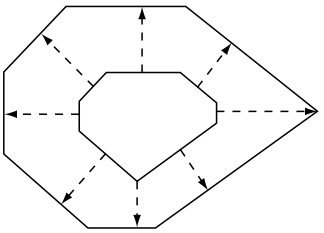

Figure 4 Illustration of the growth of a single crystal. Slower crystal growth rates lead to larger crystal faces.

crystal), ΔG achieves a maximum at some crystal size r^*, termed the *critical nucleus size* (see Figure 2). The critical nucleus size is so named because crystals smaller than r^* will dissolve spontaneously, whereas crystals larger than r^* will grow spontaneously.

The process of crystal growth requires the transfer of mass to the growth interface and the dissipation of heat generated by crystallization. The rate of crystal growth therefore depends on the rates of mass and heat transfer, which in turn depend on the viscosity of the medium and the degree of agitation. Impurities strongly absorbed to crystal surfaces can significantly retard crystal growth and modify crystal morphologies.

Crystallization rate depends on temperature because temperature affects both the molecular motions required for nucleation and growth and the degree of supersaturation. If crystallization occurs from a single-component melt, supersaturation becomes irrelevant, and a characteristic temperature dependence often emerges (Figure 3). The crystal growth rate, r_G, usually increases with temperature until the arrival of the crystal melting point, above which no crystallization is possible. Contingent upon the formation of molecular clusters, nucleation requires a low temperature, but not too low so that molecular mobility becomes limited. Thus, the nucleation rate, r_N, plotted against the temperature typically shows a maximum below the melting point. The combination of the two temperature effects leads to the fastest crystallization rate, r_C, achieved at an optimal temperature that is intermediate between the preferred temperatures for nucleation and growth.

Crystal growth from solution does not proceed at the same rate in all directions. As crystals grow, distinct morphologies or habits emerge as a result of face-specific growth rates. Slower growth rates translate to larger crystal faces and *vice versa*, as shown in Figure 4. The face-specific growth rate depends on both the internal structure of the crystal and growth conditions (e.g., supersaturation and impurities), enabling crystals of the same internal structure to develop different external habits.

A crystallization process may produce crystals of different sizes. The control of particle size distribution relies on the control of nucleation and growth, which can be achieved by adjusting supersaturation, seeding, agitation, resident time, etc. Crystals allowed to remain in contact with a saturated solution can undergo *ripening*, which causes small crystals to

dissolve and large crystals to grow. The driving force for ripening is the slightly higher solubility of smaller crystals owing to their higher surface energies.

Polymorphism is the ability of a molecule to crystallize in multiple crystal forms that differ in molecular packing and/or conformation. A related phenomenon, *pseudopolymorphism*, arises if a molecule can cocrystallize with solvent molecules, forming a *solvate*. A solvate may be stoichiometric or nonstoichiometric, depending on whether the amount of solvent is fixed or variable. Since polymorphs and solvates have different physical properties (e.g., solubility and crystal morphology), more stringent control may be necessary for their crystallization. In crystallizing polymorphic compounds, unstable polymorphs sometimes crystallize first and then transform into stable forms. This observation is summarized by Ostwald's step rule, which states that the first form to crystallize is the most soluble (the least stable) form, which then transforms to the next most soluble form through a process of dissolution and recrystallization, and so on. This rule, which has not gone unchallenged, is applicable to crystallization initiated at sufficiently high supersaturations that the least stable (most soluble) polymorph is driven to crystallize. Obtaining metastable polymorphs frequently requires rapid crystallization and immediate harvest because of potential conversion to more stable polymorphs.

Molecular Aspects of Crystallization

Crystallization at the most basic level is the assembly of molecules; thus, an understanding of the molecular events of crystallization promises the ultimate control of crystallization. Certain crystallization processes have been identified as the assembly of molecular aggregates, rather than single molecules. These molecular aggregates, called *prenucleation aggregates* or *growth units*, are often in the form of dimers, trimers, or high multimers of molecules. The growth units of some carboxylic acids, for example, are found to be cyclic dimers held together by hydrogen bonds. Thus, in the molecular theory of crystallization, a multistep process is envisioned: the association of molecules into prenucleation aggregates in solution, the assembly of prenucleation aggregates into crystal nuclei, and the growth of crystal nuclei into macroscopic crystals (Figure 5).

The identification and manipulation of prenucleation aggregates underlie molecular strategies for crystallization control that go beyond traditional approaches based on the nucleation-growth model. Examples of such strategies include the use of 'tailor-made additives' for polymorph control, morphology modification, and inhibition of unwanted crystallization. Chemical principles of molecular structures and interactions are used to guide the selection of such additives. For example, molecular details of a dominant growth surface can be analyzed to determine suitable impurities that may preferentially bind to and inhibit the growth of the surface, thereby altering the crystal habit. The introduction of impurities with molecular conformations resembling those present in one polymorph ('conformational mimicry') has been used to prevent its crystallization, leading to the crystallization of another polymorph.

Crystal engineering is the design of crystal structures with desired properties (e.g., nonlinear optical activity arising from noncentrosymmetric structures) from molecular structures. The same chemical principles guiding the molecular control of crystallization are employed in such engineering of crystals, as are reliable structural patterns of intermolecular interactions in crystals (e.g., close packing, hydrogen bonding and organometallic coordination chemistry).

The separation of mirror-related molecules that are not superimposable with each other (*enantiomers*) is called *chiral resolution* and is an important application of crystallization. With some molecules, chiral resolution occurs spontaneously; that is, a solution containing opposite enantiomers crystallizes to yield a physical mixture (*conglomerate*) of crystals containing pure enantiomers. A conglomerate can be separated manually into crystals of pure enantiomers, as Louis Pasteur famously demonstrated with sodium ammonium tartrate. With seeding, one enantiomer can be induced to crystallize from a self-resolving solution. This process, known as *kinetic resolution*, requires that the system does not come

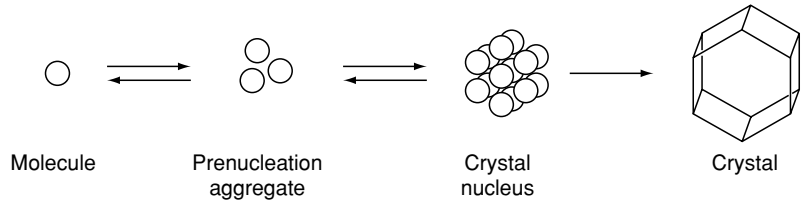

Figure 5 Molecular model of crystallization.

into equilibrium to precipitate both enantiomers. For most chiral molecules, spontaneous resolution is impossible, and opposite enantiomers crystallize together to form a so-called *racemic compound*. In these cases, chiral resolution usually requires the addition of a resolving agent, which is a chiral molecule that forms a crystal with one enantiomer more readily than with the other. Preferential crystallization of one enantiomer may also be accomplished with a chiral solvent, in which the solubility of the opposite enantiomers is different.

Techniques of Crystallization

Crystallization techniques differ in the way in which supersaturation is generated and relieved, and nucleation is initiated. The importance of selecting an appropriate technique lies in the fact that the same crystallization performed under different conditions can yield crystals of different properties (size, morphology, chemical purity, polymorphic form, etc.). The design of a cost-effective crystallization process requires many types of data, including mass and heat transfer and equilibrium solubility as a function of solvent, temperature and pH.

To induce crystallization from a solution, the necessary supersaturation can be generated in several ways, including solvent evaporation, temperature change, antisolvent addition, and chemical reaction. In Figure 1, solvent evaporation at a constant temperature corresponds to a vertical line from the undersaturated to the supersaturated region. Solvent removal at controlled temperatures can be performed either with or without vacuum. Slow evaporation of solvent is frequently used to obtain large, high-quality single crystals.

Crystallization induced by temperature change (*temperature gradient*) takes advantage of the temperature dependence of solubility. In Figure 1, the generation of supersaturation by temperature change without solvent removal corresponds to a horizontal line from the undersaturated to the supersaturated region. If solubility increases with temperature, a high-temperature solution can be cooled to generate supersaturation. In general, slower cooling rates lead to nucleation at higher temperatures, producing fewer and larger crystals. To effect additional control, it is customary to seed the solution so that crystallization is initiated at the desired temperatures. Once crystallization begins, the suspension can be cooled to improve the product yield (assuming that solubility increases with temperature).

Crystallization by *antisolvent addition* (also called *drowning out*) depends on the solvent dependence of solubility. With this technique, a solution to be crystallized is mixed with an antisolvent, which is miscible with the initial solvent and in which the solute is less soluble. The addition of antisolvent lowers the solubility and generates supersaturation. The onset of crystallization is signaled by turbidity, after which precipitation usually follows.

Vapor diffusion is a common technique for growing high-quality single crystals. With this technique, an antisolvent is diffused into a solution through the vapor phase and slowly generates supersaturation. An analogous technique, *liquid diffusion*, is carried out by slow addition of a lower-density antisolvent, allowing the initial solution to float to the top. As the antisolvent gradually diffuses into the initial solution, crystals may grow at the interface.

Crystallization may directly follow chemical reactions that produce low-solubility products. For example, an acidic or basic solute may be crystallized as a less soluble salt with an appropriate counter ion. Acid–base titration is a recrystallization technique used to purify free acids and bases, whereby a soluble salt is first generated at a high or low pH, and then the solution is neutralized to the starting pH to precipitate the solids.

The condensation of vapors produced by *sublimation* provides a way to grow crystals from the gas phase. With this technique, a solid is placed near a condensation surface and heated to produce sufficient vapor pressure. The condensation surface supplies a substrate for the formation of crystals.

Freeze-drying, also called *lyophilization*, is a drying process in which the solvent (typically water) is first frozen and then removed by sublimation in vacuum. Owing to the low temperature used, freeze-drying is frequently a gentle drying technique, especially suitable for thermally labile substances (e.g., proteins and peptides). The low processing temperature often prevents solute crystallization in freeze-drying; nonetheless, many solutes crystallize predictably (e.g., glycine, mannitol and NaCl). (*See* **Freeze-drying**: The Basic Process; Structural and Flavor (Flavour) Changes.)

Spray-drying is a one-step drying process that converts a solution to a powder. In a spray-drier, the feed solution is first atomized into a spray. The spray is then dried through contact with heated air streams. The dried powder is usually separated from the air stream via a cyclone separator and collected at the base of the drying chamber. Spray-dried particles are often roughly spherical and have a narrow size distribution. (*See* **Drying**: Spray Drying.)

Crystallization with the aid of *supercritical fluids* takes advantage of the dissolving power of a substance (e.g., CO_2) existing in the supercritical state, a state of matter created by high pressure and

exhibiting gas- and liquid-like properties. A supercritical fluid rapidly returns to the gaseous state upon reduction of pressure (e.g., by expansion through a nozzle). When this happens, solutes dissolved in a supercritical fluid will precipitate quickly, often yielding fine, evenly sized, and spherical particles. It is also possible to use a supercritical fluid to rapidly extract the solvent from a solution, causing the solute to precipitate.

Spherical crystallization is a technique of forming dense and spherical agglomerates of crystals. This technique is based on adding to a crystallizing medium a small amount of an immiscible liquid (bridging agent) that preferentially wets the developing fine crystals and encourages them to compact into spherical agglomerates.

Epitaxy refers to the oriented growth of one crystal on the surface of another crystalline substance, with the crystallization promoted by the matching periodicity of the two crystal lattices. The lattice match lowers the activation energy for nucleation and growth. Structural studies by crystallography and microscopy of substrate-promoted crystallization have identified epitaxial match as the underlying cause for oriented growth of crystalline overlayers. Epitaxy is also invoked as an explanation for nucleation induced by foreign particles.

CURING

M Shimokomaki and E Youssef Youssef, Londrina State University, Londrina, PR, Brazil
N N Terra, Santa Maria Federal University, Santa Maria, RS, Brazil

Introduction

The use of salt and curing is undoubtly the technological procedure which is most commonly employed to transform meat into a meat product of quality. This practice has been applied before Roman times in order to preserve meat products. Curing methods consist of the application of salt (sodium chloride), sodium nitrate, and nitrite, and reducing agents. There is no curing processing without salt and probably nitrate was discovered as an impurity of salt. Sodium nitrite is the most important component since it plays many roles in meat curing. It is the chemical agent which develops the typical color cured meat products through the formation of nitric oxide compound from the reaction of nitrite-myoglobin. In contrast, it helps to develop the typical flavor and increases the stability for oxidative reactions. Most importantly, nitrite inhibits the development of several undesirable pathogenic microorganisms, including *Clostridium botulinum*. These

multiple functions of nitrite make it difficult to find an ideal nitrite substitute; nitrite gives rise to nitrosamine compounds, which are known to be potent carcinogenic agents. However it has recently been reported that on average only one third of daily-ingested nitrite originates in cured meat products. This article will discuss the events that occur in curing processing.

Raw Material

Care should be taken in relation to the raw material. The meat system characteristically presents a weak acid, pH 5.5–6.0, after completion of rigor mortis. This final pH value is important for curing reactions because under these conditions nitrite forms nitrous acid which also participates in curing reactions. This pH control is very relevant, for instance, during cooked ham processing; the pH of the semimembranosus muscle should be above 5.8 and refrigerated pork meat pieces should not be frozen because freezing would create colour defects. The meat temperature should not be too cold as the full series of color reactions cannot take place and the final cured color formation is impaired.

Ingredients

The ingredients applied for curing processing are salt, phosphates, nitrite, sugar, reductants, binders and extenders, and antioxidants.

Salt

Salt (NaCl) is the main ingredient in quantity and has two major functions. It solubilizes myofibril proteins, helping to stabilize meat emulsion: the concentration of 6–8% solution is most effective. In contrast, salt, being a dehydrating agent, would alter osmotic pressure and thus inhibit bacterial growth and subsequent spoilage. Years ago, it was common to use a high concentration of salt and presently this concentration is around 2–3%, therefore it is necessary to store derived meat products under refrigeration. Under higher salt concentrations with subsequent lower water activity values, these products are able to resist bacterial spoilage, for instance, copa, salami, charqui meats in South America, and biltong in South Africa; these are known as intermediate-moisture meat products. Their shelf-life can be extended, even at room temperature, for several months. NaCl is also an important factor to enhance the flavor of meat products. This is a beneficial factor and is why it is included in the preparation of these products but can cause problems by increasing consumers' high blood pressure. However the amount of sodium chloride can be reduced by mixing with potassium chloride, up to 50% concentration.

Sodium Nitrite

Nitrite in meat products has the following functions: (1) it stabilizes the color; (2) it contributes to the flavor of cured meat; (3) it inhibits the development of spoilage microorganisms, in particular avoiding the appearance of botulism; and (4) it delays the development of rancidity. Nitrate is used as a source of nitrite formed after the action of microorganisms and it has not been used so frequently, since it has been substituted by nitrite in meat processing. There are a few exceptions to this: country cured hams and Lebanon bologna.

The color formation in cured meat is the result of a series of complex chemical reactions involving sodium or potassium nitrite (NO_2). This complex series of chemical reactions can be summarized as follows:

$$2KNO_3 > 2KNO_2$$

$$2KNO_2 > 2HNO_2$$

$$2HNO_2 > H_2O + N_2O_3$$

$$N_2O_3 > NO + NO_3$$

The nitric oxide formed combines with myoglobin heme, a constituent of meat pigment, and this colored complex pink color (hemocrome) becomes stable after it has been heated. The other reaction for nitrite is a direct interaction with myoglobin (Fe^{2+}); as this is a strong oxidizing compound, it can produce brown oxidized metmyoglobin (Fe^{3+}). The Fe^{3+} ions formed have the capacity to be active promoters of oxidative reactions and there is a need to convert them to inactive and stable Fe^{2+} forms. This can be achieved by the action of reducing agents added as ascorbate or erithorbate. In the final cured meat, it has been found that residual nitrite found reduced to 10–20% of the original amount added. Only about 5–10% of added nitrite reacts with myoglobin, 1–5% combines with lipid components, and 1–5% forms volatile components.

Phosphates

Sodium phosphates are used in meat processing in order to increase water-binding capacity because this helps to solubilize myofibril proteins. In these functions, only alkaline phosphates are efficient for this role because they raise the pH value, becoming effective water binders. Also they bind heavy metal, having in the end a preservative role to inhibit the development of microbial growth. Normally, phosphates are used in most pumped meats, i.e., ham, bacon, roast

beef, and pastrami, which give the advantage of reducing the cookout, improvement of sliceability, retention of flavor, and juiciness. There is a limit on the quantity of phosphates used of a maximum of around 3000 mg kg^{-1}, because above that level would give a metallic or soapy taste to the product.

Sugar

The addition of sugar to the curing process is primarily for flavor. The presence of sugar counterbalances the harsh taste promoted by a high concentration of salt. In case of fermented products, the addition of sugar is necessary as an energy source for microorganisms to perform fermentation. When heat treatment is used during processing, a browning reaction results in a burning flavor.

Reductants

The isomers ascorbate and erythorbate are commonly used in modern curing practice. Because of their reducing role, their function is primarily as a curing accelerator reducing nitrite to nitric oxide and reducing the meat pigment, thus giving stability to meat product color. By stimulating nitric oxide formation they suppress nitrosamine formation and therefore become an important ingredient, in particular for bacon.

Binders and Extenders

These are used to increase the binding properties of a meat mixture, giving an economic advantage to the producers. Thus, they improve emulsion stability, give better yields and better sliceability, and are permitted in cooked sausage at 3.5%. These compounds are nonmeat proteins like soy and its hydrolyzed products, several starches and of course hydrocolloids like carrageenan.

Antioxidants

There is a group of compounds which function to prevent rancidity. Butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), tertiary butyl hydroquinone (TBHQ), and propyl gallate are the major antioxidants in use. Recently the application of natural compounds has become popular and the practice of including for example, vitamin E, in the dietary ration for daily animal consumption has been shown to extend the meat product shelf-life greatly.

Processing

In practice, there are at least three methods of curing: (1) dry curing; (2) wet (pickle) curing; (3) and combined dry and wet curing.

Dry curing

This old-time procedure is the easiest method of curing since all that is needed is to rub the salt alone or in combination with nitrite and/or nitrate and sugars into the surface of the meat. This technique is applied without any water, thus the curing ingredients are dissolved in the moisture of the original samples and then they diffuse. Also, fermented dry-cured sausages are prepared by mixing minced meat and ingredients and stuffing them into natural pork or lamb casings or artificial casings made from reconstituted collagen. Depending on the type of product, they are placed in natural or air-conditioned drying chambers at a specific temperature and time, hence natural microorganisms develop, constituting the ripening of the product. In some cases, starter cultures are added to accelerate the fermentation process and concomitantly sugars are transformed into lactic acid, lowering the pH value. This final pH is similar to the meat isoelectric point lowering the water-holding capacity that would further help the dryness of the product. The advantage of this methodology lies in the higher shelf-life because of the intermediate water activity values and firmness and the product presents more flavor. The disadvantages are economical since more labour is required and there is a waste of processing laboratory space; the process is time-consuming, and the final product has a harsh salty flavor. The list of cured products derived from the application of this technique includes ham (Spanish serrano, Italian parma, French bayonne, American country-style, German westphalia), South American charqui meats, and Italian copa.

Wet curing

Historically this method originally involved the immersion of meat pieces into cold brine containing dissolved curing salts. Although the diffusion of these ingredients was quicker than rubbing dry salt into the meat, it was in fact a time-consuming technology. A technique to speed up curing is injecting pickle into the entire ham through artery pumping. The needle is usually inserted in the femoral artery using the same ingredient as for dry curing but the brine is dissolved in water to make a pickle. Thus, the need to speed up even more this curing technology brought about the multiple-needle stitch automatic injection that is currently used to prepare ham and bacon, followed by tumbling to accelerate brine diffusion and give uniformity of the curing mixture. To finish this process, these products are exposed to heat and/or smoke.

Finally, for the wet curing of minced meat, the curing mixture is added to the meat and fat to prepare the meat emulsion. In order to prevent excessive heat,

ice is included to cool down the process. This helps emulsion stabilization by avoiding protein denaturation and fat fusion point. Thus the product is stuffed in cellulose, plastic, or reconstituted collagen casings, followed by heat treatment, and can be smoked. This technique is applied to process frankfurters, Bologna sausages, and mortadella. However, the disadvantages are again the poor utilization of space and the products have a milder flavor in comparison to dry curing, although less labor is required.

Combined Dry/Wet Curing

Some cured products are processed by applying a combination of both techniques. This is the case for South American charqui meat processing. The conditions for charqui meat preparation are to incorporate the curing ingredients into the meat to achieve uniform distribution, and thus to accelerate curing and to stabilize the color. Figure 1 shows a flow diagram for charqui processing. Essentially it is prepared by using the whole sides of muscles, immersing them in concentrated brine of approximately 25 °B containing 3–4% sodium or potassium nitrite for hours, allowing the brine to diffuse through the meat. The curing procedure can be considerably shortened by injection of brine into the meat to achieve uniform distribution. In a more modern technique, multiple injections are applied automatically, and brine is injected simultaneously. Thereafter samples are submitted to dry salting on a concrete floor on which the meat pieces are stacked into piles separated from each other by layers of coarse sea salt (approximately 1 mm thick). After about 8 h, the meat is restacked and the uppermost meat pieces are repositioned at the bottom of the new piles. The maneuver is repeated every 24 h (three to five times), and, after washing to remove excess salt from the meat surface, samples are subjected to the drying stage directly in the sun on wooden rails. At night, meat pieces are collected and piled on the concrete floor and covered with a tarpaulin. Finally, samples are packed under vacuum in polyethylene bags of 1–5 kg and commercialized.

Functional properties of cured products

The changes promoted by curing processing in relation to raw materials are relevant and consequently color, flavor, texture, and nutritive values are described below.

Color formation

Fresh meat color is primarily determined by the oxidation state of iron and the radical attached to the heme group of the myoglobin pigment that also presents the globular protein portion, globin, in its structure. Myoglobin can be found in three forms: (1) desoxymyoglobin (Mb) or reduced myoglobin, which is a purple red color, with the iron state of Fe^{2+}, (2) oxymyoglobin (MbO_2), oxygenated myoglobin, which is a bright red color with Fe^{2+}; and (3) metmyoglobin (MMb), oxidized myoglobin, brown color with Fe^{3+}. During the curing process, because nitrite is a oxidizing agent for Mb, it converts Mb and MbO_2 to MMb. Thus, nitric oxide reacts with MMb to form nytrosylmetmyoglobin (brown with Fe^{3+}) that is reduced to nitric oxide myoglobin, nitrosylmyoglobin (MbNO), which is the desired bright pink color, although unstable, with Fe^{2+}. Finally, MbNO when heated is denatured to form nitrosylhemochrome (stable pink color). This is the typical cured-meat color with Fe^{2+}, as shown in Figure 2.

Flavor

Cured meat flavor is a complex issue and the chemical reactions responsible for its formation are not well understood. This is understandable since it is believed that there are nearly 1000 volatiles compounds in the fresh meat. The presence of sodium nitrite decreases not only rancidity but also the warmed-over flavor present in cured meat. The reaction of the heme group with nitric oxide giving a typical color is also connected to the cured meat flavor.

Texture

Texture is a subject which is seldom discussed with reference to cured meat. However, some insights have already been reported with whole meat such as charqui meats. Before consumption charqui meats are immersed in several changes of water in order to remove salt. Because of the meat buffering properties, about 3–4% is the final amount of remaining salt. These meat products are tougher than control raw samples. There is five to six times the increase in texture in charqui meat in comparison to raw material and two to three times in relation to desalted charqui, as measured by a texturemeter. A similar pattern is observed after cooking these samples. The water content plays a significant role in the texture of charqui. The moisture content determined in raw material is 76% and the measured shear force is 17 N; charqui contains 46.3% moisture and 96.5 N and desalted charqui 59.0% moisture and 46.5 N shear force. Cooked samples have a moisture value of 52.0, 31.7, and 44.8%, in control, charqui, and desalted charqui, respectively and shear force equivalent to 52, 300 and 86 N for control, charqui, and desalted charqui, respectively. There is an inverse relationship between the amount of water and

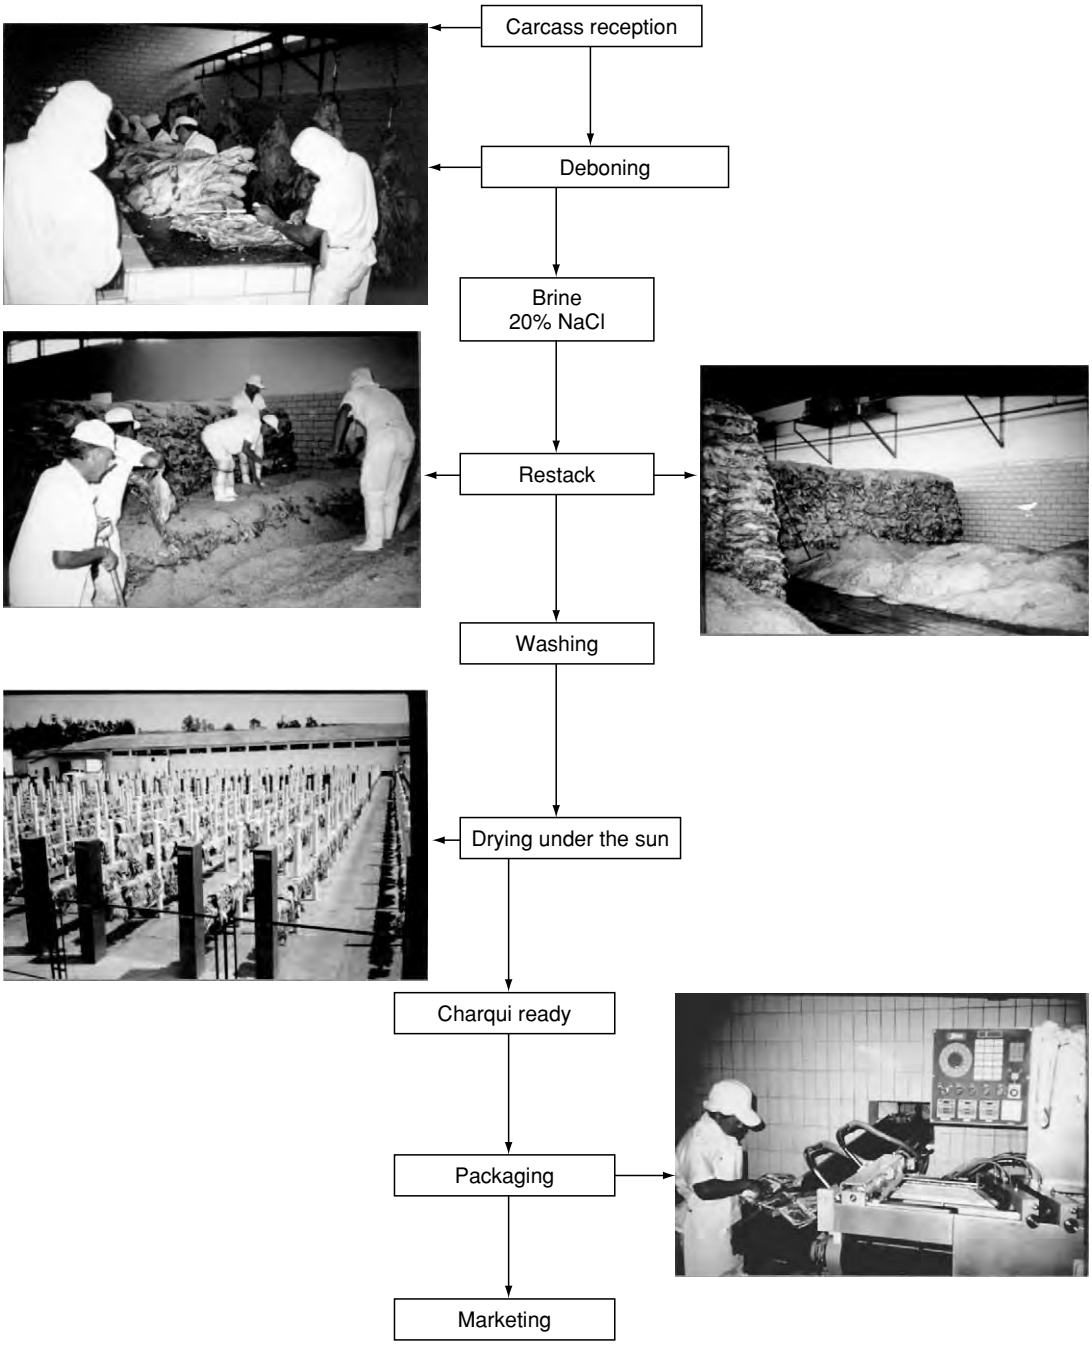

Figure 1 Flow diagram showing charqui meat processing with pictures of the steps of deboning, stacking, drying under the sun, and packaging. Photos courtesy of Industrias Allyson, Santana da Parnaíba, Brazil.

charqui texture, and the shear force increases exponentially with water loss.

Nutritive Value Evaluation

Cured meat products have the disadvantages of the presence of nitrosamine that is formed during curing. This compound is a potent carcinogenic component and has been detected in bacon after frying. On the other hand, because of the high biological value of protein, they present a high nutritive value. This is the case for intermediate-moisture meat such as charqui meats. Recent experiments with cooked samples have demonstrated high protein efficiency ratio of 2.07 and net protein utilization of 87.7, which is close to those of casein: 2.33 and 94.6, respectively.

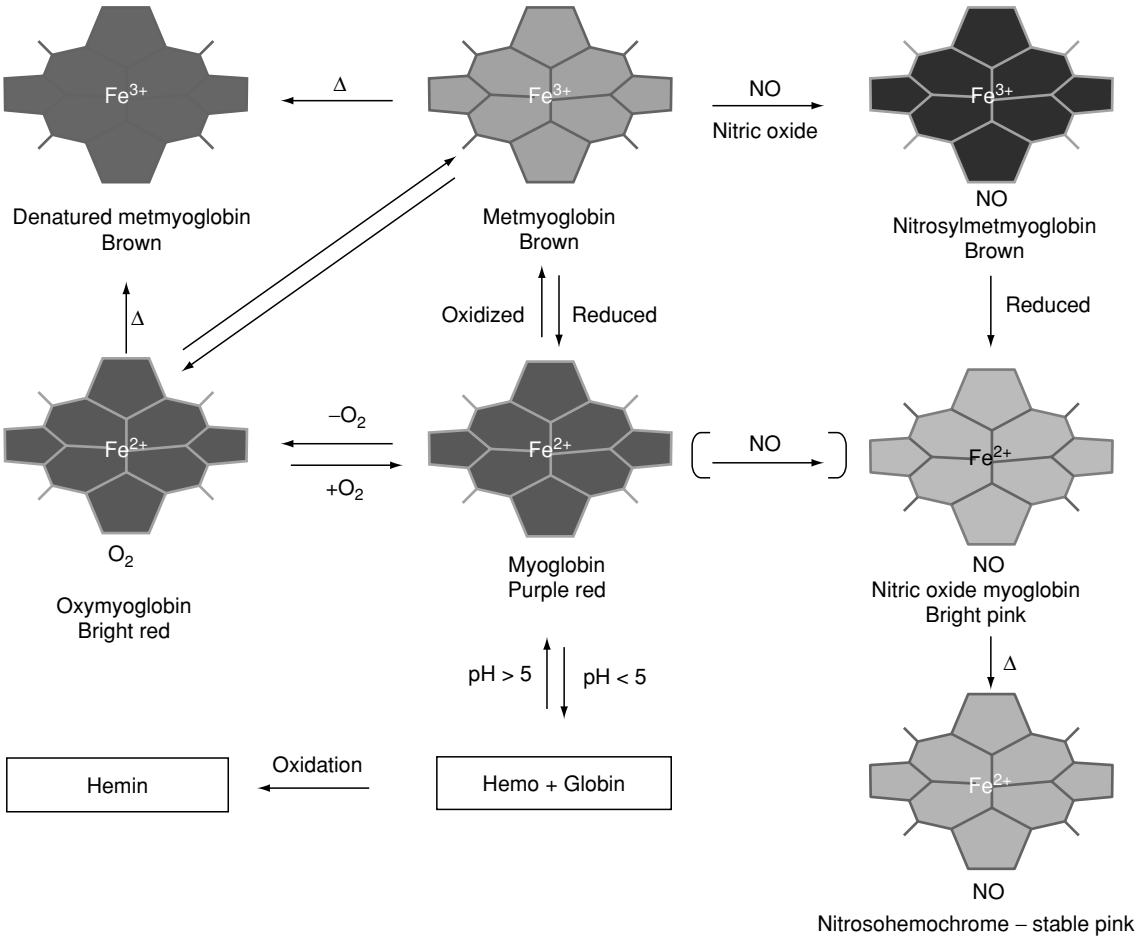

Figure 2 (see color plate 41) Changes in the pigment heme during curing and respective color and iron state.

Fermentation

Fermentation is an old technology applied to meat products that has a preservative activity and also gives rise to specific products with characteristic flavors. Initially, the type of microorganism was naturally selected; today there is an enormous technological advance with the application of starter cultures. In this way, a quicker and more uniform product can be obtained. In general, starter can be be used in two ways: maturation and surface. *Lactobacillus, Pediococcus, Micrococcus*, and *Staphylococcus* normally represent maturation starters. *Lactobacillus* and *Micrococcus* are characterized by the production of lactic acid which brings down the pH from 5.7–6.2 to as low as 5.3, with some processes dropping to pH 4.6: this is important for the reduction of nitrite to nitrous acid. The presence of *Micrococcus* and *Staphylococcus* is also important because they are capable of reducing nitrate to nitrite. In general, fermented meat products can be divided into two major groups: products using whole-meat pieces such as country ham products and charqui meats; and products using small chopped meat (the most representative quantitatively), as fermented sausage with various types of salami.

Microbiological Safety

It is known that curing processing inhibits the development of deteriorating bacteria. It follows the application of the so-called hurdle technology theory, that involves the application of sequential hurdles. Thus, nitrite would inhibit several kinds of bacteria, but Gram-positive bacteria, i.e., *Lactobacillus* and Micrococcaceae, are more resistant and play a relevant role in fermentation. Therefore nitrite has the important function of selecting microflora in particular in fermented sausages. The most important role, though, is to inhibit the development of *Clostridium botulinum*. Salt quantity and the resultant water activity inhibit the bacterial outgrowth, including the enterogenic *Staphylococcus aureus*.

Public Health Concern for Cured Meats

Nitrosamine as a carcinogenic agent is a worldwide concern, therefore its quantity is limited for curing. The amount of 120 p.p.m. is permitted to process bacon in USA, although 40–80 p.p.m. of residual nitrite level is sufficient to inhibit *C. botulinum* spore outgrowth. In Europe an estimated maximum level of 150 p.p.m. for sodium nitrite is permitted for cured meat. This quantity varies depending on the type of products and also on the processing technique. Sodium nitrate is not allowed in bacon and is only permitted to be used in dry-cured meat whilst nitrite is applied in the wet-curing processes. In South America, a level of 200 p.p.m. is allowed for cured meat products and 50 p.p.m. for cured charqui meats.

CURRANTS AND GOOSEBERRIES

N Heiberg, The Norwegian Crop Research Institute, Leikanger, Norway
F Maage, Agricultural University of Norway, Aas, Norway

Background

The domestication of currants and gooseberries has taken place within the last 400 or 500 years. Horticulturally, these fruits are not major crops, but they are widely grown in northern European regions. The crop is mainly used in the production of juices, jams, and jellies. Blackcurrant has strong color and aromatic taste, and is an excellent source of ascorbic acid. Long before vitamins were known, people used blackcurrants for medical purposes, mostly as a hot drink against the common cold.

Global Distribution

The genus *Ribes* of the Saxifragaceae family, consists of about 150 species of currant and gooseberry, mainly distributed in the northern temperate regions of Europe and North America. Of the edible types, the main commercially grown species are blackcurrant (*Ribes nigrum* L.) red- and whitecurrants (*R. rubrum* L., *R. sativum* Syme, and *R. petraeum* Wulf.), and the gooseberry (*R. grossularia* L.).

Commercial Importance

The majority of currants and gooseberries are produced in Europe (**Table 1**) with Germany, Russia, and

Poland as the main producers. Blackcurrants account for more than half of the total world production; this species is dominant in the UK, Scandinavia, and New Zealand, and is gaining importance in other countries. About a quarter of *Ribes* production is gooseberry, but the production of this fruit is decreasing in most countries. Germany, the UK, Poland, Czech Republic, and Russia are the major gooseberry-producing countries. Countries with a high proportion of redcurrant compared with blackcurrants are Germany, Belgium, The Netherlands, and Austria. Currants and gooseberries are at present of little commercial significance in North America, as they are alternative hosts of white blister rust (*Cronartium ribicola* Fisch.), but there is increasing interest in *Ribes* fruits in the USA, and some legislative controls on their cultivation are changing.

Machine harvesting is prevalent in industrial production of blackcurrants. The machines may be used for redcurrants as well but work less satisfactorily for gooseberries.

Besides commercial production, currants and gooseberry are important home garden crops in many countries. They tolerate both low summer and winter temperatures and therefore may be grown far to the north, where few other fruits can be cultivated.

Blackcurrant Cultivars

Old cultivars such as Roodknop and Øjebyn are still grown in Europe, but the 'Ben' cultivars from the UK have been commercially successful in many countries and their hectarage is increasing. Ben Lomond has been dominant so far, but in most countries, there is a swing towards newer cultivars like Ben Alder and Ben Tirran. The main cultivar in New Zealand has been Magnus, but north European cultivars such as Ben Ard and Ben Rua are becoming more widespread there. In the expanding Polish hectarage, Titania, Roodknop, Ben Lomond, and Ben Nevis are popular besides the traditionally grown Øjebyn. Russia has a large range of cultivars adapted to the climatic conditions in the different regions. Breeders are working on blackcurrants in several countries, and new cultivars are released yearly.

Red- and Whitecurrant Cultivars

The major red cultivars grown in Europe are Jonkheer van Tets, Red Dutch, Rondom, and Stanza. Red Dutch is winterhardy and is widely grown in the most northern areas. For the fresh fruit and dessert markets, Red Lake and Jonkheer van Tets have been popular because of their good eating quality. However, more recent cultivars from Holland, Rovada, Rolan, Rosetta, and Rotet, and Junifer from France, are gaining in popularity. White Dutch and White Versailles are most widespread among the whitecurrant cultivars. The whitecurrants lack red pigments and are in fact a color form of redcurrants.

From Maage F (unpublished).

Gooseberry Cultivars

In the nineteenth century, gooseberry was a popular fruit in home gardens in Europe, especially in the UK, and amateur breeders raised hundreds of cultivars. Selection was mainly for fruit size. However, the appearance of American gooseberry mildew (*Sphaerotheca morsüvae*) in 1905 soon drastically reduced the acreages of gooseberry, as the large-fruited types all proved more or less susceptible.

Mildew-resistant cultivars have been released, but so far, they have been inferior to the old types in terms of both fruit size and quality. One that is gaining popularity is Invicta from the UK. Among the old, nonresistant cultivars, the green-fruited cultivar Whitesmith and the red-fruited Whinham's Industry are still grown. New cultivars such as Greenfinch and Pax from the UK, and Rixanta, Rokula, Reflamba, and Rolanda from Germany have been widely tested.

Other *Ribes* Cultivars

Artificial hybridization between *R. nigrum*, *R. divaricatum*, and *R. grossularia* has given rise to the new species *Ribes* × *nidigrolaria*. The fruit quality is somewhere between blackcurrant and gooseberry. Josta, the first cultivar to be released from Germany, is planted mostly in home gardens.

Morphology and Anatomy of the Fruit

The fruits of currants and gooseberry are true berries with the seeds enclosed in a fleshy pericarp. The berries are born in clusters, with every single fruit adjoined to the main strig by a short stem. The fruits ripen in order along the strig, the fruit closest to the branch first and the terminal last. The fruit closest to the branch is largest, and the fruit in the end of the strig is smallest. Gooseberry fruits develop singly or in small clusters with two or three fruits, the distal fruit often being smaller than the others. The fruits on the plant are harvested at the same time, often mechanically. At harvest, the stem follow the fruit, and in the

distal end, the rest of the flower is found. Table 2 lists the range of variation concerning fruit characteristics. Gooseberry has the largest fruits with a great variation between cultivars, redcurrant being the smallest. Redcurrants have the lowest number of seeds and the largest seeds of the berries. The skin of some gooseberry cultivars is hairy, whereas the skin of currants is always hairless.

The pigments of the blackcurrant fruit are located in the skin, the flesh remaining green. The pigment of redcurrants and gooseberries, however, is also present to some extent in the fruit flesh. Unlike currants, the cultivars of gooseberry cover the whole range of fruit colors, from dark to light red, through various shades of green, yellow, and almost white. Blackcurrants have a dark purple color, whereas redcurrants are pure red. The white currants are lacking anthocyanins and have a light yellow–greenish color.

Chemical and Nutritional Composition

The energy in fruits of currants and gooseberries comes mainly from carbohydrates (Table 3). Only a small part comes from protein and fat. Fructose and glucose are the main sugars, with roughly equal amounts of each (Table 4). Sucrose is present, but to a lesser extent. Gooseberries contain small amounts of sorbitol, whereas only traces of sorbitol are present in currants. A characteristic feature of the fruits is the high content of acids. Citric acid is predominant in currants, whereas citric acid and malic acid are present in almost equal quantities in gooseberries.

Ascorbic acid (vitamin C) has probably received more attention than any other constituent of blackcurrants. Less than 50 g of the fruit meets the

recommended daily requirement of ascorbic acid. However, considerable variation exists between cultivars. Other vitamins are also present in the fruits, and the content of minerals is also worth mentioning, especially the high content of potassium.

Attention is now being focused on naturally occurring antioxidants. Besides ascorbic acids, currants, especially blackcurrants, contain many substances that have an antioxidant activity. Blackcurrants possess a high flavonoid content compared with other soft fruits. The most important group of the flavonoids is the anthocyanins. The anthocyanins are the dominant pigments, and blackcurrants contain from 1250 to 2000 mg per kilogram of fresh weight. The anthocyanins of blackcurrant are mainly cyanidin and delphinidin 3-glucosides and 3-rutinosides. In redcurrant, six different cyanidin glycosides have been isolated. Most red European gooseberry cultivars contain only cyanidin 3-glucoside and 3-rutoniside. Another important group of flavonoids is the flavonols, of which glycosides of kaemferol, quercetin and myricitin are present in currants and gooseberries.

The characteristic aromatic compounds of blackcurrant are present in the whole plant. Several studies have been carried out to identify the aromatic components of blackcurrants, and a wide range of volatile components have been identified, but the exact chemical nature of the specific aroma in blackcurrants is unknown.

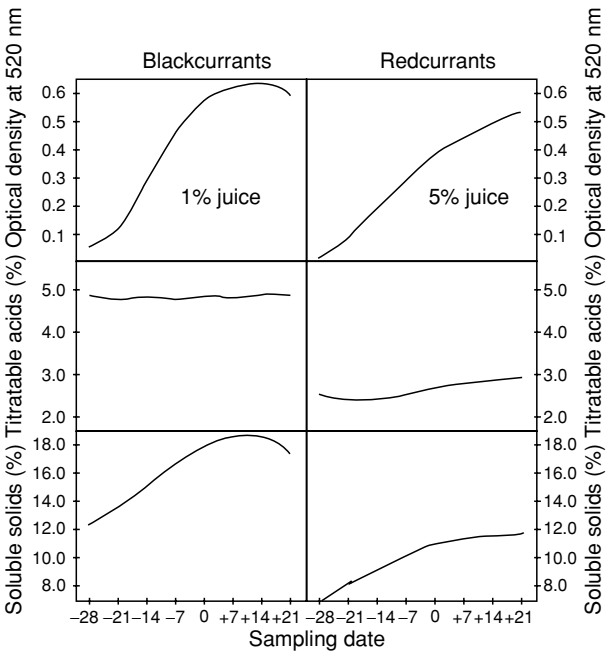

Figure 1 Changes in fruit quality components in black- and redcurrants from 28 days before to 21 days after normal harvest time (titratable acid expressed in terms of citric acid). From Måge F and Heiberg N (unpublished).

The degree of ripening has a great influence on the quality characteristics. The color intensity, content of dry matter, soluble solids, and sugars increase with ripening, whereas the viscosity and content of ascorbic acids decrease. The content of titratable acids reaches its peak about 2 weeks before harvest and changes little during ripening. The development of some quality factors is shown in Figure 1.

The seeds of currants and gooseberry contain about 20% fat, of which 5–20% is γ-linolenic acid, with the highest content occurring in blackcurrant.

Handling and Storage

The strong flavor and the high acidity of currants, especially blackcurrants, make them less attractive for fresh consumption. However, in Europe, there is a market for fresh fruits, especially red currants, which are used for desserts and decoration purposes. With a combination of out-of-season production and storage under controlled-atmosphere conditions, growers are able to market fresh fruits most of the year. Gooseberries have a milder flavor, and a considerable part of the crop is used for dessert purposes. Gooseberries are sold both as unripe, green fruits and as ripe fruits.

For fresh consumption, the *Ribes* fruits are still picked by hand, because harvesting machines reduce the postharvest quality. The currants are picked on strigs, whereas gooseberries are sold as single fruits. The berries should be picked in a dry condition, as they spoil quickly if gathered and packed when wet.

Compared with many other soft fruits, currants and gooseberries keep reasonably well, but without cooling, the fruits decay rapidly after harvest. The weight loss may reach 2–3% within 24 h without cooling. The fruits are usually cooled to 0–5 °C immediately after harvest. Forced-air cooling is recommended. At low temperatures, the blackcurrants have a shelf-life of 2–6 days and redcurrants 2–4 weeks, dependent on maturity stage. Picking the berries slightly unripe increases the shelf-life. The fruits should be kept cooled during transportation and marketing. To increase the shelf-life, the fruits must be stored in a controlled atmosphere, in which it is possible to store blackcurrants for 3–4 weeks, gooseberries for 6–8 weeks, and redcurrants for 8–14 weeks.

Industrial Uses

The most important products of blackcurrant are different types of juices and syrups. Most of the UK crop is used to produce the proprietary brand name drink 'Ribena.' Owing to the special aromatic taste, and the high content of ascorbic acid, blackcurrant products are popular in northern Europe and are

commonly regarded as healthy preparations. The fruits are also used for jams and jellies, and are suitable for flavoring other foods, such as yogurt, icecream, and other diary products, and in bakery products such as pies.

Red currants are mainly grown for juice and jelly processing, often mixed with other fruits with lower acidity, and are used as a component in mixed juice, where they add a stronger character to the product.

Gooseberry is mainly used for jam and canned products and, to some extent, for juice production. All three fruits are used for berry wine production, alone or in combinations with other raw materials. Blackcurrants are also used for sweet liqueurs, such as 'Crème de cassis' in France.

Blackcurrant is rich in polyphenolic color products, and the γ-linolenic fatty acid produced from blackcurrant seeds is used as a health preparation. Manufacture of the oil is based on press cake from blackcurrant juice processing. In blackcurrant, other parts of the plants are also of commercial interest. The leaves may be used for tea, and bud extracts have been used as a flavor component in other foods and as an ingredient in some fragrances.

CYCLAMATES

J F Lawrence, Sir F.G. Banting Research Centre, Ottawa, Ontario, Canada

Introduction

'Cyclamate' is the term given to the artificial sweetener cyclamic acid (cyclohexylsulfamic acid) and its calcium or sodium salts (see **Figure 1**). Cyclamate was discovered in 1937 at the University of Illinois, following the accidental contamination of a cigarette with a derivative of cyclohexylamine. In 1940, DuPont obtained a patent for its production, and in 1950, it was available to consumers. Consumption of cyclamates increased steadily from that time up to about 1969, when it was banned in the USA and other countries due to safety concerns related to its potential carcinogenicity. However, recent studies have contradicted the earlier work, and cyclamate continues to be used in many countries (see section on 'Metabolism and Safety'). Cyclamate is not metabolized by the human body, so it contributes no energy to the diet and is considered a nonnutritive sweetener.

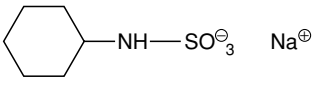

Figure 1 Structure of cyclamate (sodium salt).

Sweetness

In comparison with other intense sweeteners, cyclamate is perhaps the least sweet, being only 30–80 times as sweet as sucrose in actual food uses, depending upon concentration, pH, flavoring agents and other ingredients that may constitute a part of the food product. Aspartame, by comparison, is about 200 times sweeter than sucrose, whereas saccharin is about 300 times sweeter. In high concentrations, cyclamate has an unpleasant aftertaste. However, at low concentrations, it has some bitterness-masking ability that makes it attractive for use in pharmaceutical products. During the 1960s, cyclamate–saccharin combinations became very popular. At ratios of 10:1 (cyclamate:saccharin) on a weight basis, the combination resulted in a pleasant sweetness, minimizing the somewhat disagreeable aftertastes of both sweeteners individually. The synergistic effect of saccharin in combination with cyclamate increased the sweetening power of the mixture compared with the individual sweeteners.

Production, Physical, and Chemical Properties

Cyclamate and its calcium or sodium salts are white crystalline powders with intensely sweet tastes. Cyclamate has a melting point of about 169–170 °C. It is soluble in water up to a concentration of about 1 g in 7.5 ml, whereas the calcium and sodium salts are slightly more soluble, to the extent of about 1 g in 4 ml of water. Cyclamate is rather acidic (the pH of a 10% aqueous solution being 0.8–1.6), whereas similar solutions of the calcium and sodium salts are neutral (pH 5.5–7.5). Cyclamate is relatively heat-stable, microbiologically inert, and nonhygroscopic.

Cyclamate is synthesized by sulfonation of cyclohexylamine with chlorosulfonic acid in chloroform followed by treatment with barium hydroxide and sulfuric acid. Variations of this reaction scheme followed by treatment with sodium or calcium hydroxides yield the salts of cyclamate. Commercial production of cyclamate reached a peak in the USA in 1968, when an estimated 7400 tonnes were

Table 1 Cyclamate use levels in diet food products

Diet food	*Cyclamate level*
Table top sweeteners	25 mg g^{-1}
Milk beverages	0.8 mg ml^{-1}
Beverages and beverage bases	4 mg ml^{-1} prepared drink
Gelatin, puddings, filling	27 mg ml^{-1}
Salad dressings	1.6 mg ml^{-1}
Jellies, jams, preserves	30 mg ml^{-1}
Sweet sauces, toppings, syrups	30 mg ml^{-1}
Chewing gum	20 mg per stick
Hard confectionery	5 mg g^{-1}
Baked goods, baking mixes	2.6 mg g^{-1}

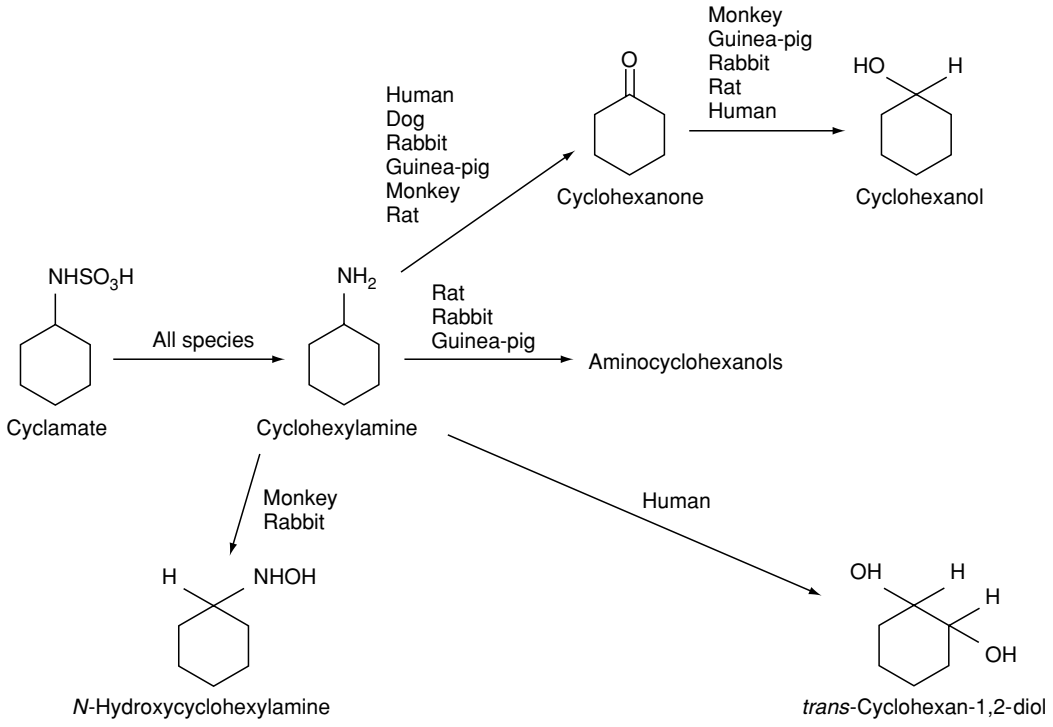

Figure 2 Schematic of the metabolic routes for cyclamate in several mammalian species.

produced. Commercial production dropped dramatically after bans on its use in foods came into effect in many countries around 1970.

Food Uses

Cyclamate is not permitted as a food additive in a number of developed countries, including Canada and the USA. Prior to 1970, cyclamate was used in a variety of diet food products. In 1969, 70% of the usage of cyclamate was in beverages, whereas 15% was in dietetic foods and 15% in table top products. Table 1 lists some of its past applications and approximate concentration levels. Like saccharin, cyclamate is rather stable to heat and moisture, and thus it was suited to sweetening a wide variety of food products. It found wide use as a sweetener in combination with saccharin, as mentioned above.

Metabolism and Safety

Figure 2 shows a schematic of the overall metabolism of cyclamate in a number of mammalian species. In humans, orally administered cyclamate is rapidly excreted via both the urine and feces. More than 98% of the dose is excreted within 1–2 days. Studies with rats and dogs have shown that small amounts of cyclamate can be distributed to all tissues (except the brain), although accumulation is negligible.

Conversion of cyclamate to cyclohexylamine in human subjects was first reported by Japanese researchers in 1966. Very small amounts of cyclohexylamine (0.7% of the administered dose) were found in the urine. This finding stimulated a large number of feeding studies in humans and animals. It appears that Enterococci organisms in the intestine convert cyclamate to cyclohexylamine. Cyclohexylamine may be converted to other metabolites as shown in Figure 2. The metabolism of cyclamate to cyclohexylamine and other products is dependent on the individual concerned. In one study involving 1000 human subjects, 10–30% of the subjects converted ingested cyclamate to cyclohexylamine mostly in the range of < 0.1–8% of the administered dose. However, some individuals converted up to 60% of the cyclamate.

Cyclamate was banned from use in many countries because the results of some rat-feeding studies showed the substance to cause bladder tumors. Many scientists questioned the results of the original studies, and this led to many follow-up studies in a variety of animal species. Of note are the results of a 22-year feeding study in monkeys carried out by the National Institutes of Health in the USA that showed that neither cyclamate (nor saccharin) demonstrated any evidence of carcinogenic effects. The prevailing opinion today is that neither cyclamate nor cyclohexylamine is likely to be carcinogenic to humans, especially at the levels recommended for diet foods (see Table 1). The main reason now that cyclamate is not permitted is that during the follow-up feeding studies to evaluate its carcinogenicity, it was observed that cyclohexylamine, the main metabolite of cyclamate, caused irreversible testicular atrophy in rats. Further research is required to study this effect in detail. The Food and Agriculture Organization/World Health Organization has determined an acceptable daily intake (ADI) value (the maximum amount that could be consumed daily for a lifetime without appreciable risk) for cyclamate to be 11 mg per kilogram of body weight. However, in the UK, a temporary maximum ADI of only 1.5 mg per kilogram of body weight has been established until the results of further research are known.

Analysis

Methods for the determination of cyclamate in foods are not as simple or as straightforward as for those sweeteners such as acesulfam-K, aspartame, and saccharin, which strongly absorb ultraviolet light. The latter can be measured by direct means (usually high-performance liquid chromatography) without recourse to chemical derivatization.

The most common analytical methods for cyclamate involve chemical conversion to cyclohexylamine followed by determination of the amine by gas chromatography with flame ionization detection. Several methods employing high-performance liquid chromatography have been evaluated, which offer potential for cyclamate determination without the need to convert to cyclohexylamine or other product. These employ direct conductivity detection, indirect ultraviolet absorption detection, or postcolumn ion-pair extraction detection.

CYSTIC FIBROSIS

R W Shepherd, Washington University School of Medicine, St Louis, MO, USA

Introduction

Cystic fibrosis (CF), a common autosomal recessive hereditary disease in Caucasians (1/2200 live births) is characterized by recurrent pulmonary infections, pancreatic insufficiency with maldigestion, malabsorption, and abnormal levels of sweat electrolytes. The abnormal gene locus is localized on the long arm of chromosome 7, most commonly at delta F 508 (in approximately 70% of cases). Biochemical studies have suggested that the defect occurs in the regulation of ion (mainly chloride) transport across epithelial cell membranes, resulting in abnormal exocrine function. This in turn results in a wide range of clinical effects (Figure 1). Recent advances in therapy have greatly improved life expectancy, such that most patients now survive into adulthood. This has resulted in an increasing population of patients requiring long-term medical care best managed through multidisciplinary clinics.

The adverse effects of CF on nutrition and growth have long been recognized and, with improving life span, the assurance of normal nutrition and growth has become an increasingly important aspect of management. Nutritional growth retardation continues to affect a substantial number of patients and is a major factor adversely affecting survival. Optimal nutritional management is, therefore, crucial in terms of growth, quality of life, and perhaps long-term outcome. This review considers the nature and causes of nutritional growth retardation in CF, explores the consequences and range of nutritional deficiencies documented in this disease, and describes current best practice with respect to nutritional therapy.

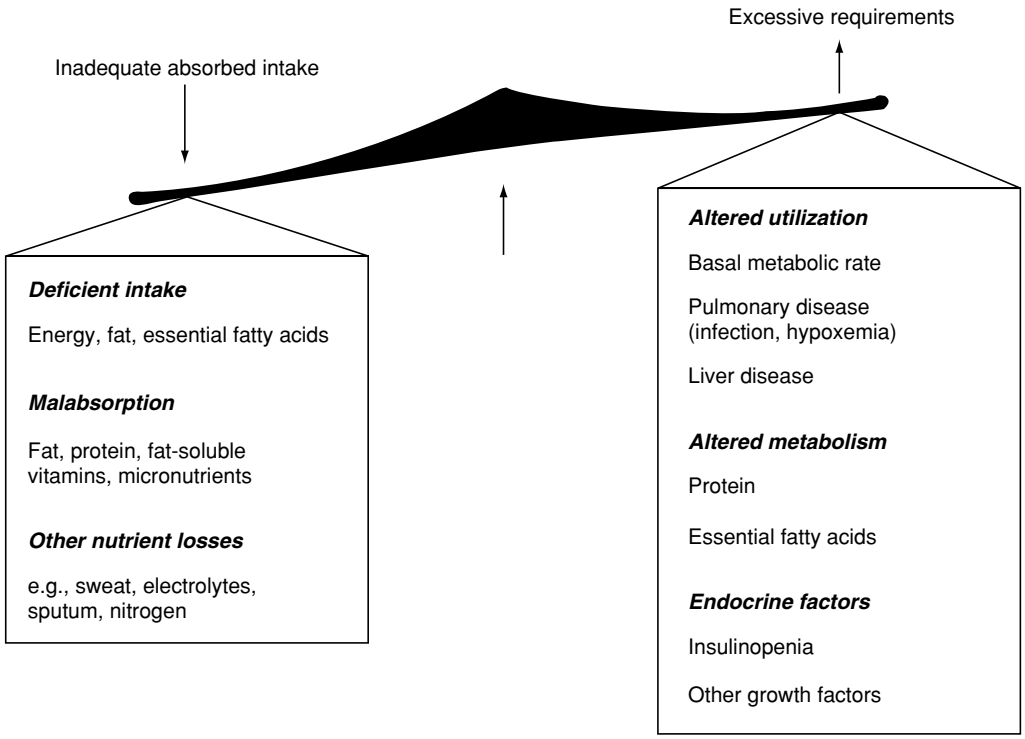

Figure 2 Factors affecting energy balance in cystic fibrosis. Reproduced from Cystic Fibrosis. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The Nature of Malnutrition in CF

A wide range of nutritional deficits causing many deleterious effects have been described in CF. The heights and weights of many CF patients are markedly skewed towards the lower centile bands, particularly with increasing age. Body composition studies have suggested that underweight CF children have a deficit in body cell mass and body fat, with a reduction in mass, muscle mass, and an excess in extracellular water compared to controls. Whole-body protein turnover studies have suggested that many malnourished patients with severe lung disease are catabolic with a reduction in whole-body protein turnover synthesis occurring during pulmonary exacerbations. The deficit of the body cell mass observed in CF from total body potassium counting can be present from the first few weeks of life, as judged by studies of newborn CF infants diagnosed by neonatal screening. Prior to neonatal screening, which has allowed the earlier introduction of preventive therapy, overt hypoproteinemia was a common presenting symptom. Specific deficiencies of essential fatty acids, fat-soluble vitamins, some water-soluble vitamins, and specific micronutrients, including zinc, iron, and selenium, are well described. Another important consideration, particularly in tropical climates, is continuing specific loss of sodium chloride resulting from the sweat gland defect. Some patients develop CF-related diabetes or CF-related hepatobiliary disease, which can both further contribute to nutritional failure.

The range of nutritional abnormalities occurring in CF seems likely to be caused by a combination of inadequate absorbed intake, nutrient losses, and increased requirements (Figure 2). Although many textbooks describe voracious appetites in CF children, in reality, objective measurements often show an inadequate energy supply compared to recommended intakes, and such patients with apparent excessive appetites may often be attempting to compensate inadequately for requirements and excessive losses. A poor appetite may be due to malnutrition *per se*, but also appears to occur where there is poor pulmonary function and during active pulmonary infection. This latter problem may have a cumulative effect on nutritional status over years as lung disease progresses. (*See* **Energy:** Energy Expenditure and Energy Balance.)

Nutrient losses occur mainly from malabsorption, but in some cases excessive nitrogen loss in sputum, and excessive sodium losses from the sweat gland abnormality (Figure 1) are also important. Fat and protein malabsorption are present in approximately 85% of patients because of pancreatic exocrine deficiency. The pancreatic abnormality involves both water-electrolyte (mainly bicarbonate) secretion as well as lipase, trypsin, and amylase deficiency.

Reduced bicarbonate secretion is universal, but a functional level of digestive enzyme capacity is retained in 10–15% of patients termed pancreatic-sufficient. These individuals may develop recurring pancreatitis and some may eventually become deficient. In untreated cases where enzyme outputs are less than 10% of normal, steatorrhea, azotorrhea, starch intolerance, and malabsorption of fat-soluble vitamins, some minerals, and vitamin B_{12} occur.

There has been a growing interest in the nature of energy and protein metabolism in CF since the recognition of an apparent maladaptation to undernutrition, and the suggestion that there may be an energy-requiring basic cellular defect in this disease. There is good evidence that resting energy expenditure is elevated in CF irrespective of age and gender but is genotype-specific. The energy cost of activity is increased in those with more severe lung disease. These factors play an incremental role in elevating total energy expenditure and the high energy requirement observed in CF patients (up to 150% recommended dietary intake or RDI).

The Consequences of Malnutrition in CF

The major effects include nutritional growth retardation, delayed puberty, adverse effects on pulmonary disease, particularly lung growth and, ultimately, a poorer prognosis. Patients dying of CF have marked nutritional failure in the 1–2 years prior to their death. Malnutrition *per se* can compromise absorptive and immune function, and all of the specific deficiencies mentioned above can have a wide range of secondary adverse effects.

A close relationship exists between malnutrition and pulmonary disease in CF. Pulmonary disease apparently adversely affects energy requirements and whole-body protein metabolism. As previously mentioned, CF patients who have chronic but stable pulmonary disease tend to have excessive protein catabolism and elevated total energy expenditure, while those malnourished patients studied during acute pulmonary exacerbations have a significantly reduced level of whole-body protein turnover. Thus both acute and chronic pulmonary disease appear to have a major effect on energy utilization. There is also evidence that malabsorption and malnutrition *per se* adversely affect the course of pulmonary disease. An improved respiratory prognosis has been observed in those patients with pancreatic sufficiency, and a number of specific effects of malnutrition on the respiratory system have been documented. Malnutrition can affect the central respiratory drive mechanism, the respiratory muscles, and the growth of the lungs. Long-term studies of nutritional rehabilitation of malnourished patients have suggested that improved nutrition may favorably affect the course of pulmonary disease.

Nutritional Management in CF

Treatment of CF patients has become increasingly specialized and is most satisfactorily performed at major referral clinics where a comprehensive and intensive management program is available. It would seem likely that early diagnosis by neonatal screening and the institution of an aggressive therapy program, before irreversible lung damage and chronic nutritional deficits have occurred, may prolong survival. Studies of neonatal screening programs to date have indicated lower morbidity and improved nutrition in those children diagnosed by neonatal screening compared with a clinically diagnosed group, and one study from Denmark has indicated that there may also be a lower mortality. The adverse effects of chronic pulmonary disease on nutritional status and, conversely, the adverse effects of malnutrition on pulmonary status, particularly lung growth, require an early aggressive approach to both aspects of the disease. Pulmonary therapy is beyond the scope of this discussion, but its importance in the prevention of malnutrition in CF cannot be overstated. Optimal nutritional therapy involves the restoration of energy balance by regular nutritional surveillance, and the maintenance of an adequate absorbed protein-energy intake with the prevention and management of specific deficiencies (**Table 1**). Certain phases of the disease, such as those occurring in infancy, during and after pulmonary exacerbations, and during puberty, may be especially important for

Table 1 Nutrient requirements in cystic fibrosis

Nutrient	*Requirement*
Energy	120–150% RDA
Protein	120% RDA
Essential fatty acids	5% of total energy (kJ)
Vitamin A	5000–10 000 IU per day (water-miscible)
Vitamin E	100–300 IU per day (water-miscible)
Vitamin K	5 mg twice weekly
Vitamin D	800 IU per day in temperate zones
B vitamins	200% RDA
Vitamin C	200% RDA
Iron and zinc	120% RDA
Pancreatic supplements (as pH-sensitive microspheres)	Infants: 2000 units of lipase per 120 ml of formula Older children: 500–4000 units of lipase per g dietary fat Maximum dose 10 000 units kg^{-1} day^{-1}

RDA, recommended dietary allowance.

optimal nutritional therapy. Overtly malnourished patients can benefit from long-term enteral nutrition delivered via either nocturnal nasogastric or gastrostomy feeding.

Surveillance

An important part of the routine management program is the regular evaluation of protein-energy balance. This involves assessment of intake, absorbed energy, possible nutrient losses, and the recording of anthropometric data. An example of a computerized surveillance program at the Royal Children's Hospital, Brisbane, is given in Figure 3, showing the benefits of longitudinal evaluation. Certain noninvasive research techniques are deserving of wider application as markers of changing nutritional status in CF. Although many of these patients are within the normal centile bands for weight, measurements of total body potassium (which provide a much more sensitive indicator of growth of the body cell mass) suggest many patients have cell mass deficits. Body impedance, which can be measured by a simple bedside technique, correlates well with body potassium in CF and may serve as a reliable clinical tool for the surveillance of fat-free mass. The advent of measures of total energy expenditure in free-living humans should also help to establish an evaluation of true nutritional requirements in this disease.

Dietary Therapy

Dietary counseling, and dietary and pancreatic enzyme supplements remain mainstays in the preventive management of nutritional problems in cystic fibrosis. To achieve an adequate absorbed protein-energy intake (Figure 2), daily intakes >130% of RDI are usually necessary to compensate for stool losses and increased requirements. In general, it is usually possible to achieve normal growth and nutrition in CF children with dietary counseling, pancreatic enzymes, and high-energy supplements. Although in the past it was standard practice in many CF clinics to prescribe low-fat, high-carbohydrate diets, low-fat diets offer no benefit to CF patients, impair total energy intake, and contribute to essential fatty acid deficiency. Indeed, mortality was higher in clinics prescribing low-fat diets, favoring the prescription of a moderate- to high-fat diet. Since fiber has been shown to inhibit pancreatic enzymes *in vivo* and *in vitro*, fiber-enriched diets should be avoided. Patient tolerance of normal fat intakes of 40% of total energy is satisfactory, provided that appropriate enzyme preparations are used. Palatable and

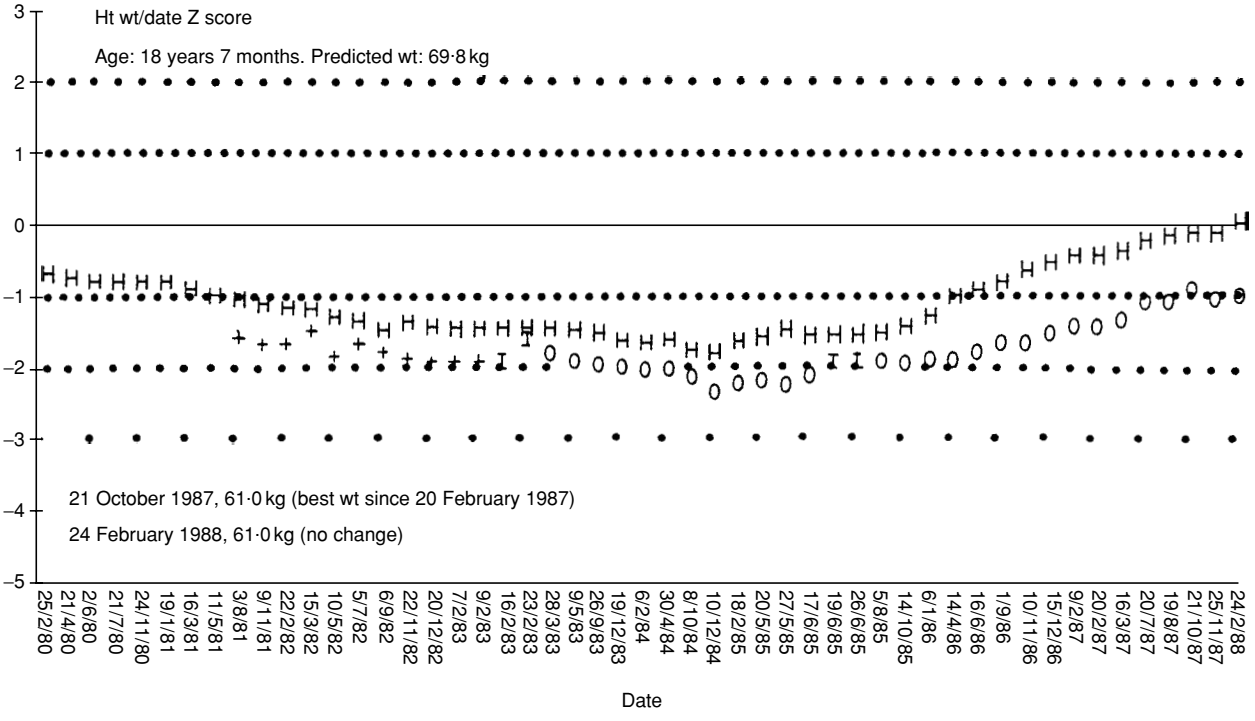

Figure 3 Serial height and weight standard deviation scores from the computerized clinic data records of an adolescent with cystic fibrosis from the age of 10–18 years. Note the gradual decline in both height (H) and weight (I, weight as an inpatient; 0 or +, weight as an outpatient), until about the age of 14 years, when long-term enteral nutritional supplements were instituted by nocturnal intragastric feeding. By the age of 18 there was a gradual improvement in these parameters. Reproduced from Cystic Fibrosis. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

nutritious high-protein energy foods are encouraged and special milk drinks with added energy sources, such as chocolate-flavored protein-enriched powders, glucose polymers, and other foods, represent a good way of increasing total energy intake.

A full range of vitamin and mineral supplements is necessary to prevent vitamin and mineral deficiency. In particular, fat-soluble vitamins presented in a water-miscible form are required in all patients with steatorrhea, administered in a dosage twice the RDI. As mentioned previously, where oral intake with supplements fails to achieve satisfactory height and weight gain, or if the patient is overtly malnourished, enteral supplements can be used. A metaanalysis of 18 studies of enteral supplementation have demonstrated significant benefits in terms of weight gain, growth, body protein accretion and stabilization, and, perhaps, improvement of pulmonary function. High-energy defined semielemental formulae are most suitable for use in the nutritional rehabilitation of malnourished CF patients, and are generally well tolerated. As illustrated in Figure 3, surveillance of weight gain and growth provides a reasonable clinical indicator for nutritional intervention and the assessment of benefits derived.

Pancreatic Enzyme Replacement Therapy

Pancreatic enzyme replacement therapy (PERT) needs to be tailored to individual requirements and is required in about 85% of CF patients, according to the amount of food (particularly fat) eaten and the degree of malabsorption. It is appropriate to assess quantitatively the degree of malabsorption and the ability of the therapy to correct this. Some measures to improve the efficacy of PERT have been a recent area of study in CF, as conventional preparations rarely fully optimize absorption. The objectives of PERT include correction of maldigestion, elimination of symptoms and signs of malabsorption, and sustaining normal nutrition.

A bewildering number of pancreatic enzyme preparations are commercially available in the form of tablets, capsules, enteric-coated microspheres, granules, and powders. Some products have not been designed specifically for the treatment of exocrine pancreatic insufficiency, but for patients with unspecified abdominal pain. Some contain bile salts; in general these should be avoided in patients with pancreatic insufficiency because high concentrations of bile salts may aggravate diarrhea. Preparations that are protected against peptic acid inactivation are preferable to unprotected preparations: unprotected ingested enzymes are degraded to a significant degree as a result of increased gastric acidity, and lowered duodenal pH secondary to depressed bicarbonate secretion for the pancreas. The lipase content is the most important determinant of the effectiveness of these products. Between 80% and 90% of unprotected ingested lipase and trypsin is inactivated in the stomach. It was thought that PERT was complication-free, but excessive doses have been associated with renal calculi, and prolonged excessive dosages with serious fibrosing colonopathy. Guidelines for the safe correct use of PERT have been published. In the UK, the Committee of Safety of Medicines suggests doses of no more than 10 000 u lipase kg^{-1} day^{-1}.

It has been calculated that, in an adult, assuming there is no inactivation of enzymes in the stomach, approximately 30 000 IU of lipase is required to be delivered to the duodenum with an average meal containing about 6 g of fat for normal digestion. In children approximately 500–4000 IU is required per gram of fat ingested. The distribution of fat content of different meals and the mixing enzymes with food in the duodenum seems to be important. Granulated preparations or microspheres are better than tablets in that they enable higher enzyme activities to reach the duodenum and mix with the food. The majority of enzyme preparations contain between 5000 and 20 000 IU of lipase. It can thus be calculated that, for the average adult, if some defence against gastric inactivation is provided and there is an adequate enzyme–meal mix, between 2 and 10 capsules are required per meal to control steatorrhea. Studies in children comparing conventional tablet enzyme therapy to enteric-coated microspheres of pancrelipase have shown that significantly less steatorrhea and azotorrhea occur with the use of the microsphere preparation. In addition, there is an improvement in compliance because significantly fewer capsules are required. Irrespective of the preparation used, there is good evidence that the enzymes need to be delivered appropriately and dispersed evenly throughout a meal, in order to achieve maximum exposure of food to the ingested enzymes.

The success of enzyme therapy is assessed by bowel symptoms, quantitative absorptive tests, such as fecal fat analysis, and the maintenance of normal nutrition. In children, assessment of growth is also essential. Azotorrhea is more frequently abolished by pancreatic enzyme supplements than is steatorrhea, possibly because trypsin secretion is better preserved than lipase secretion in pancreatic insufficiency, and because trypsin is not inactivated by acid but only by pepsin. Poor response to pancreatic enzyme preparations may result from poor compliance, inappropriate timing of administration, the presence of another condition causing steatorrhea (e.g., bacterial overgrowth), or the use of an unprotected, acid-sensitive enzyme preparation.

Adjuncts to Pancreatic Enzyme Therapy

Adjunctive treatment to neutralize or inhibit gastric acid and help to protect pancreatic enzymes against acid inactivation may be useful in selected cases. The use of antacids with pancreatic supplementation to neutralize gastric acid has achieved variable results, probably because some antacids form calcium soaps and precipitate glycine-conjugated bile salts. Histamine H_2-receptor antagonists are of theoretical value because many causes of pancreatic insufficiency (particularly CF) are associated with gastric hypersecretion. If there is adequate reduction of gastric activity, the addition of cimetidine does appear to be effective when used with enteric-coated, microsphere, pH-sensitive preparations. However, these enzyme preparations do not disintegrate and release their contents until encountering an alkaline pH, and despite acid suppression therapy, in some cases, complete correction of steatorrhea has not been possible. Recently, a new approach to adjuvant therapy has been suggested with the use of misoprostol, a synthetic methylated prostaglandin E_1 analog, which decreases secretion of gastric acid and increases duodenal bicarbonate secretion. This therapy may have inherent advantages over histamine H_2-receptor antagonists as adjuvant therapy for pancreatic insufficiency because of the latter effect.

Conclusions

Nutritional problems are common in CF and have an increasingly important role in management. Malnutrition is a major factor influencing survival, and may even influence the course of lung disease as there appears to be a close bilateral relationship between the progression of pulmonary disease and undernutrition, although the factors responsible for such a relationship are incompletely defined. Although it is widely recognized that factors such as nutrient losses from malabsorption, a variable but often inadequate intake, and chronic lung disease contribute to malnutrition, recent studies have also suggested that the primary defect may require energy. A wide range of nutritional deficits occurs in CF; many patients have deficits of body fat and body cell mass, and appear to be in a state of chronic catabolic stress. Whole-body protein turnover would also appear to be abnormal in many CF patients, particularly during pulmonary exacerbations. Specific deficiencies of essential fatty acids, fat-soluble vitamins, and some micronutrients also occur and may compromise pulmonary function and immunity. Optimal nutritional management in CF includes the provision of adequate protein and extra energy as fat and carbohydrate, and an appropriate dosage and administration routine with food, of pancreatic enzyme supplements in a form which minimizes acid–peptic inactivation. Newer adjuncts to pancreatic enzyme therapy, such as prostaglandin analogs, show promise. Food supplements should provide extra energy, essential fatty acids, fat-soluble vitamins in a water emulsion, salt supplements in hot weather, and water-soluble vitamins, and micronutrients. Routine surveillance of nutritional status and absorbed energy should be performed at regular intervals. Deviations from normal weight gain and growth may require nutritional intervention. Recent studies by a number of groups confirm that long-term supplementation can achieve sustained catch-up weight gain and growth, and provide support for the view that reversible nutritional factors may have an important influence on the course of pulmonary disease in those CF patients who have deteriorating lung function, and who are unable to sustain normal growth and nutrition by the oral route. Obviously, the overall goal should be to prevent this situation and provide the CF patient with as normal a lifestyle as possible, with management aimed at preventing progressive pulmonary disease, maintaining normal growth and nutrition, and preventing complications.

Background

Indian curd, known as 'dahi,' is a very well-known fermented milk product consumed by large sections of the population throughout the country, either as a part of the daily diet or as a refreshing beverage, e.g., lassi. Dahi is also used for the production of Shrikhand: some whey is removed from dahi, and the concentrated curd is mixed with an equal weight of sucrose. Dahi has been a very popular fermented dairy product in the Indian subcontinent, which includes India, Pakistan, Bangladesh, Nepal, and Sri Lanka. The name of this product has been found in the ancient Hindu scriptures, and its medicinal value has also been well documented. Dahi may be consumed directly either sweetened or salted and spiced. It is also consumed with other foods such as rice and wheat loaf. Dahi has assumed a special place in the daily diet of Indian people, who prefer to have dahi once or twice a day at morning or evening meals. In 1999–2000, the production of dahi was estimated to be about 7% of total milk production in India. Since conversion of milk into dahi is an important intermediatary step in manufacture of indigenous fat-rich dairy products like butter and ghee, it can be said that over 40% of the total milk production in India is converted into dahi.

Definition

According to the Bureau of Indian Standards, dahi is a product obtained by lactic fermentation of cow or buffalo milk or mixed milk through the action of single or mixed strains of lactic acid bacteria. This definition does not include milk coagulated by the addition of acids or milk coagulating enzymes. As per the Prevention of Food Adulteration Act (1988), dahi or curd is a product obtained from pasteurized or boiled milk by souring natural or otherwise, by harmless lactic acid or other bacterial culture. Dahi may contain added cane sugar. It should have the same percentage of fat and solids-not-fat as the milk from which it is prepared. Where dahi or curd, other than skimmed milk dahi, is sold or offered for sale without any indication of the class of milk, the standards prescribed for dahi prepared from buffalo milk should apply. This is similar to yogurt made from boiled milk after inoculation with a mixed starter culture which consists of dahi left over from the previous lot. However, it is less acidic than yogurt.

Starter Cultures for Dahi

In the production of dahi, inoculation with a small quantity of the desired fermenting flora, named the starter culture, (since the culture initiates or starts fermentation). The most important organisms in starter cultures are the homofermentative and heterofermentative lactic acid bacteria. Dahi starter cultures can be classified into two groups, according to the characteristics of the microorganisms: mesophilic and thermophilic. Mesophilic starters and cultures are used at a temperature of 16–30 °C and contain mesophilic organisms (Table 1). The most typical representatives are the homofermentative *Lactococcus lactis* ssp. *lactis* and *Lc. lactis* ssp. *cremoris*, which are similar, although the former is able to produce free amino acids, which are believed to stimulate the growth of *Lc. lactis* ssp. *cremoris* strains. Another important species in mesophilic starters is the homofermentative citrate$^+$ *Lc. lactis* ssp. *lactis*, which is able to produce lactic acid and in the presence of lactose to ferment citric acid into a number of other compounds such as diacetyl and carbon dioxide. However, at a pH below 5, carbon dioxide and a number of compounds similar to diacetyl, but non-aromatic, are produced. The heterofermentative *Leuconostoc mesenteroides* ssp. *dextranicum* and *Ln.*

Table 1 Designation of dahi based on the type of starter culture

Designation	*Cultures used*	*Remarks*
Sweet dahi	*Lactococcus lactis* ssp. *lactis, Lactococcus lactis* ssp. *cremoris*,	Single or in combination with or without aroma producers like *Leuconostoc mesenteroides* ssp. *dextranicum, Leuconostoc mesenteroides* ssp. *plantarum*
Sour dahi	*Lactobacillus delbrueckii* ssp. *bulgaricus* and *Streptococcus thermophilus*	Single or in combination with or without aroma producers

mesenteroides ssp. *plantarum* are able to ferment citric acid into carbon dioxide, diacetyl, and several other products. Unfortunately, the *Leuconostoc* species may reduce diacetyl into nonaromatic compounds. The intensity of reduction varies between the various representatives of the strains. Homofermentative thermophilic starter organisms like *Lactobacillus delbrueckii* ssp. *bulgaricus* and *Streptococcus thermophilus* are used to obtain mildly sour dahi. These starters play an important role in producing a good-quality dahi with a firm and uniform consistency, sweet aroma, and clean, acidic taste.

Classification of Dahi

Broadly speaking, dahi may be classified into two types:

1. dahi for churning into desi (indigenous) butter;
2. dahi for direct consumption.

Dahi for direct consumption is further classified into the following subtypes:

1. whole-milk and skim-milk dahi;
2. sweet (or mildly sour), sour, and sweetened dahi.

Technology of Sweet and Sour Dahi Manufacture

The steps involved in the manufacture of sweet (or mildly sour) and sour dahi are shown in Figure 1. The manufacture is as follows:

Preliminary Treatment of Milk

The preparation of the basic mix involves selection of milk, preheating, filtration/clarification, and standardization of milk. The different methods for standardizing the milk indicate the possibilities that exist for either increasing or reducing the various milk constituents, especially the fat content. However, the choice of any particular method is primarily governed by the following factors:

- cost and availability of the raw materials;
- scale of production.

The composition of dahi varies considerably. The composition of dahi made from buffalo milk is detailed in Table 2. Commercial dahi tends to contain around 14% milk solids; the use of ultrafiltration to concentrate the solids in cows' milk and skim

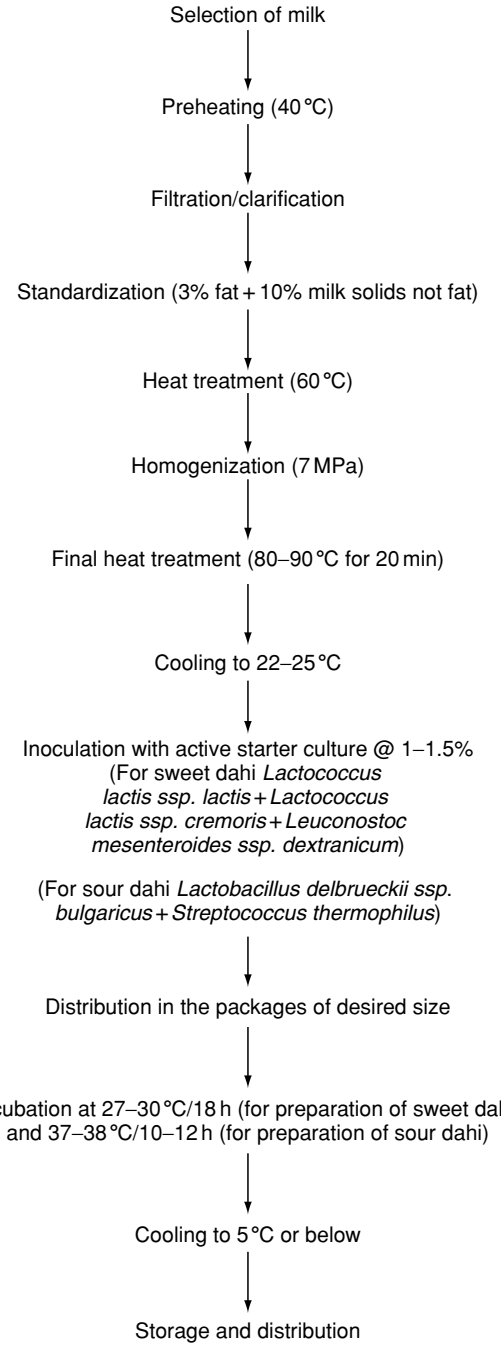

Figure 1 Flow diagram for preparation of dahi.

Table 2 Composition of buffalo milk dahi

Constituents	*Level (%)*
Moisture	85–88
Fat	5–8
Protein	3.2–3.4
Lactose	4.6–5.2
Ash	0.7–0.75
Lactic acid	0.5–1.0
Calcium	0.12–0.14
Phosphorus	0.09–0.11

milk is being considered as a feasible alternative. The importance of total solids stems from the improved consistency imparted to the dahi coagulum, an improvement that is carried further by the homogenization stage by employing a pressure of 17 MPa. Homogenization of milk improves the texture of the coagulum and also reduces the likelihood of whey separation. Homogenization is followed by a final heat treatment of 80–90 °C for a prolonged period of 20 min. The effect of this drastic heat treatment can be summarized as follows:

1. The bacterial load in the milk is reduced, and hence the starter culture has less competition from the contaminating organisms.
2. The whey proteins (albumins and globulins) are denatured and interact with the casein molecules, which form a three-dimensional network on acidification. The network traps the whey proteins, and the dahi coagulum subsequently produced is rendered more viscous.
3. There is a reduction in the amount of oxygen in the milk, and as the normal dahi cultures are microaerophilic, the lowered oxygen tension encourages their growth.
4. Some limited damage to the milk proteins may occur during heating, and the breakdown products can stimulate starter activity.
5. The heat treatment imparts a cooked flavor for misti dahi.

Fermentation of Milk

The acidification of milk during the manufacture of dahi is an important biochemical process which must be carried out under controlled conditions in special incubators and/or fermentation tanks. Fermentation tanks are used as incubators only, and they are usually insulated in order to maintain the appropriate temperature. The processing of the milk and the cooling of the dahi are carried out in other equipment in the production line. Cabinets are also used for this purpose. These comprise a small insulated room which is divided into compartments, and most incubators of this type are multipurpose chambers capable of circulating hot or cold air. Hot air is circulated during the fermentation period, followed by cold air during the cooling stage. Sometimes, these cabinets are used as incubators only, and the dahi can be cooled in refrigerated cold storage. In the case of mildly sour (sweet) dahi manufacture, the temperature is maintained at 27–30 °C, while for sour dahi, it is 37–38 °C.

Cooling of Dahi

After the incubation period, dahi is cooled in order to control the level of lactic acid in the product. The rate of cooling can affect the structure of the coagulum. Thus, very rapid cooling can lead to whey separation, if the protein filaments are concentrated too rapidly, which in turn affects their hydrophilic properties.

Microbiological Quality of Dahi

An examination of the microbiological quality of a product is usually concerned with two aspects, namely: protection of the consumers from exposure to any health hazard and ensuring that the material does not suffer microbiological deterioration during its anticipated shelf-life. Both these aims are of importance to the consumer and producer alike. Thus, over and above any moral responsibility that a company accepts for the integrity of its product, the financial losses that follow a public health incident, or even a high level of consumer complaints, provides a very strong incentive for a manufacturer to give quality assurance a high priority. The type of hazard that may be encountered depends on the nature of the product, and in general terms, dahi can be regarded as 'hygienically safe.' The reason for this confidence stems from the level of acidity present (around 0.7–1.0% lactic acid), for this situation, potential pathogens such as *Salmonella* spp. will be largely inactive. Similarly, 'coliforms' will be unable to survive the low pH encountered, and this inhibition is reinforced by the production of antibiotic substances by the dahi starter organisms. Microbiological standards for dahi are given in Table 3. Typically, the shelf-life of dahi is 2–4 days at 4 °C.

Table 3 Indian Standard Institute specifications for dahi

Characteristics	*Requirement*	
	Sweet dahi	*Sour dahi*
Acidity, lactic (% wt) (max.)	0.70	1.0
Yeast and mold count g^{-1} (max.)	100	100
Coliform count g^{-1} (max.)	10	10
Phosphatase test	Negative	Positive

Technology of Sweetened Dahi (Misti Dahi) Manufacture

Misti dahi (syn. sweetened dahi, red dahi, payodhi) is a traditional sweetened fermented milk product of the Eastern region of India. It is prepared on a cottage scale by sweetmeat makers everyday to meet local demands. Traditionally, milk with added cane sugar is continuously heated in an open pan at a simmering temperature (68–70 °C) for 6–7 h to concentrate and develop the intense cooked flavor and brown color, increase the viscosity, and induce other physicochemical changes. After cooling to about 40 °C, the mix is inoculated with a commercial misti dahi starter culture, which is generally a mixed lactic culture like LF-40 or *Lb. delbrueckii* ssp. *bulgaricus*, *St. thermophilus*, and some aroma-producing organisms, as in mildly sour and sour dahi. Wide variations in total solids content (27–43%), milk-solids-not fat (11–16%) and sucrose (13–19%) in market samples of misti dahi sold in Calcutta city have been reported. Many flavor defects such as fruity, alcoholic, highly acidic, flat, etc., and textural defects like gassiness, weak body, wheying off, and a thick crust on the top surface have been observed in most of the market samples. In view of the increasing nationwide demand for this product and the growing interest in organized dairy plants for large-scale manufacture, the technology has been developed to suit industrial-scale production. The manufacturing technology for the industrial production of misti dahi is outlined in Figure 2. Fresh buffalo milk is standardized to 3.5% fat and 9% milk-solids-not fat, heated to 65 °C in a plate heat exchanger, and homogenized at a pressure of 56 kg cm^{-2} (one stage). Milk is concentrated to 1.44-fold in a vacuum evaporator. After adding cane sugar (7–15%), the milk is heated at 85 °C for 10 min to generate a cooked flavor. The mix is water-cooled to 40 °C before inoculation with the mixed culture, LF-40. In some cases, sugar, caramel, jaggery, and artificial colors are added to impart a brown color. The inoculated mix is aseptically distributed into presterilized polystyrene containers of the desired size and mechanically transferred to an incubation chamber at 40 °C. During curd formation, the milk must remain stationary. In all postfermentation activities, the gel should be subjected to minimal external influences. Diacetyl is the predominant flavor component, but microquantities of acetoin, acetic acid, and carbonyls are also present. Off-flavors in this product can be traced back to poor-quality raw milk, use of contaminated cultures, a high incubation temperature, and contaminated packages.

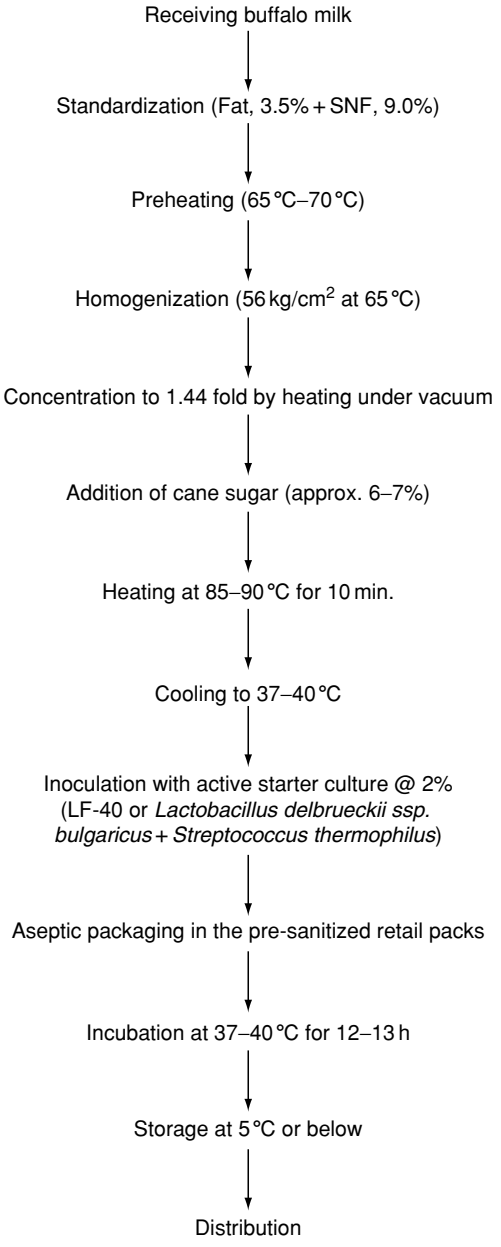

Figure 2 Flow diagram for the preparation of misti dahi (sweetened dahi). The temperature of homogenization is different for both types.

Food and Nutritive Value and Therapeutic Benefits of Dahi

Indian literature has described in detail the importance of dahi in human nutrition. Scientific investigations have proved that dahi is digested and assimilated more easily by virtue of its buffering action and supplies more nutrients than milk. Tricalcium phosphate is converted into monocalcium phosphate, and some insoluble minerals are rendered more soluble due to lactic acid production. Many researchers have found an increase in the levels of

Table 4 Mineral and vitamin content (per 100 g) of dahi

Constituents	*Milk*	*Dahi*
Mineral matter (g)	0.8	0.8
Calcium (mg)	149.0	149.0
Phosphorus (mg)	96.0	93.0
Vitamin A (IU)	118.0	102.0
Thiamin (μg)	55.0	49.0
Riboflavin (μg)	167.0	157.0
Nicotinic acid (μg)	96.0	86.0
Biotin (μg)	29.0	3.2
Pantothenic acid (μg)	202.0	183.0
Folic acid (μg)	161.0	178.0
Vitamin B_{12} (μg)	0.15	
Ascorbic acid (mg)	1.4	1.3

riboflavin (vitamin B_2) and thiamin (vitamin B_1) in dahi.

Converting milk into dahi also tends to stabilize the vitamin C potency more than fresh milk, which is vitally important for the growth and repair of tissues in bones, teeth, and blood vessels, health of gums and teeth, overall body growth, and resistance to infection. Lactose-fermenting bacteria have been found to synthesize vitamin B, present only in small quantities in milk. The mineral and vitamin contents in dahi are listed in Table 4.

Dahi obtained from cows' milk has been found to cure dysentery, diarrhea, thirst, coughs and colds, indigestion, headache, weakness, and many other diseases and ailments. It improves the digestibility of food and allays the fear of diseases of any nature by checking the undesirable putrefactive fermentations in the alimentary canal. The putrefying bacteria inhabiting the human intestines are harmful, because they poison the food with the products of their metabolism. Since the bacterial flora of the intestines live in an alkaline medium, the best thing would be to create an acid medium in the lower intestine. For this reason, the introduction of regular use of dahi is advocated. Its palatability and pleasant flavor have an appetizing effect. Those who do not relish milk like dahi. It is beneficial to youngsters and pregnant and lactating females. It is a good dietary item for all and deserve a high priority in our daily menu for healthful living.

Industrial methods have been developed during the last decade to mechanize the production, packaging, and storage of dahi, and it is now produced regularly on a factory scale. The need for more promising mechanization and upgrading of production technologies, packaging, preservation, and distribution of dahi has now been recognized. Attempts to develop any large-scale process for dahi-based sweets must aim at using the existing processes in dairy plants rather than relying on a new plant design and fabrication, which carry limitations of available engineering skill, high costs, and time loss. In view of the growing market demands for dahi and its derivatives, there is a great scope for modernizing the existing technology for industrial production.

DAIRY PRODUCTS – NUTRITIONAL CONTRIBUTION

J Buttriss, British Nutrition Foundation, London, UK

Introduction

Dairy products are traditional dietary items in many parts of the world, in particular in regions such as northern Europe where the cooler climate is especially suited to dairying. The history of milk as a food has been documented over the centuries and examples of early dairying are depicted in Egyptian friezes such as that from the sarcophagus of Queen Kawit from Der-al-Bahri, between Luxor and Karnack, dating back 4000 years. There is an even earlier Mesopotamian frieze from the temple of Nin-khasarg, near Ur, which is thought to be 1000 years older.

The popularity of milk as a staple food over the centuries must partly be due to its versatility. Early humans discovered that it could be churned to make butter and fermented with bacterial cultures to produce cheese and yogurt, all of which were methods of preserving some or all of the nutrients in milk for consumption at a later date. (*See* **Cheeses**: Dietary Importance; **Milk**: Dietary Importance; **Yogurt**: Dietary Importance.)

This article summarizes the nutritional contribution made by milk and milk products.

Variety

Today, the range of dairy products on the market is immense. In most countries, a range of milks with differing fat contents is available. For example, in the UK consumers can choose between Channel Islands milk, with 5.1 g per 100 g fat, through whole milk (3.9 g per 100 g) to semiskimmed (1.6 g per 100 g fat) and skimmed milk, which has virtually no fat. Similarly, a wide range of cheeses exists with varying fat contents: at one end of the spectrum are soft fresh cheeses, made with skimmed milk and, at the other, hard cheeses such as cheddar. Also available is cheese made with nonanimal rennet, suitable for vegetarians. In the UK alone, almost 200 different cheeses are produced, and cheese is particularly popular in countries such as France, where an even greater variety is available.

Fermented milk products such as yogurt, smetana, and kefir have always been popular in Middle Eastern countries, but their popularity, particularly that of yogurt, is dramatically increasing in the UK. Again, a wide range of yogurts exists, from the very-low-fat to the creamier, whole-milk or Greek-style product, including set yogurts, stirred yogurts, fruit yogurts, frozen yogurts and fromage frais. (*See* **Fermented Milks**: Types of Fermented Milks; **Yogurt**: The Product and its Manufacture.)

Traditional products such as cream and butter are still in demand, in spite of their relatively high fat content, and are being joined by other 'luxury' products, such as real dairy icecreams, fresh cream desserts, and luxury mousses. To meet the demand for a spread with a buttery flavor, spreads have been developed which incorporate butterfat for taste but often have a lower fat and calorie content. (*See* **Butter**: The Product and its Manufacture; **Cream**: Types of Cream; **Ice Cream**: Methods of Manufacture.)

A number of products also exist to which nutrients have been added, such as the calcium-enriched milks, and yogurts fortified with additional vitamins.

Nutritional Value

Most dairy products offer a wide range of nutrients and this is reflected in the contribution made by milk and milk products to dietary intake in many countries. For example, in the UK, milk and milk products provide over half the calcium in the average diet and make a significant contribution to the needs of other nutrients (Table 1).

Nutritional Significance of Milk and Milk Products

In countries where dairying has traditionally been a strong industry, milk and milk product consumption tends to be widespread and makes a significant contribution to nutrient needs. For example, the average daily intake of milk in the UK in 1998 was a little under half a pint per person (285 ml). Table 2 shows the contribution this quantity of whole milk makes to the nutrient and energy needs of a 4-year-old girl and a man. Skimmed or semiskimmed milk would make smaller contributions to intake of energy and fat-soluble vitamins.

In Scandinavian countries, where dairying is also traditional, liquid milk consumption is typically higher than in the UK. However, in warmer climates, in particular the Indian subcontinent, Africa and

South America, climatic conditions lend themselves less readily to cows' needs, so that the development of dairying and, hence, milk-drinking habits has been far more patchy. Exceptions exist, such as the Masai in Eastern Africa, whose culture is dominated by the cow. Similarly, in parts of India, cows have religious significance but have not until recently been intensively managed for their milk. Table 3 presents estimates of milk consumption in different countries.

As it is rich in calcium needed for skeletal development and maintenance, milk has traditionally been seen as an important food during childhood, pregnancy, and lactation, when calcium requirements are particularly high. This view is still supported today by a recent UK government report. A pint of milk (0.568 l) provides about 700 mg of calcium. (*See* **Calcium**: Properties and Determination; **Children**: Nutritional Requirements.)

Claims of Adverse and Beneficial Effects to Health

Allergy or Intolerance to Cows' Milk

True milk allergy is typically seen in infants. Although estimates vary, it is thought that at its peak incidence in 1–3-year-olds, cows' milk allergy affects about 1% of infants. Most children outgrow this reaction to the protein in milk by their fifth birthday and in many instances it is short-lived, being brought on by a gastrointestinal upset.

Intolerance to the sugar in milk – lactose – occurs in those people who lack or who have low levels of the enzyme lactase, which digests lactose to its components, glucose and galactose. This enzyme is invariably present in the intestines of infants to enable them to

digest their mother's milk, but levels fall off in some adults, particularly those who come from areas of the world where milk consumption is not traditional. Hence, in the UK, lactose intolerance is rare among Caucasians but is experienced by some ethnic groups of Indian, African, or Chinese extraction. In many cases, sufferers have low levels of the enzyme and can thus tolerate small quantities of milk and larger quantities of foods such as cheese or yogurt. In the case of cheese, the lactose has largely been lost with the whey in the cheese-making process. In the case of yogurt, it is suggested that the β-galactosidase enzyme, present in the bacterial culture used to make yogurt, may be able to digest some of the lactose. (*See* **Food Intolerance**: Lactose Intolerance.)

Table 3 Estimates of liquid milk consumption in a selection of countries in 1998

	Liquid milk consumption (kg per person per year) 1998

Health Benefits of Yogurt

A number of health benefits of yogurt have been claimed, including an ability of certain types of bacteria used in the manufacture of yogurt to colonize the gut and help fend off harmful bacteria.

Coronary Heart Disease

One of the risk factors for coronary heart disease (CHD) is a raised plasma cholesterol level. A number of factors, including genetic make-up, influence an individual's plasma cholesterol level. One such factor is thought to be intake of saturated fatty acids, particularly in genetically susceptible people who are less able to remove low-density lipoproteins (LDLs) from their blood stream.

Many governments have issued guidelines on diet in relation to heart disease. In the UK, guidelines of energy and nutrient intake include recommendations on total fat intake and on fatty acid intake. The guidelines on saturated fatty acids (saturates) have been set with a view to reducing average plasma cholesterol

Table 4 Contribution of sources of fat and saturates in the household food supply

concentration by 0.4 mmol l^{-1}, thus bringing it down to a level associated with a substantially lower incidence of CHD than witnessed in the UK at present.

In 1999, saturates provided an average of 14.9% of energy intake. The Department of Health report advises that average consumption is reduced to 10% of total energy (11% of food energy). This advice does not apply to children under the age of 2 years.

Intake of specific foods has not been linked directly with CHD risk. However, a reduction in foods contributing significant amounts of fat (Table 4), especially saturated fatty acids, to the diet has been recommended for those people with a high fat intake. Such advice calls for a reduction in foods such as whole milk and its products, fatty meats, fried foods, spreading and cooking fats, and baked goods such as biscuits, cakes, and pies.

A wide range of lower-fat milks and milk products is now available, so that those people concerned about their fat intake can change to a lower-fat option rather than cutting down on dairy products and losing a valuable source of calcium and other essential nutrients.

Dairy Products and Dental Health

The frequency of sugar consumption is positively related to the incidence of dental caries. Although lactose (milk sugar) is moderately cariogenic if consumed in isolation, when it is consumed as part of milk any cariogenicity is counteracted by protective factors in milk. Consequently, milk without added sugars can be considered to be virtually noncariogenic. (*See* **Dental Disease**: Etiology of Dental Caries.)

Cheese is now recognized to help protect against dental decay. Dental caries results from acid production at the tooth surface, following fermentation of sugar by the bacteria present in dental plaque. It has been known for some time that eating a small amount of cheese at the end of a meal can counteract this effect; however, a recent study indicated that cheese incorporated within a meal confers similar benefits, in so far as it reduces the fall in plaque pH recognized to be associated with decay.

A number of possible mechanisms have been offered to explain this beneficial effect of cheese. Eating cheese causes an increased flow of saliva, which is slightly alkaline and acts as a buffer to the acid. Also, cheese favors remineralization of any damage since it is rich in calcium and its consistency brings calcium and phosphorus into contact with the tooth surface.

DATE PALMS

A A A Kwaasi, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia

Background

The date palm (*Phoenix dactylifera* **L.**) has been known for as long as recorded history. Apart from its importance as a food source for man and animals, all parts of the plant have their use in medicine, pharmacognosy, chemistry, and religion, and in the fishing, horticulture, and construction industries. Like all economic plants, dates are also afflicted by a number of diseases from microbes, insects, and rodents. Dates are one of the few foods that have a high potassium content and, at a certain stage of development, have a low sucrose content. As knowledge in agriculture, medicine, and industry develops, so does the number of new agents that are found to be harmful or useful to man. In the last two decades, there has been a dramatic increase in the number of foods that have been found to be allergenic, and accidental consumption of these foods by susceptible individuals has led to fatalities. Date fruit and pollen are no exception. Results of recent research have revealed that both date pollen and fruit peptides from certain date cultivars can elicit allergic responses in susceptible individuals and share a number of cross-reactive epitopes with some well-known allergens. The beneficial properties of the date are such that its cultivation should be expanded.

History

The date palm has provided inhabitants of the hot dry regions of the world with a highly desirable food and has therefore been thoroughly exploited. The earliest archeological finds dated 5000–6000 BC were from Iran, Egypt, and Pakistan. Remnants of dates have been found in excavations of Neolithic sites dating back 7000–8000 years and in the tombs of Egyptian Pharaohs. The earliest cultivated finds dated around 4000 BC were from Eridu, Lower Mesopotamia in the Bronze Age. Dates are mentioned in Akkadian and Sumerian cuneiform sources (*c.* 2500 BC) and later. The date palm has historical and religious fame in Judaism, Christianity, and Islam. Date palm fronds are used on Palm Sunday and are thought to have been used in Jesus' triumphant entry into Jerusalem (Synoptic Gospels, New Testament), and the book of Psalms states that 'the righteous shall flourish like a palm tree.' Date fruits are eaten by most Christians during Christmas and are used in breaking the fast during the Islamic Holy Month of Ramadan. It is mentioned in the Qur'ān (Maryam 19:25–26) in relation to Jesus' birth, and there are a total of 26 references to dates in this holy book.

Origin and Distribution

The palm is presumed to have originated in the Persian Gulf area and in Western India, but its exact origin is difficult to establish. Apart from remnants of some wild dates still present in areas around Jordan and the Iraq–Iran border, all dates known today are fully domesticated. The date was naturalized in Arabia and spread through Northern Africa, Spain, the drier parts of the Nile valley, and around the Euphrates River. From Spain, it was introduced to America, where it is now grown commercially in the warm valleys of Southern California and Arizona. Dates are cultivated throughout the desert regions of the world and grow well between latitudes of 15 and 35 ° N, from the Canaries and Morocco in the west, to India in the east. It is recorded from all the inner and littoral parts of North Africa, the southern parts of the Balkan Peninsula, and Asia Minor, from Syria, Palestine, Transjordanian, Iraq, Arabia Peninsula, Iran and Baluchistan regions. Dates are grown on family compounds and along streets and highways, and are seen in every conceivable space in the Middle East. The date is cultivated as an ornamental plant in South Europe, where it seldom matures into fruit, except in southern Italy and Spain, and is cultivated in parts of Queensland, Australia.

Botany

The date palm belongs to the Class: Monocotyledoneae, Subclass: Areciae and is a member of the Family Arecaceae (formerly Palmaceae). It is an aborescent, erect, unbranched stem with large petioles that are sheathed at their bases. The tree is characterized by numerous offshoots that are produced at the base of the trunk of young palms. The average mature tree is about 20 m tall, but some may be as high as 30 m. A young, actively bearing date palm, showing offshoots and fruits at the end of the 'khalaal' stage is shown in Figure 1.

The trunk of the palm is covered with persistent grayish leaf bases. It is surmounted by a handsome array of pinnately divided long leaves and needle-sharp fronds. Between 10 and 20 new leaves are

Figure 1 (see color plate 42) (a) Young actively bearing date palm with offshoots or suckers. (b) Bunches of fruit from the same tree photographed at the end of the 'khalaal' stage.

produced annually. Date palm leaves are subtended at their bases by a cylindrical sheath of reticulate mass of tough, fibrous material, together forming a tight protective envelope for the terminal bud. Even though the phyllotaxy of date palm is not always clear, it forms the basis for the identification of some cultivars.

The palm produces many long rope-like adventitious roots that arise from the spherical base of the stem, often traversing long distances in search of water and nutrients. In Egypt and Algeria, mycorrhizal association of the root tips with arbuscular fungi of the genera *Glomus*, *Autochthon*, *Aoufous*, and *Sclerocystis* is common, but *Glomus mosseae* has been found to be most efficient in helping the date palm maintain water balance.

Male and female flowers are borne on different plants (dioecious), but all date plants look alike. Both male and female inflorescences are branched and are completely enclosed during development by sheathing fibrous spathes. The female inflorescence has pendulous branches, and florets (small flowers) are spread out along their entire length. A female flower with branches of male inflorescence inserted and tied, and a male inflorescence with abundant pollen are shown in **Figure 2a** and **2b**, respectively.

A typical female flower (gynoecium) has a small cup-shaped calyx tube formed from three outer perianth segments. It has three inner perianths, which are small and circular, and are closely appressed to the three carpels of the superior apocarpous ovary, each of which is surmounted by a short, hooked stigma. Only one ovary develops into a seed after fertilization. The floral formula of the female flower is: $K_3C_3A_0G_3$.

The male palms produce between 30 and 50 inflorescences yearly. Their spathes are narrower and shorter than the female flowers and are covered with a rust-colored powdery coating (*See* **Figure 2b**). The inflorescence consists of a short, stiff peduncle with numerous copious branches and white, sweet scented flowers along their length. The male flower has six stamens bearing long flattened anthers with undulate margins and has the floral formula: $K_3C_3A_6G_0$. The center of the androecium bears a (vestigial) small rudimentary ovary. Pollen production is prolific, and typical pollen is light, small, and pale yellow in color, and measures about 8 by 25 μm. Date pollen is distinct and only slightly resembles the pollen of *Sabal palmetto* and *Ginkgo biloba* (see scanning electromicrograph of pollen grains in **Figure 3**).

Figure 2 (see color plate 43) (a) Female flower with branches of male inflorescence inserted and tied to the female. (b) Opened male inflorescence with abundant pollen.

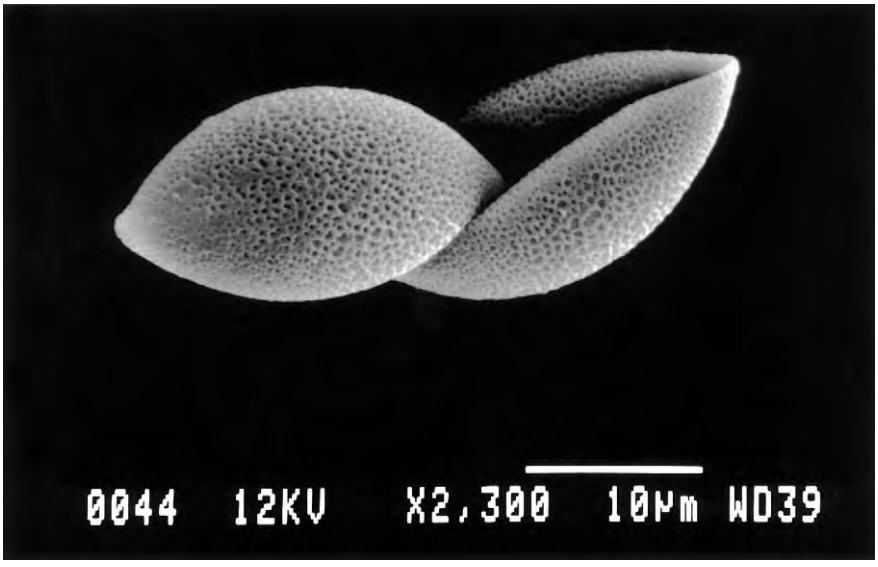

Figure 3 Scanning electromicrograph of two pollen grains.

Genetic Diversity

The heterozygous nature of the palm, its dioecious habit and the long period of cultivation, has led to the establishment of thousands of different date cultivars. In Riyadh (Saudi Arabia) alone, about 100 different cultivars are sold in the local open markets during harvest. A photograph of 18 of these cultivars is

shown in Figure 4. Results of enzymatic and genetic studies have been carried out on the fruits of several cultivars in Algeria and Iraq, and other studies of isoenzymes in leaves demonstrate that there is a high percentage of polymorphic loci, strong heterozygosity, and genetic diversity among cultivars. Extensive date breeding continues, and reports from the African Centre of Diversity indicate that date cultivars able to withstand such characteristics as alkaline soil, drought, frost, heat, heavy soil, high pH, salt, sand, slope, smog, and water logging have been bred. Furthermore cultivars with such fruit qualities as attractiveness, resistance to spoilage, heavy yield, late or early maturity, richness of flavor, smoothness of skin, and coloration are available in the germplasm repository of USDA, California, USA.

Many of the native palms in the Arabian Peninsula and North Africa have originally grown from either volunteer or intentionally nursed seedlings, but in modern date culture, many different cultivars are propagated vegetatively from offshoots or suckers (*See* Figure 1a). There are hundreds of established varieties or cultivars, and it is estimated that there are 350 cultivars of soft dates in the Basra region of Iraq alone.

Dates can be categorized into three different groups depending on the type of fruits they produce: soft, semisoft, and dry. Soft dates have a soft fleshy consistency and contain about 60% sugar in the form of glucose and fructose, and this concentration is sufficient to prevent undesired fermentation. They are used fresh or preserved in the form of 'agwa,' a pressed mixture of dates. Semisoft dates have a firmer flesh and contain much more sugar than soft dates. Dry dates contain much more sugar than soft and semisoft dates (65 to $\geq$70%), and they ripen and dry to a hard consistency while still on the palm tree.

Ecology

The environmental demands of date palms are summed up in the old Arab adage that 'the date palm needs its feet in running water and its head in the fire of the sky.' Date palms enjoy high temperatures and can withstand very low temperatures for short periods only. Temperatures below $-8\,^{\circ}C$ are harmful. They can tolerate annual precipitation of between 31 and 403 mm and grow well in regions of low humidity and where rainfall is low or nonexistent. Flowering is favored by long, hot, and

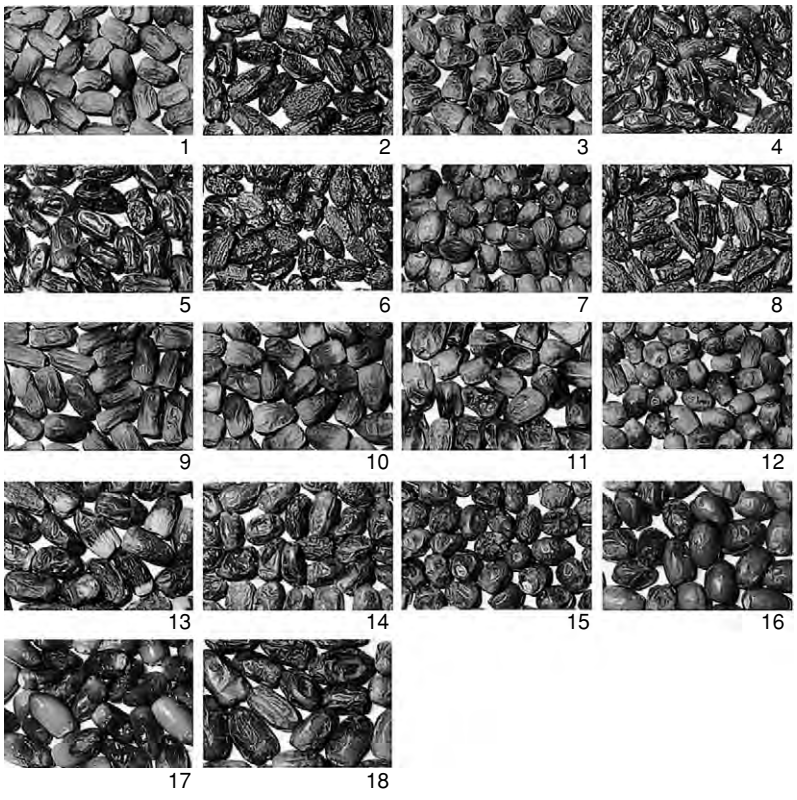

Figure 4 (see color plate 44) Eighteen of the most popular date cultivars sold in Riyadh, Saudi Arabia. Their names are as follows: 1 = Assela, 2 = Labana, 3 = Sabbaka, 4 = Rothana, 5 = Manifi, 6 = Naboot-Ali, 7 = Sefri, 8 = Mabroom, 9 = Roshidia, 10 = Sokary, 11 = Khodri, 12 = Safawi, 13 = Halaw/Helwa, 14 = Hanini, 15 = Barhi, 16 = Juffair, 17 = Qattar, 18 = Seeleg.

completely dry periods, and an average temperature of 30 °C is considered optimal for proper ripening. The plants can tolerate a wide variety of soil types and a fair amount of alkalinity (pH range of 5–8.2) with the only proviso that the soil be well aerated. To bear well, the roots must be in a stratum with less than 1% of alkali salts. Recently, salt-tolerant date cultivars have been bred, and cultivation in halophytic (salty) soils close to the sea has been made possible. Most date palms are grown under carefully controlled irrigations or in oases. Date trees must be pruned to allow new leaves to grow, to prevent rodent and insect infestation, and to facilitate pollination, fruit setting, and harvesting.

Propagation

Dates can be generally grown from seeds or vegetatively propagated from offshoots, but in recent years, organogenesis has been researched, and the use of plantlets from tissue culture has become popular. Although impractical for the poor peasant farmer, it has the advantage that several plantlets can be produced in a very short time from a small amount of meristematic tissue.

Growth of dates from offshoots is, however, the preferred option for the native grower and has almost completely replaced the old fashioned growth from seeds. Adult date palms in their early years produce many offshoots, and these offshoots are removed from the parent plant and transplanted about 9.2 m apart. The young transplanted tree needs protective wrapping or shelter against cold, heat, and wind, and should be watered daily during the first week and once weekly thereafter until the roots have fully developed. In Saudi Arabia, it is common practice for whole mature trees to be dug out and transplanted as a 'quick fix.' Growth from seeds is still used in a few areas for pollen production. Date plantations should be irrigated and the soil fertilized. Intercropping of date trees with citrus and other fruit plants is common practice, and alfalfa (*Medicago sativa*) is often grown.

Pollination, Fruit Formation, and Development

It is estimated that one male plant is sufficient to pollinate 50–100 female date trees, and it is common practice to plant 2.4 male plants per hectare. In Saudi Arabia, dates usually flower between February and April, and dates are pollinated during these months. Date pollen can be stored at various temperatures for differing lengths of time without much loss of viability or ability to fertilize female flowers. Dates should be naturally wind-pollinated, but there is a small contribution from visiting insects and birds. However, the native form of pollination is to insert one to three branches of male inflorescence in the fully exposed female inflorescence (*See* **Figure 2a**). In order to effect efficient fertilization and to maximize fruit yield, this method has largely been replaced by hand pollination, in which pollen is placed in porous sacs or dusters and spread as dust on female flowers or by mechanical spraying. A temperature of 35 °C is optimal for pollen germination. After successful pollination and fertilization, one of the three ovules of the ovary develops into a one-seeded drupe with a fleshy inner tissue and an outer shiny chitinous skin.

The fertilized rudimentary fruit is referred to in Arabic as 'hababauk.' Dates take about 200 days to reach maturity. After pollination, the fruit passes through four distinct phases, known in Arabic as 'kimri,' 'khalaal,' 'rutab,' and 'tamr' stages. The kimri stage is the time from which the rudimentary seed is formed until it is about 17–19 weeks old. The fruit increases rapidly in size and weight, and in its reducing sugar, acid, and moisture content. This ends the time of botanical maturity, and the fruit turns yellow or red, depending on the cultivar. The khalaal stage is the second stage of development (from 19 to 25 weeks). Weight gain is slow, but sucrose content increases, whereas the moisture content decreases. Tannins start to precipitate, leading to a reduction in astringency, making some varieties palatable and commercially mature at this stage. At the rutab stage, which sets in from around 26 to 28 weeks, there is further moisture loss, and in some varieties, sucrose turns into inverted sugar, and there is browning and skin softening. The moisture content decreases to about 35%, and this is the time during which fresh soft dates are sold. The final stage, tamr, is used only to refer to dates that are left on the palm trees to undergo further ripening, and some dates become self-preserving at this stage.

World Date Production

It is estimated that there are about 90 million date palms in the world. One United Nations Food and Agricultural Organization statistical report names 31 countries as the main date-producing countries. Out of these, only 21 countries export any appreciable amount of their produce. However, 72 countries throughout the world import between 11 and over 500 000 tonnes of dates annually. In the year 2000, the world date production totalled 5.21 million tonnes. Date production figures for each of the 20 leading date-producing countries (except India) are shown in **Figure 5**.

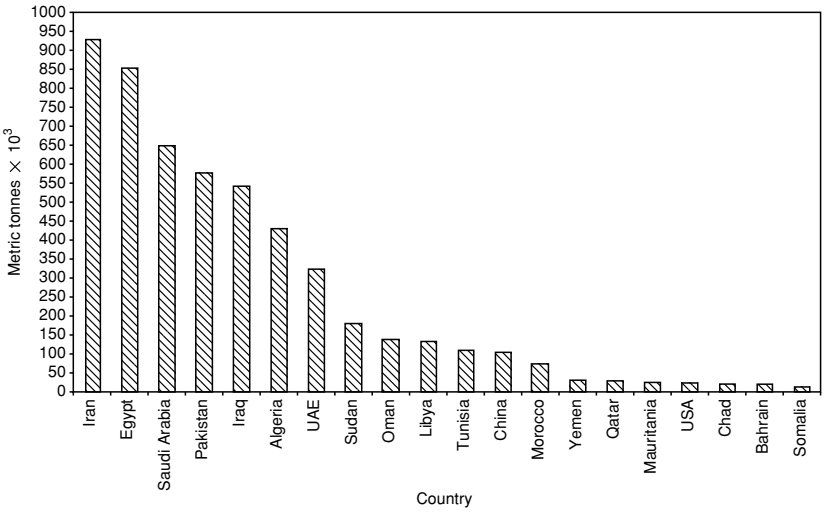

Figure 5 World date-production figures (shown as histograms) for the 20 date-producing countries (figures for India not provided).

Pests, Diseases, and Losses

Dates are afflicted by a number of pests and diseases, which result in substantial losses. Even though new diseases keep emerging, the most important and widespread of these is Bayoud disease, a fungal wilt disease of date trees caused by the fungus *Fusarium oxysporium* f. sp. *albenidis*. Plants infected by this and other wilt fungi make way for opportunistic microbes and pests to cause more damage. Some newly emerging diseases are fungal rhizosis (*Ceratocystis radicicola*) in South Africa and *Serenomyces* in California, and two new pathogens, *Phomopsis phoenicicola* and *Fusarium equiseti*, have been reported from Iraq. The most recently reported diseases (December 2000) are the phytoplasma 'white tip die-back' in Northern Sudan and the 'slow decline' disease in North Africa.

Dates can also be attacked by a range of pests: the scale insect is important in the Dangola District of Northern Sudan, and termite damage is common. Pakistani dates are mainly attacked by borers (*Coleoptera* spp.) and the red palm weevil, *Rhynchosporus ferrugineus*. Recently, this weevil has spread to Israel, Jordan, the Palestinian Authority, and Saudi Arabia. An isolated report from Oman implicates the Indian palm weevil (*Pseudophilus testaceus*) as the cause of some date tree infestations.

Ants and locusts are troublesome, and mice and other rodents feed on leaves, tender roots, and fruits. Damage to fruit through direct infestation by fungi results in the production of phytoalexins, and aflatoxin contamination causing severe fungitoxicity during packaging or marketing has been reported in the cultivars Lulu and Naghal. A list of other disease causing agents, pests, and some of the resultant symptoms is given in Table 1.

Table 1 Diseases of the date palm

Agent	*Symptom/disease*
Alternaria spp.	Leaf spot
Alternaria citri	Brown spot of fruit
Alternaria stemphylioides	Fruit rot
Aspergillus niger	Calyx end rot
Auerswaldia palmicola	Leaf infection
Catenularia fuligenea	Fruit rot
Ceratostomellara dicicola	Root rot
Colletotrichum gloesporoides	Leaf infection
Diplodia phoenicum	Leaf stalk rot, fruit rot, and shoot blight
Endoconidiophora paradoxa	Black scorch and heart bud rot
Fusarium spp.	Inflorescence blight and fruit rot
Graphiola phoenicis	Leaf spot and false smut
Meliola furcata	Black mildew
Meloidogyne spp.	Root knot nematode
Omphalia pigmentata	Decline disease
Omphalia tralucida	Decline disease
Penicillium roseum	Fruit rot
Pestalotia spp.	Leaf spot
Phomopsis phoenicola	Fruit rot
Phymatotrichum omnivorum	Saprophytic contaminant on roots
Pleospora herbarum	Fruit rot
Poria spp.	Wood rot

Harvesting, Packaging, and Storage

Under optimum conditions, dates start fruiting in 3–5 years of planting an offshoot and reach full maturity in 12 years. Dates are usually harvested from July to September, and the estimated yield of dates per bunch is about 5–15 kg. After harvest, dates are packed or transported loose to the market, packing, or processing plants. The majority of techniques that are applied by commercial growers to prevent infestation and spoilage are fumigation, heat treatment, chilled storage, and irradiation. The most

popular fumigant is hydrogen phosphide. Methyl bromide was also commonly used, but, owing to its toxicity to man and animals, it has been banned in most parts of the world. Heat treatment is an effective method for disease and spoilage control, because a 100% mortality can be achieved at all stages of the life cycle of some insects. Refrigeration at 4 °C is used to prolong the storage life of dates, making it possible to keep dates of 20% moisture content for a year without any changes in appearance and taste. Analyses have confirmed that glucose, fructose, sucrose, and protein contents are the same in irradiated as in nonirradiated dates. Combined treatments seem to be the best choice for overall pest and microbial control.

Quality Control Procedures in Date Production

In organized date-handling companies, dates are sorted and cleaned to achieve homogeneity. Different date cultivars ripen and mature at different times and are therefore picked at different times. Dates are often delivered to the processing or packing plants as a mixture, where they are sorted, cleaned, and graded into cull dates, first-, second- and third-grade dates. Cull dates are used for animal feed, whereas first- and second-class dates are packaged, and third-grade dates are used for commercial date products. After sorting and grading, dates are dry-cleaned by moving them over damp towelling, on mechanical shakers, or on rotating cylinders. They are then air-dried and, depending on their use, are sent for further processing, such as dehydration, hydration, glazing, coating, and pitting.

General Uses

There is an old Arab adage that 'there are as many uses for dates as there are days in the year'. The date palm is primarily cultivated for its fruit, which is eaten fresh, dry, or variously processed. It is a high-energy food, containing mainly sugar. In areas where dates are a staple food, the variety of date products includes date honey, date sugar, and date wine, which are made from fresh date fruit juice. A date drink called 'nabidh' is prepared by soaking mashed up dates in water for one night. The traditional use of date syrup in some Islamic countries used to be mainly on a specific occasion: it would be poured on fermented dough (asseda) and eaten on the occasion of the Prophet's birthday. Early records indicate that date syrup has been an overland export material between the Middle East and China for many years, and it is widely used on breads, in softening and preserving dates in jars, and in home-made confectionery. In recent years, date syrup has been used as a base for beverages and bakery products, and in icecreams. Even though attempts to use it in the preparation of soft drinks have proved difficult, a carbonated date syrup-based soft drink of Swiss origin (Tamra) is marketed in Saudi Arabia. Dates are customarily cooked and packaged as candies for local consumption or for export.

Date palm flour is made from the pith of the tree, young leaves are cooked as vegetables, and the terminal bud and palm heart are eaten as salad. Oil is made from the seeds (pits or kernel), which is mainly used for making soap. It was believed in ancient Egypt that when a woman of childbearing age ate two date seeds, she would be childless for several years. The kernel can be ground and used as animal feed. Crystallized inverted sugar from dates is sold in certain date-producing countries, and the seeds can be strung and used as beads. In medieval times, the palm was believed to prevent sunstroke, avert lightning, cure fevers, and drive away mice and fleas. Several other uses have been recorded in folk medicine, and it has been observed that there is a very low incidence of cancers in the Bedouins, attributable to their heavy dependence on dates as a staple food.

Mats, hats, and baskets are woven from date leaves, and the fibers are used for ropes and thread and for rigging boats. In traditional Arab villages, the leaves are used for roofing, and the midribs are used for fencing. The leaves are used as manure, and shredded palm leaves serve as a good substrate for the growth of tomatoes and cucumber. The sap and inflorescence (mostly from senile plants) after fermentation are a good source of palm wine or toddy (alcoholic content 5%), which is either drunk in its natural state or made into liquor. Arrak is an example of an alcoholic beverage distilled from dates. The wood from the trunk is used as firewood, timber for doors, beams, camel saddles, roofing rafters, cords, ropes, baskets, crates, and furniture.

Chemistry of the Different Parts of the Date Palm

Dates, like many plants, are a source of different chemicals. One unexpected compound in date tissue is serotonin, with levels of up to 850 μg per 100 g. Date leaves contain coumarin, luteolin-7-glucoside, luteolin-7-rutinoside, and glycosylapigenin. The main minerals in the leaves and petioles are nitrogen, phosphorus, potassium, and ash.

Date pollen mainly contains cholesterol, rutin, carotenoids, and estrone, and is known to exert

gonadotrophic activity in rats. Pollen mixed with honey is eaten as an aphrodisiac. The main hemicellulose in date pollen is made up of arabinose (46%), galactose (25%), xylose (18%), rhamnose (9%), and 2% uronic acid.

Dry date fruit pulp has an average moisture content of 22.5% with an energy yield of 1151 kJ. It contains 1.9–2% protein, 0.45% lipids, 73.5% carbohydrates, and 7.5% fiber. Its mineral content, in decreasing order, is: potassium > phosphorus > magnesium > calcium > sodium > selenium > iron, but it also contains trace amounts of zinc, copper, and magnesium. Workers in some parts of the world have reported similar chemical contents, but in India, a small amount of arsenic has been detected. Other constituents in the pulp are leucanthocyanins, pipecolic acid, tannins as well as baikiain, and the sarocarp has been shown to contain cholesterol, campesterol, stigmasterol, β-sitosterol, and isofucosterol. Date fruit pulp contains some vitamins: vitamin A, folate, and niacin are in appreciable quantities, but riboflavin, palmitic acid, vitamins B_6, and E, and thiamine are present in trace quantities. (*See* **Vitamins**: Overview.)

The lipid content of date pulp can be as low as 0.2%. It is higher in monounsaturated 16:1 and 18:1 fatty acids than the polyunsaturated fatty acids of 18:2 and 18:3 species. The low protein content of dates is reflected in its poor amino acid content: apart from glutamic acid, aspartic acid, proline, and glycine, which are present at 213, 126, 106, and 95 mg per 100 g, respectively, of date pulp, it contains only trace amounts of most of the other essential amino acids. Some workers have reported high amounts of arginine, but generally, tryptophan, isoleucine and lysine are absent.

Date pits (seeds or kernel) make up between 6 and 12% of the total weight of date fruit and have a moisture content of 5–10%. Other constituents of pits are 7% proteins, 10% oils, 10–20% crude fiber, 55–65% carbohydrates and 1–2% ash. Date pits are relatively high in fatty acids, oleic/linoleic acids, (mostly c. 44–52%) and contain appreciable amounts of tannic acid, 17–24% lauric acid, about 10% each of myristic acid, palmitic acids, and linoleic acid, and trace amounts of stearate, capric, and caprylic acids. At the tamr stage, the pit contains cholesterol, estrones, polysaccharide A (with D-mannose and D-galactose at a ratio of 10:1), polysaccharide B, and xylose. (*See* **Carbohydrates**: Classification and Properties; **Fatty Acids**: Properties.)

Of the essential amino acids, glutamic acid, aspartic acid, and arginine account for about half of the total proteins in date pits, whereas tryptophan is the most limiting, followed by isoleucine and lysine. The oil extracted from date pits has some uses and has the following physico-chemical properties. It has a specific gravity of 0.9207 (at 15 °C), a refractive index of 1.4580 (at 40 °C), an iodine value of 50–55, and a saponification value of 205–210. Date pits also contain a few minerals. These are, in decreasing order: potassium > phosphorus > magnesium > calcium > sodium. The only important microelements detectable in date seeds are iron, manganese, zinc, and copper. From a general human nutrition point of view, date pits are unimportant but have one asset, a high digestibility. The only known human food is the Bedouin dish called 'canua,' which is made from roasted date seeds. However, date seeds are an invaluable source as a main or supplementary diet for animals. It has been suggested that date seed meal can replace barley in chick rations. Ground date seeds can replace 20–75% of ruminant rations, and 75.5% of a wheat bran–barley mixture can be used for feeding carp. Traditionally, date pits are used in feeding pigs, sheep, and camels, for fattening cattle, and for blending in chicken feed. (*See* **Amino Acids**: Properties and Occurrence.)

Commercially Available Date-Derived Products

The only time that dates are used for derived products is when there is a temporary surplus, when dates are damaged, or when dates are undersize or unattractive. Date products can be classified under: sweets, preserves, condiments, breakfast foods, and desserts. Dates are used to a larger extent in the bakery and confectionery industry than they are credited for, probably due to poor or cryptic labeling of such products. It is estimated that over 500 biscuits, cakes, cookies, cereals, toffees, chocolates, breads, and other products that contain date products or are predominantly made from dates can be found in supermarkets, health food stores, and other outlets around the world. One date merchant alone in Saudi Arabia stocks over 110 pastries, and each of these items contains dates or is decorated with dates or date syrup.

Figure 6 shows a basket, woven from date fiber, filled with a decoration of 110 different confectionery products, dates from 14 different dry date cultivars, a background of semisoft brown dates, date leaves, and bunches of mature dates.

Dates are a common supplement in a number of sauces, chutneys, jams, sauces, preserves, and cereals in supermarkets throughout the world. Major worldwide commercial food manufacturers such as Shields Dessert Products, Sun Country, Quaker, Kellogg's, Pillsbury, Betty Crocker, Bakery Wagon, IBSO, Edfina, HP, Crosse & Blackwells, and Shaws use dates in a number of their products. Cereals containing dates

Figure 6 (see color plate 45) Basket, woven from date fiber and filled with 110 different confectionery products made from dates and date syrup (and dates from 14 different dry date cultivars). The background shows semisoft brown dates, date leaves, and bunches of mature dates.

are mostly combined with oatmeal, raisins, walnuts, sultana, and almonds, and products with these combinations have energy yields of between 116 kcal (485 kJ) and 360 kcal (1527 kJ) per 100 g.

Date juice, presscake, and date syrup are the most common commercially derived date products. The raw juice is the main product, and presscake is the byproduct. Date syrup is obtained after evaporation of date juice. Analysis of date syrup from Iraq and Libya reveals an average of 76% total solids, 69–72% inverted sugar, 0.9–3.2% sucrose, 0.9–1.2% proteins, 0.06–0.17% tannin, 0.25–0.60% total pectin (as impure calcium pectate), 0.46–0.76 citric acid, and 1.6–1.8% ash, and a pH of between 4.14 and 4.66. A number of products like date spread, date syrup, caramel, and liquid sugar are made from date juice concentrates. The fruit pulp is used in semisolid infant foods mixed with whey and skimmed milk, and date liquid sugar is used by some manufacturers as a replacement for sucrose in the white layer in cakes. Some low-calorie sweeteners in soft drinks are prepared from dates.

Fermentation Products

Dates should theoretically be used as a main nutrient for microbial conversion to produce a range of useful fermentation products. Unfortunately, unlike beet or cane sugar, date fruit is not a typical sugar crop because most date cultivars contain high levels of inverted sugar. At the consumable stage, most of the sucrose has been inverted by the enzyme invertase into glucose and fructose. In addition, dates are expensive and have a high tannin content that restricts its use as a cheap fermentation product. (*See* **Fermented Foods:** Origins and Applications.)

Dates have, however, been used in the production of a number of products. Lipids have been successfully produced using the fat-producing fungi *Penicillium lilacinum, P. soppi*, and *Aspergillus nidulans*. *Aspergillus niger* has been used for the production of citric acid from date syrup and molasses, and fodder yeast has been produced from Iraqi dates. Postextraction waste material is used as a cultural medium for *Candida utilis* and *Trichoderma viride*, and date seeds are also used to produce citric acid from *Candida lipolytica*.

Dates were used as a reinforcement and flavoring agent in beer-making in ancient Egypt, and references to date wine can be found in early history. What is not clear in these old records is whether the wine referred to was fermented or not. Dates are generally not suitable for wine-making because they lack natural acidity, flavor, and astringency. However, in Iraq, good-quality light-colored dry wines have been produced from zahdi dates, and a darker sweeter wine is fermented from the date syrup, dibis. Pure alcohol can be produced from the fermented mother liquor by distillation, and a so-called sherry can be obtained from the transitional product between wine and the

distilled pure alcohol. Vinegar (*vin-aigre*, from the French meaning 'sour wine') or acetic acid can also be made from date wines that turn sour.

A number of organic acids can be produced either directly or indirectly from date sugars. Single-cell protein from date products has been the focus of investigations for a number of years, and promising results have indicated that bakers' yeast can be produced on date extracts in the same way as it is traditionally produced on molasses.

Allergenicity of Date Fruit and Pollen

Numerous epidemiological studies have reported a steady and significant increase in the world-wide prevalence of allergic diseases in the last two decades. In Saudi Arabia and most of the Middle Eastern countries, it is common knowledge amongst the inhabitants that date pollen causes asthma and allergic rhinitis, and some of the fruits, on ingestion, can cause itching of the mouth and throat. In spite of these observations, there have been no published references on date palm allergens. Results of pioneering studies carried out at the King Faisal Specialist Hospital and Research Centre in Riyadh, Saudi Arabia on the allergenicity of date pollen and fruits in Saudi Arabia have confirmed that date pollen and fruits of some cultivars are allergenic. In the allergic population studied, 25% were allergic to the pollen and 13% to the fruits. These results have been confirmed by workers in Spain, Israel, Kuwait, and France, and cases of anaphylactic shock have been reported. Six pollen components of ≤ 12, 14, 27–30, 37–40, 57, and 65–67 kDa, three fruit components of ≤ 14.3, 27–33, and 54–58 kDa have been found to be the major date allergens. These allergens have been found to share cross-reactive epitopes with a number of foods that have been implicated in the oral allergy syndrome. These allergenic peptides are novel and are unique to some date pollen and fruits cultivars only. However, amino acid sequencing has indicated that date allergens albeit novel, have similar isoelectric points (p*I*s) to, and share sequence homologies with, known allergenic structures, namely profilins, wound-induced proteins, cross-reactive carbohydrate determinants, pathogenicity-related, acidic class III chitinase, and endochitinase proteins.

General Comments and Future Prospects

Clearly, the date palm is an important plant, and date-derived products used in foods are more common the world over than had been known. It is also clear from the production, export, and import data that there is an imbalance in production, consumption, and export. The need to increase date production to meet increasing demand is indicated. Date fruit cultivars that have a high inverted sugar content can be developed further to yield more fructose at their inverted stage. Since dates have a high potassium content, and some hypertensive patients who take diuretics need potassium supplements in their diet, cultivars that have a high potassium, high fructose, and low glucose content can be bred to help with the dietary management of diabetes mellitus. Even though the palm has been known for many years to be one of the most disease-resistant and hardy plants, it appears from the range of infectious agents listed here that the date palm is under threat from new and old pathogens. More effort should be concentrated on breeding high-yielding, disease-resistant, and hypoallergenic varieties. Phytopathological research needs to be focused on, and all aspects of date production improved and diversified.

DEHYDRATION

S P Allison, University Hospital, Nottingham, UK

Definition

Dehydration strictly means lack of water but has come to be used more colloquially to mean salt and water depletion and, even more loosely, to mean a deficit in body fluid of any kind. It is unfortunate that such loose terminology leads to loose thinking, imprecise diagnosis, and, in some cases, inappropriate treatment. In contrast, the terms 'water depletion,' 'salt and water depletion,' and 'plasma volume deficit,' have more precise diagnostic meaning and imply the appropriate treatment for their correction. Pure water depletion is in fact rare. The most obvious example is diabetes insipidus, caused by a lack of antidiuretic hormone. In contrast, salt and water depletion, or desalination, is extremely common. A prime example is that caused by diarrheal diseases, which kills millions of children throughout the world each year.

Physiology

The loss and gain of fluid by the body to and from its surroundings are normally small compared with the enormous daily flux between the different compartments within the body. Assuming the maximal concentrating ability of healthy kidneys, the volume of urine required to excrete waste products may be as little as 500 ml, although it is safer to allow 1–1.5 l. Insensible loss by evaporation from the lungs may be 500 ml, and from the skin surface 400 ml, although this may be greatly increased in hot climates or during fever, owing to sweating. The amount lost from the gastrointestinal tract as feces is usually as little as 100 ml, but in the presence of diarrheal disease, this may increase enormously. Thus, the minimal daily input of fluid to maintain balance in a healthy adult in a temperate climate is approximately 1500 ml, although 2 l provides a safer margin. In warmer climates this requirement is increased considerably. (*See* **Renal Function and Disorders**: Kidney: Structure and Function.)

The distribution of body fluids in an adult between different compartments is shown in **Figure 1**. Total body water is approximately 60% of the bodyweight (more in small children, less in the obese). The intracellular fluid (ICF) is just over 40% of body weight and extracellular fluid (ECF) just under 20% of bodyweight; 25% of the ECF is within the intravascular space, i.e., plasma; the remaining 75% is termed the 'interstitial fluid' and surrounds the cells. The integrity of these body fluid compartments is maintained by the properties of their separating membranes (e.g.,

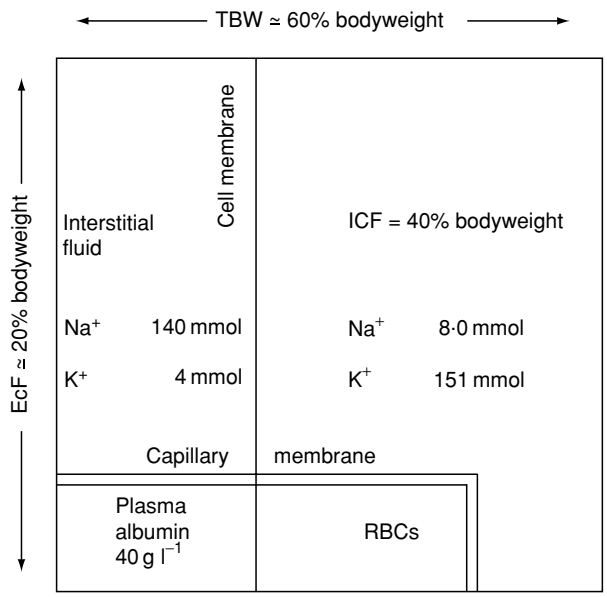

Figure 1 Diagrammatic representation of body fluid compartments and concentrations of sodium ions (Na^+), potassium ions (K^+) and albumin. TBW, total body water; ICF, intracellular fluid; ECF, extracellular fluid; RBCs, red blood cells. Reproduced from Dehydration, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

the cell membrane with its sodium pump, and the capillary membrane and its pore size) and their osmotic or oncotic content (e.g., sodium ions Na^+, for ECF; potassium ions, K^+, for ICF; albumin for plasma). Not only is the external fluid balance important, but also changes in fluid compartments, where shifts may be large. For example, the rate of exchange of albumin between the intravascular and interstitial spaces is normally 10 times its rate of synthesis. Fluid deficits may also have different effects on each compartment. In an average adult, a deficit of 2 l of pure water reduces the total body water evenly by 2 l (and, incidentally, the weight by 2 kg) with a 1400 ml reduction in ICF, a 600-ml reduction in ECF fluid, and a 150-ml reduction in plasma volume. However, a loss of 2 l of salt and water, at a concentration of 140 mmol Na^+ per liter, reduces the total body water by 2 l and the weight by 2 kg but causes a selective loss of 2 l from the ECF, with a consequent reduction in plasma volume of nearly 500 ml. The clinical problems presented by these two situations are of an entirely different order. (*See* **Potassium**: Physiology; **Sodium**: Physiology; **Water**: Physiology.)

To understand the problems of fluid deficit, it is also necessary to consider the large daily volume of secretions, particularly those into the gastrointestinal tract (Table 1). Under normal circumstances, these are almost entirely reabsorbed, with a minimal daily loss of 100 ml in the feces. With gastrointestinal disease, e.g., vomiting, diarrhea or fistula, large volumes of water and electrolytes may be lost to the outside or, in the case of intestinal obstruction or ileus, pooled in the gut and lost to the functional compartments. In an adult, during a normal day, 8000 ml of fluid enter the small bowel; 500 ml as saliva, 1200 ml as gastric fluid, 600 ml as bile, 1200 ml as pancreatic juice, 2000 ml as small bowel secretion, and the remainder as ingested fluid. All but 1.5 l is reabsorbed in the small intestine, and a further 1.4 l is reabsorbed in the colon with much of the remaining sodium chloride. Approximate electrolyte content of gastrointestinal secretions is shown in Table 1.

Table 1 Approximate electrolyte content of gastrointestinal secretions

Secretion	*Sodium (Na^+) ($mmol\,l^{-1}$)*	*Potassium (K^+) ($mmol\,l^{-1}$)*	*Chloride (Cl^-) ($mmol\,l^{-1}$)*
Saliva	44	20	
Gastric	70–120	10	100
Small intestine	110–120	5–10	105
Bile	140	5	100
Pancreas	140	5	75
Diarrhea			
Cholera (adult)	120	15	90
Cholera (child)	100	27	90
Nonspecific (child)	56	25	55

Diagnosis and Monitoring

In common with most diagnoses, that of dehydration depends mainly on the history and examination. The history, combined with a knowledge of the natural history of the presenting condition, provides the main clues to the presence of salt and water depletion, the likely progress of the condition and the necessary treatment.

The physical signs are helpful, but none are pathognomonic. The facies and eyes appear sunken, but this is also seen in cachexia. The mouth and tongue are dry, but this can also be caused by mouth breathing. The skin turgor, assessed by pinching up a fold of skin and observing its recoil, is diminished with salt depletion but also in old age, cachexia, and extreme cold. A marked fall in blood pressure between the lying and sitting or standing positions is also characteristic of salt and water depletion, as is tachycardia. A low output of concentrated urine, associated with a rise in blood urea owing to prerenal failure, is also seen.

Other biochemical indices are less useful in diagnosis. The plasma sodium concentration gives no clue to the total body sodium content, unless water balance is also known. It merely reflects the relative proportion

of sodium and water in the extracellular space. Thus, with pure water lack, the plasma sodium concentration increases. With a mixed deficit of sodium and water, the plasma sodium reflects the relative proportion of the two that are lost.

Progress is first monitored by observing the improvement in the appearance of the patient; guard against fluid overload by watching for edema, a raised jugular venous pressure, or pulmonary edema. A fluid balance chart is valuable, but water balance is best measured by changes in weight, which should be monitored at least daily. Plasma sodium concentration changes can then be interpreted in the light of water balance.

Conditions Associated with Water and Salt Depletion

Diarrhea

Worldwide, diarrhea is by far the most important numerically, causing large numbers of childhood deaths from dehydration. Its severity varies from cholera, in which the stool output may be up to $1\,l\,h^{-1}$ (for electrolyte losses, see Table 1), to other infective conditions in which stool losses are smaller, although potentially life-threatening. Treatment is usually by oral rehydration therapy (see below), although severe cases require intravenous or subcutaneous fluid replacement, where logistically possible. Formulae are shown in Table 2 and are based on the principle that small bowel sodium absorption is linked to that of glucose. The presence of starch, polysaccharide, or glucose in such formulae is vital. Amino acids and peptides also enhance sodium reabsorption.

Vomiting or Nasogastric Aspiration

An examination of Table 1 reveals the likely loss of electrolytes from vomiting or nasogastric aspiration and the logical replacement requirements. Aspirate volumes must be measured and replaced appropriately.

Intestinal Fistula or Short Bowel Disease

Up to 4 l per day may be lost from an upper jejunal or duodenal fistula. Parenteral nutrition is almost mandatory in this situation and must be combined with adequate salt and water replacement guided by measured losses, daily weight changes, plasma electrolyte measurements, and a knowledge of electrolyte concentrations in the fluid lost. Lower bowel fistula or short bowel can be treated by the enteral route, enhancing water and salt absorption using principles similar to those used in oral rehydration therapy. If enteral tube feeding is employed, a feed with sodium content less than 90 mmol causes net sodium secretion into the jejunum, whereas levels greater than this are associated with net absorption. The presence of carbohydrate and protein ensures the additional effect of glucose and amino acids on sodium absorption. The rate of administration may also be important. Too rapid rates may overwhelm the capacity of a shortened bowel to absorb all the fluid presented to it. The total osmolar content should also be considered, although the number of osmoles administered per unit time is more important than concentration.

Metabolic and Renal Disorders

The hyperglycemia of diabetes mellitus causes an osmotic diuresis, leading to large deficits of water, sodium and potassium during acute loss of control, e.g., diabetic ketoacidosis. An osmotic diuresis may also result from excessive urea production owing to excessive protein administration. Hypercalcemia poisons distal tubular function, leading to excessive production of dilute urine. Diabetes insipidus owing to a lack of antidiuretic hormone (ADH) has already been referred to. Alcohol excess dehydrates through inhibition of ADH. Acute or chronic renal damage may be associated with tubular dysfunction, loss of renal concentrating capacity, and water and salt deficit. This may be observed most strikingly in the polyuric phase of recovery from acute renal failure or following relief of obstructive uropathy. Treatment consists of the appropriate administration of water and electrolytes either orally or intravenously.

Excessive Use of Diuretics

Excessive use of diuretics is a common cause of water, sodium, and potassium depletion in the elderly and results from regimens that are too rigid and from lack of patient education. Patients need to know, for example, that if they fall ill from some condition that prevents salt and water intake or leads to excess loss, they should stop their diuretics.

Table 2 Concentration of electrolytes in oral rehydration solutions

	Sodium (Na^+) ($mmol\,l^{-1}$)	*Potassium (K^+) ($mmol\,l^{-1}$)*	*Chloride (Cl^-) ($mmol\,l^{-1}$)*	*Citrate or bicarbonate ($mmol\,l^{-1}$)*	*Glucose[a] ($mmol\,l^{-1}$)*
For mild to moderate diarrhea	35–60	13–25	50	10–20	100–200
For severe diarrhea	90	20	80	10	111

[a]Glucose may be substituted by sucrose, maltose or rice water according to local availability.

Excessive Sweating

Excessive sweating, e.g., in the tropics, merits appropriate replacement. Before adaptation takes place, those going from temperate to hot climates are particularly prone to dehydration and heat stroke. A liberal water intake, combined, if necessary, with additional salt, should be taken prophylactically.

Errors in Diagnosis

Errors in diagnosis are particularly common in already hospitalized patients who are more often the victims of excess fluid administration than of dehydration. This results commonly from a naïve interpretation and reliance on one or more physical signs, e.g., dry mouth, or from a failure to understand the compartmental distribution of body fluids and how these are affected by disease. A proper understanding of simple fluid balance concepts is a prerequisite for managing the many conditions in which dehydration or salt and water depletion are common. Salt and water are also intrinsic components of food and of the regimens used in the nutritional support of the sick.

Oral Rehydration Therapy

Solutions enhance the absorption of water and electrolytes through their substrate content, e.g., glucose, while replacing electrolyte deficit safely, e.g., avoiding hypernatremia in infants. They should be palatable and acceptable to children, readily available and simple to use under all conditions. An alkalizing agent to counter acidosis may be advantageous. Solutions used in the UK for mild to moderate diarrhea contain less sodium and more glucose than the World Health Organization (WHO) formula, which is used for severe diarrhea, e.g., cholera. Dose is according to fluid loss, but a rough guide for adults is 200–400 ml for every loose stool, for children 200 ml per motion, and for infants 1–1.5 times the usual feed. In severe cases, doses may be higher. The WHO policy is to promote its own single oral rehydration solution and to prevent hypernatremia in children by giving extra water between doses. For further details, see *British National Formulary*.

Structure of Teeth

M E J Curson and M S Duggal, University of Leeds, Leeds, UK

Background

The teeth comprise the hardest structures of the human body and as such, once fully formed, change little throughout life. Their resistance to destruction is such that they play a major role in archeological and forensic studies. Teeth as archeological remains are well known to survive for thousands, if not millions, of years after the death of the animal of which they were a part.

Despite their apparent indestructibility in relation to physical damage, and the ravages of time as skeletal remains, the teeth are susceptible to chemical damage during life by acid dissolution, a process known as dental caries. This disease has occurred in

humans for as long as they have existed. Even in the earliest human skull specimens, the teeth show signs of dental decay, albeit of a limited extent, with only one or two cavities occurring in the mouth of an individual. The susceptibility of the teeth to dental caries has therefore always been present, but the prevalence and incidence of the disease have varied. This will be discussed more fully elsewhere, but an understanding of the dental caries process is based upon a knowledge of the structure of the teeth, which is discussed in this article in overall terms of the teeth and the components that make up a tooth.

Teeth

In all mammals, there are two sets of teeth; in humans, a primary (baby) or deciduous set of 20 teeth is replaced between the ages of 6 and 12 by a secondary or permanent set of up to 32 teeth.

Primary Teeth

The primary teeth are laid down *in utero* and commence calcification at or immediately after birth. The first teeth to erupt are usually the incisors at about 6 months of age, and the final primary teeth to come into the mouth are the second molars between the ages of 2 and 3 years.

The primary teeth have the same basic structure as the permanent teeth, i.e., enamel, dentine, cementum, and pulpal (nerve) tissue. However, the overall morphology of a primary tooth does differ somewhat from the permanent successor. The major difference lies in the crown, particularly of the primary molars, which are more bulbous. The bulbosity is most pronounced on the first primary molar in the lower jaw, or mandible.

The roots of the primary teeth are shorter, smaller, and, in the molar, more curved than the permanent successors. There is therefore less dentine in a primary tooth. As the enamel is also thinner than in permanent teeth, so dental caries progresses through to the nerve faster in primary teeth. Furthermore, as the nerves or pulps of the primary teeth are relatively larger and more prominent, so the risk of abscess, as a result of caries penetrating through to the pulp is that much greater.

Permanent Teeth

In a full set of permanent teeth, there are 32, although not all teeth always develop, so one or several teeth may be missing. The commonest tooth to be absent is the third molar, or wisdom tooth.

The morphology of the permanent teeth is very similar to the primary teeth, but larger and with much bigger roots relative to crown size. The enamel is also much thicker. The dentine comprises the bulk of a permanent tooth and becomes thicker with age. This is because, as teeth age, the wear on the outside of the enamel caused by eating slowly removes the enamel. In wearing away the tooth, the masticated foods produce a response in the nerve, which is slowly reduced as dentine is produced by the odontoblasts. In time, the nerve can shrink to the extent that the pulp chamber almost disappears. Where a coarse, abrasive diet is used, this process of laying down secondary dentine can occur earlier in life and at a much faster rate.

Structure of Teeth

The differences in the structure between primary and permanent teeth are therefore those of size and thickness. The chemical compositions of the enamel, dentine, and cementum of primary and permanent teeth are essentially the same. As the chemistry of their structure affects their subsequent resistance or susceptibility to dental caries, it is appropriate to discuss their structure in detail.

Enamel

Tooth enamel comprises a hard, porcelain-like cap covering the whole of the clinical crown of a primary or permanent tooth. The crown is defined as that part of a tooth that is erupted and is visibly present in the mouth. It is distinct from the anatomic crown. However, with age, as the tooth continues to erupt, the clinical crown becomes the same as the anatomic crown.

The enamel comprises calcium, phosphate, water (as OH) of a form known as hydroxyapatite ($Ca_{10}(PO_4)_6$. 2OH). This basic chemical structure is widespread in the animal kingdom and is the building block of all calcified tissue. Where enamel is unique is that the percentage of inorganic component making up enamel is higher than any other tissue. Analysis of enamel shows that an average of 98% is made up of the inorganic component, largely the hydroxyapatite. (*See* **Calcium**: Physiology.)

Developing enamel, which is of ectodermal origin, is composed of up to 18% calcium and heterogeneous proteins. The majority of the developing enamel matrix consists of amelogenin, which is protein-rich. The remainder of the enamel protein is a high-molecular-weight phosphoprotein, known as enamelin. As the enamel continues to develop, the amelogenin is replaced as the enamel calcifies and then matures. During this process, over 90% of the amelogenin is removed. If this process does not occur properly, e.g., during some metabolic disorders, enamel hypoplasia occurs. At a later stage, if

calcification does not proceed properly during maturation, hypocalcification results. In both instances, the tooth may be more susceptible to dental caries.

Mature enamel consists of enamel crystallites of the aforementioned hydroxyapatite. These crystallites mature rapidly in width but slowly in thickness. The end result is a crystallite of large size.

The crystallinity of enamel varies, depending on its purity and the degree of incorporation of other elements. However, enamel is never a pure substance and always includes other inorganic or organic components during the developmental stage. The main component of interest is fluoride, which may be substituted for part of the hydoxyl ion to form fluorapatite. This is of considerable interest in dentistry, as this change produces an enamel that has a much greater resistance to acid dissolution. The incorporation of fluoride in the enamel will also provide a reservoir of fluoride ion, which plays a role not only in resisting dissolution but more importantly in remineralization.

The crystallinity is affected not only by incorporation of other ions, but also in surface enamel and in physicochemical ionic exchanges. Posteruptively, these changes in enamel chemistry are notably influenced by the uptake and release of fluoride and a reduction in carbonate. The latter is about 2.5% by weight, compared with calcium at 36% and phosphorus at 18%. However, it is felt that the carbonate component, as it is less stable than pure hydroxyapatite, may lead to a disruption of the enamel crystallinity and probably play an important role in enamel maturation. It is felt that as carbonate is more acid-labile than other components, it is lost during early caries or may make a high-carbonate enamel more susceptible to acid dissolution.

Enamel is laid down during development by specialized cells called ameloblasts, and if a higher concentration of fluoride is available in the bloodstream, this trace element becomes incorporated by the ameloblasts in the developing enamel. This mechanism is important when discussing the resistance of enamel to dental caries, but also in the formation of mottled enamel associated with high fluoride intake.

As mentioned above, enamel is laid down by ameloblasts by a process of secretion of an enamel matrix, which then becomes calcified. Further calcium and phosphate salts are laid down as the enamel matures prior to, and soon after, eruption in the mouth. During this period of maturation, the enamel appears to be more susceptible to acid dissolution, demineralization, and the development of carious cavities. The carbonate content of such enamel is high; carbonate is subsequently lost during maturation, but this will be offset by incorporation or the presence of fluoride in the oral environment.

The enamel surface of the outermost layers of 10 μm is of a slightly different histological structure. During the formation of the enamel, the ameloblasts lay down an outer 'surface layer' of different, higher mineral composition. If an increased level of fluoride is incorporated in this layer, that tooth will have a greater resistance to subsequent decay. Even during the process of early demineralization, this 'surface zone' remains intact, probably by a process of continuous remineralization by inorganic ions released from the inner layers of enamel as it dissolves. During the early stages of demineralization (caries), when the inner layers of enamel are dissolved, the outer layer retains its structure but becomes whitish in appearance when seen clinically. This is known as a 'white spot' or 'incipient caries' and is the first clinical sign of decay, but can be reversed by remineralization. The rate at which demineralization occurs will depend not only on the level and frequency of acid attack but also on the resistance of the enamel. This in turn will depend on the degree of mineralization, maturation, and fluoride and carbonate content.

Dentine

The major part of a tooth is dentine. The structure is laid down by cells called odontoblasts, which secrete tubules of dentine from the junction with the enamel to the nerve or pulp of the tooth. The odontoblasts are mesenchymal in origin and the structure they lay down has a lower level of mineralization, as well as smaller crystallites than enamel.

The dentine differs from the enamel in composition, being only 79% inorganic, although this inorganic material is the same hydroxyapatite as in the enamel and resembles bone in composition. The higher organic component consists of collagen type I, making up the walls of the dentine tubules and the dentine process in the centre of the dentinal tubules.

Unlike enamel, dentine has an innervation by means of nerve endings located at the pulpal end of the dentinal tubules. It is for this reason that pain is experienced when dentine is exposed in the mouth. This exposure may occur as part of the carious process when weak or undermined enamel breaks away to form a cavity. Alternatively, when a cavity is drilled by a dentist, in the process of removing decay, the sensitive dentine is cut, also causing pain unless some form of anesthesia is used.

Because of the higher organic content of the dentine, the process of dental decay is somewhat different to that of the enamel. While the caries in enamel is almost entirely a chemical dissolution by acids produced by bacteria, such as *Streptococcus mutans*, a secondary process of proteolytic removal of the collagen occurs in dentinal caries.

Although most cases of dental caries originate with dissolution of the enamel, the structure of the teeth is such that should the gingival tissues or gums recede, the neck of the tooth may be exposed. If this occurs, dentine is quickly exposed, leading to sensitivity of the tooth and, subsequently, dentinal or root caries. As receding gingiva occurs with age, so root caries is associated with the aging dentition and is seen mostly in patients over 50 years of age.

Cementum

The dentine of the root of the tooth is covered by a thin layer of cementum. This structure, also of mesenchymal origin, is again composed of inorganic and organic material but is closer to bone in the proportion of the two components. (*See* **Bone**.)

Cementum provides a mean of bonding the teeth into the bony sockets of the jaws by means of strands of collagen, known as periodontal fibers. The whole root is surrounded by many of these fibers, attaching the tooth to the bone, and providing a system of 'elastic bands,' or a hydraulic system, so that the tooth can be pressed deeper into its socket under biting forces. This mechanism takes up heavy forces on the tooth without them being transferred directly to the bone, which would be very uncomfortable on biting.

The cementum may break down as part of the dental caries process or during gum disease, or be worn away by excessively hard tooth brushing. Because of its lower inorganic content, its resistance to decay or wear is far less than either enamel or dentine, and if exposed, it can wear away quite quickly.

Etiology of Dental Caries

M S Duggal and M E J Curson, University of Leeds, Leeds, UK

Introduction

Dental caries or tooth decay is a pathological process of localized destruction of tooth tissues. It is a form of progressive loss of enamel, dentine, and cementum initiated by microbial activity at the tooth surface. Loss of tooth substances is preceded by a partial dissolution of mineral ahead of the total destruction of the tissue. It is because of this characteristic that dental caries can be differentiated from other destructive processes of the teeth, such as abrasion through mechanical wear and erosion by acid fluids.

Current Concepts of Caries Etiology

There is overwhelming evidence that the initial phase of dental caries involves demineralization of the tooth enamel by localized high concentrations of organic acids. These acids are produced by the fermentation of common dietary carbohydrates by bacteria that accumulate in dental plaque on the teeth. This concept of dental caries etiology is based essentially on the interplay of four principal factors: a susceptible host (the tooth), microflora with an acidogenic potential, a suitable substrate available locally to the pathodontic bacteria (carbohydrate), and a fourth important dimension, time (**Figure 1**). Because of the multiplicity of factors which influence the initiation and progression of dental caries it is often referred to

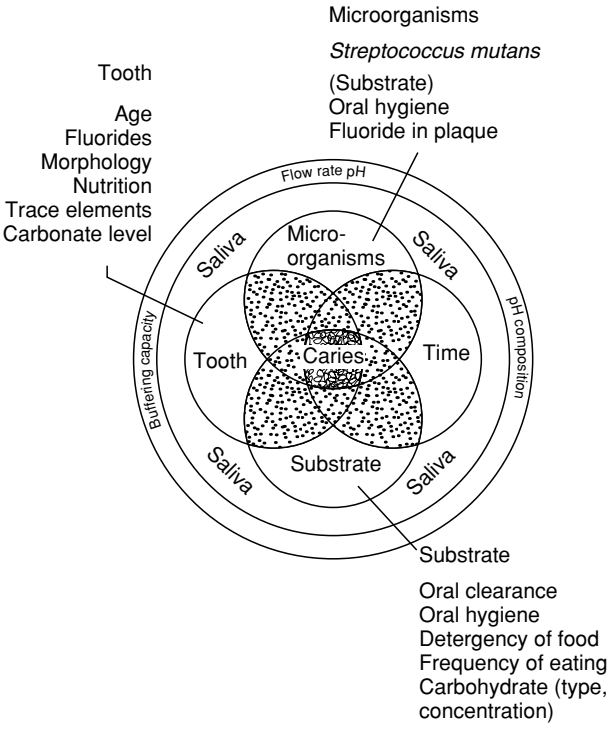

Figure 1 Diagrammatic representation of the parameters involved in the carious process. All factors must be acting concurrently for caries to develop. Dental Disease/Aetiology of Dental Caries, Reproduced from *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

as a disease of a 'multifactorial etiology', an old but appropriate description. In this article the role of microflora and the host susceptibility are discussed. The role of carbohydrates in the diet is discussed later. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism; Requirements and Dietary Importance.)

The Role of Microorganisms

Considerable difference of opinion exists within the dental research community as to which microorganisms cause dental caries and whether indeed a specific strain of bacteria is responsible in its causation. However, there is evidence that microorganisms, which accumulate in dental masses (dental plaque) on the teeth, cause fermentation of dietary carbohydrates, producing organic acids which cause demineralization of the tooth enamel. This concept is a combination of Miller's acidogenic theory of 1889 and that of dental plaque introduced by Williams in 1897. Subsequent research has supported this original view and the evidence implicating oral microorganisms in the etiology of dental caries is summarized below:

1. Germfree animals do not develop dental caries.
2. Addition of penicillin to the diet of rats prevents caries.
3. Plaque bacteria can demineralize enamel *in vitro* when incubated with dietary carbohydrates.
4. Microorganisms can be found invading carious enamel and dentine.
5. Animals in which diet or dietary carbohydrates are delivered directly into the stomach through a tube do not develop caries.

Role of Dental Plaque

Dental plaque is the name given to the aggregations of bacteria and their products which accumulate on the tooth surface. Plaque collects rapidly in the mouth, although the actual rate of formation varies from one individual to another. When plaque accumulates on the crowns of teeth the natural, smooth, shiny appearance of the enamel is lost and a dull, matt effect is produced. As it builds up, masses of plaque become more readily visible to the naked eye. In direct smears, the early plaque is dominated by cocci and rods, most of which are Gram-positive. In the mature plaque (after about 7 days) the percentage of cocci in the plaque decreases rapidly and filaments and rods constitute about 50% of organisms in plaque. The ecological term for this shift from a predominantly coccal type in the beginning to a predominantly mixed, filamentous flora a few days later is bacterial succession.

There is no doubt that the presence of plaque is required for caries development in humans. The best available evidence suggests that a carious lesion results from the action of bacterial metabolic end products localized to the enamel surface by dental plaque. It is therefore the acidity generated by the microorganisms in the plaque after exposure to carbohydrates that is directly responsible for causing demineralization. This is under the influence of many factors.

Regulators of Plaque Acidity

Various parameters have been studied for their effect on plaque acidity, and hence their effect on caries; these are listed in Table 1. The role of saliva will be discussed later, and carbohydrates as regulators of plaque pH are discussed elsewhere.

Bacterial mass in relation to caries Plaque is required for caries initiation, although the relationship between the plaque quantity and dental caries activity is unclear. Some earlier studies, using a crude methodology, showed a positive correlation between caries increment and oral hygiene, but more controlled investigations failed to establish this finding. Many individuals remain caries-free in spite of an unfavorable oral hygiene. This lack of a clear-cut relationship between amount of plaque and dental caries suggests that plaques vary in their microbial composition and, although present in equal amounts, might vary in their cariogenicity. Impressive evidence indicates that the qualitative nature of the plaque flora determines the metabolism and the potential for caries production. This view has been referred to in the literature as the specific plaque hypothesis.

Bacterial composition of plaque and caries Most published data on gnotobiotic animals have concentrated on the cariogenic potential of streptococci, especially *Streptococcus mutans*. However, several organisms have been found capable of inducing carious lesions when used as monocontaminants in gnotobiotic rats. These include *S. mutans, S. salivarius, S. sanguis, S. milleri, Lactobacillus acidophilus, Peptostreptococcus intermedius, Actinomyces viscosus*, and *A. naeslundii*. However, not all organisms are equally cariogenic. Table 2 shows the acidogenicity and

Table 1 Factors influencing pH of dental plaque

Carbohydrates	*Saliva*	*Plaque*
Quantity of intake	Flow rate	Bacterial mass
Frequency of intake	Buffer capacity	Bacterial composition
Retentiveness	Other factors, e.g., urea, ammonia	Acid production
Modifying effects of other ingredients of foodstuffs		Acid tolerance Acid retention

Table 2 Acidogenicity and acid tolerance of some plaque bacteria

	pH				Initiation of growth
	< 4.0	4.1–4.5	4.6–5.0	> 5.0	
Streptococcus mutans	+	+			5.2
S. sanguis		+	+		5.2–5.6
S. salivarius	+	+			5.2
S. mitis		+	+		5.2–5.6
Lactobacillus	+	+			< 5.0
Actinomyces			+	+	?
Enterococci		+	+	+	?

acid tolerance of plaque bacteria. In evaluating data shown in Table 2 it should be noted that the final pH represents the pH observed after incubation of pure bacterial cultures in broth with excess carbohydrates. Table 2 also indicates the tolerance of bacterial systems of plaque to acid. Though these data do not reveal the rate at which acid is produced or the pH at which growth ceases, they give some insight into the relative acidogenic, i.e. cariogenic, potential of plaque bacteria.

Bacterial Specificity and Dental Caries

Investigations into the relationship between various plaque organisms and dental caries have mainly focused on streptococci, lactobacilli, and filamentous bacteria.

Streptococci

Studies of *S. mutans* strongly suggest its active involvement in the initiation and progression of dental caries. Members of this species are nonmotile, catalase-negative, Gram-positive cocci. On *Mitis salivarius* agar they grow as highly convex colonies. When cultured with sucrose they form polysaccharides which are insoluble. This property of forming insoluble polysaccharides from sucrose is regarded as an important characteristic contributing to the caries-inducing properties of the species. *S. mutans* can invariably be isolated from incipient lesions as well as lesions that have cavitated on pits and fissures, approximal and smooth surfaces. It can also be isolated with highest frequency from plaque over carious lesions, and the isolation frequency decreases when the samples are taken further away from the lesions.

S. sanguis is also one of the predominant groups of streptococci which colonize the tooth surface. Evidence suggests that caries from this strain is significantly less extensive than that from *S. mutans* and occurs primarily in pits and fissures, whereas *S. mutans* causes smooth surface caries as well.

It would therefore appear that *S. mutans* is the most cariogenic of the family of streptococci. Its cariogenicity is attributed to several important properties:

1. It synthesizes insoluble polysaccharides from sucrose.
2. It colonizes all tooth surfaces.
3. It is a homofermentative producer of lactic acid.
4. It is more acidogenic than other streptococci.

Lactobacilli

Lactobacilli have also been implicated in the etiology of dental caries for many decades. Although a few studies have suggested their involvement in the initiation of caries, they are most often found in large numbers in carious cavities. This and the fact that lactobacilli have a relatively low affinity for the tooth surface suggest that they might have a more important role to play in the progression rather than initiation of dental caries.

Filamentous Bacteria

Filamentous bacteria, especially actinomycetes, have been found to be associated with root surface caries. *Actinomyces viscosus*, an acidogenic bacterium, is almost always isolated from plaques overlying root lesions. The role of *A. viscosus* in the initiation of root lesions is difficult to assess because they are often predominant on the sound root surfaces in subjects experiencing and resisting root caries. More definitive studies are needed to determine the association of *A. viscosus* and root caries.

It must be remembered that most of the microorganisms implicated in dental caries etiology are indigenous organisms and exist in a dynamic relationship with the host. Disease is not a necessary outcome of this association but it may ensue when the balance is greatly disturbed. With *S. mutans* this may occur, for example, when its numbers on teeth are increased owing to a higher or more frequent consumption of carbohydrates.

The Host Factors

Saliva

Saliva significantly influences the carious process. For example, removal of the salivary glands of hamsters greatly enhanced the caries activity when they were fed a high-sucrose diet. Human studies have demonstrated the same results and have shown that if the exposure of teeth to saliva is restricted by blocking the opening of the salivary glands the pH values of plaque, after exposure to carbohydrates, are lower.

Salivary flow and caries rate Humans suffering from xerostomia or decreased secretion of saliva as a consequence of a pathological condition such as sarcoidosis, Sjögren's syndrome, etc., often experience a higher rate of caries. The tooth destruction as a result of desalivation is typically quite rapid. Rampant caries has been demonstrated in patients who have been treated by radiotherapy to the head and neck as irradiation of the salivary glands leads to decreased salivary flow and usually leads to extensive caries in the cervical region of the teeth. These observations have led to the conclusion that saliva is in some way important to maintain the integrity of the tooth substance.

Salivary buffering and dental caries Saliva contains bicarbonate-carbonic acid and phosphate buffer systems. The buffering capacity acquired by saliva by virtue of these ion systems tends to correct pH changes caused by concentration changes of acidic ions produced by fermentation of carbohydrates. A typical reaction of plaque to carbohydrate challenge is an immediate drop in plaque pH followed by a gradual rise to the resting value. However, if plaque and teeth are isolated from the influence of saliva the pH of plaque drops further and remains low for prolonged periods. Thus the buffering capacity of saliva is an important factor in reducing the time the tooth enamel is exposed to the acidogenic challenge.

Other protective factors in saliva Saliva contains a number of factors of glandular origin, including lysozymes and a peroxidase system. Interest has also been focused on the immunological aspect of caries, and specific immunoglobulin A (IgA) antibodies to *S. mutans* have been detected in saliva by immune assays. The concentration of secretory IgA in whole saliva has been reported to be significantly less in subjects with a high caries rate as compared with those with a lower caries experience. Although substantial evidence suggests that the aforementioned factors form an antibacterial system in saliva, the extent to which they contribute to caries resistance of the host is not yet clear.

Tooth

Tooth morphology and dental caries A susceptible host is one of the factors which is required for caries to occur. The morphology of the tooth has long been known to be one of the major determinants of its susceptibility. Clinical observations have suggested that pits and fissures of posterior teeth are highly susceptible to caries. This is thought to result from impaction of food and microorganisms in the fissures which are also difficult to reach with routine oral hygiene aids. An interesting observation is that there is a positive correlation between the depth of the fissures and caries susceptibility.

It has also been observed that certain surfaces of a tooth are more prone to caries than other surfaces. For example, the occlusal surface and the buccal surface of the lower first permanent molar are more likely to develop caries as compared with the lingual, mesial, or distal surfaces, probably because of the presence of the fissures on the occlusal surfaces and the buccal pit on the buccal surface. Similarly, an intraoral variation in susceptibility to caries exists between different teeth. The caries susceptibility by tooth type, in descending order, is as follows: first permanent molar, second permanent molar, second premolar, upper incisor, first premolar, with the lower incisors and canines least likely to develop caries.

Arch morphology and caries Irregularities in the arch form and imbrication of the teeth also favor the development of caries. It has been shown experimentally that enamel in stagnation areas is more likely to develop demineralization, which is manifested as white spot lesions.

Tooth composition and dental caries It is well known that the surface enamel is more resistant to caries attack than the subsurface. This is attributed to a higher concentration of fluoride and other trace metals, such as zinc and lead, which are thought to protect the surface enamel from demineralization. It is because of this that dental caries is often said to be subsurface in origin. Although there is plenty of evidence to support the direct relationship between the fluoride content of the surface layer of enamel and its resistance to caries attack, the relationship of other trace elements is unclear and still being investigated.

Role of Diet

M S Duggal and M E J Curson, University of Leeds, Leeds, UK

Introduction

The driving force for the development of preventive dentistry and its effective use in patient management has been the expanding understanding of the disease of dental caries itself. As already discussed, dental caries is now recognized as a disease of altered ecology in which the host, oral microflora, and diet interact to present a challenge too strong for the normal defense mechanisms. It is wrong, however, to regard caries as a simple, continuing acid demineralization of the tooth enamel. Although teeth may be frequently exposed to acid environment, caries does not always arise as it is a result of a dynamic interaction of demineralization and remineralization. These are under the influence of a whole range of both cariogenic and protective factors (Figure 1). It is clear from this model that diet forms a part of a large spectrum of etiological factors involved in the caries process. Sugar and other fermentable carbohydrates in the diet constitute an essential aspect of cariogenic potential of food, with other factors, such as the frequency of intake, retentiveness, and buffering potential of foods, also playing an important part. These are in addition to the tooth structure, saliva flow and composition, and the presence of oral bacteria. This article is concerned with the discussion of the dietary considerations related to the etiology of dental caries.

The Role of Diet in the Etiology of Dental Caries

Epidemiological studies have been used to try to establish the relationship of various types of diets and dietary components to caries incidence. Circumstantial evidence linking sucrose consumption and prevalence of dental caries can be readily found in several epidemiological surveys. For example, the prevalence of caries among the native population of Tristan da Cunha, and among Eskimos and Australian Aborigines, was low before western-type food was introduced into their diets. Controlled human studies, mostly on institutionalized subjects, also indicated that sucrose-containing diets were cariogenic.

It is well known that when eating foods containing fermentable carbohydrates the pH of plaque drops, implying localized generation of acid. The drop in pH is the result of fermentation carbohydrates by the plaque bacteria, producing lactic and other organic acids, and is followed by a gradual return to the resting or near-resting pH. This recovery depends on a number of factors, including the buffering potential of plaque and the food, retention, or the rapidity of clearance from the mouth. The whole cycle of pH drop and recovery was first described by Stephan in 1940 and is commonly known as the Stephan curve (Figure 2). (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism; Requirements and Dietary Importance.)

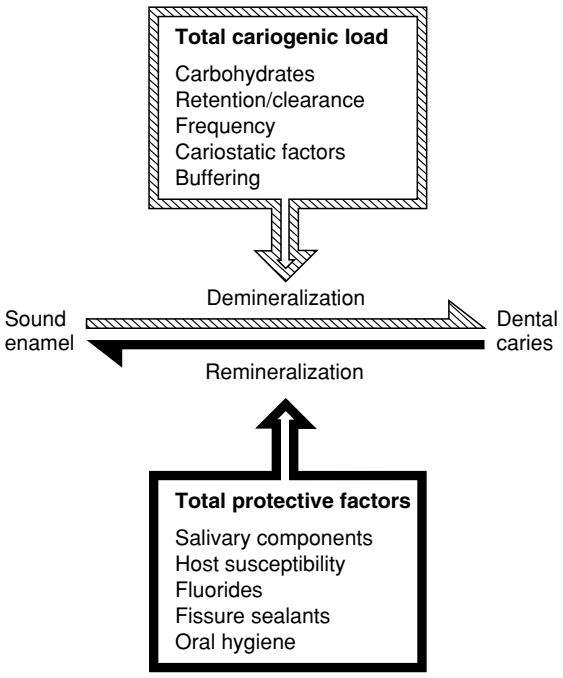

Figure 1 A dynamic model of caries. Reproduced from Dental Disease/Role of Diet, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

It is agreed that foods which produce a pH drop below pH 5.5, known as critical pH, are considered detrimental to teeth. The pH value 5.5 is considered critical because it is thought that enamel demineralization occurs below this point. Some authors regard values below 5.7 as being cariogenic. Foods giving a pH drop between 5.5 and 6.0 are also dubious. This form of ranking is referred to as relative potential cariogenicity. Of greater importance is the relative cariogenic potential of foods compared with known foods of high cariogenicity (sucrose) and low cariogenicity (sorbitol), as agreed at the international conference on cariogenicity of foods at San Antonio in 1985.

In one study, using the plaque-harvesting method, a representative sample of plaque was removed from human mouths before and after consumption of foods, and the pH response of that plaque was

assessed. The response followed a typical Stephan curve and the potential acidogenicity of the foods was compared by measuring the minimum pH recorded and the area enclosed by the curve under the resting pH value. Acidogenicity in a range of snack foods is assessed in Table 1. Interestingly, some foods which are perceived to be 'better for teeth' actually fare quite badly in such a ranking, compared with foods traditionally thought of as 'bad for teeth,' such as chocolate.

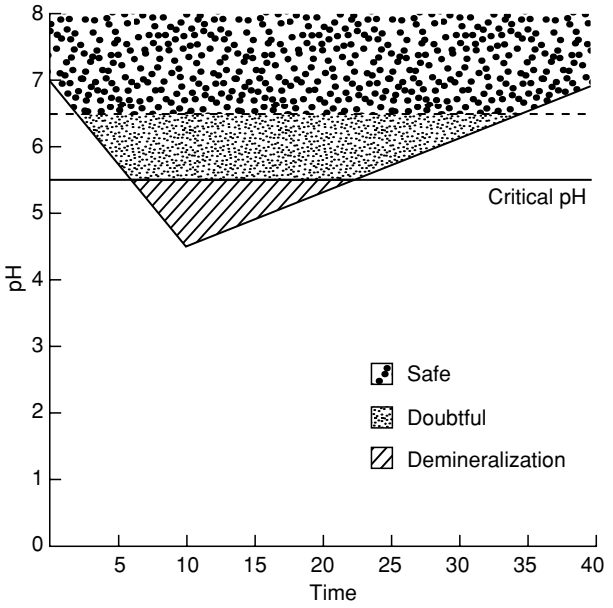

Figure 2 A typical Stephan's curve. Reproduced from Dental Disease/Role of Diet, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

This study bore out a previous study demonstrating that ingestion of chocolate or even apples resulted in a similar pH response. Later work, using the same test procedure, also showed that a wide range of foods containing either sugar or starches, or combinations thereof, are potentially acidogenic and thus possibly cariogenic.

It is important to note that the concentration of fermentable carbohydrate in a food does not affect the pH drop in the mouth, although the period of time taken to return to normal pH levels may be related to concentration. This return to resting pH is as much related to the buffering capacity of the saliva or plaque, buffering capacity of the foods, and the physical properties of the food itself. The retentiveness, and hence clearance rate, of a food is therefore an important determinant of the cariogenic potential of that food. The concentration of a single ingredient of a food has little relation to the cariogenicity; it is the ability of the whole food to promote caries that is important.

Tests for Cariogenicity of Foods

Animal experiments have been used to rank different foods in the order of their cariogenicity. In one such study a selection of human snack foods was ranked by their cariogenic potential index (CPI) by feeding

Table 1 Acidogenic potential of carious snack foods (US) grouped by category and acidogenicity

Group	*Beverages*	*Fruit, etc.*	*Baked goods*	*Sweets*
Least acidogenic	Milk	Peanuts		
	Chocolate milk	Potato chips (crisps)	Bread and butter	
		Apple	Graham crackers	Caramels
				Sugared gum
				Chocolate
				Licorice
				Sugarless gum
	Carbonated beverages	Banana	Cream-filled cakes	
			Sandwich cookies	Orange jellies
	Apple juice	Dates	Doughnut	
		Raisins	Bread and jam	
	Orange juice	Sweetened cereal	Whole-wheat bread	
			Plain sweet biscuits/cakes	
			Apple pie	Rock candy
			Chocolate	Clear mints
			Graham	
			Angel food cake	
Most acidogenic				Sourballs
				Fruit gums
				Fruit
				Lollipops

Table 2 Selected rankings of cariogenic potential index (CPI) in rats using human food as snacks

Food tested	*CPI*
Sucrose	1.0
Filled chocolate cookie	1.4
Cereal (14% sucrose)	1.1
Cereal (8% sucrose)	1.0
Cereal (60% sucrose)	0.9
Coated chocolate candy	0.9
Potato chips	0.8
Caramel	0.7
Chocolate bar	0.7
Cereal (2% sucrose)	0.5
Starch	0.5
Sucrose plus 5% Dical	0.4
No meals by mouth	0.0

After Bowen WH, Amsbaugh SM, Monnel-Torrens S *et al*. (1980) A method to assess cariogenic potential of foodstuffs. *Journal of the American Dental Association* 100: 677–681.

laboratory rats via a gastric tube, thus bypassing the mouth. Sucrose was used as a reference food and given a CPI of 1.0. Foods with a score of less than 1.0 were considered less cariogenic than sucrose, while those with a score above 1.0 were thought to be more cariogenic. Interestingly, the concentration of sucrose in a breakfast cereal made little or no difference to the CPI. The results, given in Table 2, show that potato chips (crisps) actually score higher than chocolate bars. It is clear from most of these experiments that any foodstuff containing carbohydrate has the potential to cause significant amounts of acid to be produced at certain sites in the dentition, which can be followed by demineralization of the enamel and subsequent caries. However, it must be remembered that not all occasions of a drop in plaque pH are accompanied by demineralization of the enamel. This has prompted many investigators to question the significance of acid production as a measure of the cariogenicity of the foods. It has also been shown that the total amount of titratable acid produced by the foods does not necessarily parallel the amount of enamel it will dissolve. It is now well accepted that the cariogenic potential of a food is influenced by a number of other factors, including the ability of the foods to remain in the oral cavity and, in some cases, the sequence of food intake. Thus, studies on the relationship between food and dental caries should consider not only foods in themselves but also their relationship to other items of diet with regard to their nature, timing, and order of usage.

Cariostatic Factors in Food

Some components of foods may be cariostatic. Proteins may assist remineralization of enamel or reduce the rate of crystal dissolution. Some fatty acids have been shown to reduce caries in rat studies while phosphates have been shown to have a marked protective effect. Inorganic phosphates have been demonstrated to have a protective influence when added to a cariogenic diet. Organic phosphates such as phytates and glycerophosphates also have a cariostatic action and are thought to reduce the cariogenicity of diets. Although the exact mechanism of action is unknown, studies have indicated that it might be a local modifying influence in the oral cavity, rather than a systemic effect through ingestion. The local effects of phosphates can be attributed to various properties:

1. Phosphates are good buffers; thus they can buffer organic acids produced by plaque flora.
2. Phosphates are known to reduce the rate of dissolution of hydroxyapatite.
3. Phosphates can desorb proteins from the enamel surface; thus they can possibly have a modifying influence on acquired pellicle.

The protection afforded by fluoride is well documented and has led some researchers to refer to dental caries as a fluoride-deficiency disease. These materials are all components of various foods. Furthermore, some cariostatic agents have been isolated from cereals and cocoa and these factors may all influence the level of caries caused. Accordingly the level of fermentable carbohydrate in a food will not be directly related to the degree of caries caused.

Food Retention

Tests have illustrated that, contrary to popular opinion, foods that are perceived to be 'sticky,' such as caramel, tend to clear from the oral cavity faster than many other foods considered cariogenic. As Table 3 shows, after 15 min, white bread was retained in higher quantities in the oral cavity than cake, chocolate, or hard mint. After 30 min, there was more residue from raisins than from caramel. Raisins have been consistently shown to be highly cariogenic.

Beverages, which are perceived to clear quickly from the mouth, actually sustain a low pH level for the same period as a 'sticky' confectionery. In a recent study a range of fruit drinks which were advertised as 'sugar-free' or as 'no added sugar' were assessed on the basis of their ability to reduce the pH of plaque. It was found that the fact that most of these drinks had little natural sugar (sucrose) did not affect their ability to reduce the pH of plaque; when compared with a standard 10% sucrose rinse they were equally acidogenic. This was attributed to the presence of natural sugars – fructose and glucose – in these drinks. These so-called natural sugars are also fermentable by oral

Table 3 Representative figures (mg) for food retention in mouth after eating

Food	*Food retention (mg) after*		
	5 min	*15 min*	*30 min*
Peanuts	4.9	3.3	2.6
Dentyne gum	5.0	3.9	3.1
7-Up	6.3	2.4	2.1
Chocolate milk	7.4	3.8	1.9
Potato chip	12.3	4.9	2.5
White bread	16.1	10.0	3.6
Raisins	16.8	5.7	3.0
Sponge cake	18.8	6.0	4.2
Caramel	19.0	4.2	2.5
Milk chocolate	19.0	6.8	3.0
Cracker (oil-sprayed)	23.8	8.5	3.7
Hard mint	31.9	9.4	2.5
Cracker (plain)	33.6	10.4	3.3
Sandwich cookie	35.0	8.4	4.9

After Bibby BG (1981) Foods and dental caries. In: Hefferren J (ed.) *Foods, Nutrition and Dental Health*, vol. 1, pp. 257–278. Illinois: Pathotox.

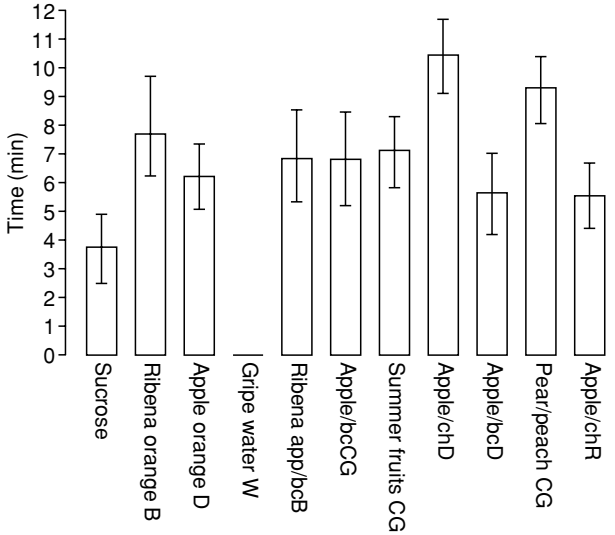

Figure 3 Bar graph showing mean time spent below pH 5.5 for fruit drinks compared with a 10% sucrose rinse. Reproduced from Dental Disease/Role of Diet, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

bacteria and their presence instead of sucrose does not render the drinks any safer for teeth. In fact, when the fruit drinks were compared with 10% sucrose it was obvious that the pH recovery was slower after consumption of fruit drinks and the pH remained below 5.5 for a longer time (Figure 3). This is because of an inherent buffering potential of fruit drinks which gives them an ability to resist any attempts by saliva to buffer the acid. These drinks can therefore be deemed to be more cariogenic than a pure 10% sucrose solution. This research highlighted the fact that the concentration of sugars alone is not the sole determinant of the acidogenicity, and hence cariogenicity, and other factors discussed above are equally important. (*See* **Carbohydrates: Metabolism of Sugars.**)

Eating Pattern and Frequency

On a population level, the average amount of sucrose consumed per capita relates to the average level of caries in the population. However, more detailed studies show the relationship to be less consistent and of low statistical significance. In the classical study often referred to as the Vipeholm study, inmates of a Swedish Medical Institute were fed increased sucrose or other foods in different patterns and caries experience was monitored. Groups of patients receiving high levels of sucrose (up to $330\,g\,day^{-1}$) with their meals experienced minimal increase in caries. But if smaller quantities of sucrose were consumed between meals, very high levels of caries ensued. The relationship was not therefore between quantity of sucrose and caries but rather frequency of intake and caries experience. This relationship, which has been confirmed in human and animal research, sheds light on why population studies do not demonstrate a clear and consistent relationship between sugar consumption and caries. For example, long-term diet–caries studies carried out in the UK showed that statistical correlation of sugar concentration to caries was 0.16 and explained only 4% of the caries variance.

Experience from primitive and developing cultures with little access to sucrose but abundant access to starch is often cited as evidence that sucrose and not starch results in dental caries. This evidence purports to be strengthened by the fact that introduction of western diet (including sucrose) immediately results in development of dental caries. It can be argued that introduction of a western diet is accompanied by increased affluence and an altered eating pattern. Such changes also include differences in the use of cooked starches as much as differences in use of sucrose. Frequency of intake of any food increases dramatically, along with the potential incidence of dental caries. It is also interesting to note that caries has been shown to be associated with a diet consisting of sago starch, as in the Sepik villages in Papua New Guinea.

Sugars and their Role in Caries

In western society, eating frequency has generally increased and snacking has become an accepted aspect of life. This change took place over a long period of the nineteenth and early twentieth centuries

when the incidence of dental caries increased. However, in the past 20 years, while sucrose usage has not changed, dental caries has dramatically decreased. In the case of 5-year-olds, the percentage with tooth decay fell from 73% in 1973 to 48% in 1983.

Reducing the frequency of eating just one of these foods, or reducing the concentration of sugars in a food, is unlikely to have a significant effect on the incidence of caries as nearly all foods contain some fermentable carbohydrate. It has been assumed tacitly both by practicing dentists and by too many dental investigators that the cariogenicity of an individual food is directly proportional to its content of sucrose or other fermentable carbohydrates. There are no quantitative data to support this belief. The effects of high sucrose concentrations in increasing the rate of food clearance of some foods from the mouth and in inhibiting the fermentation process make it seem improbable that high sugar content of itself would be particularly damaging to teeth. The Vipeholm study has been mentioned as evidence for the cariogenicity of sucrose, although investigators have questioned the reliability of a single clinical study from a mental institute. There are a number of contradictory studies that have not been widely recognized. For example, one group of investigators, studying English children, found that they could substantially increase sugar as sucrose in the children's diet without increasing the incidence of caries.

It is the frequency of consumption rather than the amount consumed which is associated positively with dental caries incidence. Considering the already substantial decline in the incidence of dental caries in the west, where frequency of eating has generally increased, and given the fact that dietary manipulation is difficult to achieve, it is reasonable to assume that alternative preventive measures such as the use of fluoride would be unfortunate if public hopes were raised to believe that dietary control alone would solve the problem of dental caries.

Fluoride in the Prevention of Dental Decay

H Whelton, University College Cork, Cork, Ireland

Introduction

Dental decay or caries is a ubiquitous disease in established market economies and in many developing countries. Dental caries poses a threat to the dentition throughout life. The early caries lesion is known as a 'white spot.' This white spot can do one of three things. It can stay the same, progress to a cavity, or regress to sound enamel. The fate of the white spot is influenced by its exposure to fluoride. Fluoride can help to prevent progression of the lesion and can aid remineralization, in which case the early white-spot lesion can disappear clinically.

Fluoride is widely used in the prevention of dental caries. It is estimated that over one billion people use fluoridated toothpaste worldwide. The second most common vehicle for fluoride is water. Water fluoridation is the controlled addition of fluoride to a public water supply for the purpose of preventing dental caries. In many parts of the world, the level of fluoride in water supplies is adjusted to 1 part per million (ppm). It is estimated that about 317 million people

in 39 countries benefit from artifically fluoridated water. A further 40 million benefit from water supplies which are naturally fluoridated. The fluoridation of toothpastes and public water supplies has been acknowledged as a major public health success in the prevention of dental caries. The addition of fluoride to water supplies and to oral health products has helped to bring about a remarkable decline in dental caries levels since the 1960s. In this paper the occurrence of fluoride in nature, the history of the discovery of its effects on the dentition, its use in the prevention of dental caries, and the risks associated with ingestion of excess fluoride will be considered.

Fluoride in Nature

Fluorine is a naturally occurring element, apparently ubiquitous in nature. Number nine on the periodic table of the elements, it is a halogen gas. It ranks 13th among the elements in order of abundance in the earth's crust. Fluorine is the most electronegative and reactive of all elements. It is a pale yellow, corrosive gas, which reacts with practically all organic and inorganic substances. The element was isolated in 1886 by Ferdinand Frederic Henri Moisson who used an apparatus constructed from platinum. He won the Nobel Prize for chemistry in 1906. Fluorine occurs chiefly in fluorspar (or fluorite, calcium difluoride, CaF_2), cryolite (Na_2AlF_6), and in many other minerals. Ionic fluoride, also referred to as inorganic or free fluoride, is the biologically important form of the mineral.

Fluoride is found in fresh water, sea water, and earth and in foods. Fluoride is present in both groundwater and surface water. The level of fluoride in groundwater varies from less than $0.1\,mg\,l^{-1}$ to more than $25\,mg\,l^{-1}$ according to the geological, chemical, and physical characteristics of the water-supplying area. The fluoride concentration in fresh surface water is generally low, ranging from 0.01 to $0.03\,mg\,l^{-1}$. In sea water, fluoride is found at approximately 1.5 ppm. Marine plants and animals are therefore constantly exposed to large amounts of fluoride. Fluoride in soils is derived primarily from the geologic parent material. Samples of nonindustrially contaminated soils from Germany, Greece, Finland, Japan, Morocco, New Zealand, Sweden, the USA and former USSR have been reported as containing from 30 to 500 ppm fluoride. Soils near fluorite and other types of mineralization may show levels up to more than 5000 ppm.

The normal accumulation of soil fluoride in plants is small. However, a few species of plants are known to accumulate high levels of fluoride, for example tea. The concentration of fluoride in dried tea leaves varies widely (approximately 4–400 ppm) while those of brewed tea range from 1 to 6 ppm depending on the amount of dry tea used, the fluoride concentration of the water, and the brewing time. High levels of fluoride are also found in fish: early reported concentrations range from 0.6 to 2.7 ppm. These samples may have contained bones. With its high affinity for calcium, most absorbed fluoride is deposited in bones therefore fish bones are a source of concentrated fluoride levels. More recent studies which excluded bone fragments from fish reported a range of fluoride values from 0.05 to 0.17 ppm. Other dietary constituents which contain fluoride are fluoridated water and infant formulas and beverages reconstituted with fluoridated water. Most other foods have fluoride concentrations well below 0.05 ppm.

History of Water Fluoridation

In 1901 a letter in the US Public Health Report from JM Eager of the US Public Health Service, stationed in Naples, Italy, reported the occurrence of 'a dental pecularity' known locally as denti di chiae. Denti di chiae were called after Prof Stefano Chiae, a celebrated Neapolitan who first described the appearance of a condition which was later to become known as dental fluorosis.

A similar condition, known as Colarado brown stain, was observed in Colorado Springs, USA, in 1901 by a dentist, Fredrick McKay. The condition manifested itself as a stain of varying intensity from fine white patches to a disfiguring brown mottling. Some 87% of the population in the area were affected. In 1916, McKay, with the help of GV Black, a prominent figure in dentistry at the time, published a thorough description of the condition, describing its appearance as mottled enamel. By the 1920s McKay had suspected drinking water as the source of the problem. In Oakley, Idaho, where mottling was severe, McKay noticed that children living on the outskirts of town who drank from a private spring had no mottling. He advised the town to change to this supply, which they did in 1925. Children born in the town subsequently had no mottling.

In 1931 new methods of spectrographic analysis led to the discovery of fluoride in the water supplies of areas where mottled enamel was endemic. The condition then became known as dental fluorosis.

In 1928 McKay published the observation that, in areas where mottled enamel was found, the prevalence of dental caries appeared lower than would be expected. In 1933 Ainsworth in England showed that dental mottling in Maldon in Essex was associated with a high level of fluoride in its water (4.5–5.5 ppm). He also noted that the prevalence of caries in permanent teeth amongst the children in the area was lower than that for England and Wales as a whole.

The discovery of fluoride (known to act as a protoplasmic poison in some circumstances) as the causative agent in mottling of the teeth was a cause of concern to the US Public Health Service. In response they appointed a dentist, H Trendley Dean, to investigate the condition. Dean devised a six-point scale of severity of dental fluorosis which is still used today. Dean's index facilitates regional and international comparisons of dental fluorosis as well as temporal comparisons. However the index is relatively subjective and the appearance of enamel varies according to lighting conditions, drying of the enamel, and angulation of viewing. Dean's index categorizes the enamel into normal, questionable, very mild, mild, moderate, and severe (Figure 1). Some of the limitations of Dean's index have since been overcome by the development of a standardized photographic method for the recording of dental fluorosis.

Dean combined measurement of the condition of the enamel with analysis of the drinking water throughout the USA. He then set out to identify the water fluoride levels, which represented the best compromise between low caries experience and a level of fluorosis, which could be deemed acceptable. The resulting study became known as the '21 cities' study. Dean recorded the level of dental caries and dental fluorosis in 7257 12–14-year-old children who had been lifetime residents of 21 cities with varying levels of natural fluoride in their water supplies from 0.0 to 2.6 ppm.

The marked inverse association between the fluoride content of the drinking water and the experience of caries in the population is shown in Figure 2. This study showed that, above a concentration of 1 ppm fluoride in the water, very little further reduction in caries was obtained. Dean also illustrated the dose–response relationship between water fluoride levels and dental fluorosis in the '21 cities study.' He found that, where the fluoride concentration exceeded 1.0 ppm, undesirable mottling would be seen in about 10% of the population.

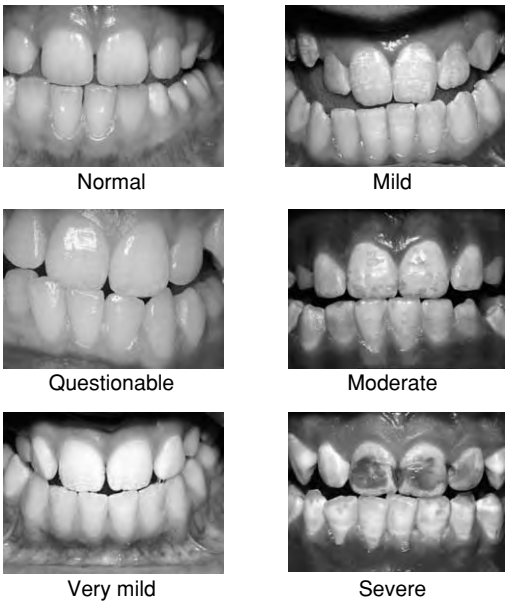

Figure 1 (see color plate 46) Categories of dental fluorosis according to Dean's index.

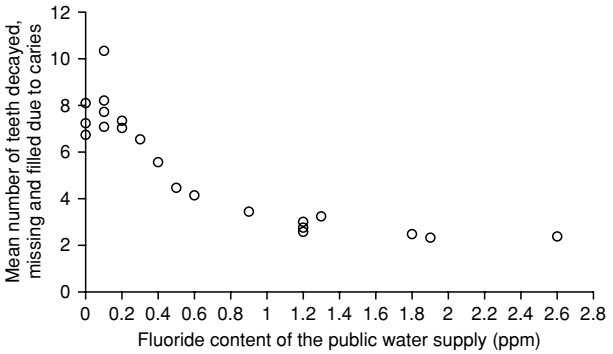

Figure 2 The relation between caries levels observed in 7257 selected 12–14-year-old white school children of 21 cities of four states and the fluoride content (ppm, horizontal scale) of public water supply. Open circles, DMFT (mean number of teeth decayed, missing, and filled due to caries). (Reproduced from F.J. McClure (ed.) (1962) *Fluoride Drinking Waters*, by kind permission of the National Institute of Dental and Craniofacial Research).

In 1945 and 1946 four cities in the USA and Canada began to add fluoride to their water supplies at a concentration of 1 ppm as part of the first controlled field trials of water fluoridation. The fluoridation of water to 1 ppm reduced the number of carious teeth per child by on average 60% relative to children in nonfluoridated cities.

Fluoridation Worldwide

Throughout the world it is estimated that about 317 million people drink artificially fluoridated water and that a further 40 million drink water in which the natural fluoride level is high enough to provide a significant degree of protection against tooth decay. Countries with fluoridation schemes include the USA, Canada, Mexico, Argentina, Ireland, UK, Spain, Australia, New Zealand, Hong Kong, and Singapore.

The USA is the most extensively fluoridated country in the world, with some 135 million people – over half the population – currently receiving artificially fluoridated water and another 10 million receiving naturally fluoridated water. The national health promotion and disease prevention objectives in Healthy People 2010 call for increasing the percentage of

Americans on public water supplies drinking fluoridated water from 62 to 75%.

Within the European Community (EC), the UK, Ireland, and Spain are currently operating fluoridation schemes. In Ireland, fluoridation of public water supplies is mandatory. An EC directive relating to the quality of water intended for human consumption (98/83/EC) sets a maximum admissible concentration (MAC) for fluoride at 1.5 parts of fluoride per million parts of water, irrespective of climate.

Some countries, such as France, Switzerland, and Germany, have implemented salt fluoridation.

Fluoride Ingestion and Absorption

Approximate estimates for daily dietary fluoride intake are shown in Table 1. It is estimated that 75–90% of daily fluoride intake is absorbed. Of that absorbed, the amount excreted varies; it is estimated that on average approximately 50% of absorbed fluoride is excreted, primarily by the kidneys in urine. In the very young more fluoride is retained. Most retained fluoride is deposited in bone because of its strong affinity for calcium.

Assessing fluoride levels in plasma, ductal saliva, or in urine can help monitor recent total fluoride exposure of individuals or populations. Research is ongoing into the use of fingernail clippings as a biomarker for fluoride intake some weeks prior to clipping. Dental fluorosis is a convenient biomarker for fluoride intake; however it is relevant only to the first 6 years of life. Dental fluorosis is a convenient biomarker for fluoride intake, however it is relevant only to the first 6 years of life. Dental hard tissues provide a marker for fluoride exposure during defined developmental periods. Bone provides information on the accumulated body burden of fluoride over a lifetime.

Fluoride Toothpastes

Studies of the effectiveness of fluoride toothpaste in the 1940s and early 1950s failed to demonstrate a caries-preventive effect. It is now believed that the sodium fluoride was not bioavailable due to a reaction with the calcium carbonate or calcium orthophosphate abrasive in the formulation. Since the 1950s studies of 2–3 years' duration have reported that fluoride toothpaste reduces caries experience among children by a median of 15–30%. A dose–response relationship has been demonstrated showing greater caries-preventive effects for higher-dose fluoride toothpaste. The two most commonly used forms of fluoride added to toothpaste are sodium fluoride (NaF) and sodium monofluorophosphate (MFP). There are many different formulations of fluoride toothpaste on the market. The concentration of fluoride in toothpastes varies from 250 to 2800 ppm. The most commonly sold toothpastes contain 1000–1500 ppm. In the European Union the maximum permissible concentration in fluoride toothpaste to be sold over the counter is 1500. Hence toothpaste formulations with greater than 1500 ppm fluoride are available at pharmacies only.

Manufacturers commonly list fluoride levels in toothpaste as a percentage. Table 2 shows the common percentages of NaF and NaMFP found in toothpastes, expressed as ppm in toothpaste.

Fluoride toothpaste contributes to the risk of enamel fluorosis because the swallowing reflex of children aged under 6 years and especially in those aged under 3 years is not well controlled. Early use of fluoride toothpaste by children is associated with the development of dental fluorosis. Ingestion of excessive amounts of toothpaste during the period of enamel formation can cause fluorosis. Enamel formation for all of the anterior teeth and most of the posterior teeth is complete by age 7. The critical window of vulnerability for anterior teeth to develop fluorosis from ingested fluoride has been reported to be 15–24 months for boys and 21–30 months for girls. The amount of toothpaste used accounts for an estimated 60% of the variation in the amount of toothpaste swallowed by children under age 7. It takes 0.75–1.0 g of toothpaste to cover a full head of a child-sized toothbrush. For a 1000 ppm toothpaste, this represents 0.75–1.0 mg fluoride. To minimize toothpaste ingestion up to age 7, manufacturers advise supervision and use of only a pea-sized amount of toothpaste (0.25 g). Many experts also recommend that toothpaste should not be used when brushing children's teeth up to the age of 2 years. The risk of ingesting fluoride toothpaste has led to the development of low-fluoride pediatric toothpastes with 250 or 550 ppm fluoride. These toothpastes have not been shown to be as effective in preventing caries as the

Table 1 Estimated daily fluoride intake from dietary sources

	Fluoridated area	*Nonfluoridated area*
Adults	1.0–3.0 mg	≤1.0 mg
Children	0.5 mg	0.25 mg

0.22	0.76	1000
0.11	0.38	500

1000 ppm formulation. Over the age of 7 years, when there is little risk of swallowing toothpaste, children who are able to expectorate the toothpaste properly may be allowed to use a greater quantity of toothpaste with up to 1500 ppm fluoride.

Other Fluoridated Products

Many other vehicles for the delivery of fluoride for the prevention of dental caries have been shown to be effective. Under the appropriate circumstances, fluoridated salt (250 ppm) has been shown to be as effective as water fluoridation. Fluoridated domestic salt is available in Switzerland, France, and Germany. Fluoridated milk and sugar have been tested on a pilot basis. Among the other products available are fluoride tablets for daily use, drops, mouth rinses for daily (0.05% NaF, 230 ppm) or fortnightly (0.2% NaF, 910 ppm) use, and products for application by dental professionals, including topically applied gels and varnishes. Applying fluoride gel (2.72% NaF, 12 300 ppm) or other products containing a high concentration of fluoride to the teeth leaves a temporary layer of calcium fluoride-like material on the enamel surface. The fluoride in this material is released when the pH drops in the mouth in response to acid production and is available to promote enamel remineralization. Dental filling materials have also been developed which release fluoride over time; however, fluoride release is limited to a relatively short period after placement. Other products have also been developed for placement in the mouth which would slowly release fluoride over months, if not years. Human clinical trial data on the effectiveness of these products are not yet available. Fortnightly school-based fluoride mouth rinse programs for the prevention of dental caries have been shown to be successful for the duration of the program. However in programs that cease at age 12, the effects have been shown to fade after 4 years.

Mechanism of Action of Fluoride in the Prevention of Dental Caries

Dental enamel is a highly mineralized tissue made up of 96% mineral and 4% organic material and water. The inorganic content of enamel consists of a crystalline calcium phosphate known as hydroxyapatite. The dissolution of these crystals by acid is the start of the caries process. Fortunately, enamel can remineralize as well as demineralize and the enamel surface is in a constant seesaw between demineralization and remineralization. Saliva provides a supersaturated solution of ions and acts as an ion reservoir during this process. When the equilibrium is disturbed, caries can progress.

In the early days scientists thought that the anticaries activity of fluoride was a preeruptive systemic effect as a result of its incorporation into the enamel crystal to form fluorapatite during the time of enamel formation. This crystal is more stable and resistant to acid demineralization than hydroxyapatite. However, investigators have failed to show a consistent correlation between anticaries activity and the specific amounts of fluoride incorporated into the enamel. The theory of preeruptive fluoride incorporation as the sole or principal mechanism of caries prevention has been largely discounted. Another theory was that fluoride inhibits bacterial metabolism; however, the low levels of fluoride found in the mouth after toothbrushing with fluoride-containing dentifrices are ineffective in interfering with processes of growth and metabolism of bacteria. The current theory is that the caries-preventive effect of fluoride is mainly attributed to the effects on demineralization/remineralization at the tooth–oral fluids interface. Levels well under 1 ppm of fluoride in saliva are effective in shifting the balance from demineralization, leading to caries, to remineralization. This is attributed to the fluoride-enhanced precipitation of calcium phosphates, and the formation of hydroxyfluorapatite in the dental tissues.

Benefits and Risks of Fluorides in Contemporary Society

In the 1950s and 1960s dental caries was an overwhelming problem in many countries. For example, in Ireland prior to the introduction of water fluoridation, in the early 1960s 12-year-old children had on average five teeth with decay. In the 1990s 12-year-old children whose domestic water supplies were fluoridated had on average one decayed tooth, and those without water fluoridation had on average two decayed teeth. The dramatic decline in the level of caries both in fluoridated and nonfluoridated areas reflects changes seen in the other established market economies.

Whilst early studies reported up to a 60% reduction in caries with water fluoridation, more recent estimates of effectiveness are lower with an 18–40% difference in caries levels. This apparent reduction in effectiveness is probably due to the widespread use of fluoridated toothpaste in both fluoridated and nonfluoridated communities. In addition, the consumption of foods and drinks manufactured using fluoridated water and consumed in nonfluoridated areas may confer some protection against dental caries to populations in nonfluoridated areas. This is known as the halo effect. Thus, where nonfluoridated communities are exposed to fluoride from sources

Table 3 Objectives and conclusions of the systematic review of public water fluoridation conducted by the NHS Centre for Reviews and Dissemination, University of York, 2000

Objective	*Number of studies included in review*	*Conclusion*
The effects of fluoridation of drinking water supplies on the incidence of caries	26	The best available evidence suggests that fluoridation of drinking water supplies does reduce caries prevalence
The effect over and above that offered by the use of alternative interventions and strategies	9	Water fluoridation has an additional beneficial effect
The effect of water fluoridation on levels of caries across social groups and between geographical locations	15	Inconclusive evidence
Negative effects		
Fluorosis	88	Yes, dose–response relationship with water fluoridation
Bone fracture and bone development problems	29	No association found
Cancer	26	No association found
Other negative effects	33	No clear association found
Differences in the effects of natural and artificial water fluoridation		Not enough evidence to draw conclusions

other than water, the observed effectiveness of water fluoridation is reduced. In Ireland water fluoridation was introduced in the 1960s and the use of fluoridated toothpastes became widespread in the 1970s. Whilst the level of caries has declined, the prevalence of fluorosis amongst Irish children appears to have increased since the 1980s when it was first measured. The alteration in the pattern of caries, the changes in the severity of the disease, and the use of multiple sources of fluoride have prompted a number of reviews of the risks and benefits of fluoridation. In 2000 the University of York presented a systematic review of the evidence on the positive and negative effects of population-wide drinking-water fluoridation strategies to prevent caries. The review summarized the best available and most reliable evidence on the safety and efficacy of water fluoridation. Of all the studies found in the literature search, 214 satisfied the inclusion criteria for consideration in the appraisal of the evidence. Outcomes for the five objectives of the review are shown in Table 3.

The reviewers were critical of the lack of high-quality research on water fluoridation. They recommended: 'the evidence of a benefit of a reduction in caries should be considered together with the increased prevalence of dental fluorosis.'

Those who oppose water fluoridation do so on three main grounds:

1. the effectiveness of water fluoridation in preventing caries in contemporary society
2. the safety of water fluoridation. Concerns around the general health effects of fluoride have been raised. For example, fluoride has a high affinity for calcium and most fluoride, which is absorbed and not excreted, is deposited in bones, hence, the effect of fluoride on bone health has been questioned
3. the ethics of administering fluoride through the public water supply and removal of the right to choose whether one's water supply is fluoridated or not

With regard to effectiveness, the current evidence continues to demonstrate a positive protective effect of water fluoridation against dental caries. Concerning safety, studies have failed to find harmful effects of water fluoridation at 1 ppm. Finally, the ethical debate is a philosophical one and is outside the scope of this paper.

Conclusion

Fluoride has been shown to be effective in the control of dental caries. Its effect is mainly topical at the plaque–enamel interface. The aim of fluoride therapy is to maintain the ambient level of the fluoride ion in the saliva at a constant optimum level. The evidence suggests that the effects of fluoridated water and fluoride toothpaste are additive. However, the risk associated with excessive ingestion and absorption of fluoride is the development of dental fluorosis.

Down Syndrome

B Lucas and S Feucht, University of Washington, Seattle, WA, USA

Etiology

Down syndrome (DS) (Trisomy 21) is one of the most common chromosomal abnormalities, affecting one in 600 live births. DS results from the presence of extra genetic material (a third copy) on chromosome 21. It occurs during the prenatal period and affects all races. The incidence of DS increases with maternal age, although 80% of children with DS are born to mothers less than 35 years of age due to increased fertility of younger women. Current knowledge describes three types of genetic changes in chromosome 21 that cause DS:

- nonfamilial trisomy 21, occurring in 95% of individuals;

- unbalanced translocation between chromosome 21 and another chromosome, in 3–4%; of these, approximately 25% result from a familial balanced translocation, and parents may be at increased risk of having another child with DS;
- mosaicism, in 1–2% of individuals with DS, resulting from two present cell lines – one normal and one trisomy 21; these individuals are usually affected less severely than the other types.

Recent research has studied the role of folate and homosysteine metabolism in women who had children with DS. Although no conclusions could be drawn from the small numbers, more work is needed. It is possible that both genotype and nutrition may play a role in the etiology of DS, as it does with neural tube defects.

Features and Characteristics

Individuals with DS demonstrate physical features and other characteristics that define the syndrome and determine the extent of health care, special education, therapies, and vocational planning needed. Developmental delay, hypotonia (reduced muscle tone), and short stature are seen in all individuals with DS. Cognitive levels usually range from mild to moderate mental retardation. See Table 1 for common characteristics.

Overweight and obesity are frequently seen in individuals with DS, resulting from a variety of factors. Other health concerns occurring less frequently, but impacting nutrition, feeding, or physical activity, include congenital heart disease, hearing problems, vision problems, cervical spine abnormalities, seizure disorders, and thyroid disease.

Down syndrome is associated with premature aging, often beginning in the fourth and fifth decades of life. Along with this aging, there is reported to be an increased incidence of Alzheimer's disease, senility, autoimmune diseases, and cataracts. Preliminary studies had documented *in vitro* chronic oxidative stress in persons with DS compared with their control siblings, but the role of this or other biomarkers in accelerated aging is controversial.

Table 1 Characteristics of persons with Down syndrome

Hypotonia
Mental retardation
Short stature
Flat facial profile
Eye features (upward slanting eyelids; skinfolds in corners of eyes)
Dental hypoplasia and irregular tooth placement
Increased risk of overweight and obesity
Accelerated aging process, i.e., Alzheimer-like brain changes, cataracts
Increased incidence of congenital heart disease, thyroid disease, leukemia

Services for individuals with DS are primarily community-based, compared with the past when most of this population would be found in residential institutions. Currently, the diagnosis is made at, or shortly after, birth, and early intervention services and therapies are begun in early infancy. Full inclusion in social, educational, and work environments is supported in most all communities and countries. As adults, many people with DS live in the community (with family, in group or individual homes) and are in vocational programs or gainfully employed.

Growth

Individuals with DS grow more slowly and are shorter in final stature than those without the syndrome of the same age and sex. The growth differences begin in the prenatal period. By puberty, children with DS are typically 1–2 inches (2.5–5 cm) shorter than their peers. The onset of the growth spurt may be delayed 6–12 months in adolescents with DS, and some may never have a growth spurt. Specific medical conditions such as congenital heart disease may also impact growth and weight gain for a child with DS. Since the onset of overweight can begin in late infancy or the preschool period, appropriate prevention strategies by the health care team should begin early.

Specialized Growth Charts

Specialized growth charts have been published for children with DS from birth to 36 months of age and from 2 to 18 years of age. They provide a better picture of length or stature in relation to other children with DS. These DS charts reflect small sample numbers (longitudinal data for weight and length/height for 400 males and 300 females), and include some children with congenital heart disease. The data were collected from 1960 to 1986 on children living at home, and they reflect a tendency to overweight. It is essential to use these specialized charts in combination with standard growth charts, such as the Center for Disease Control Growth Charts: United States 2000. The DS charts do not include head circumference data for younger children, nor do they compare weight/length or height in younger children or body mass index for children over the age of two.

Overweight and Obesity

Increasing rate of weight gain is a risk in persons with DS due to physical characteristics, medical conditions, and environment (see Table 2). With wellness

programs for this population and their families/caregivers, however, obesity can be prevented. A 1992 study of 30 sibling pairs, aged 2–14, found no significant differences between the DS children and their siblings in terms of BMI. The children with DS were less active than their siblings. Although children with DS who grow up with their own families have less overweight and obesity than their institutionalized peers, adults with DS living in the community are more likely to be overweight or obese than those in institutional settings. In 1995, Prasher reported on an assessment of overweight and obesity in 201 adults with DS living in the UK. Using BMI values, 31% of males were overweight, and 48% were obese (BMI > 30). For females, 22% were overweight, and 47% were obese; they also had the more severe forms of obesity. This study found no association between overweight/obesity and the severity of learning disability. Of note was the decreasing fall in BMI with increasing age, but it is unclear if this is an effect of the precocious aging or other related medical conditions.

For children, weight should be closely monitored on standard growth charts to prevent rapid or excessive gain that may not be as clearly seen on the DS charts. Overall, the velocity of growth and weight gain is more important than the actual percentile on either growth chart (see Table 3). For adults, regular health assessment should include weight and BMI monitoring. Adults with DS and their older parents may not have had the benefit of early intervention programs and may not be as enthusiastic about physical fitness and healthy diet plans as younger persons. Regardless of the etiology, the hazards of obesity make prevention and intervention important.

Inclusion in social, educational, and vocational environments brings new dietary challenges. Food choices, from vending machines and fast food outlets, typically favor high-fat, high-energy, nutrient-poor foods and beverages. Nutrition education is required to assist individuals with DS to make healthy food choices for themselves in their communities.

Table 2 Risk factors for overweight and obesity in individuals with Down syndrome

Risk factors	*Effect*
Hypotonia Short stature Low resting metabolic rate Hypothroidism Decreased pulmonary function Cardiac malformations Premature aging Limited instruction in wellness Food used as a reward Limited physical activity	Easily tired Excess energy intake Poor food choices Preference for indoor activities Disinterest in physical exercise

Adapted from Pipes P and Powell J (1996) Preventing obesity in children with special health care needs. *Nutrition Focus Newsletter* 11(6): 1–8.

Table 3 Guidelines for growth monitoring and obesity prevention in children with Down syndrome

Use standard growth charts for assessing weight for length, weight for height, and/or body mass index (BMI)
Down syndrome-specific growth charts may be used with parents to compare their children with their peers for length/height
Height and activity level should be used to determine individual energy requirements (a baseline for children 5–11 years of age is 16.1 kcal (67 kJ) per centimeter of height for males and 14.3 kcal (60 kJ) per centimeter of height for females)
Physical exercise is an important adjunct to an appropriate diet to increase lean body mass and, if needed, decrease fat tissue

Nutrition and Feeding Issues

Individuals with DS require the same nutrients and a varied healthy diet as anyone else. However, the syndrome characteristics may make them more at risk for nutrition and feeding problems. Owing to early development delays, some feeding issues can arise that affect the overall nutrient intake. Some infants may be poor feeders due to hypotonia. As the child grows, delays may be seen in the introduction of textured foods and the transition to feeding themselves table foods. Concerns have also been raised about low energy intake, which may result from efforts to prevent excessive weight gain. This low energy intake may lead subsequently to a low nutrient intake. With adequate monitoring and teamwork with the family, issues around feeding and nutrition can be identified early and appropriate interventions considered. Table 4 provides some general guidance to support positive development of food habits and prevention of excessive weight gain.

Table 4 Nutrition recommendations for children with Down syndrome

Establish early acceptance of a variety of foods
Develop a predictable eating pattern, i.e., three meals a day and snacks, if needed
Eat together as a family as often as possible; do not expect the child to eat alone
To establish good food habits early, limit access to non-nutritious foods
Carry low-energy foods, e.g., vegetable juice, fruit, when away from home
Have water readily available to drink
Avoid the use of food reinforcers in educational settings or for behavior management
Physical activity limits excessive snacking while increasing energy expenditure. (Note: To prevent aspiration, children should not be engaged in physical activity while eating.)

Adapted from Pipes P and Powell J (1996) Preventing obesity in children with special health care needs. *Nutrition Focus Newsletter* 11(6): 1–8.

Energy and Nutrient Intake

Since body mass and rate of growth determine basal energy expenditure, individuals with DS require less energy than their peers. Several studies of 5–11-year-old children, living either in an institution or at home, reported less energy intake than what is recommended for their age groups, or compared with the intake of their typically developing siblings. Obese teenagers with DS consumed 12–13 kcal (50–54 kJ) per cm (between the 10th and 50th percentile of energy intake for typically developing teens).

Over the years, nutrients of concern in children with DS have included calcium, iron, copper, zinc, and vitamins A, C, and E. Some reports have shown the overall intake of vitamins and minerals to be lower in children with DS compared with their controls. This is a concern for those children with a lower weight/height ratio and may be related to food/energy restriction. Earlier vitamin A studies demonstrated a lower intake, decreased absorption, and decreased plasma levels of retinol. How this might relate to abnormal immune response remains speculative.

A recent study by Hopman of 44 children (birth to 4 years) with DS indicated that, while there was delayed introduction of solid foods, the overall nutrient intake was adequate. Iron was the exception, and was low for both the subjects and controls. Energy intake was 27% below the RDA, but when assessed using energy per kilogram of body weight, this group reached the recommended level (102 kcal (427 kJ) per kg). These young children with DS as a group weighed less than their controls and were younger than those previously studied. With concerns about low energy intake and the risk of inadequate nutrient intake, a nutrition referral is appropriate for children with Down syndrome, especially in the early months and years of life.

Feeding Problems

Feeding difficulties and concern about related nutrient intake occur most often during the infant, toddler, and preschool years. If feeding issues continue into older childhood, they may have multiple causes and be more severe. Early feeding problems may include difficulties with coordination of suck and swallow. Most infants with DS are not ready for semisolids by the usual 4–6 months of age. They are usually not able to sit without support due to the hypotonia, and immature oral motor abilities make eating from a spoon difficult, if not unpleasant. If solids are not offered when the child is developmentally ready, however, subsequent feeding problems can occur. Delays in introducing solid foods due to oral motor issues sometimes can lead to a refusal to progress and/or chew more textured foods when the child is developmentally able to do so.

Because of the delayed development, parents often do not have adequate guidance or cues regarding when and how to progress in food textures and self-feeding skills. Feeding problems can also develop from negative experiences and interactions around feeding, i.e., choking or gagging, force-feeding. Infants and children with DS benefit from periodic screening to assess feeding development with subsequent referral to therapists or a feeding team if concerns are present. This screening should begin in infancy.

Supplement Use in Down Syndrome

The use of alternative treatments, such as supplemental vitamins and minerals, is relatively common in individuals with developmental disabilities. Vitamin supplements, with varying formulations and sometimes at high levels, have been promoted for persons with Down syndrome for at least 60 years. Related to the theory of increased oxidative stress, there have been various studies using individual nutrient supplements, i.e., zinc, vitamin A, selenium, and vitamin B_6. The results of these studies were inconsistent, and most had major methodological limitations.

The current popular approach is 'targeted nutrition intervention.' The supplement promoted promises to 'alleviate certain harmful symptoms of Down syndrome (e.g., the susceptibility to infections), and attempt to keep other harmful effects of the syndrome (e.g., mental retardation) from getting worse.' It contains vitamins and minerals for which there is a dietary reference intake (DRI) or a recommended dietary allowance (RDA), amino acids, and other compounds such as coenzyme Q10 and papain, which have no established dietary requirement. When provided as recommended for a child's weight, the supplement does not provide excessive doses of fat-soluble vitamins, which could lead to toxicity. However, some of the water-soluble vitamins are excessively high for infants, i.e. 60 times the dietary reference intake for vitamin B_{12}. Although such high levels are not reported to be deleterious in adults, studies in infants and young children are virtually nonexistent. Therefore, monitoring of these supplements is indicated, as well as education and counseling for families regarding recommended nutrient intakes for infants and children.

Anecdotal reports and testimonials of the benefits of these and similar supplements are widely distributed in lay publications and on the Internet, but no controlled studies have been conducted on these supplements.

When a similar supplement was popular in the 1980s, several double-blind, controlled studies using

the same protocol were conducted with children with DS. There was no difference in the health, development, and cognition between the children receiving the supplements and those who received the placebo. All groups showed improvements in all areas, as would be expected over time.

Health and education professionals working with families who are using such supplements need to be supportive and open, yet make sure that the practice does no harm. They should ask: Is the product safe? Does it work? What is the cost to the family? Are diet, feeding, and growth concerns being addressed at the same time? Is the child still obtaining education and needed therapies?

Other Nutrition-related Issues

Constipation

Constipation is a frequent problem due to hypotonia and decreased motor activity. The colon may retain stool longer leading to loss of water and result in hard, dry stools and long periods between stooling. Typical interventions include increasing the amount of fiber-containing foods and fluids in the diet and participating in appropriate exercise. If feeding problems are present, dietary treatment may be a challenge. Behavior-management techniques are sometimes helpful. Additional medical management may be needed with the use of stool softeners or addition of medical fiber products. Generally, the use of laxatives, suppositories, etc. is not appropriate for children, unless the child's primary care provider is consulted.

Children with DS have an increased incidence of Hirschsprung disease. In this condition, nerve endings are missing in the colon, so stools are not pushed along in the large intestine. This condition is usually identified early in life with subsequent surgical intervention.

Celiac Disease

Celiac disease may occur in 7–16% of children with DS, mostly documented from European sources. Individuals with DS may be predisposed to this condition because of the known increased incidence of autoimmune disorders. Symptoms usually resolve following institution of a gluten-free diet.

Dental Issues

Persons with DS often have smaller jaws and palates. Protruding of the lower jar can lead to poor alignment, which can affect chewing. The tongue also may be increased in size (or the jaw may be too small to support the tongue) and be more furrowed, leading to crevices that retain food and plaque. This can foster bacteria growth and/or bad breath. Dry mouth (xerostomia) is common and is believed to be due to reduced saliva as well as an open mouth and mouth breathing due to the tongue and jaw size.

Tooth eruption is delayed in children with DS until 12 and 18 months of age. There is also a risk for enamel abnormalities that can cause pitting and retention of food and plaque. Gum disease also occurs with greater frequency.

These problems can impact the individual's ability to eat and chew. With the increased risks of dental problems that can impact food intake, early and regular tooth and gum care is essential. For children with DS, the first visit to the dentist is recommended immediately after the first teeth erupt or by the first birthday.

Physical Activity

Individuals with DS are known to be less active than peers and to spend significantly more time indoors. Hypotonic children tire easily and use movement patterns requiring the least expenditure of energy. However, hypotonia tends to improve with age and therapy. The low level of physical fitness is partially explained by findings such as blood pressure, which does not rise regularly with the workload increment. The Health Care Guidelines for Individuals with Down Syndrome recommend establishing regular exercise and recreational programs early in the child's life. Enrollment in an early intervention program, which includes a focus on gross motor activities, is usually recommended within the first months of life.

Many children with DS have few restrictions in physical activity and should be encouraged to be active to increase their function, improve fitness, expend energy for weight management, and have fun. Sports should be limited to noncontact sports that challenge development, coordination, balance, and agility, and are fun to encourage life-long participation. The Special Olympic programs fosters life-long participation in physical activity and has many social rewards.

Approximately 10–40% of individuals with DS have atlantoaxial dislocation (ligaments in the cervical vertebra are more relaxed) resulting from hypotonia. This instability may increase the risk for spinal cord compression and injury. Activities that cause or require significant flexion of the neck, such as high jumping, gymnastics, diving and the butterfly stroke, should be avoided or done under medical supervision.

Promotion of Health and Nutrition

Optimal nutrition and growth, a healthy weight, and overall wellness are positive goals for persons with DS

and their families/caregivers. These are achieved not only by appropriate health care, but also by health and nutrition curricula in educational settings, and wellness programs in vocational and work sites. Key elements in a comprehensive wellness program for individuals with DS throughout the life span include:

- access to accurate and consistent nutrition, wellness, and fitness information and anticipatory guidance;
- interdisciplinary health care teams who develop trusting relationships with families and support access to scientific information and interpretation of that information;
- focus on good food choices and appropriate physical activity (beginning in infancy) to prevent overweight and obesity;
- practical nutrition education (appropriate to cognitive level) related to good food choices, basic food preparation, and physical activity for older children and adults with DS in the community.

Prader–Willi Syndrome

M S N Gellatly, Chelmsford, Essex, UK

Prevalence and Incidence

Prader-Willi Syndrome (PWS) is a complex genetic disorder.

In early 2002, the best estimate of incidence is 1 in 38 000–40 000. Increased awareness of the syndrome and improved diagnostic procedures should not be confused with an increase in prevalence.

PWS occurs in all races and across all ethnic groups.

Characteristics

The documented characteristics of PWS are summarized in **Table 1**. The range and severity of these vary considerably.

Body Composition

People with PWS have an abnormal body composition. Part of the explanation can be attributed to lowered gonadal hormones and their contribution to normal development. The most significant abnormality is a peculiarly high fat to fat-free mass ratio. Bone composition irregularities include lower mineral density, which contributes to the increased risk of osteoporosis, while bone age may be advanced if the child is significantly obese. Hypotonia (poor muscle tone) is primarily caused through central nervous system abnormalities; muscle abnormalities may be observed, such as size variations in type 1 and deficiencies in type 2B fibers.

Table 1 Characteristics of Prader–Willi Syndrome (PWS)

Regulatory
Hypotonia (poor muscle tone)
Hypogonadism (undersized or nonexistent genital organs)
Hypoactivity
Hyperphagia (overeating)
Poor temperature control
Decreased pain threshold and sensitivity
Sleep disturbances
Respiratory disturbances
Rumination
Physical
Distinctive facial characteristics: almond-shaped eyes, high forehead, small downturned mouth, slightly open mouth, prominent nasal bridge
Central obesity
Small hands
Straight ulnar border
Small feet
Dental abnormalities: crowded teeth, poor dental enamel
High palatal arch
Myopia
Strabismus
Cognitive
Learning disabilities
Speech and language delay
Poor articulation
Perseveration (repetitive speech)
Argumentative
Food-seeking
Food-stealing
Compulsions
Stubbornness
Temper outbursts or tantrums
Aggressive behavior to objects and others
Self-injury
Skin-picking
Emotional lability
Other characteristics frequently present in PWS
Obesity
Pale skin
Increased bruising
Reduced motor control
Poor dentition
Reduced salivary flow
Thick, sticky saliva
Absent or irregular menstruation
Undescended testes
Diabetes mellitus
Scoliosis
Osteoporosis
Epilepsy
Narcolepsy
Heart compromise
Cellulitis
Respiratory compromise
Bowel irregularities
Mental health (illness): depression, psychosis, schizophrenia

Modified from Greenswag LR and Alexander RC (1995) *Management of Prader–Willi Syndrome*, 2nd edn. New York: Springer-Verlag; and Waters J (2001) *Babies and Children with Prader–Willi Syndrome*, revised edn. USA: Prader–Willi Syndrome Association.

Endocrine System

Growth hormone and insulin-like growth factors are low in PWS. Gonadotrophins, estrogen, and/or testosterone are usually low in PWS. Increased visceral fat is one cause of glucose intolerance and may lead to diabetes mellitus.

Growth hormone treatment is licenced for children with PWS in many countries, including the UK, USA, and Scandinavia. In addition to aiding linear growth, body composition is altered by increasing the fat-free to fat mass ratio. Early indications from ongoing studies show that adults can also benefit from this treatment.

Neurotransmitters and Peptides

Several of these have been found to be abnormal in PWS. Plasma cholecystokinin (CCK) is raised, yet there is a resistance to the satiety effects. Gamma-aminobutyric acid (GABA) has also been found to be raised in plasma. Leptin levels have been found to be different from those in matched controls in several studies, although the significance of alterations is as yet inconclusive. Increased turnover of serotonin in PWS has been found, and this may contribute to the loss of satiety.

The Syndrome and its Management

The condition is characterized by two distinct phases with multisystem involvement. The hypothalamus is the probable site of major dysfunction as there are numerous alterations to the body's homeostatic mechanisms.

Decreased fetal movement is common. Infants present at birth with severe hypotonia. They are frequently unresponsive to their own needs or to their environment.

Failure to thrive during Phase 1 is common; special feeding measures, e.g., nasogastric tube feeding, are usually necessary, but respiratory support, such as artificial ventilation, is not.

Phase 2 is characterized by hyperphagia (overeating), usually developing between 1 and 6 years of age – although this may be earlier or later – resulting in life-threatening obesity unless energy intake is restricted. The phenomenon of food-seeking and stealing, and surreptitious eating, exhibited in this population is poorly understood by many professionals.

Motor and language development are delayed. Learning difficulties range from very mild to severe.

The placid infant develops into a smiling, friendly child. Most children and adults are loving and

warm; nevertheless, behavior problems are frequently exhibited, e.g., short-lived temper outbursts, stubbornness, manipulative tendencies, including attention-seeking and obsessions, frequently focused on, though not restricted to, food. Sometimes such problems develop into major mental health issues. There appears to be an increased risk of developing recurrent psychoses; these must be distinguished from behavioral phenotypes. Perseveration (repetitive speech) is common; it is unclear if this has an underlying physical or psychiatric basis.

Almost without exception, adults are unable to live completely independent lives.

Prognosis

Gross obesity, leading to premature death, is avoidable and not inevitable. Individual treatment plans and/or programs should be devised and provided in a supportive environment. The management program should include good dietary management at an appropriate energy intake level, to insure weight is kept within reasonable limits.

The most significant development in recent years is the beneficial effect of growth hormone treatment.

Medical Complications

As well as affecting life expectancy, many of these medical complications not only affect health but can precipitate an alteration in living conditions, e.g., to emergency nursing care; crisis management rarely provides the best alternative living environment.

Diabetes Mellitus (DM)

Diabetes mellitus has been frequently reported – almost entirely Type 2 (noninsulin-dependent) – directly linked to obesity. Until weight loss occurs, insulin therapy may need to be prescribed. Blood pressure control, along with no smoking, may be more difficult to achieve in the PWS population.

Osteoporosis

The recorded incidence of osteoporosis appears to be on the increase; this may be due entirely to a longer life span, influenced by lack of hormonal secretions in females, or may simply be more readily recognized as a complication of PWS.

Skin-Picking

Skin-picking can be severe. Infected sores, which were originally minor spots, bites, or operation scars, remaining as open wounds for months or even years, may be related to reduced pain threshold.

Sleep Apnea

Oxygen deprivation leads to sleep disturbances and somnolence; control of weight helps reduce the severity.

Pulmonary Involvement

There are reports that sudden onset of severe chest infection and/or pneumonia can result in death, extremely suddenly, at any age.

Diagnosis

Clinical Diagnosis

Clinical diagnosis criteria were agreed in the early 1990s, and continue to be revised (Table 2).

Table 2 Clinical diagnostic criteria

Major criteria: awarded 1 point each
- Hypogonadism; genital hypoplasia; pubertal deficiency
- Infantile central hypotonia
- Infant feeding problems – failure to thrive
- Rapid weight gain between the age of 1 and 5
- Characteristic facial features
- Developmental delay/mental retardation

Minor criteria: awarded ½ point each
- Small hands and feet for height and age
- Narrow hands with straight ulnar border
- Hypopigmentation
- Myopia, esotropia
- Thick, sticky saliva
- Typical behavior problems
- Skin-picking
- Decreased fetal movement and infantile lethargy
- Short stature compared with family at age 15
- Sleep disturbances/apnea
- Speech articulation defects

Supportive criteria[a]*: no points*
- Temperature control problems
- Unusual skill with jigsaw puzzles
- Scoliosis/kyphosis
- High pain threshold
- Decreased vomiting
- Early adrenarche
- Normal neuromuscular studies
- High pain threshold

Diagnosis should be strongly suspected:
- In those under 3 years of age with five points, three of which must be from major criteria
- In those over 3 years of age with eight points, four of which must be from major criteria[b]

[a]Some clinicians consider more emphasis should be given to some of these.

[b]Smith A, Haan E, Warne G *et al*. (1998) Prader–Willi syndrome: a new study of the Australian Paediatric Surveillance Unit. *Journal of Paediatric Child Health* 34(4): 398–399 require for those:
- under 3 years of age, three major and two minor findings
- 7over 3 years of age, four major and six minor criteria.

Genetic Diagnosis

Clinical diagnosis should be confirmed with genetic studies. PWS is caused by the absence of normally expressed genes on the paternally derived chromosome 15, on the long arm (q11 – q13). The majority with PWS – approximately 70% – have a deletion observed during fluorescence *in situ* hybridization (FISH). Some 29% have maternal uniparental disomy (UPD), confirmed by molecular studies. The remaining 1% have neither deletion nor disomy but an abnormality in the imprinting center in q11–q13. About 5% with deletion or disomy have a translocation or other structural abnormality causing the abnormality in the Prader–Willi critical region (PWCR).

Clinical Differences

Differences are emerging between those with deletion and disomy PWS. However, many early findings are still subjective both in reporting and interpretation. Some of these currently indicate that birth weights seem to be lower in those with deletion, and that a shorter time for tube feeding is needed amongst those with UPD, possibly reflecting a lesser degree of hypotonia.

African-Americans are less likely to have small hands and feet.

Nutritional Management

Early appropriate intervention is essential. Sadly, many individuals still do not receive correct nutritional and dietary management at an early stage.

Whenever a diagnosis is confirmed (or even suspected), dietary treatment should commence.

Poor feeding leading to failure to thrive and hyperphagia leading to rapid onset of weight are the complete antithesis. Yet in individuals with PWS, both are present at different stages of development; nutritional management must therefore encompass these two extremes.

PWS is clearly an eating, and not simply a weight, disorder. It is the most common example of genetic obesity secondary to an impaired satiety response, and must neither be confused nor compared with bulimia nervosa in causality or treatment.

Phase 1

Neonates have a decreased suck, thus breast-feeding is rarely successful. Special methods of feeding, e.g., nasogastric tube feeding, are required almost without exception. Some mothers choose to express breast milk; others find this option impossible to maintain and may therefore need reassurance that infant formula is acceptable.

Transition from tube- to bottle-feeding should not be delayed longer than necessary, but an adequate oral intake is essential before finally removing the tube.

Milk delivery at the right pace is essential; attention should center on three reflexes: lip closure, sucking, and swallowing. In addition to diminished suck, poor head and neck control is common – due to hypotonia – and exacerbates the difficulties encountered during feeding. Advice about positioning the infant is important. Small frequent feeds are advisable.

Infants with PWS rarely wake for feeds and are normally unresponsive to both their own needs and their surroundings.

Alternative Bottles and Teats

Use of a special bottle, e.g. Haberman, Chicco, Mead Johnson Soft, has been found to be invaluable for many parents and infants, although professional opinion as to their suitability is divided. Thus, caution when recommending these is needed. Special teats, supplied with the above bottles, or lamb's or orthodontic types fitting normal feeding bottles may also aid feeding, although it must be noted again that professional opinion as to their advisability is divided.

Provided a safe swallow is present, feeding systems with a soft spout may be suitable.

Cup Feeding

Not only does this method fit with the baby-friendly hospital initiative, but it is recommended for use with sick and low-birth-weight infants by the World Health Organization and UNICEF.

Spoon-Feeding

Sometimes it may be preferable to give liquids from a spoon.

Supplements

It may be necessary to increase the energy density of the feed to insure an adequate energy level is taken. Alterations to feed concentration must always be done under the supervision of a professional, e.g. dietitian or health visitor.

Thickening feeds may help and there are several commercial products available. Again, this should never be done without professional supervision.

Advice relating to vitamin and mineral supplements needs to be given on an individual basis.

Weaning

Introduction of solids may commence around 4 months; parents/carers may need reminding of the

Table 3 Signs of poor feeding

- Poor weight gain in infancy
- Slow intake
- Excessive time spent feeding the child
- Multiple swallows to clear mouth
- Irritability during feeding
- Frequent respiratory infections
- Excessive wet burps
- Excessive drooling
- Family fatigue from special food preparation
- Coughing while swallowing
- Difficulty in moving to new textures so food needs thickening
- Delay in accepting new textures, e.g., more lumps
- Chronic constipation
- Excessive weight gain – due to limited variety of foods because of inability to accept new textures

Adapted from Morris M (1993) Feeding the young child with PWS. *The Gathered View* XVIII(1): 6–7.

risks of commencing solids too early, particularly as infants with PWS often take solids from a spoon better than liquid from a bottle. Introduction of solids not only introduces the infant to new foods and tastes and textures, but assists with mouth muscle development, which is necessary for later speech development. Without good feeding skills it is unlikely that good articulation skills will be present.

Signs of poor feeding within this population are subtle and are summarized in Table 3.

Fluids

Fluid intake may continue to be compromised in toddlers and young children, so particular attention to insure an adequate intake is essential. Thickening of fluids may need to be continued.

Sugars and other concentrated carbohydrate, e.g., honey and sweetened baby drinks should be avoided both to lessen the risk of a 'sweet tooth' or dental caries developing, and to limit energy intake.

Energy Intake

Carers (normally parents) are usually delighted when the infant develops an appetite and takes food easily. At this stage of development, energy intake needs to be adequate but not excessive; comprehensive nutritional assessment by a qualified professional (usually a dietitian) who understands the syndrome is necessary to insure appropriate intakes.

However, it is not uncommon for parents to contribute unwittingly to the failure to thrive – they are so anxious to prevent overweight or obesity, they actually 'starve' the child, who fails to gain weight or achieve expected linear (height) growth. Theoretical needs must be matched by actual intakes. As weight gain can be extremely rapid – there are reports of excess fat deposits preceding the increase in appetite – achieving the right balance is not easy.

Weight should be recorded regularly, at a minimum monthly, but in infants under 12 months, weekly weighing is recommended. Length/height measurements are necessary. Results should be plotted on standard height/weight or body mass index charts – developmental records quickly show any deviation from normal patterns of growth. Linear growth should continue on the same centile, even though this is well below the average; weight should continue along the same centile and not be allowed to become more than two centiles higher than the height one. PWS-specific growth charts have been devloped in some countries.

Energy Requirements

An appreciation of the abnormal body composition is essential; this provides a partial explanation of the need for a lower energy intake. Observations indicate that, while normal children grow on 11–14 kcal (46–59 kj) cm^{-1} height, those with PWS require only 10–11 kcal (42–59 kj) cm^{-1} height. To achieve weight loss, levels of 7–8 kcal (29–33 kj) cm^{-1} height may be needed.

Phase 2

To follow any dietary regime is difficult. Adhering to a strict regime for life is particularly restrictive. For people with PWS not only is an energy-controlled diet necessary, but it is made even more difficult because of the inherent lack of satiety. Teenagers with the syndrome do not exhibit the normal pubertal growth spurt.

Obsessions around food further compromise successful management. Such obsessions with food must never be underestimated and may include:

- needing to know what is for lunch and supper at breakfast time
- creative play revolving around making meals
- collecting recipes and pictures of food
- wanting to watch every food and cookery program on TV

Nevertheless, children can be taught, for example: what is/is not acceptable

- e.g. quantities of food consumed at mealtimes
- what is a 'good' food and what should be avoided because of a high energy density
- normal social behavior, e.g., it is OK to want something to eat late afternoon but not immediately after lunch
- to eat slowly, replacing cutlery on the plate between each mouthful and not gorging

Unsurprisingly, there is no single successful diet. The one that should be followed is that which is acceptable to client and carer, fits in with the family (residential or group home) eating pattern, and provides all macro- and micronutrients at the right energy level to maintain growth and/or weight. The current emphasis amongst professionals for 'healthy eating' regimes at an unspecified energy level is unhelpful to both those with PWS and parents/carers supporting them, because of the satiety problems.

It is possible for older people with PWS to lose weight and return to an acceptable agreed level, provided they are in a suitable environment with understanding and sympathetic support. A body mass index of 30 is an achievable and realistic goal for adults.

As weight reduces, mobility increases; increased self-esteem must not be undervalued.

Fluids

Fluid intake needs to be at the right level. Water softeners, which exchange calcium with sodium salts, must never be used with infants and young children as high sodium intakes would be dangerous. Caution must be observed with artificially sweetened drinks to insure acceptable daily intake levels of such sweeteners are not exceeded.

Water intoxication has been reported (although only as a side-effect or in conjunction with medication), resulting in coma. Thus, statements such as 'you can drink as much as you like' need to be tempered, e.g., up to 1 liters diluted low-energy squash.

Contributory Factors

Successful management of PWS is not restricted to nutritional considerations.

Accessibility of Food

Food-seeking and stealing are peculiar phenomena, hard for the uninitiated to accept, and difficult characteristics to manage. Environmental controls are frequently essential, e.g., locking food cupboards, refrigerators, and freezers. Other measures, which conflict with normally acceptable social behavior, are often needed. These may include restricting access to money (and shops) and insuring no food is accessible, e.g., in a fruit bowl or in another family member's (or resident's) bedroom.

Some individuals will steal and consume any food they find, including some normally not eaten by humans (pica), e.g., cat and dog food, berries and other garden produce, frozen products, discarded food scraps in dustbins.

Research indicates that denial of food-stealing and consumption is related to cognitive learning problems and is not deliberate deception. Strategies for dealing with such events must be known to all concerned and without exception followed – inconsistency complicates management and confuses the individual. A written contract is helpful.

Special Occasions, Holidays, and Treats

People with PWS should be included in social activities, although the importance of planning ahead and providing the necessary supervision should never be underestimated. The preferable approach is to reduce overall energy intake prior to such events rather than afterwards.

People with PWS can have as rough a day as anyone else and may benefit from an occasional extra treat.

Reinforcers or Tokens

People with PWS respond well to programs that allow collection of points towards a predefined reward, or as a reinforcer. Alternatives to foods are preferable, e.g., books, games, toiletries, make-up; some people with PWS respond well to an additional period of attention and time.

Rules and Routine

Consistency in both these is essential – individuals do not respond well to alterations to routine or inconsistency in overall care.

Occasionally rules have to be made which affect others, e.g., eating only at mealtimes. Any management program must insure all involved in care, both direct and indirect – family, friends, teachers, social workers, neighbors, welfare assistants, club organizers – realize the importance of decisions and adhere to them.

Exercise

Parents can assist with improving muscle development from a very early age. The individual program may be devised by a physiotherapist or be adapted from a scheme such as Portage, which is a programme of exercises to assist the development of handicapped babies and young children. All those with PWS, not only children, must be encouraged to participate in physical exercise daily to assist both with improving muscle tone and increasing body metabolism.

The beneficial effects of growth hormone treatment, both increasing muscle mass and improving muscle tome, makes physical activity easier. Increased activity in turn allows a higher energy intake to be consumed.

Education

Many children commence at a mainstream infant school, progressing to a similar junior/primary school. It is acknowledged that the pace of learning falls off from about the age of 8 years, after which time most children, though not all, have difficulties in keeping up with their peers. Few individuals complete education without additional support (welfare assistants or extra individual teaching) in a mainstream setting. A move to a different school, e.g., for those with mild or moderate learning difficulties, may be the better option. Others may require specialist help for other developmental difficulties, e.g., physical handicap or speech delay, and this is best found in specialist schools.

The need to restrict access to food makes adult vocational training difficult but not impossible. Many young adults have false expectations – some of which educators have encouraged, through ignorance rather than intent – which can rarely be met. Failure results and is frequently accompanied by a rapid and unacceptable weight gain. Yet in the right environment people with PWS have achieved success with qualifications in academic, craft, or practical subjects. Many are extremely good with young children and the elderly, provided appropriate supervision is in place.

Behavioral Management

Frequent references have been made to behavior management programs. Each must have individual needs assessed by the appropriate professionals who then devise a sustainable program. The importance of regular reviews, including dietary management, cannot be overstated.

Residential Options and Independence

Adults with the syndrome may give the impression of being eminently capable of both looking after themselves and making appropriate decisions. This frequently leads to inappropriate or inadequate support. Professionals have a duty to plan suitable care in a safe environment. This may be a group home – the Prader–Willi Syndrome Association (USA) led the field in developing PWS-specific homes – a concept gathering momentum in other countries in Europe and Australia. A care village or community, hostel, or sheltered housing may suit some adults better.

Each residential environment must be considered on its own merits as to whether it can handle the multifarious problems of PWS, alongside other residents, and whether it is suitable for the particular individual.

Placements which break down are generally those where proper insight into the complexities of the syndrome are lacking, by frequently dismissing, through disbelief, these management and support issues.

Realistic expectations are essential and no carer should have guilt feelings about restricting access to food.

Support Groups

There are, at the time of writing (early 2002) support groups for parents and professionals in 41 countries. An international body – International Prader–Willi Syndrome Organization (IPWSO) – was constituted in 1991 and each of the 25 constituent countries has both a parent and professional delegate. International conferences are arranged every 3–4 years, when scientists, professionals, carers, parents, and those with PWS are brought together for lectures, seminars, and workshops.

DEXTRAN

J N BeMiller, Purdue University, West Lafayette, IN, USA

Source, Structure, and Properties

Dextran is a generic term for a family of glucans made by polymerization of the α-D-glucopyranosyl moiety of sucrose in a reaction catalyzed by the enzyme dextransucrase. The common feature is a preponderance of (1 → 6)-linked α-D-glucopyranosyl units.

Several microorganisms produce dextrans with ranges of molecular weights and with structures varying from slightly to highly branched. Commercial dextran is biosynthesized by the nonpathogenic organism *Leuconostoc mesenteroides* NRRL B-512. The basic reaction catalyzed by dextransucrase is n sucrose → (α-D-glucopyranosyl unit)$_n$ + n D-fructose. Branches arise from position O-3 of the glucosyl units. The degree of branching of commercial dextran is about 5%. About 40% of the side chains are single α-D-glucopyranosyl units; about 45% are two units long, and about 15% contain more than 2 units. The average molecular weight of native commercial *Leuconostoc mesenteroides* NRRL B-512 dextran can range from 9 million to 500 million. Dextran of lower molecular weight is produced for clinical applications. Dextran produces relatively low-viscosity solutions, which distinguishes it from other high-molecular-weight polysaccharides. It is a neutral polymer.

Food Uses

Many uses of dextrans in foods have been described and patented, but dextrans are not permitted as foodstuff additives in the USA or Europe. (The generally recognized as safe (GRAS) status was removed by the US Food and Drug Administration, USA, in 1977 because dextran was not being, and had not been, used as an ingredient.) The principal potential uses of dextran in foods appear to be related to its capacity to prevent crystallization, retain moisture, and provide body, but the fact that it is not being used as an additive indicates that no particularly useful functionality that cannot be provided by another hydrocolloid(s) is known. Small amounts of dextran, primarily produced by species of *Leuconostoc* and *Lactobacillus*, are likely to be present in fermented foods that originally contained sucrose.

Dextran formation is detrimental to sugar (sucrose) production, as dextran inhibits crystallization; increases viscosity and, hence, decreases filterability and heat transfer in evaporators, crystallizers, and pans; and results in poor clarification. As a result, steps are taken to minimize dextran formation by contaminating bacteria. Dextranases may be employed to break down any dextran produced. Prevention of crystallization of sugar in foods, beverages, and confections is a potential use.

Metabolism

Dextrans are not broken down by human digestive enzymes. They are degraded by enzymes of bacteria in the large intestine and the released glucose can be absorbed as well as fermented anaerobically.

Medical and Other Uses

Dextran of average molecular weight of 70 000 is used clinically as a plasma volume expander for the treatment of shock and prevention of impending shock. The antithrombic effect of a preparation of average molecular weight of 40 000 provides a prophylactic treatment for venous thrombosis and pulmonary emboli. These and other applications reveal that dextrans of various molecular weights can be safely injected into the blood stream. A complex of ferric hydroxide and dextran is used in the treatment of neonatal anemia in pigs. A principal use is in the

preparation of gels in bead form for size exclusion, ion exchange, and hydrophobic chromatography.

DEXTRINS

J N BeMiller, Purdue University, West Lafayette, IN, USA

Background

Dextrin is a generic term applied to a variety of products obtained by heating a starch in the presence of small amounts of moisture and an acid. Dextrins can be made from any starch and are generally classified as white dextrins, yellow (or canary) dextrins, and British gums. Each is more water-soluble and produces less viscous solutions or dispersions than its parent starch. Each is produced by combinations of slight depolymerization (hydrolysis) and transglycosylation (molecular rearrangement). Transglycosylation produces more highly branched structures and forms glycosidic linkages not found in native starches. Most dextrins are used as adhesives for paper products. Only white dextrins and only small amounts of them are used in prepared foods. White dextrins are prepared by heating a dried, acidified starch.

Other hydrolytic breakdown products from starch are characterized by their dextrose equivalency (DE), which is the percent of reducing power compared to anhydrous D-glucose (dextrose). The DE value is inversely related to molecular weight, i.e., the degree of polymerization (DP), and is, therefore, an indicator of the degree of hydrolysis. (The DE value of anhydrous D-glucose is 100. The DE value of native starch is 0.) When all products of starch hydrolysis were made by treatment of starch with acid, the properties of a product were largely a function of DE. Now with a variety of treatments and processes being used, two products with equivalent DE values (average degree of polymerization) can have rather different properties because of different distributions of molecular sizes.

Maltodextrins are those products having DE values of less than 20, generally DE 5–19. Syrup solids are those products of starch hydrolysis with DE values of more than 20 that are available as dry powders; in other words, they are dried low-DE glucose syrups.

While dextrins are little used in foods; maltodextrins and syrup solids are used extensively. Both are produced from starch by hydrolysis only, i.e., without molecular rearrangement, and are of lower average molecular weight than either dextrins or acid-thinned (thin-boiling) starches, the latter being slightly depolymerized starches that remain in granular form. The primary difference between thin-boiling starches, maltodextrins, and syrups/syrup solids is the degree of depolymerization. The primary difference between dextrins and thin-boiling starches is the method of preparation.

Production

Dextrins are prepared by heating a starch moistened with dilute hydrochloric acid or heating a moist starch in the presence of gaseous hydrogen chloride until a cold-water-soluble product is formed.

Maltodextrins and syrup solids are prepared in basically the same way as are starch-based glucose syrups, except that the process is stopped at an earlier stage to keep the DE value low. Depolymerization of a starch can be effected with either an acid or an enzyme(s) or by combination treatments. These processes are referred to as acid conversions, enzyme conversions, and combination conversions, respectively. Conversions to produce maltodextrins are usually done in a continuous process. In a typical process, a starch slurry (30–40% dry solids, 17–22 Bé) at pH 6.0–6.5 is pasted, generally in a jet cooker ($\sim$105 °C), followed by an atmospheric flash. Conversion (liquefaction) is accomplished with a thermostable bacterial α-amylase at 95–100 °C. Depolymerization is stopped after 60–120 min by enzyme inactivation, and the pH is adjusted. The solution is filtered, treated with carbon, concentrated, and spray-dried to give a maltodextrin or syrup solid preparation. In

Table 1 Typical analysis of a maltodextrin product

	%
Carbohydrate	94.5
Moisture	5
Protein	< 0.1
Fat	< 0.1
Crude fiber	< 0.1
Sodium	< 0.1
Calcium	< 0.03
Phosphorus	< 0.03
Magnesium	< 0.01
Potassium	< 0.005
Sulfite	< 0.001
Iron	< 0.00025
Zinc	< 0.0001

a lower-temperature batch process, steam is introduced into a starch slurry for pasting, which is accomplished at 80–90 °C. Otherwise the processes are identical, except that a debranching enzyme may be used in the batch process. (*See* **Enzymes**: Functions and Characteristics.)

For an acid conversion, a starch is acidified with a food-grade acid, generally to a pH value of about 2. Hydrochloric acid is preferred because of a preference for sodium chloride in the final product. The slurry is passed through a jet cooker to paste the starch and then through a converter to depolymerize it. Alternatively, the starch can be pasted, the pH adjusted after pasting, and the conversion done in a batch process. The degree of hydrolysis, i.e., the DE value, is controlled by a combination of time, temperature, and acid concentration. The process is terminated via cooling and neutralization. The resulting liquor is clarified, treated with carbon, concentrated, and spray-dried.

A variety of maltodextrins can be produced. The variables in the process are the starch source, the means of conversion (including the specificities of enzymes used), and the extent of breakdown (i.e., the DE value of the product). In general, DE values range from 5 to 19; the amount of D-glucose (dextrose) ranges from 0.5 to 3%; and the moisture level is 4–6% (Table 1). As much as 98% of the components can be of DP 3 or higher.

Properties

Dextrins are cold-water-soluble. Upon drying of a dextrin solution, clear films are obtained. Maltodextrins are generally even more soluble, although special crystalline and less soluble types are produced. Depending on the type, 15–60% solutions can generally be made easily at room temperature. Syrup solids are slightly sweet, hygroscopic, semicrystalline, or powdery amorphous products. Maltodextrins are less hygroscopic because of their lower monosaccharide content. They are available as spray-dried powders and in agglomerated and other forms, all of which are essentially white, free-flowing powders. They have the ability to absorb flavor oils and other nonaqueous liquids. Their flowability, compressibility, and low hygroscopicity make them excellent excipients. They provide good to excellent solution clarity. They provide moderate to very low solution viscosity, and low to extremely low browning. They are generally bland, and generally resist caking. They form protective films with oxygen-barrier properties and provide binding, surface sheen, and high solids content without affecting freezing points. Characteristics and properties that increase as DE increases are bulk density, hygroscopicity, ability to participate in Maillard-type browning reactions, solubility, clarity of solutions, osmolality, freezing-point depression, sweetness, and particle size. Characteristics and properties that decrease as DE increases are abilities to form a film, build viscosity, serve as a binder, and provide body.

Typical properties of typical maltodextrins with average DE values of about 5 are formation of clear solutions at concentrations up to 15% at room temperature, production of significant viscosity at 20–40% concentration, very minimal hygroscopicity and sweetness, and excellent film-forming characteristics. Typical properties of typical maltodextrins with average DE values of about 10 are formation of clear solutions at concentrations up to 30% at room temperature, very low hygroscopicity, and low sweetness and ability to effect browning. Typical properties of typical maltodextrins with average DE values of about 15 are formation of clear solutions at concentrations up to 50% at room temperature, slight sweetness, and low hygroscopicity and ability to effect browning. (*See* **Browning**: Nonenzymatic.)

Especially prepared, low-DE, more crystalline maltodextrins produce a fatty mouthful. They are most often made from potato or tapioca starch; oat flour and bran is another source; rice flour has also been used for their preparation. These products, when hydrated, form soft, spoonable gels with a creamy texture. They generally have DE values less than 3.

Food Uses

Dextrins are usually used to produce protective coatings such as those applied to panned confections. Maltodextrins are used in a wide spectrum of food products, including baby foods, bakery products, beverages, breakfast cereals, canned fruit

products, condiments, confections, dairy products, desserts, dietetic and nutritional beverages, frozen meals, infant formulas, jams, jellies, margarines, meat products, dry mixes of all kinds, peanut butter, pet foods, preserves, sauces, snack foods, soups, and syrups. Applications are divided approximately as follows: as carriers for spray-dried and extruded flavors (20–25% of total market), as bulking agents for flavoring materials and high-intensity sweeteners (20–25%), as fat sparers and replacers (20–25%), in nutritional beverages (15–20%), and in confections and coatings (5–15%). Properties that make them useful in these applications are low hygroscopicity (prevention of caking) while being easily dispersible and readily soluble, generally bland taste, encapsulation of essential oils and other flavors (ability to act as a carrier), film formation (ability to coat), binding action (adhesiveness), provision of lubricity, control of expansion of extruded products, provision of bulking, and texture creation. They prevent sugar crystallization and improve chewiness in soft confections, increase shelf-life and maintain moisture levels in hard confections, and speed up the panning process. They are effective binders and excipients for direct compression confections (and pharmaceutical tablets). They control the freezing point and ice crystal growth in frozen dairy products. They control sugar crystallization and sweetness and add solids to bakery fillings, frostings, and glazes. They provide a chewy texture and extend the shelf-life of fruit leathers and granola bars. Maltodextrins are generally excellent spray-drying aids and are used for agglomeration of food gums. Partially crystalline maltodextrins are effective fat sparers and replacers in low-fat or nonfat dairy products. All maltodextrins are digestible, having an energy value of about $3.8\,\mathrm{kcal\,g^{-1}}$. (*See* **Cereals**: Breakfast Cereals; **Dietetics**; **Fat Substitutes**: Use of Fat-replaced Foods in Reducing Fat and Energy Intake; **Infant Foods**: Milk Formulas; **Infants**: Nutritional Requirements; **Low-fat Foods**: Types and Manufacture; Low-fat Spreads.)

Syrup solids are generally used alone or in combination with maltodextrins when one or more of the following characteristics are desired: browning, freezing-point depression, greater solids content, increased solubility, some sweetness, increased clarity.

Digestion and Metabolism

All products made by simple depolymerization of a starch (food dextrins, thin-boiling starches, maltodextrins, dried syrups, syrups) are nutritive saccharides. They are generally recognized as being safe and nontoxic. Human digestive enzymes (pancreatic α-amylases and maltooligosaccharidases of the epithelium of the small intestine) convert each product into D-glucose, which is absorbed, raising blood sugar levels. The D-glucose is then metabolized, so each of these products provides approximately $3.8\,\mathrm{kcal\,g^{-1}}$. Maltodextrins and syrup solids are the carbohydrates of choice for sports drinks and liquid diet formulations because of the low osmolality of their solutions. These properties and their easy digestibility also make them suitable for infant formulas. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism.)

DIABETES MELLITUS

Contents

Etiology

J Wright, University of Surrey, Guildford, Surrey, UK

Definition and Classification

Diabetes mellitus is a complex disorder of metabolism (fat and protein as well as carbohydrate) caused by either a deficiency of, or defective action of, insulin. It is not a single disease entity, but rather a syndrome of variable clinical presentation and etiology (**Table 1**). (The terms insulin-dependent diabetes mellitus (IDDM) and noninsulin-dependent diabetes mellitus (NIDDM) should now be abandoned in favor of type 1 and type 2 diabetes.)

Basic Features of Diabetes

Type 1 (insulin-dependent) and type 2 (noninsulin-dependent) diabetes account for the great majority of patients. They differ in terms of their clinical presentation, etiology, and basic metabolic defect. Type 1 diabetes is characterized by absolute insulin deficiency owing to B-cell destruction, and type 2 diabetes by relative insulin deficiency due to a combination of dysfunctional insulin secretion and resistance to insulin.

Successful treatment of diabetes with diet, oral hypoglycemic drugs, or insulin enables the majority of patients to lead long and near-normal lives. Increasingly, it is the long-term complications of the disease which are the major challenge in the treatment of diabetes. The most important of these are the microvascular complications (retinopathy and nephropathy), the macrovascular complications (atherosclerosis, coronary artery, and peripheral vascular disease), and neuropathy. These complications are uncommon in type 1 diabetes of less than 10 years' duration but are not uncommon at presentation in type 2 diabetes, probably because of the long period of asymptomatic hyperglycemia which usually precedes the clinical diagnosis. In the majority of patients it is relatively easy to achieve good or at least reasonable health in the short term. However, with increasingly convincing evidence that the incidence of long-term complications can be reduced by maintaining good glycemic and metabolic control, this has become the major emphasis in the clinical monitoring and management of diabetes.

The major differences between types 1 and 2 diabetes are shown in Table 2.

Table 1 Etiological classification of diabetes

Type 1: insulin-dependent diabetes mellitus (IDDM)[a]
Autoimmune
Idiopathic

Clinical diabetes represents a continuous spectrum from the young, underweight, ketotic, and sometimes comatose patient on the one hand to the elderly, obese and frequently asymptomatic patient on the other. The majority of patients with types 1 and 2 diabetes conform to the patterns in Table 2 but there are frequent exceptions; it is increasingly recognized, for example, that the elderly sometimes develop typical type 1 diabetes. There is more uniformity in young patients, almost all of whom require insulin. An exception is the syndrome of maturity-onset diabetes of the young (MODY), a group of rare inherited disorders which usually present before the age of 25 years, and which, in the first instance at least, do not usually require treatment with insulin.

Diagnosis

Although both insulin deficiency and insulin resistance result in abnormalities of fat, protein, and carbohydrate metabolism, it is upon the changes in blood glucose levels that both diagnosis and monitoring are primarily based.

Until recently, the diagnosis of diabetes was based upon the criteria set by the World Health Organization (WHO), using a standard oral glucose tolerance test (OGTT). In the vast majority of patients, a GTT is unnecessary, and the diagnosis is made on the basis of clinical history, and the random and/or fasting blood glucose level, which are usually unequivocal. (The exception is pregnancy, during which screening for gestational diabetes using a GTT is common practice.) However, strict criteria and a standard diagnostic procedure are important, particularly for epidemiological purposes. The interpretation of a GTT is based on the glucose level in the fasting state and 2 h after a 75-g glucose load (or equivalent); neither the 1-h glucose level nor measurements of urine glucose or plasma insulin are of diagnostic use. The glucose load should be dissolved in 250–300 ml of water and drunk within 5 min after an overnight fast; dietary carbohydrate should not have been restricted during the 3 days prior to the test.

The WHO criteria have recently been revised, and the new criteria are shown in Table 3. The major reason for the changes is the fact that the 1-h postload plasma glucose level of 11.1 mmol l^{-1} (the most important criterion for the diagnosis of diabetes) correlates better with a fasting level of 7 than 6 mmol l^{-1}. A new category of 'impaired fasting glucose' (fasting plasma glucose 6.1–7.0 mmol l^{-1}) has also been proposed because it has been shown that prevalence of diabetic complications (retinopathy) starts to increase significantly in people with a fasting plasma glucose above 6 mmol l^{-1}. (*See* **Glucose**: Maintenance of Blood Glucose Level; Glucose Tolerance and the Glycemic (Glycaemic) Index.)

Impaired glucose tolerance (IGT) is not a separate etiologic category. It is associated with an increased risk of developing diabetes (10–25% within 5 years) and, importantly, the risk of developing the syndrome of obesity, hypertension, and hyperlipidemia as well as the macrovascular complications of diabetes. Individuals with IGT should therefore be monitored carefully, and treated with dietary restriction and weight loss where appropriate. (*See* **Hyperlipidemia (Hyperlipidaemia)**; **Hypertension**: Nutrition in the Diabetic Hypertensive.)

Table 3 Diagnostic values for the oral glucose tolerance test (WHO, 1999)

	Venous plasma glucose (mmol l^{-1})
Diabetes mellitus	
Random, or	≥ 11.1
Fasting, or	≥ 7.0 (whole blood ≥ 6.1)
2 h after glucose load	≥ 11.1
Impaired glucose tolerance (IGT)	
Fasting, and	< 7.0
2 h after glucose load	≥ 7.8 but ≤ 11.1
Impaired fasting glycemia (IFG)	
Fasting	≥ 6.1 but < 7.0

Epidemiology

The current and predicted prevalence of diabetes worldwide is shown in Table 4. As can be seen, it is anticipated that the prevalence of diabetes will (approximately) double by the year 2010, with the major increase occurring in 'developing' countries. Around 98% of the increase is accounted for by type 2 diabetes.

Type 1 Diabetes

There are dramatic differences in the prevalence of type 1 diabetes, both racially and geographically. The

Table 4 Estimated prevalence of diabetes (millions)

Worldwide 1997	124 m[a]
2010	221 m
West Asia 1995	3.6 m
2010	11.4 m
South/central Asia 1995	28.8 m
2010	57.5 m
South-east Asia 1995	8.6 m
2010	19.5 m
East Asia 1995	21.7 m
2010	44 m

[a] ~2% population; 3.5 m type 1, 120 m type 2.

From Amos AF, McCarty DJ and Zimmet P (1997) The rising global burden of diabetes: estimates and projections to the year 2010. *Diabetic Medicine* 14: S7–S15.

annual incidence rate in young people below the age of 20 years varies from around 30 per 100 000 per year in Finland and Scandinavia to less than 1 per 100 000 per year in oriental populations such as the Koreans and the Japanese. Rates are generally much higher in northern than southern Europe (with the exception of the island of Sardinia, which has an incidence similar to Scandinavia), and higher in whites than blacks from the same geographical area. Racial differences in the prevalence of type 1 diabetes may relate to differences in the frequency of susceptibility genes in the population.

The peak age of onset of type 1 diabetes is between the ages of 11 and 13 years. Thereafter, the incidence rate is low during middle life but there is a further peak in the elderly, in whom the presenting features of the disease may be similar to those seen in children. The etiology in this group may be different, but they frequently have islet-cell antibodies, indicating an autoimmune process. In addition to age-related differences in incidence, there is also a seasonal variation, seen only in older children, with a maximum during the winter months, possibly related to seasonal variations in viral illnesses involved in the etiology of the disease. Of particular concern is the fact that the incidence in children appears to be increasing steadily in some countries, including the UK. The reasons for this are unclear.

Type 2 Diabetes

There are also marked differences in the prevalence and incidence of type 2 diabetes. The lowest rates are found in underdeveloped rural communities in Africa and Asia. The prevalence in most European countries is between 1% and 3%, and it is estimated that there may be a further similar number of cases which are undiagnosed. Unlike type 1 diabetes, surveys in the USA show that the prevalence of type 2 diabetes is higher among blacks than among whites.

The anticipated explosion in the prevalence of type 2 diabetes is already evident in certain ethnic groups who have been subjected to rapid 'westernization.' The most extensively studied are the Pima Indians in Arizona and the Micronesian population of the Pacific island of Nauru where inheritance appears to be autosomal dominant, and the prevalence in adults may be as high as 80%. Recently, high rates have also been found in a number of migrant populations, particularly in those from the Indian subcontinent to the west. It has been suggested that these peoples possess a 'thrifty genotype' which confers the advantage of metabolic efficiency when food is in short supply but which leads to obesity, insulin resistance, and type 2 diabetes when food becomes plentiful.

Complications and Mortality

The pattern of complications varies between type 1 diabetes and type 2 diabetes. In both, the major cause of death is from cardiovascular disease, but in type 1 diabetes, microvascular complications (nephropathy and retinopathy) remain important, with a significant increase in deaths from renal disease and its sequelae. Similar microvascular complications occur in type 2 diabetes, but the increased mortality is largely attributable to deaths from cardiovascular disease. These differences probably reflect fundamental differences in the pathophysiology of the two conditions.

Causes

The underlying lesions in type 1 and 2 diabetes are different and result from different pathogenic processes. In the majority of cases of type 1 diabetes there is loss of insulin secretion due to autoimmune destruction of B cells, while in type 2 diabetes there is usually minimal loss of B cells but evidence of dysfunctional insulin secretion and peripheral insulin resistance. In both cases the disease process is complex and almost certainly involves genetic, environmental, and possibly dietary factors.

Type 1 Diabetes

Genetic factors About 60% of the genetic predisposition to autoimmune type 1 diabetes is accounted for by genes of the major histocompatibility complex (MHC), particularly the human leukocyte antigen (HLA) genes which code for a series of cell-surface glycoproteins, class I and class II HLA antigens. Class I proteins are expressed on the surface of most nucleated cells and are involved in the presentation of processed antigens to cytotoxic T lymphocytes. Class II proteins are expressed on B lymphocytes, macrophages, and activated T cells, and are involved in the presentation of antigens to T-helper lymphocytes. Class II proteins comprise α and β chains which are encoded for by genes within the DP, DQ, and DR regions of chromosome 6.

The major association with type 1 diabetes is with possession of the HLAs DR3 and DR4 (**Table 5**).

Table 5 Human leukocyte antigen (HLA) associations and the relative risk of type 1 diabetes

HLA-DR antigen	*Relative risk of type 1 diabetes*	*95% confidence limits*
DR2	0.1	0.05–0.3
DR3	5.0	2.9–8.8
DR4	6.8	3.8–12.1
DR3 and DR4	14.3	6.3–32.4

Data from the Barts-Windsor Study (1983).

However, these are too frequent in the general population to be solely responsible for susceptibility to diabetes, and the reason that these haplotypes appear to confer susceptibility is that they are in linkage disequilibrium (i.e., transmitted together) with other true susceptibility alleles, particularly within the DQ region. One particular DQ polymorphism determines the presence of an aspartate residue at position 57 in the DQ8 β chain. The presence of an aspartate residue in this position changes the configuration of an antigen-presenting cleft in the DQ protein; aspartate confers a more efficient antigen-presenting configuration, and thus enhances antigen recognition and the subsequent immune response. In addition to conferring susceptibility, the possession of certain HLA alleles may confer protection (e.g., DQ6, DQ18).

While a considerable amount is known about the MHC/HLA genes, very little is known about the genes which may account for the remaining 40% of genetic susceptibility. There is some evidence that the insulin gene may be a susceptibility locus, but conclusive evidence is lacking.

Environmental factors Twin studies have shown that the concordance for type 1 diabetes between genetically identical individuals may be less than 40%, indicating that other environmental factors are also involved in triggering the autoimmune process. The most likely of these is viral infection, and several candidate viruses have been identified. The best documented is congenital rubella, with type 1 diabetes developing in 10–20% of affected individuals. Others include mumps, and coxsackie B, cytomegalovirus, and Epstein–Barr virus. There may be several mechanisms by which viral infections may cause B-cell damage. These include direct B-cell infection and damage, induction of antigenic determinants in the B-cell membrane, either as a result of incorporation of viral proteins or exposure of autoantigens, and molecular mimicry (immunological cross-reactivity between viral antigens and B-cell components).

Other possible environmental triggers include toxic and/or nutritional factors. Nitrosamines in smoked mutton have been implicated in the pathogenesis of childhood diabetes in Iceland. Currently there is considerable concern that bovine serum albumin (BSA) in cows' milk may be able to initiate an autoimmune response because of cross-reactivity between BSA and a B-cell component; this issue is clearly of major importance but the connection remains unproven.

Immune factors It is likely that type 1 diabetes develops as the result of an environmental injury in genetically predisposed individuals, the combination of which initiates an autoimmune process which results in insulitis and B-cell death. The precise details of this process are unclear but it is probable that an initial event such as a viral infection results in B-cell damage and exposure of antigens which are usually hidden from the immune system. This triggers a macrophage response and subsequent release of cytokines such as tumor necrosis factor and γ-interferon which are capable of inducing aberrant expression of class 2 antigens on B cells, thus enabling B cells to act as antigen-presenting cells, and to present surface autoantigens directly to T cells. Neither A nor D cells appear to be capable of being induced to express class 2 antigens and are therefore spared.

The result of the autoimmune process is the production of autoantibodies which can be detected in the circulation of almost all newly diagnosed cases of type 1 diabetes. Antibodies may be directed against either cytoplasmic antigens (islet-cell antibodies, ICAS) or against surface antigens (islet-cell surface antibodies, ICSAS), and even against insulin itself (insulin autoantibodies, IAAS). They may be complement-fixing and therefore cytotoxic. Candidate cytoplasmic autoantigens include the enzyme glutamate dehydrogenase (GAD), while candidate cell-surface autoantigens include the glucose transporter GLUT-2.

Autoantibodies may be present in the circulation for months or even years before the clinical presentation of the disease, during which time insulin secretion may decline gradually. There may then be a final event which precipitates the development of clinical diabetes, either a further viral infection or reexposure to the original triggering infection, thus explaining the seasonal peaks in the incidence of new cases of type 1 diabetes.

Idiopathic type 1 diabetes In a small proportion of patients, there are no genetic or autoimmune markers, and the underlying cause (or possibly, causes) of diabetes in this group is unknown. This has been termed idiopathic type 1 diabetes. It has been proposed that type 1 diabetes should be subdivided into type 1A (autoimmune) and type 1B (idiopathic) diabetes, but this classification is not yet generally accepted.

Type 2 Diabetes

The major pathophysiological components of type 2 diabetes are dysfunctional insulin secretion and insulin resistance. Indeed, in the majority of patients with type 2 diabetes, the condition is part of a wider syndrome – the 'insulin resistance' or 'metabolic' syndrome (previously known as syndrome X or Reaven's syndrome), the features of which are shown in Table 6. The definition, nature, and assessment of insulin resistance are described in the following

Table 6 Features of the insulin resistance ('metabolic') syndrome

Impaired insulin-stimulated glucose uptake
Hyperinsulinemia
Central male-pattern obesity
Glucose intolerance or type 2 diabetes
Dyslipidemia*
• Increased plasma triglycerides
• Decreased HDL-cholesterol
• Increased small dense LDL particles
Hypertension
Hyperuricemia (gout)
Hypercoagulable state (increased PAI-1 and factor VII)
Polycystic ovary syndrome
Microalbuminuria

*The 'Atherogenic Lipoprotein Phenotype'.
HDL, high-density lipoprotein; LDL, low-density lipoprotein; PAI-1; plasminogen activator inhibitor-1.

chapter (**Diabetes Mellitus**: Chemical Pathology). Insulin resistance arises from the interplay of a series of genetic factors on the one hand, together with social and environmental factors on the other.

Genetic factors Genetic factors are clearly much stronger in type 2 than in type 1 diabetes. In most cases it is possible to obtain a family history, and concordance is greater than 90% for type 2 diabetes in monozygotic twins compared with around 40% for type 1 diabetes. In high-risk populations, the risk of diabetes in offspring when both parents have type 2 diabetes may be greater than 50%, and as high as 80% in Pima Indians and Nauru islanders when parents develop the disease before the age of 45 years. Despite these figures, much less is known about the genetic associations of type 2 than those of type 1 diabetes. A number of genetic defects have been identified which are responsible for rare diabetic syndromes (**Table 7**) but in the great majority of cases, inheritance is almost certainly polygenic, with environmental factors playing a major role. There is no evidence for association with MHC or HLA markers, and only limited evidence for the involvement of a number of other candidate genes including the insulin gene itself, and insulin receptor and glucose transporter genes.

Social and environmental factors The major non-genetic factors which predispose to the development of insulin resistance are obesity, physical inactivity, nutritional factors, and smoking.

Increasing obesity is associated with deterioration in glucose tolerance, and the majority of patients with type 2 diabetes are overweight: around 75% have a body mass index (BMI) of over 25 $kg\,m^{-2}$. Of course, the fact that not all obese people develop diabetes is evidence that other factors (particularly genetic predisposition) are important. If obesity has a role in the cause of type 2 diabetes, it is probably in modulating the speed of progression to symptomatic disease, possibly by contributing to the development of insulin resistance and the earlier onset of B-cell exhaustion. The risk of developing type 2 diabetes is related to not only the degree but also the distribution of obesity, with the greatest risk seen with male-pattern central obesity. (The precise determinants of fat distribution are uncertain but it too is at least in part genetically determined.) Central adipose tissue is more metabolically active with higher lipolytic activity than peripheral fat, and it is thus a richer source of nonesterified fatty acids (NEFA). Furthermore, the venous drainage of visceral adipose tissue in particular goes directly to the liver. High levels of NEFA stimulate hepatic gluconeogenesis, impair peripheral (muscle) glucose uptake, and inhibit hepatic degradation of insulin, all of which predispose to the development of hyperglycemia and insulin resistance.

Although obesity is an important risk factor for diabetes, both insulin resistance and the hyperinsulinemia which results from it are predictive of diabetes independently of body weight.

Physical exercise influences both glucose transport systems (GLUT 4) and a number of enzyme systems (e.g., glycogen synthase) in skeletal muscle which have a marked effect on insulin sensitivity. The contribution of smoking to the development of insulin resistance is minor but significant.

As far as diet is concerned, the relative roles of fat and carbohydrate in the pathogenesis of insulin resistance and diabetes is unclear and, indeed, controversial. In many countries where the prevalence of diabetes is low, dietary fat intake is also low and dietary carbohydrate tends to be unrefined, with a low glycemic index and a high proportion of soluble and insoluble fiber, all of which mitigate against the development of diabetes. However, overall energy intake tends to be low in this situation and the prevalence of obesity is low. The situation in 'developed' countries is somewhat different. There is general agreement that diets high in saturated fat predispose to the development of insulin resistance, and as far as overall macronutrient balance in the diet is concerned, high-carbohydrate diets appear to increase rather than decrease insulin resistance when compared to diets high in mono- or polyunsaturated fat.

Thrifty phenotype or thrifty genotype? The reason that the incidence of insulin resistance and type 2 diabetes is so high in 'developing' societies has been ascribed to the possession of a 'thrifty' gene which, in an environment with an unstable, poor food supply, confers a survival advantage due to metabolic efficiency. When individuals with this genotype are exposed to a copious western diet, metabolic efficiency predisposes to weight gain, insulin resistance, and diabetes.

An alternative, or perhaps complementary hypothesis (the thrifty phenotype) derives from an increasing amount of evidence which indicates that nutrition *in utero* and in early infancy influences insulin sensitivity in later life; babies who are small at birth and at 1 year of age tend to be more obese in later life, with insulin resistance and a high risk of type 2 diabetes, hypertension, and coronary heart disease. These two hypotheses are clearly not mutually exclusive.

Other Specific Types of Diabetes

In addition to the common patterns of type 1 and type 2 diabetes described above, IGT or diabetes may occur in association with a large number of other conditions, as shown in Table 7. The majority of these conditions are very uncommon or, indeed, rare. In the majority, the precise mechanism of the carbohydrate intolerance is unclear but in some (the various forms of maturity-onset diabetes of the young (MODY), for example), identification of the underlying biochemical defect has provided useful insights into the mechanisms that may be involved in the common polygenic form of type 2 diabetes.

Screening and Prevention

Type 1 Diabetes

Different arguments can be advanced for screening for the different types of diabetes. Screening for susceptible individuals or for preclinical type 1 diabetes might be justified as part of a prevention program if means were available to avert or delay for a significant time the onset of clinical disease. Once glucose intolerance starts to develop, the progression to clinical disease is usually rapid. Measurement of blood or urine glucose is therefore useless, and screening would, of necessity, be limited to testing for susceptible genotypes or the presence of autoantibodies in children or young people with a family history of the disease. Sporadic cases would, of course, remain undetected, and since a high proportion of patients do not have a family history, this would clearly limit the effectiveness of screening. Any such program would be extremely costly and at present there is insufficient evidence that early intervention might be effective. Measures such as immunosuppressive therapy with ciclosporin or treatment with nicotinamide have been shown either to induce limited remission or to slow the rate of deterioration of B-cell function. A further possible approach is to immunize high-risk individuals against viruses capable of precipitating diabetes but this, too, remains an unproven strategy.

Ultimately, preventive measures are likely to involve gene therapy, but until both the technology and ethical issues of such treatment have been resolved, extensive screening for type 1 diabetes is probably not justified.

Type 2 diabetes

Below the age of 45 years, the prevalence of type 2 diabetes in the population is over 3%, and screening on a large scale is probably not cost-effective. However, the nature of type 2 diabetes (frequently asymptomatic), the high prevalence of diabetes (predominantly type 2 diabetes) in older age groups (**Table 8**) and the high prevalence of complications, both at presentation and in the early years after diagnosis, provide some justification for the establishment of screening programs in the older population. Problems arise in deciding when to rescreen subjects who were initially negative, since the pick-up rate will clearly be lower on retesting. In addition to the elderly, screening may be justified in those ethnic

Table 8 Age-related prevalence of diabetes in white Caucasians

Age group (years)	*Prevalence of diabetes mellitus*
0–9	0.5
10–19	1.8
20–29	4.0
30–39	4.6
40–49	7.5
50–59	13.8
60–69	21.3
70–79	37.1
80+	35.6

groups in whom there is known to be a high incidence of type 2 diabetes.

To some extent, however, the question of establishing specific screening programs is becoming redundant as testing for diabetes forms part of a more general health screen which general practitioners are encouraged to provide.

Screening can be based upon testing for glycosuria, measuring fasting or random blood glucose levels or upon measurements of glycated hemoglobin (HbA_1). Of these, blood glucose measurements are more precise and probably to be preferred, provided that they are interpreted in relation to the time of meals.

Morbid Anatomy of the Pancreas

The Normal Pancreas

Insulin is secreted from the B cells of the islets of Langerhans. There are approximately one million islets distributed throughout the pancreas. Individual cells can be identified using immunocytochemistry, whereby cells are stained using antibodies directed at their secretory products. The B cell is the dominant cell type of the islet but there are a number of others, as shown in **Table 1**. There is a complex functional and anatomical relationship between the cells of the islet and their products. A and D cells are situated on the periphery of the islet with a central core of B cells. It is not entirely clear whether arterial capillary blood reaching the B cells has first passed via both A and D cells, transporting glucagon and somatostatin to the B cells where they act as paracrine factors, respectively enhancing and inhibiting the insulin response to stimuli, or whether capillary blood first supplies the B cell

Table 1 Cell types and secretory products of the islet of Langerhans

Cell type	*Secretory product*
A	Glucagon
B	Insulin
D	Somatostatin
PP	Pancreatic polypeptide

with insulin, then exerts a paracrine effect on glucagon and somatostatin secretion. The function of pancreatic polypeptide is not known.

In addition to insulin, B cells also secrete amylin (also known as islet amyloid polypeptide), a 37-amino-acid peptide which is similar to calcitonin gene-related peptide (CGRP, ~50% sequence homology). It is found in secretory granules and appears to be cosecreted with insulin. Initial studies suggested that amylin may induce insulin resistance in skeletal muscle. Whether altered amylin secretion contributes to the metabolic abnormalities of diabetes is as yet unclear. In type 1 diabetes, amylin production is lost as a result of B-cell damage. In type 2 diabetes, amylin secretion is diminished and the peptide accumulates as amyloid fibrils which are found between the B cells and the adjacent capillaries; there is some evidence that this may impair insulin secretion and play a role in the pathogenesis of type 2 diabetes.

Type 1 Diabetes (IDDM)

In the majority of cases, type 1 diabetes is caused by autoimmune destruction of B cells, probably triggered by a viral infection in genetically susceptible individuals (*See* **Diabetes Mellitus**: Etiology). The first visible stages in this process involve the appearance of macrophages within the islets and the establishment of a typical chronic inflammatory reaction with lymphocytic infiltration; this is termed 'insulitis.' Loss of B cells is a gradual process which may first be detectable several years before the development of clinical diabetes. In some patients, residual B-cell function persists for many years after the onset of diabetes, with persistence of insulitis in remaining B cells. Continuing insulin secretion (as assessed by a positive C-peptide response to glucagon stimulation) is characteristically associated with easier glycemic control.

In established type 1 diabetes, there is almost total loss of B cells. As a result, the islets appear atrophic, although the number and distribution of A, D, and PP cells remain almost normal.

Type 2 Diabetes (NIDDM)

Unlike type 1 diabetes, the gross morphology of the islet is normal (with the exception of islet amyloid accumulation). The extent of B-cell loss is variable and usually only minimal, although there is occasionally a loss of up to 50% of B cells; the number of A and D cells remains unaffected.

The Metabolic Effects of Insulin Insufficiency

The major stimulus to insulin secretion is an increase in blood glucose concentration. A number of other physiological factors also stimulate insulin secretion (**Table 2**), in particular the hormones of the enteroinsular axis (glucose-dependent insulinotrophic polypeptide and glucagon-like polypeptide-1) which augment the insulin response to oral carbohydrate and fat, but only in the presence of a raised blood glucose level. The cephalic phase of insulin secretion, which occurs in anticipation of eating, is mediated by the vagus nerve.

Insulin is thus the hormone of the fed state with low circulating levels in the postabsorptive state, and its metabolic actions (**Table 3**) are primarily concerned with the coordinated disposal, metabolism, and storage of the major nutrients. The major effects are upon carbohydrate metabolism, with control of blood glucose level being the most obvious of these. This depends on a balance between output from the liver and peripheral uptake, utilization and storage of glucose; this balance is largely dependent on those tissues which require insulin for intracellular transport of glucose, particularly skeletal muscle. (*See* **Glucose**: Maintenance of Blood Glucose Level.)

Since diabetes is characterized by the absence of effective insulin activity, it is possible to view the major metabolic features of diabetes as a reversal of the actions in Table 3. This can be due to absolute insulin deficiency (type 1 diabetes) or to a combination of dysfunctional insulin secretion plus insulin resistance (type 2 diabetes).

Counterregulatory hormones Insulin is the only major anabolic hormone in the body (growth hormone also has anabolic properties but these are only manifest in the presence of insulin). The action of insulin is opposed by a number of other counterregulatory hormones, including glucagon, cortisol, catecholamines, vasopressin, and growth hormone. The action of these hormones is important in maintaining fuel supplies (fatty acids and ketones as well as glucose) in the fasted state. These actions are unopposed in the absence of insulin, and in the extreme situation of diabetic ketoacidosis they are probably responsible for many of the metabolic abnormalities. However, the importance of counterregulatory hormones in the pathogenesis of diabetes is uncertain; the ratio of

hepatic insulin to glucagon may be an important metabolic determinant but it is interesting that diabetes which occurs as a result of tumors secreting an excess of any one of the counterregulatory hormones is usually mild, indicating the relatively greater importance of insulin. (*See* **Hormones**: Adrenal Hormones; Pituitary Hormones.)

Insulin Resistance

The concept of insulin resistance has been challenged on the grounds that it is not a discrete entity which is always associated with pathology. This is undoubtedly true, and insulin sensitivity (the 'reciprocal' of insulin resistance) is clearly a continuum: in a high proportion of the nondiabetic population, the level of insulin sensitivity can be shown to be similar to that in people with type 2 diabetes. In the majority, normal carbohydrate tolerance is maintained by hyperinsulinemia, but in a proportion, insulin secretion diminishes over time, leading to the development of impaired glucose tolerance and, ultimately, diabetes. The reasons for the decline in insulin secretion are complex: 'glucose toxicity' (the process by which sustained hyperglycemia results in impaired insulin secretion) may play a role, but genetic factors are clearly particularly important.

As shown in Table 4, a number of tests have been used to measure insulin sensitivity. The euglycemic hyperinsulinemic clamp remains the gold-standard method but is both labor-intensive and costly. Mathematical modeling of the fasting insulin-to-glucose ratio (homeostasis model assessment: HOMA), the frequently sampled intravenous glucose tolerance test and the short insulin tolerance test are reasonable alternatives. In simple terms, a high insulin-to-glucose ratio apparently indicates insulin resistance, but there may be difficulties in interpreting these findings. When the high blood glucose level is taken into account, the concomitant insulin level may, in fact, be relatively low, although the absolute rise in insulin level with blood glucose may be similar to that seen in nondiabetics, suggesting a change in the 'set' of insulin level.

Table 4 Tests used to measure insulin sensitivity

Fasting insulin-to-glucose ratio (IGR)

Short insulin tolerance test (ITT)
Euglycemic hyperinsulinemic clamp

Adapted from Hermans MP, Levy JC, Morris RJ and Turner RC (1999) Comparison of insulin sensitivity tests across a range of glucose tolerance from normal to diabetes. *Diabetologia* 42: 678–687.

A further problem which complicates the interpretation of insulin levels in type 2 diabetes lies in the lack of specificity of immunoassays for insulin, nearly all of which cross-react with either proinsulin, or insulin/proinsulin intermediates ('split proinsulin'), or both. Using a range of highly specific two-point immunoassays for insulin, it has been shown that the level of circulating proinsulin and insulin/proinsulin intermediates (all of which are physiologically much less active than insulin itself) is high in type 2 diabetes, presumably resulting from dysfunctional processing and packaging of insulin by the B cell, and that the level of true, bioactive insulin may, in fact, be low rather than high. To an extent, this challenges the concept of 'hyperinsulinemia' in type 2 diabetes.

The insulin resistance of type 2 diabetes affects both carbohydrate and fat metabolism, and is demonstrable in liver, skeletal muscle, and adipose tissue. Hepatic insulin resistance results in unsuppressed glucose output which is the major cause of fasting hyperglycemia, while resistance to insulin-mediated glucose uptake in skeletal muscle is the major determinant of postprandial hyperglycemia.

The adipocyte is more sensitive to the action of insulin than either muscle or liver, but the dose–response curve is shifted to the right in type 2

diabetes, and adipose tissue lipolysis (particularly central adipose tissue) is increased in the fasting state and incompletely suppressed postprandially. As a result, plasma free (non esterified) fatty acid levels are characteristically elevated, but, in type 2 diabetes, since insulin is always present, lipolysis is never completely uninhibited. As a result, ketosis is not a feature of type 2 diabetes. In contrast, in untreated type 1 diabetes resulting from absolute insulin deficiency, not only is lipolysis uninhibited, but reesterification of free fatty acids to form triglycerides is impaired because of the reduction in supplies of α-glycerophosphate from glycolysis. In the liver, glycolysis is not insulin-dependent and triglyceride synthesis is unimpaired and may even be increased because of an increased supply of free fatty acids. (*See* **Fatty Acids: Metabolism.**)

Hyperglycemia and Glycosuria

Blood glucose concentration is normally carefully controlled and maintained between fairly narrow limits as a result of a balance between hepatic output and peripheral uptake of glucose. Even following carbohydrate feeding, around 60% of absorbed glucose is extracted during the first pass through the liver under the influence of insulin, such that the postprandial rise in blood glucose is normally modest.

Glucose is freely filtered by the glomerulus and reabsorbed by an active transport system in the proximal tubule. Under normal circumstances, the urine contains virtually no glucose as the capacity of the renal tubules to reabsorb glucose exceeds the filtered load. However, as the blood glucose rises, there comes a point at which the filtered load of glucose in the renal tubule exceeds the absorptive capacity, and glucose appears in the urine; this is the renal threshold for glucose. The normal renal threshold is between 6 and 7 mmol l^{-1}. It is lower in those individuals with idiopathic renal glycosuria and during pregnancy. The presence of glucose in the urine exerts an osmotic effect in the distal and collecting tubules of the kidney, countering physiological mechanisms for urine concentration, resulting in an increase in urine volume (polyuria). The resultant loss of water from the body (plus the direct effect of hyperglycemia on osmoreceptors in the hypothalamus) results in polydipsia (excess thirst) and, if fluid intake is inadequate, dehydration.

Clinical Features and Symptoms

Type 1 Diabetes

The classical features of type 1 diabetes are weight loss, polydipsia, and polyuria. This is the direct result of the osmotic diuresis which results from hyperglycemia; the weight loss results from dehydration plus loss of both fat and muscle due to the catabolism which occurs in the absence of insulin. In addition to these specific symptoms, there is frequently a history of increasingly severe, nonspecific symptoms such as tiredness, lack of energy, muscle cramps, and general ill health, often over a period of some months, which may only be recognized retrospectively after the development of full-blown diabetes. In children particularly, the onset may be more rapid, with ketoacidosis supervening before the diagnosis is established.

Type 2 Diabetes

In contrast to type 1, the symptoms of type 2 diabetes are very insidious, frequently very mild, and often absent altogether; up to 50% of type 2 diabetes in the general population may be undiagnosed. Most patients are overweight. Indeed, older patients presenting with weight loss are likely to have type 1 diabetes and to require treatment with insulin from the outset. Polyuria and polydipsia may be noticed, and a history of urinary tract infection and vulval candidiasis can frequently be elicited. Ketoacidosis does not occur but occasional patients present with hyperosmolar, nonketotic coma.

Complications such as neuropathy, arterial disease, and retinopathy are frequently present at diagnosis and may be a presenting feature. In many patients, however, the condition remains asymptomatic and is only detected on routine screening.

Coma in Diabetes

Three types of coma occur in diabetes:

- Hypoglycemic coma.
- Hyperglycemic coma, either ketoacidotic coma (diabetic ketoacidosis: DKA), or hyperosmolar, nonketotic coma.

Hypoglycemic Coma

Hypoglycemia occurs predominantly in patients taking insulin but also in patients taking sulfonylureas, particularly long-acting preparations such as chlorpropamide and glibenclamide. The factors which commonly predispose to hypoglycemia, either alone or in combination, are:

- too much insulin or sulfonylurea
- too little food or delayed meal
- too much physical exercise.

In addition to simple overdosing with insulin, variations in absorption from different injection sites, or

even inadvertent intravenous injection, can also precipitate hypoglycemia. Similarly, exercise, as well as lowering blood glucose in its own right, may provoke hypoglycemia by increasing the rate of absorption of insulin from an injection site. A further important cause of hypoglycemia is alcohol which, by inhibiting gluconeogenesis, potentiates the action of insulin and delays recovery from hypoglycemia.

The onset of hypoglycemic symptoms is usually rapid. The pattern of symptoms varies from patient to patient but is usually constant for any individual. The symptoms are those of neuroglycopenia (incoordination, impaired intellectual function, confusion, inability to concentrate, blurring of vision) and of sympathoadrenal activity (sweating, anxiety, tremor, hunger, palpitations). Unless treated by immediate ingestion of carbohydrate (preferably sucrose or glucose), the patient may lose consciousness. Untreated, the resultant coma may last for several hours, but spontaneous recovery owing to counterregulatory hormone (epinephrine (adrenaline), glucagon, cortisol, and vasopressin) and sympathetic stimulation of gluconeogenesis is the rule. Treatment of the comatose patient consists of glucose gel smeared inside the mouth, intramuscular glucagon (1 mg) or intravenous glucose. It is important to avoid giving excess intravenous glucose, particularly in young children in whom the osmotic effects of resultant hyperglycemia can result in cerebral damage. The dose of intravenous glucose in an adult should not normally exceed 50 ml of a 20% solution. Prolonged coma is occasionally seen in association with massive (sometimes intentional) insulin overdosage, with alcohol and with sulfonylurea-induced hypoglycemia, and may require prolonged intravenous glucose infusion.

Particular care should be taken to identify nocturnal hypoglycemia. This frequently occurs during sleep without waking the patient, and therefore may not give rise to typical symptoms. It commonly causes restlessness or sweating at night, vivid dreams or nightmares, and morning headaches or 'hangover.' It is often associated with paradoxically high and/or rising morning blood glucose levels. This phenomenon (the Somogyi effect) is probably caused by a combination of declining insulin levels and a marked counterregulatory (particularly growth hormone) response.

A distressing experience of some patients is that of hypoglycemic unawareness, which can be both alarming and potentially dangerous. This is known to occur in over 20% of patients after 20 years of diabetes and is frequently associated with autonomic neuropathy and impaired counterregulatory response to hypoglycemia. It is also encountered in patients taking nonselective β-blocking drugs. More recently, it has been reported by a number of patients who underwent a change in treatment from animal to human insulin. The reasons for this phenomenon (if, indeed, it is real) are unclear. Human insulin given by subcutaneous injection produces a slightly faster fall in blood glucose than animal insulin but the pattern of both glycemic and counterregulatory response is otherwise virtually identical. Double-blind studies have generally failed to reproduce an association between human insulin and hypoglycemic unawareness even in patients who have reported the condition. Part of the explanation for the loss or, at least, change in symptoms may be attributable to the fact that, when patients were transferred to human insulin, the opportunity was taken to review and, frequently, to encourage stricter glycemic control, which is known to be associated with a reduction in hypoglycemic awareness.

Hypoglycemia is unpleasant and distressing for patients and their families. It also causes swings in blood glucose control because of both the physiological response and overcompensation by the patient. It should be avoided as far as possible, but not at the expense of abandoning attempts to obtain good control.

Diabetic Ketoacidosis

DKA is the most serious metabolic emergency associated with type 1 diabetes. It is the largest single cause of death in young diabetics and, although uncommon in older patients, when it does occur, it has a very high mortality in this age group. The fundamental cause is either absolute insulin deficiency or, less commonly, relative deficiency associated with an acute physiological stress, in association with increased secretion of counterregulatory catabolic hormones. The resultant metabolic effects consist of the following:

1. Hyperglycemia, owing to grossly impaired peripheral glucose uptake and utilization, plus continuing, uninhibited gluconeogenesis, leading to increased polyuria and severe fluid and electrolyte loss.
2. Ketoacidosis, owing to accelerated lipolysis and ketogenesis, with production of excess acetyl coenzyme A, which is partially oxidized to the ketoacids acetoacetic and β-hydroxybutyric acid. Along with acetone derived from acetoacetate, these 'ketone bodies' accumulate in larger amounts than can be metabolized, and are excreted unchanged in urine and on the breath. Both acetoacetic and β-hydroxybutyric acids are weak acids, but in the amounts produced lead to a metabolic acidosis with a concomitant rise in hydrogen ion concentration (fall in pH).

Precipitating causes include infection (in about one-third of cases), inappropriate insulin treatment (too often due to the erroneous advice to reduce insulin dosage when unwell and not eating) and myocardial infarction. DKA is occasionally the presenting feature in new cases of type 1 diabetes. In around 25% of cases no precipitating factors can be identified.

DKA develops relatively slowly (compared with hypoglycemic coma), usually over a period of 24–36 h. Symptoms include an increase in thirst and polyuria, general ill health, nausea, vomiting, drowsiness, and eventually coma. Clinically, the patient is often febrile, with evidence of dehydration (thin, rapid pulse, postural hypotension). Hyperventilation (owing to the metabolic acidosis) is an important feature, and there is frequently a strong smell of acetone on the breath. Treatment should be instituted as a matter of urgency as soon as the diagnosis is confirmed by the finding of hyperglycemia and ketonuria without waiting for the results of other laboratory tests (blood gases and acid–base status; plasma sodium, potassium, and creatinine; full blood count; urine, sputum, and blood cultures). Treatment consists of replacement of fluid and electrolyte deficits which, in established DKA in adults, are in the order of 5 l of fluid and 500 mmol each of sodium, chloride, and potassium. It is important to remember that plasma potassium levels may not reflect this, and may even be paradoxically high due to the effects of acidosis. Although there may be a similar theoretical deficit of bicarbonate, replacement is unnecessary and even counterproductive; small amounts only should be given as required to raise the blood pH above 7.0. Insulin is given in relatively small doses (5–10 units per hour initially) either by intravenous infusion or intramuscular injection. Intravenous potassium should be given either immediately or as soon as plasma potassium levels start to fall, with regular laboratory monitoring of plasma levels.

Nonketotic Hyperosmolar Coma

Nonketotic hyperosmolar coma only occurs in type 2 diabetes, sometimes as a presenting feature, and consists of gross hyperglycemia and dehydration but without ketosis and significant acidosis. The mechanism of this is uncertain. The condition develops more insidiously than DKA, allowing time for a greater degree of dehydration to develop. Treatment consists of fluid replacement and low-dose insulin therapy. The prognosis is poor, with a significant mortality especially in older patients.

Treatment and Management

J Wright, University of Surrey, Guildford, Surrey, UK

Aims of Treatment

The main objectives in the treatment of diabetes can be summarized as follows:

1. alleviation of symptoms
2. maintenance of good general health
3. prevention of long-term complications.

It is relatively easy to achieve the first of these objectives and, in the majority of patients, reasonable or good general health can be maintained in the short or medium term without necessarily achieving good diabetic control. However, there is now convincing evidence that good control of both blood glucose and blood pressure influences the development of microvascular complications (nephropathy and retinopathy) in both type 1 and type 2 diabetes although, as far as macrovascular disease is concerned, the situation is more complicated. Coronary heart disease (CHD) is the major cause of death in long-standing type 1 diabetes, and in type 2 diabetes even of relatively short duration. Evidence suggests that glycemic control is not closely related to the risk of atherosclerosis and other risk factors such as smoking, hypertension, dyslipidemia (raised triglycerides and

low high-density-lipoprotein (HDL)-cholesterol), physical inactivity, male-pattern obesity, and ethnic origin appear to be more important determinants. The presence of microalbuminuria (which is probably a marker of generalized arterial endothelial damage) is a particularly strong marker of risk from ischemic heart disease. (*See* **Atherosclerosis**; **Coronary Heart Disease**: Intervention Studies.)

Thus it is clear that, if a major objective of treatment is to prevent long-term or associated complications, as much attention must be paid to these other risk factors as to control of blood glucose.

Choice of Treatment Regimen

Diet, oral hypoglycemic agents, and insulin remain the cornerstones of treatment of diabetes. Dietary advice is required by all patients, but the selection of other treatment measures is largely based on individual clinical assessment along with measures of glycemic control. The criteria used in the selection of treatment are summarized in Table 1.

With the exception of pregnancy, in which strict criteria are generally agreed, the classification of hyperglycemia into mild, moderate, or severe is personal to both the physician and the individual patient. A common dilemma is the overweight patient with uncontrolled hyperglycemia in whom treatment with insulin, while improving glycemic control, frequently results in increasing weight gain and little in the way of symptomatic improvement. (*See* **Glucose**: Maintenance of Blood Glucose Level; **Pregnancy**: Nutrition in Diabetic Pregnancy.)

Table 1 Treatment options in diabetes

Treatment option	*Criteria*
Diet alone	Moderate hyperglycemia only Obesity
Oral hypoglycemic drugs[a]	
Sulfonylureas	Moderate to severe hyperglycemia Near-normal body weight
Biguanides	Moderate to severe hyperglycemia Obesity Insulin resistance
Insulin[a]	Severe hyperglycemia Ketosis Unintentional weight loss Nonspecific symptoms (general ill health, tiredness) Specific symptoms (painful neuropathy, amyotrophy) Pregnancy Intercurrent illness, surgery, myocardial infarction

[a]Plus diet.

Diabetic Diet

Although the importance of diet in the treatment of diabetes has been recognized for centuries, fashions have changed considerably, even in recent years. Prior to the introduction of insulin treatment, a number of desperate dietary measures were tried, including semistarvation (leading to such gross reduction in body fat that severe ketoacidosis could not occur). With insulin, it became possible to liberalize energy consumption but, with continuing carbohydrate restriction, diets were inevitably high in fat. The evolution in dietary policy since 1921 is illustrated in Table 2. After 1950, in response to the perception that a high-carbohydrate diet does not have a deleterious effect on diabetic control, and that high-fat diets may contribute to the risk of CHD, there was a marked swing away from carbohydrate restriction, and the promotion of diets high in carbohydrate (particularly complex carbohydrate and fiber) and lower in fat than previously. More recently, a number of studies have shown that high-carbohydrate diets may in fact increase insulin resistance and adversely affect the lipoprotein profile, while diets high in monounsaturated fatty acid (MUFA) result in an improved lipoprotein profile (lower triacylglycerols and higher HDL-cholesterol) without loss of glycemic control. (High-polyunsaturated fat diets have a similar effect but are not recommended because of concerns that they result in increased lipid peroxidation.) An opposing view is that high-carbohydrate diets in which most of the carbohydrate has a low glycemic index achieve at least similar metabolic control. However, many people find such diets difficult to manage and unpalatable, and, given the low level of compliance with high-carbohydrate diets, there are both practical and evidential reasons for recommending an increase in the (monounsaturated) fat content of the diet. As yet, however, a number of national diabetic associations have not modified their guidelines, and the one recommendation with respect to fat which remains universally accepted is that saturated

Table 2 Historical perspective of dietary recommendations for diabetes

	Distribution of calories (% dietary energy)		
Year	*Carbohydrate*	*Protein*	*Fat*
Pre-1921	Starvation diets		
1921	20	10	70
1950	40	20	40
1971	45	20	35
1986	Up to 60	12–20	< 30
1994	[a]	10– 20	[a,b]

[a]Based on individual assessment and goals.
[b]Less than 10% calories from saturated fat.

fat should be restricted to less than 10% of dietary energy. (*See* **Glucose**: Glucose Tolerance and the Glycemic (Glycaemic) Index.)

There are no great differences between the general principles of dietary treatment in insulin-dependent diabetes mellitus (IDDM) and those in noninsulin-dependent diabetes mellitus (NIDDM), although there is frequently more emphasis on weight loss in NIDDM, while meal distribution may be more important in IDDM. In patients treated with insulin, the importance of timing of meals and of taking snacks between meals in order to prevent hypoglycemia should be stressed. Overall energy intake should be determined on an individual basis, and the diet designed to achieve and maintain desired body weight. (*See* **Energy**: Energy Expenditure and Energy Balance.)

The place of fish oils (high in long-chain *n*-3 fatty acids) in the diabetic diet is unclear. There has been concern that fish oils may have an adverse effect on glycemic control, but there is a growing consensus that this potential adverse effect is offset by a greater beneficial effect of fish oils on lipid profile and cardiovascular disease risk. Cholesterol intake should be less than 300 mg day^{-1}. (*See* **Fats**: Requirements; **Fish Oils**: Dietary Importance.)

High salt intake should be discouraged, particularly in hypertensive patients. At the same time, a relatively high potassium intake (particularly from vegetable sources) should be encouraged. (*See* **Potassium**: Physiology; **Sodium**: Physiology.)

In patients with early nephropathy, protein intake should not exceed 12% of total dietary energy. (*See* **Protein**: Requirements.)

Alcohol

Guidelines are similar to those for the general adult population, i.e., a maximum of 30 g (3 units) per day for men, and 20 g (2 units) per day for women. Patients taking insulin need to be especially careful since alcohol, by inhibiting gluconeogenesis, can predispose to severe hypoglycemia, especially at night. (*See* **Alcohol**: Alcohol Consumption.)

Special Foods

In general, special 'diabetic' foods are not recommended. Artificial sweeteners are acceptable in moderation.

Individualization

The most important of all the recommendations is that diets should be specifically tailored for individual patients. This is critical in certain groups, such as growing children, pregnant women, and the elderly, in whom restrictive diets may be inappropriate.

Oral Hypoglycemic Agents

Oral hypoglycemic agents rely on residual insulin secretion for their action. Their use is largely restricted to the management of type 2 diabetes. The number of classes of oral agents has increased in recent years, and further developments are anticipated in the near future. Those currently available are summarized in Table 3.

Sulfonylureas

The sulfonylurea group comprises a large number of closely related compounds (**Table 4**). The important clinical differences between individual drugs are related to differences in half-lives, in route of metabolism and excretion, and in receptor binding (second-generation drugs bind more avidly to the specific sulfonylurea receptor on pancreatic B cells and are effective at lower doses).

The major effect of the sulfonylureas is to stimulate insulin secretion, an effect which appears to be maintained in the long term. The glucose-lowering potency of sulfonylureas is directly related to the starting blood glucose level – the higher the fasting blood glucose, the greater the decrease achieved by sulfonylurea treatment.

Table 3 Oral antidiabetic agents

Class of drug	*Example(s)*	*Mode(s) of action*
Sulfonylureas	Chlorpropamide Tolbutamide Glyburide (glibenclamide) Gliclazide	Enhance insulin secretion
Biguanides	Metformin	Increase peripheral insulin sensitivity Inhibit gluconeogenesis
α-Glucosidase inhibitor	Acarbose	Impairs starch digestion and glucose absorption
Thiazolidenediones	Troglitazone Pioglitazone Rosiglitazone	Increase adipocyte differentiation and net triglyceride deposition; reduce plasma nonesterified fatty acids; increase insulin sensitivity
Non S-U insulin secretagogue	Repaglinide	Enhances insulin secretion

Table 4 Examples of sulfonylurea drugs

Drug	*Half-life (h)*	*Duration of action (h)*	*Daily dose (mg)*	*Doses per day*
First-generation				
Chlorpropamide	35	60	100–375	1
Acetohexamide	4–6	12–18	250–1500	2
Tolbutamide	3–8	6–12	500–2500	2–3
Tolazamide	4–7	12–24	100–1000	1–2
Second-generation				
Glyburide (glibenclamide)	5	12–24	2.5–15	1–2
Glipizide	1–5	12–24	2.5–40	1–2
Gliclazide	12	10–15	40–320	1–3
Gliquidone	4	6–8	15–60	1–3

The fact that the sulfonylureas increase insulin secretion means that, if anything, they tend to encourage weight gain. They are therefore most suitable for lean patients and should be used sparingly in the obese. Weight gain may be less marked with those drugs which have a shorter half-life; if given before meals, these have been claimed to enhance the insulin response to food without inducing sustained hyperinsulinemia.

The major adverse effect of the sulfonylureas is hypoglycemia which may be both profound and prolonged. This is seen particularly with those drugs which have a longer half-life or where this is prolonged by hepatic or renal dysfunction. Chlorpropamide, for example, should be used with caution in the elderly and should be avoided in patients with renal impairment. Other adverse effects are uncommon and include nausea, dizziness, blood dyscrasias, cholestatic jaundice, skin rashes, and water retention (particularly with chlorpropamide, which can be used in the treatment of diabetes insipidus). Flushing with alcohol (probably owing to inhibition of acetaldehyde metabolism) is common in patients taking chlorpropamide and can usually be improved by transfer to an alternative sulfonylurea preparation.

Biguanides

The two drugs in this group are phenformin and metformin. Phenformin has now been withdrawn in most countries because of its association with severe and occasionally fatal lactic acidosis.

Metformin reduces both fasting and postprandial blood glucose levels in diabetics but rarely causes hypoglycemia. The precise mechanism of its action is uncertain but the major effect appears to be an increase in glucose uptake and enhanced glycogen secretion in skeletal muscle, resulting in an increase in insulin sensitivity. Metformin also inhibits gluconeogenesis and thus reduces hepatic glucose output. (This results in a small increase in blood lactate concentration but less than that produced by phenformin and rarely sufficient to cause significant lactic acidosis.) Unlike the sulfonylureas, metformin does not cause weight gain; in fact, it often helps with weight loss, and is therefore most suitable in overweight patients. The drug is not metabolized but is excreted unchanged via the kidney and must therefore be used with caution in patients with renal impairment. The major side-effects of metformin are dose-related and include gastrointestinal discomfort and diarrhea. To minimize gastointestinal side-effects, treatment with metformin should begin with a low dose (500 mg daily) building to a maximum of 1000 mg three times per day as tolerated.

Thiazolidenediones

The thiazolidenediones are a new class of drug recently introduced for the treatment of type 2 diabetes. They bind to a novel nuclear receptor, the peroxisome proliferator activated receptor (PPAR-γ), which initiates effects on fat metabolism, including adipocyte differentiation and lipoprotein lipase (LPL) gene expression. The major effect of the thiazolidenediones is probably on the adipocyte, and their ability to increase muscle insulin sensitivity probably results from a reduction in circulating nonesterified fatty acid (NEFA) levels. Their effect on adipocyte differentiation and triglyceride deposition probably explains their tendency to encourage weight gain. It is unclear whether they also have direct effects on hepatic carbohydrate metabolism, such as induction of glucose transporter expression and inhibition of gluconeogenesis.

Troglitazone was the first of the thiazolidenediones to become available for clinical use but was withdrawn after only a short time in the UK because of concerns over liver damage; it remains in use in many other countries, including the USA. A number of other thiazolidenediones have been introduced recently, these include pioglitazone, ciglitazone, and rosiglitazone. Experience indicates that the glucose-lowering effect of the thiazolidenediones is less than that of sulfonylureas, although they may have a greater effect on lipid parameters. Like metformin, they can also be used in combination with insulin in type 2 diabetes.

The starting and maximal daily doses of the thiazolidenediones are 400 and 600 mg for troglitazone, 15 and 45 mg for pioglitazone, and 2 and 8 mg for pioglitazone.

Prandial Glucose Regulators

A new class of insulin secretagogs has recently been introduced, the so-called prandial glucose regulators. Those currently available are repaglinide and

nateglinide. These are chemically dissimilar to the sulfonylureas but may act via the sulfonylurea receptor on the B cell. These drugs are rapidly absorbed and have a short plasma half-life (< 1 h). Given before meals they produce a rapid release of insulin which helps control 'prandial' glucose levels. This may prove valuable since there is increasing concern that postprandial peaks in blood glucose may be an important risk factor for the development of microvascular complications.

The starting doses of repaglinide and nateglinide are respectively 0.5 mg and 60 mg three times daily with meals, rising to maximum total doses of 4 mg and 180 mg three times daily respectively.

Acarbose

Acarbose is an α-glucosidase inhibitor which competitively inhibits the action of brush-border enzymes in the digestion of oligo- and disccharides, thereby preventing the release and absorption of glucose from dietary carbohydrate. It has only a moderate glucose-lowering potency which is most marked in the postprandial phase. The drug is safe but gastrointestinal side-effects (abdominal discomfort, diarrhea, and severe flatulence) are common and frequently limit the acceptability of the drug to patients. The maximal tolerable dose is 200–300 mg day^{-1}.

Combination Therapy

Oral hypoglycemic agents may be used either alone or in combination with other agents. The combination of sulfonylurea and metformin was shown to be effective in the UK Prospective Diabetes Study. Metformin and insulin are frequently used in combination in overweight patients with type 2 diabetes. Thiazolidenediones may also be used in combination with either a sulfonylurea or metformin; they have also been used successfully in combination with insulin but this practice is not yet universal. Sulfonylureas have also been used in combination with insulin (for example with isophane insulin used overnight) but this has not gained widespread acceptance.

Insulin

Prior to the isolation of insulin in 1921, juvenile-onset diabetes was an untreatable and rapidly fatal condition. With well-managed insulin treatment, such patients can now expect to live a full and virtually normal life. Until the 1970s, insulin for therapeutic use was extracted from either beef or pork pancreas. The resulting bovine and porcine insulins differ from human insulin by two and one amino acids respectively. The majority of insulin is now bioengineered using recombinant deoxyribonucleic acid (DNA) technology. The proinsulin thus produced is cleaved to give insulin which is identical in its amino acid sequence to human insulin. Regular, soluble neutral insulin is relatively short-acting and a number of techniques have been used to produce preparations with longer duration of action. The most successful of these are the complexing of insulin with either zinc or a protein (protamine) to produce zinc and isophane insulins respectively. Within the range of zinc insulins, further variations in duration of activity are achieved by varying the pH and, therefore, the particle size to form either amorphous (microcrystalline, medium-acting semilente) or crystalline (long-acting ultralente) preparations. Lente insulin is a mixture of these two in the ratio 30% semilente to 70% ultralente; the resultant mixture is intermediate-acting. Isophane insulin (also known as neutral protamine Hagedorn, or NPH insulin) is of standard formulation and has a similar, intermediate duration of action to lente insulin.

A range of premixed insulins, containing from 10% soluble and 90% isophane to 50% of each, is available. Such premixtures are not possible with zinc insulins owing to the loss of the short-acting, soluble component which results from complexing with any excess zinc present.

Several new insulins are currently being developed and introduced into clinical practice. In these, the insulin molecule is modified in order to alter either the duration of action or receptor specificity. The first of these to be introduced (Lispro and Aspart) are very fast-acting and can be injected immediately before a meal (in contrast to soluble insulin which should be injected 15–20 min before eating). A new, modified insulin (Glargine) has been introduced recently. This provides stable 'background' plasma insulin levels over a 24-hour period, and has been used successfully in combination with very fast-acting soluble insulin analogs. It is anticipated that insulins with altered receptor specificity with, for example, differential activity on hepatocyte or skeletal muscle metabolism, will have particular advantages in different patterns of diabetes.

A number of patients who were treated initially with either pork or beef insulin and subsequently transferred to human insulin reported a marked loss of hypoglycemic awareness and, largely for such patients, some animal insulins continue to be manufactured. In total, a bewildering range of preparations is now available, but can be simplified, as shown in Table 5.

Choice of Insulin Regime

The decision to start insulin treatment is made on clinical grounds (**Table 1**). In younger patients with

Table 5 Major available insulin preparations

Formulation	Time of action (h)[a] Onset	Peak	Duration	Other names
Crystalline[b]	0.5–1	2–4	8	Regular, soluble, neutral Humalog
Zinc				
Amorphous	1–2	4–6	8–12	Semilen
Crystalline	2–4	14–20	24–36	Ultralente
Mixed[b]	2–4	6–10	12–24	Lente
Protamine[b]	2–4	6–10	12–24	Isophane
Premixed[c]	Dependent on ratios			

[a]Approximate times following subcutaneous injection.
[b]Available mixtures contain crystalline and isophane insulin in the ratios 1:9, 2:8, 3:7, 4:6, and 5:5.
[c]Animal (pork or beef) preparation still available.

Table 6 Examples of insulin regimes

Regime	Formulation
Once daily	Lente, ultralente
Twice daily	Soluble plus lente
	Soluble plus isophane (premixed or variable)
Multiple injections (basal bolus)	Soluble or Humalog two or three times daily before meals, plus either ultralente or isophane at bedtime

evidence of ketosis, the decision is usually unambiguous. Patients with type 2 diabetes frequently come to treatment with insulin but the decision to change from oral agents is often difficult. Unintentional weight loss is an important criterion, as are nonspecific symptoms such as tiredness and lack of energy which usually improve on insulin. However, in overweight but otherwise asymptomatic patients with uncontrolled hyperglycemia, large doses of insulin are often required to achieve improved glycemic control, and this is often at the expense of further weight gain and little in the way of symptomatic benefit. Age is certainly not an absolute criterion and, indeed, many newly diagnosed elderly patients need insulin treatment from the outset. Unfortunately, there are no objective biochemical criteria (apart from glucose and ketones) on which to base treatment decisions. In particular, measurement of endogenous insulin secretion (e.g. C-peptide response to glucagon stimulation), while of interest for research purposes, should not be used in the decision to treat with insulin or not.

Insulin is usually given by subcutaneous injection. Examples of injection regimes in current use are shown in Table 6. A once-daily regime may be used in the elderly but for the majority of patients, good control can only be achieved by using at least twice-daily injections. A number of pen injector devices are now available for the administration of soluble, isophane, and soluble/isophane mixtures. An alternative to intermittent insulin injections is the technique of continuous subcutaneous insulin infusion (CSII) whereby insulin is infused continuously (with boosts at meal times) via an indwelling subcutaneous cannula from a pump which is worn or carried permanently by the patient. Impeccable glycemic control can be achieved with pump treatment and although enthusiasm for it waned at one time, recent technical advances have made it a far more acceptable form of insulin delivery, and it is now widely used in a number of countries. Of the other alternative methods of insulin delivery (oral administration, intraperitoneal injection, nasal spray, implantable programmed infusion devices, etc.), some have been abandoned while others are still under evaluation. Other techniques, such as pancreatic transplantation, hold promise, but the prospects for a practical alternative to insulin injections in the near future seem remote.

Other Measures

Treatment of Hypertension

It is increasingly recognized that control of hypertension is essential in diabetes, and it has been shown to reduce the progression of both microvascular and macrovascular complications in both type 1 and type 2 diabetes. Early studies which indicated that treatment with angiotensin-converting enzyme (ACE)-inhibitors reduced the progression of nephropathy (as judged by microalbuminuria) even in normotensive patients suggested that these drugs may have a particular benefit in diabetes. However, in the UK Prospective Diabetes Study, there was no difference in outcome between patients treated with an ACE-inhibitor (captopril) or a β-blocker. Long-term studies comparing the effects of newer ACE-inhibitors, angiotensin receptor antagonists, α-blockers, and calcium channel antagonists are required to decide the optimum drug(s) for use in diabetes.

Exercise

Lack of physical activity is a major factor in the increased incidence of diabetes in the developing world. Exercise has been shown not only to have a beneficial effect on metabolic control in people with established diabetes but also, in retrospective and prospective studies, to reduce the risk of developing type 2 diabetes.

Patient Education

Perhaps more than in any other disease, the person with diabetes needs to participate in treatment and to take responsibility for the day-to-day management of

the condition. This cannot be successfully accomplished without a clear understanding of treatment objectives and the means of achieving them.

A successful educational program needs to be carefully planned and coordinated, with opportunities for individual as well as group sessions, and a commitment to long-term reinforcement. The contribution of the diabetes nurse specialist, who is usually the ideal person to undertake much of the responsibility for patient education, has proved invaluable. The traditional hospital diabetic clinic is by no means the best environment for teaching and in many areas, dedicated diabetic centers have been established for this purpose. A vast array of literature and audiovisual aids is available both from support organizations, such as national diabetic associations, and from commercial firms.

An essential part of any educational program is long-term evaluation. Despite the apparently obvious need for education, the results, when formally assessed, have not been uniformly encouraging. A reduction in hospital admissions can be achieved but this might simply reflect an improvement in care and support services in general. Furthermore, the effects may not be sustained in the long term. As yet, there is no conclusive evidence that improvements in knowledge lead to better metabolic control; poor compliance is usually attributable to factors other than simple ignorance. Successful self-treatment requires, in many people, fundamental changes in attitude and behavior. It is these benefits rather than the acquisition of knowledge that educational programs can provide.

Assessment of Diabetic Control

Glycemic Control

Regular monitoring of diabetes is essential in order to make short-term adjustments to treatment (particularly insulin dosage) and in order to assess control in the longer term. Short-term assessment is achieved by monitoring glucose in urine or blood, and long-term assessment by measurement of glycated (glycosylated) proteins. Monitoring diabetes by means of urine tests was for a long time the only practical method available, but this must now be considered crude and often misleading. The renal threshold for glucose varies widely in diabetes but is frequently well above target levels for blood glucose; the urine may therefore be free of glucose when the blood glucose is higher than desired. At the same time, urine tests are of no value in detecting hypoglycemia. Persistent, heavy glycosuria is probably an indication of poor control (except in those with a very low renal threshold) but more subtle interpretation of tests is usually impossible.

Occasional, single measurements of blood glucose are also of very limited value in monitoring control since there are wide variations in blood glucose throughout the day in both type 1 and type 2 diabetes. Once a common feature of diabetic clinics, 'one-off' blood glucose measurements have been abandoned in many centers. Regular measurement of blood glucose by patients (home monitoring) has become commonplace and is essential in managing changes in insulin treatment, and in making day-to-day adjustments in insulin dosage (especially with multiple injection regimes), particularly during periods of metabolic instability such as intercurrent illness or pregnancy. A number of test 'sticks' are available (most of which employ dry-reagent chemistry based upon glucose oxidase) and these can be read visually or using one of the many meters designed for the purpose.

Measurement of glycated proteins has become the standard method of monitoring medium-term glycemic control. These compounds result from the nonenzymatic linkage of glucose to proteins (in the case of hemoglobin, to the N-terminal valine residue of the β-chain). The initial aldimine linkage undergoes an Amadori rearrangement to form a stable ketoamine product. The rate of glycation depends on the prevailing glucose concentration, and the extent of glycation of any protein is therefore a function of the average glucose concentration during its lifetime. Glycated hemoglobin (HbA_{1C}) is most commonly used because of its availability and because the half-life of the red blood cell (around 8 weeks) is a convenient period of time over which to assess control. Laboratories should now measure the more specific HbA_{1C} fraction. The level of HbA_{1C} in nondiabetics is around 4.5–5.5%. The results of the DCCT study suggest that 7% should be the target level in well-controlled diabetes, although higher levels may be acceptable, particularly in older patients. Low values may be found in patients who are experiencing frequent hypoglycemia. Spuriously low values are found in conditions associated with reduced red-cell survival (e.g., hemolytic anemias), while high values are found in renal failure (owing to the presence of carbamylated hemoglobin).

In situations such as pregnancy, the half-life of hemoglobin is too long for HbA_{1C} to be useful in monitoring glycemic control as closely as is required. Glycated albumin (half-life of around 19 days) would be ideal for this purpose but there are currently no specific methods for this. As an alternative, measurement of glycated serum proteins or fructosamine (mostly albumin and, therefore, of similar half-life) can be used.

Nonglycemic Control

In addition to measures of glycemic control, it is clearly essential to monitor a large number of other biochemical and clinical parameters on a regular basis in an attempt to anticipate and, if possible, prevent the development of complications. Control of blood pressure is particularly important as this has been shown to influence the progression of both nephropathy and retinopathy. Monitoring is best done as part of a regular (usually annual) formal review (Table 7).

Prognosis

Despite the advances which have been made over the last 70 years, life expectancy is still reduced in both type 1 and type 2 diabetes. This is largely attributable to arterial disease (especially coronary artery and peripheral vascular disease), which occurs at an earlier age than in the nondiabetic population, and to those complications which are peculiar to diabetes, i.e., microvascular disease (particularly nephropathy), and both ketoacidosis and hyperosmolar coma. In type 1 diabetes, life expectancy is reduced by about 25%, with a peak in mortality occurring between 15 and 25 years after diagnosis.

There is a common misconception that the situation is less serious in type 2 diabetes, but this is clearly not so. Overall life expectancy is reduced by between 5 and 10 years, largely owing to the very high incidence of coronary and cerebrovascular disease. Nephropathy is relatively uncommon in type 2 diabetes, but visual loss resulting from maculopathy is as common as in type 1 diabetes and frequently occurs early in the course of the disease. It is important to remember that type 2 diabetes may be only a single aspect of a syndrome which comprises, in addition to carbohydrate intolerance, hypertension, dyslipidemia, obesity, and marked insulin resistance. The diabetes itself may be 'mild,' but patients should not be dismissed lightly in view of the high mortality associated with the syndrome. (*See* **Lipoproteins**.)

Table 7 Parameters to be reviewed at annual follow-up

Biochemical	
Blood	HbA_{1C}, creatinine, potassium
	Fasting lipid profile (cholesterol, HDL-C, triglycerides)

Problems in Treatment

B Thomas, Dorking, Surrey, UK

Pregnancy

Pregnancy in Women with Pre-existing Diabetes

It is only relatively recently that women with diabetes have been able to look forward with any degree of confidence to the safe arrival of a healthy child. Even 20 years ago, the combination of diabetes and pregnancy was associated with a greatly increased risk of pre- or perinatal death, miscarriage, congenital malformations, and even maternal death. The incidence of these has now fallen dramatically as a result of better diabetes care and monitoring techniques during pregnancy, although the risks remain slightly higher than for the nondiabetic population.

Strict control of glycemia, from the time of conception onwards, is now recognized as vital for a successful outcome to pregnancy. Maternal hyperglycemia is strongly associated with the development of congenital malformations during embryogenesis in the very early stages of pregnancy. Since such damage may occur even before pregnancy is suspected, preconceptional measures to optimize diabetic control are important. The effectiveness of the current diabetes care plan will need to be reviewed and any necessary changes in treatment implemented. Insulin regimens are usually changed to more frequent injections of shorter-acting insulin to provide a greater degree of control, and type 2 patients normally treated with oral hypoglycemic agents may be changed to treatment with insulin. All patients will need to monitor their blood glucose levels more frequently (several times per day) in order to maintain tight glycemic control.

Dietary intake will also need to be reviewed in terms of its suitability for both diabetes and pregnancy. Changes to the insulin regimen usually necessitate dietary adjustment to insure there is a balance between dietary intake and hypoglycemic medication. A stable meal pattern, usually comprised of small frequent meals and snacks, is essential. Starchy carbohydrate foods (such as bread, rice, pasta, potatoes, and breakfast cereals) should form the basis of main meals and people should be encouraged to accompany them with foods rich in micronutrients (such as fruit, vegetables, low-fat dairy products, lean meat, fish, and pulses). Newcomers to insulin treatment will require guidance on how to recognize, avert, and treat hypoglycemia.

Overweight people who are actively trying to slim should be discouraged from doing so while trying to conceive, and only attempt weight reduction before pregnancy is attempted or after it is over.

Other more general nutritional aspects of pregnancy such as the need for folate supplementation will also need to be discussed.

Once pregnancy commences, regular follow-up is necessary to insure that tight glycemic control is maintained and that the nutritional needs of pregnancy are also being met. If nausea and vomiting are a problem during the early weeks, frequent small snacks of easily assimilated sources of carbohydrate such as sandwiches, crispbread, biscuits, or soft drinks may be necessary to prevent hypoglycemia.

As pregnancy progresses, weight gain should be closely monitored so that emerging problems can be detected at an early stage. Rapid or excessive weight gain is undesirable because it will impair glycemic control and increases the risk of fetal problems. Active weight loss is rarely appropriate but weight can be stabilized, or the rate of gain lessened, by encouraging people to alter their food choice in favor of more fruit, vegetables, and fiber-rich carbohydrate, and fewer fat-rich foods and snacks. Such measures decrease the energy density of the diet without impairing its nutrient content.

Since the physiological stress of pregnancy can sometimes exacerbate or precipitate complications of diabetes such as retinopathy and nephropathy, the monitoring process needs to include these aspects.

Following delivery, breast-feeding should be encouraged. Once established, women may need considerably more carbohydrate (e.g., an additional 40–50 g day^{-1}) to meet the high energy costs of lactation. Nocturnal hypoglycemia is a particular risk while the diabetic mother is still breast-feeding the infant during the night, and extra carbohydrate at bedtime in the form of a sandwich or other starchy carbohydrate is usually necessary.

Gestational Diabetes

Gestational diabetes is a symptomless form of impaired glucose tolerance which appears for the first time during pregnancy and, in the vast majority of cases, resolves after delivery. The condition is usually detected via routine urine screening at the first antenatal visit and confirmed by a fasting blood glucose above 6 mmol l^{-1}.

The significance of a diagnosis of gestational diabetes is a matter of current debate. Pregnancy always worsens glucose tolerance to some extent and it is difficult to determine at which point physiological change becomes pathologically significant. While there is an association between gestational diabetes and macrosomia (infants of high birth weight), with its associated risks to mother and child as a result of a

more difficult delivery, it is now less certain that this is a consequence of the hyperglycemia *per se*. Maternal obesity may be the more relevant factor since this tends to worsen the glucose intolerance of pregnancy (thus taking some women into the 'gestational diabetes' range) and is also the main factor associated with macrosomia in the normal obstetric population.

The benefits of intervention have also been questioned for a number of reasons:

- By the time gestational diabetes is identified, the pregnancy will have advanced beyond the stage of embryogenesis when any risk to the fetus in terms of hyperglycemia-induced malformations can be prevented.
- Since the condition is symptomless, there is no need for symptom relief.
- While gestational diabetes may in some cases progress to frank diabetes necessitating insulin treatment, this cannot be predicted or prevented during the pregnancy itself.
- Weight loss in those who are obese is the only intervention which can improve glucose tolerance and lessen the risk of macrosomia, but active slimming is always contraindicated during pregnancy itself because of the risk of fetal undernutrition. At most, dietary measures to prevent excessive weight gain can be instituted (via adjustments in food choice which preserve high nutrient quality while lessening energy density) and these should be encouraged in all pregnant women, not just those with gestational diabetes.
- A formal diagnosis of gestational diabetes has a number of implications in terms of patient anxiety, acquisition of disease status, and perhaps unnecessary obstetric interventions such as Caesareian section. If little can be done about the condition during pregnancy itself, the justification for making such a diagnosis requires careful consideration.

It now seems more likely that the main significance of impaired glucose intolerance in pregnancy is that it is a strong marker for the development of maternal diabetes in later life, particularly if that person remains or becomes obese. The time for intervention is therefore postpregnancy when women should be encouraged to make diet and lifestyle changes which will help them achieve and maintain a healthy body weight. Such people should be considered 'at risk' for development of diabetes and regularly screened for signs of its development.

Diabetes in Children

The diagnosis of diabetes in a child is a traumatic event for the entire family, and parents usually take far longer than the child to adapt to the situation. Insulin injections, diet, and hypoglycemia are the major worries and a high level of support and reassurance from professional advisers will be required in the early stages.

Fortunately, modern management of diabetes means that the dietary constraints are no longer as disruptive to family life as used to be the case. Children with diabetes are no longer prescribed a diet restricted in carbohydrate, virtually devoid of sugar, controlled by means of complicated exchange lists, and necessitating different meals to those of the rest of the family. Instead they are encouraged to consume a diet based on healthy eating principles, regulated via appropriate meal pattern and food choice, and which is also suitable for the entire family.

The aims of dietary management in diabetic children can be summarized as follows:

1. To achieve good glycemic control without an unacceptable frequency of hypoglycemia.
2. To insure the diet is sufficient to meet the demands for growth.
3. To establish eating habits which will provide protection against complications in later life.
4. To achieve these in a way which causes the minimal amount of psychological and social disruption for the child (and family).

Specialist pediatric dietetic care is essential in order to achieve these aims.

Diet and Glycemia

Most children with diabetes will have the type 1 form of the disease and require insulin. It is therefore essential that there is a balance between dietary carbohydrate consumption and insulin action in order to maintain good blood glucose control and prevent extreme glycemic swings. Most insulin-treated patients experience a mismatch in this balance from time to time and suffer the unpleasant consequences of hypoglycaemia (low blood sugar) but this is particularly likely to occur in diabetic children because both dietary habits and activity levels tend to be more erratic. Children's food likes and dislikes may change rapidly, appetite may be highly variable and, particularly in younger age groups, food refusal may be used as a way of seeking attention or asserting independence. Physical activity levels are also less predictable in children; school breaktime may be spent sitting chatting to friends or running round the playground; at home a child may decide to ride a bike or just watch TV. It is therefore much more difficult to maintain a balance between food intake and the dual hypoglycemic effects of insulin and exercise.

In order to minimize the problem, the child needs to consume fairly constant amounts of starchy carbohydrate at frequent intervals. Dietetic expertise is needed to determine the timing and composition of daily meals and snacks which are most compatible with both the family's eating habits and the child's medication, and this pattern should form the framework of food intake. Parents and carers then need to be taught how dietary adjustments may need to be made to this pattern in the light of blood glucose monitoring results, changes in the child's food intake (e.g., due to illness), activity level, and other circumstances.

Hypoglycemia will still almost inevitably occur from time to time and everyone who has responsibility of care for the child will need to be aware of this and know how to deal with it. This may include considerable numbers of people – not just parents, carers, and school or preschool staff, but other adults such as grandparents, parents of the child's friends, leaders of youth organizations, ballet teachers, babysitters, and others.

Diet and growth

In this age group, the dietary needs for growth must not be overlooked. Dietary energy content is particularly important. In the days when diabetes was controlled by highly regulated and restrictive diets, energy intake was often inadequate and growth stunting a fairly common occurrence.

Energy needs of children vary widely and cannot be assessed accurately from tables of average needs. The best guide to individual dietary energy needs is habitual dietary energy intake. If a child is a healthy weight and growing normally, the usual dietary energy intake should remain unaltered. The underweight child will require dietary measures to boost the energy content of the diet, usually by increasing its energy density rather than the total amount of food consumed. The overweight child will require some curtailment of energy intake, usually by decreasing dietary energy density, in order to achieve weight stabilization.

It is also important that the energy and nutrient content of diabetic children's diets are reviewed at regular intervals. It is sometimes forgotten that dietary needs will change as the child grows. An energy intake which is appropriate at the time of diagnosis may be totally inadequate a year later.

Diet and the Prevention of Complications

Tight glycemic control is imperative for the long-term prevention of complications and this is primarily achieved by maintaining a day-to-day balance between carbohydrate intake and insulin activity. In addition to this, the overall composition of the diet also needs to be one which provides protection against the increased risk of developing cardiovascular disease in later life.

As with diabetic adults, starchy carbohydrate should comprise the greatest proportion of dietary energy intake. Suitable food choices which are popular with children include bread, breakfast cereals, pasta, rice, and potatoes. Wholemeal or fiber-rich varieties can be encouraged for their general health benefits, although have no particular advantages in terms of diabetic control. Cereal fiber intake should not be excessively high in very young children or those with small appetites because such foods are bulky and can compromise the intake of other foods needed to meet energy and nutrient needs. Conversely, high-fiber foods can be encouraged in the diets of children with healthy appetites who are becoming overweight.

There is no need for the diabetic child to eat a sugar-free diet. Sugar-rich foods or drinks should not normally be consumed as isolated snacks, although may at times be necessary to prevent or alleviate hypoglycemia. Candy (sweets) and chocolate can, if desired, be included in the diet as planned carbohydrate top-ups prior to exercise. Modest amounts of sugar-containing foods can be consumed as part of main meals. There are no benefits from substituting fructose or sorbitol for sucrose, nor from the use of specialist foods such as 'diabetic' chocolate; all these products are unnecessary and may cause diarrhea in children. However sugar-free 'diet' drinks sweetened with artificial sweeteners such as saccharine, aspartame, and acesulfame-K are useful alternatives to sugar-containing soft drinks.

Excessive fat intake, especially of saturated fat, should be avoided and healthy eating measures to achieve this are suitable for the entire family. Visible meat fat and poultry skin should be discarded, minimum amounts of fats or oils used in cooking or added to foods, and fat-rich foods and snacks such as pastry, pies, crisps, biscuits, and fried foods regarded as occasional treats rather than regular dietary features. However other fat restriction measures should not be overzealous in very young children or energy and nutrient intake may be compromised. For this reason, reduced-fat milks and dairy products are not suitable for children below the age of 2 years.

Protein intake should be sufficient but also not excessive. Small portions of lean meat, fish fingers, cheese, eggs, and pulse foods such as baked beans are good choices for children. Convenience foods such as burgers, sausages, and other meat products are popular but also have a high fat content so should only be provided occasionally and, where possible, reduced-fat varieties should be chosen.

Minimizing Social and Psychological Disruption

Children hate to feel different from their peers, and while the presence of diabetes inevitably imposes some constraints, every effort should be made to keep these to a minimum. Dietary management therefore has to find the best compromise between maintaining good control while keeping life as normal as possible.

The key to achieving this is individualized rather than standardized guidance. Dietary changes necessary to maintain good diabetic control and long-term health should be made by modifying existing family meal patterns and food choices as much as possible, taking account of individual food preferences, appetite, activity level, and lifestyle, rather than by imposing dietary rules which are alien to the child and disruptive to the family.

Advice should be as positive as possible, with diabetes presented as a condition which presents challenges to be overcome rather than one which precludes normal life. Diabetic children have to learn to understand that because they take insulin, they have to be more careful than other children in terms of what they eat, and when they eat. However diabetes will not stop them from eating foods which other children eat or from doing the activities which others do; it is simply that some advance planning may be needed to incorporate these things into daily life. Most children accept and adapt to this with surprising speed.

Diabetes in Teenagers

A number of factors, particularly dietary ones, can affect diabetic control during the teenage years. An increasingly independent lifestyle means that eating habits often change markedly, with trends towards consumption of snacks and fast foods rather than formal meals, a greater proportion of food consumed outside the home away from adult supervision, and alteration in food choice which may either be widened as new foods are encountered, or sometimes narrowed by the constraints of vegetarianism or slimming.

Energy and nutrient requirements will also change during these years. Sudden growth spurts, especially in boys, can result in a dramatic increase in the need for dietary energy and carbohydrate. The body's demands for micronutrients such as calcium and iron are also high. Activity levels may also alter, and in either direction; some teenagers may take up physically demanding new sports such as squash or jogging while others may give up formal sports altogether and spend increasing amounts of time sitting at a computer.

It is also likely that alcohol will be consumed and this is of major significance for people on insulin. Alcohol potentiates the effect of insulin and, if consumed on an empty stomach, can cause severe, potentially fatal, hypoglycemia. It is therefore imperative that alcohol is not consumed in excessive quantities and always in conjunction with sufficient carbohydrate. This is perhaps the most important dietary message to get across to diabetic teenagers. They do need to be aware of the risks and should be offered written guidance on safe drinking limits, how to use the alcohol unit labeling system, and how much additional carbohydrate is needed when alcohol is consumed. They should also know that many of the beers and lagers popular with this age group have an extremely high alcohol content.

Most diabetic teenagers will require modifications to their diet and insulin regimen in order to cope with the changes associated with adolescence. At the same time, many will tend to become less receptive to the advice of health professionals and begin to resent what they perceive as perpetual nagging about diet, control, and the risk of complications. Some will bend the rules as much as they can. With greater maturity, a more responsible attitude will return and the young adult will become more receptive to health guidance. In the meantime, health professionals should aim to keep the channels of communication open and encourage their clients to regard them not as people telling them 'what to do' but 'how to do it.'

Diabetes in Older Adults

The risk of developing type 2 diabetes increases with age, and increasing longevity now means an increasing prevalence of diabetes in people over the age of 65 years. In the past there has been a tendency to regard diabetes in this age group as a 'mild' form of diabetes and its management confined to mere symptom relief. It is now known that this is not the case; the risk of complications such as blindness, gangrene, renal failure, stroke, and coronary heart disease is greatly increased if the condition is not diagnosed promptly and managed effectively.

In this age group, as in any other, tight glycemic control is important. In most patients who develop type 2 diabetes in later life, this can be achieved by a combination of dietary measures and oral hypoglycemic drugs. However, if these prove inadequate for optimum control, some type 2 patients will be managed on insulin.

Although the objectives of diabetes care are no different in older adults, some specific aspects of care need to be borne in mind:

- Treatment with insulin or sulfonylurea hypoglycemic drugs always poses a risk of hypoglycemia

and in older adults this may have serious consequences in terms of falls and fractures. If patients are frail or unsteady on their feet, a balance has to be found between keeping preprandial blood glucose levels low enough to minimize complications but high enough to prevent the hazards from hypoglycemia.

- The physical effects of aging in older adults tend to impair self-management of diabetes. Poor eyesight may make it difficult to draw up the correct dose of insulin or read a blood glucose monitor; short-term memory loss may mean that a dose of an oral hypoglycemic drug may be forgotten or perhaps taken twice. Physical infirmity may make it difficult to shop, cook, or eat. Psychosocial factors such as loneliness, depression, or bereavement may result in loss of interest in food and self-care.
- Older adults are also more likely to have other diseases associated with aging such as stroke, cancer, or dementia as well as diabetes. The effects of these illnesses, and of the drugs or other therapies used to treat them, on appetite, mobility, or memory can have a profound impact on food intake and hence the maintenance of diabetic control.

Recent surveys have highlighted many inadequacies in the care of older adults with diabetes, both those living in the community and people in residential homes. It is now recognized that better and more individualized care and support could do much to reduce the unnecessary morbidity and mortality associated with the disease, and improve the quality of life in the later years.

Diabetes in People from Ethnic Minority Groups

The prevalence of diabetes is particularly high among some ethnic minority groups. People of South Asian origin living in the UK are four times more likely to develop the disease than the indigenous Caucasian population. In African-Caribbean people, the risk of diabetes is twice as high. Both these groups are also more likely to die from long-term complications of diabetes such as cardiovascular disease and renal disease.

Diagnosis and management of the disease are often hampered by the fact that access to, or uptake of, health care services by this sector of the population is often poor and language barriers can further hamper communication. In order to provide effective care, health professionals need to be sensitive to the cultural beliefs and customs of each individual and understand the practical implications of these, particularly in terms of dietary management. Dietetic expertise is vital to insure that the guidance given is both appropriate and culturally acceptable.

Secondary Complications

B Thomas, Dorking, Surrey, UK

Types of Complications

As the life expectancy of people with diabetes has increased, the long-term consequences of the disease have become more apparent. The treatment objectives of diabetes are therefore not confined to the short-term relief of its symptoms but also aim to prevent or minimize its long-term effects.

Complications of diabetes can be divided into two main categories:

1. Arterial disease of large or medium-sized blood vessels (macrovascular disease)
2. Damage to the microvascular circulation of the retina and kidneys and to peripheral nerves (microvascular disease).

There are several differences in the pathogenesis of these two types of complications. Microvascular complications are unique to diabetes, and their development is associated with prolonged exposure to hyperglycemia. In contrast, arterial disease affects both diabetic and nondiabetic populations alike, although the prevalence of the disease is greatly increased in people with diabetes. However, there are some links between diabetic complications: retinopathy and nephropathy often develop together, and patients with diabetic nephropathy have a greatly increased risk of cardiovascular mortality.

The recent findings from two major prospective studies – the Diabetes Control and Complications Trial and the UK Prospective Diabetes Study – have greatly clarified the role of different risk factors in the development of diabetic complications.

Macrovascular Disease

Macrovascular disease results from atheromatous changes in large and medium-sized blood vessels that may become partly or totally blocked. The resulting impairment can affect the cardiovascular system (causing angina and coronary thrombosis), the cerebrovascular system (causing stroke), and the peripheral blood supply to the lower limbs (causing claudication and tissue damage).

The susceptibility to cardiovascular disease is of particular concern. People with diabetes are at least twice as likely to develop heart disease as the nondiabetic population. Furthermore, the disease tends to strike at a younger age and in both sexes; diabetic women appear to lose much of their premenopausal protection against heart disease and are at a much greater risk than their nondiabetic counterparts. People with diabetes also have a two- to threefold increase in the risk of stroke.

The reason why diabetes enhances the atherogenic process has not been fully explained, but it is undoubtedly due to a combination of factors. Hyperglycemia almost certainly plays a role, probably as a result of the metabolic disturbances associated with it, in particular, disordered lipid metabolism. Abnormal blood lipid profiles are a common feature of both types of diabetes, although the pattern of dyslipidemia is usually different. Type 1 patients tend to have elevated levels of total and low-density lipoprotein (LDL) cholesterol and reduced high-density lipoprotein (HDL) cholesterol, a combination known to enhance atherogenic risk. Type 2 patients commonly have elevated very-low-density lipoprotein (VLDL) triglyceride levels, particularly if they are obese, together with increases in the highly atherogenic small dense LDL subclass. All these lipid profiles are exacerbated by poor glycemic control.

Thrombogenic factors, such as the fibrinogen level or degree of platelet stickiness, may also be adversely affected by diabetes, leading to an increased likelihood of thrombosis and blood vessel occlusion.

The presence or absence of other cardiovascular risk factors also plays a key role. Hypertension is particularly strongly associated with cardiovascular risk in diabetic subjects, and long-term tight blood pressure control in hypertensive Type 2 patients has been shown to result in a significant fall in the incidence of coronary heart disease and stroke. Other known contributors such as cigarette smoking, obesity, and physical inactivity are also particularly detrimental to people at such high risk of cardiovascular disease. Prevention of diabetic macrovascular complications therefore requires multiple risk factor reduction from all these influences, in addition to the maintenance of good diabetic control.

Diet plays an important part in cardiovascular disease prevention. The modern diabetic diet, based on healthy eating principles, confers a much greater atherogenic protection than its low-carbohydrate, high-fat predecessor. Like the rest of the population, people with diabetes are advised to obtain at least 50% of their dietary energy from starchy carbohydrate foods such as bread, cereals and potatoes. Carbohydrate food choices with a low glycemic index (such as oat-based breakfast cereals, pasta, and rice) should be encouraged in order to minimize postprandial glycemia. Dietary fat intake should be reduced to 30–35% of dietary energy, with particular emphasis on avoidance of saturated fat. Use of spreading and cooking fats and oils should be kept

to a minimum and should be mainly derived from monounsaturated sources; excessive intake of polyunsaturated fat is no longer encouraged because of the risk of lipid peroxidation. Adequate consumption of fruit and vegetables (at least five servings a day) is a particularly important dietary measure, since there is growing evidence that these foods confer significant antioxidant protection. In addition, the soluble fiber content of fruit and vegetables, together with that found in oats and pulses, may have beneficial effects on both glycemic control and blood lipids. Foods with a high content of cereal fiber (e.g., wholemeal bread) are encouraged for their high satiety value and gastrointestinal benefits but are no longer thought to offer any particular advantage in terms of glycemic control.

High sodium intakes may exacerbate or contribute to hypertension, and, along with the rest of the population, people with diabetes should be encouraged to reduce their sodium intake by about one-third (from the typical average of 9 g per day to 6 g per day). This can be achieved quite easily by not adding salt to foods, avoiding highly salted foods and making sure the diet is not over-reliant on processed manufactured foods (the major contributors to the sodium content of the UK diet) such as canned foods, ready meals, or convenience foods.

For those who are overweight, weight loss is an over-riding priority. Even modest weight loss (5–10 kg) will have marked benefits in terms of glycemic control, blood pressure, and lipid profile. In Type 2 diabetic patients, weight loss is the treatment outcome most closely related to improved life expectancy. In general, a low-energy diet relatively high in starchy carbohydrate, fiber, and low in fat is the most suitable for weight loss because of its high satiety value. Increasing the daily level of physical activity is also important.

Microvascular Disease

Nephropathy

Diabetic nephropathy results from damage to the microvascular circulation of the kidney. It is characterized by persistent proteinuria, rising blood pressure, and a progressive decline in renal function, which eventually may result in renal failure. The risk of premature death from either uraemia or cardiovascular disease is greatly increased.

Nephropathy affects about 30% of people with Type 1 diabetes, typically appearing about 10–20 years after diagnosis. In those with Type 2 diabetes, it tends to be appear after a shorter time scale, and its incidence varies with ethnic origin, ranging from about 25% in Europeans to as much as 50% in people of African-Caribbean and Asian origin.

Prior to the development of overt diabetic nephropathy, damage to the glomerular capillaries results in leakage of albumin into the urine. These losses are small and symptomless but appear to be an important predictor of the subsequent development of clinical nephropathy. Identification of patients with microalbuminuria (urinary albumin excretion in the range of 30–300 mg per day) is now regarded as an important way of ensuring that preventive measures are applied at an early stage to those at greatest risk.

It is now established beyond doubt that diabetic nephropathy is related to both hyperglycemia and hypertension. Prevention therefore requires tight control of each of these parameters.

In the early stages of the disease, strict glycemic control and effective antihypertensive treatment can reduce microalbuminuria and restore the glomerular filtration rate (GFR) to the normal range. There is evidence that the progression to clinical nephropathy can be slowed and associated mortality reduced if these measures are started early enough.

The role of protein restriction in the prevention of nephropathy remains equivocal. Dietary protein intake is known to influence renal function, and a low-protein diet can retard the progression of chronic renal failure. There is some evidence that a diet that includes moderate dietary protein restriction (to about 45 g per day or 0.6–0.7 g per kilogram of ideal body weight) may also reduce the rate of decline in GFR and reduce urinary protein excretion in some patients, particularly if started before renal impairment becomes too advanced. Further research is required to determine precisely which dietary components are important, at what stage protein restriction should be introduced, and at what level. Current recommendations in the USA are that diabetic patients with overt nephropathy should not exceed a protein intake of 0.8–0.9 g per kilogram of body weight per day. Once GFR begins to fall, a further restriction to 0.6 g per kilogram per day may be advisable.

What does seem clear is that all diabetic patients should be discouraged from consuming excessive protein intakes. In the now outmoded era of carbohydrate restriction, people were often encouraged to satisfy their hunger with protein-rich foods such as meat, cheese, and eggs. As well as being unwise in respect of atherogenesis, such a measure may well have been detrimental to renal function.

Excessive protein intake can be avoided by insuring that foods such as meat, poultry, fish, and cheese are not the largest component of a meal, and that a greater proportion of food intake comprises starchy

foods and vegetables (as recommended in *The Balance of Good Health* healthy eating plate model). Such a measure also will help decrease the consumption of saturated fat and hence improve the lipid profile. This may be particularly important in patients with diabetic nephropathy, most of whom have a disordered lipid pattern and eventually die from cardiovascular disease. Other dietary aspects that also minimize this risk, such as weight reduction and salt restriction, are also high priorities in these patients.

Retinopathy

Diabetic retinopathy is the most common cause of blindness in the UK. Damage to retinal capillaries causes microinfarcts, hemorrhages, and retinal deposits, which, if unchecked, can result in visual impairment. The risk of cataracts is also increased.

Retinal changes usually remain mild and asymptomatic for many years, so-called 'background retinopathy.' However, in time, 'proliferative retinopathy' may develop; new blood vessels appear, and progressive damage eventually leads to retinal detachment or vitreous hemorrhage and loss of sight.

The development of background retinopathy is closely associated with the duration and degree of exposure to hyperglycemia. After 20 years of diabetes, most Type 1 diabetic patients and well over half of those with Type 2 will have some degree of retinopathy. However, not all will develop the sight-threatening proliferative changes, the peak incidence of which occurs after about 15 years of diabetes and remains constant at about 3% per annum thereafter. It is unclear which factors trigger this effect. Poor control is a contributory factor (although, paradoxically, a sudden improvement in diabetic control often leads to an abrupt deterioration in retinopathy for a period).

Prospective studies have now established that long-term tight glycemic control is of primary importance in minimizing the development of retinopathy. For this reason, it is also vital that Type 2 diabetes (which can remain undetected for considerable periods of time in older adults) is diagnosed at any early stage; about 20% of these patients already have significant retinopathy at the time of diagnosis as a result of prolonged untreated hyperglycemia.

If retinopathy does occur, much can now be done to halt its progression. Laser photocoagulation can be used to prevent new retinal blood vessels from proliferating and threatening sight, and new surgical techniques may be able to improve vision or prevent further deterioration. However, these damage-limitation measures need to applied at the earliest possible stage in order to protect sight. Since retinopathy is usually asymptomatic until serious damage has occurred, regular screening of the retina is important. All diabetic patients should have annual ophthalmological examinations.

Neuropathy

Diabetes may result in damage to nerves, causing disordered motor, sensory, and autonomic function. Much less is known about the incidence and prevalence of this complication, because its effects are so diverse and difficult to classify.

About 10–20% of insulin-dependent patients may have evidence of peripheral neuropathy. Peripheral nerve damage is characterized by 'pins and needles,' numbness, or pain in the lower limbs, and is particularly likely to contribute to problems in the diabetic foot. Loss of sensitivity to pain can result in unfelt injuries, which, if associated with poor control or peripheral vascular disease, may become infected, leading to ulcers and, possibly, gangrene.

Symptomatic autonomic neuropathy is more rare, but when it does occur, it may cause severe problems, including postural hypotension, incontinence, and impotence. Neuropathy affecting the gastrointestinal tract can cause diarrhea or constipation. Gastric neuropathy may reduce gastric secretion and delay gastric emptying, causing unpleasant sensations of bloating and resulting in anorexia, or even nausea and vomiting. These problems can seriously affect dietary management. As with other microvascular complications, hyperglycemia promotes neuropathy, and its development is related to the duration of diabetes. There is some evidence that improved glycemic control may benefit nerve function.

Prevention of Diabetic Complications

The factors with the greatest influence on the development of each type of diabetic complication, and hence of most relevance to its prevention, have been outlined above. However, since all patients are potentially at risk from all complications, preventative measures have to be global in nature so that protection from all types is maximized.

Treatment Objectives to Prevent Complications

Central to the prevention of every complication is tight glycemic control. Maintaining preprandial blood glucose level between 4 and 7 $mmol\,l^{-1}$ and glycosylated hemoglobin (HbA_{1C}) at 7.0% or below are the most important treatment objectives.

Correction of hypertension and maintenance of blood pressure at 140/80 mmHg or below may be equally critical, particularly in respect of nephropathy and cardiovascular disease.

Correction of disordered blood lipids is important. Sometimes, this will necessitate drug therapy but often can be achieved by more effective management of obesity or by tightening glycemic control.

People also need to minimize the influence of other known cardiovascular risk factors, particularly those from cigarette smoking, obesity, physical inactivity, and an atherogenic diet.

These treatment objectives must be pursued with equal vigor in both Type 1 and Type 2 patients. In the past, the latter form of the disease has often been regarded as a 'mild' form of diabetes, but it is now clear that it is anything but mild in its effects.

Role of Diet in the Prevention of Complications

Effective dietary management is crucial if these objectives are to be achieved. Diet is central to the maintenance of tight glycemic control, by ensuring there is a balance between glucose entering the blood following the ingestion of food and the amount of insulin (either exogenous or endogenous) available to deal with it. This is primarily achieved by the maintenance of a stable day-to-day pattern of eating in terms of meal timing and carbohydrate consumption, to which minor adjustments are made as needed to meet fluctuations in activity level or other circumstances.

Considerable dietetic skill is needed to help people make the necessary adjustments to their normal eating habits so that carbohydrate intake is compatible with hypoglycemic medication, and also in a way that is acceptable to the individual and hence sustainable in the long term. Patients also have to be taught how to use their blood glucose monitoring results to assess whether the balance between diet and glycemia is appropriate, whether further dietary adjustments need to be made, and, if so, what form these should take.

The dietitian also has to insure that the diet is balanced in terms of energy and nutrient content and of optimal composition for the prevention of cardiovascular disease. The healthy eating guidelines detailed in the UK national food guide (*The Balance of Good Health*) are a good basis for achieving this. This model recommends that starchy cereal foods should be the main part of each meal, that at least five portions of fruit/vegetables should be consumed every day, and that the daily diet should also contain two or three servings of low-fat dairy products and up to two modest servings of meat or alternatives. The consumption of fat-rich and sugar-rich foods should be avoided as much as possible. If these guidelines are adopted, the resultant dietary composition will meet all the diabetic dietary objectives, i.e., contain a relatively high proportion of energy from starchy carbohydrate, a low proportion of energy from saturated fat, a high content of antioxidants and soluble fiber, a lower-than-average sodium content, and not excessive protein content.

In those who are overweight, effective weight management is imperative, because obesity has detrimental effects on glycemia, blood pressure, and blood lipids, and hence impacts on all types of complications. Achieving permanent weight reduction is a notoriously difficult task, but the potential health benefits of even modest weight loss justify the efforts involved. This requires far more than just providing dietary guidance; behavioral strategies and considerable support measures will be necessary to effect permanent lifestyle change

Along with other aspects of diabetes care, dietary management has changed considerably in recent years. Treatment is much more patient-centered, with the individual being encouraged to take greater responsibility for their own self-care in partnership with health professionals. The role of the dietitian is no longer to dispense standard advice to all-comers, often in the form of complicated exchange lists or restrictive diet sheets, but to assess the unique dietary and clinical circumstances of each patient, identify the nutritional priorities and help that individual make appropriate dietary changes. Dietetic expertise is an essential component of the skill mix of the diabetes care team.

Quality of Care Necessary to Prevent Complications

Prevention of diabetic complications depends, firstly, on achieving the best possible control of the diabetes and, secondly, on early diagnosis of any problems that do arise. Diabetes care that consists solely of brief routine visits to an overworked GP or busy outpatient clinic may be sufficient to maintain short-term control of diabetes, but will not provide the quality of care necessary to prevent minor problems becoming major and possibly life-threatening.

Effective diabetes management requires multidisciplinary care from a team that incorporates the skills of a number of health professionals such as dietitians, ophthalmologists, and chiropodists as well as those of clinicians and nurses. Regular monitoring and follow-up are vital; all diabetic patients should have an annual clinical and dietetic review to assess the effectiveness of current treatment, identify any emerging problems, and implement any necessary action. Care provision in the primary and secondary sectors needs to be closely integrated so that all patients have access to expert services as a matter of routine.

There is evidence that the care of many people with diabetes has been substandard, particularly that of Type 2 patients, whose susceptibility to complications has often been underestimated. It is also clear that

better care could significantly reduce much of the morbidity and premature mortality associated with the disease. In the UK, high priority is currently being given to implementing national standards of diabetes care in order to reduce the high economic and human cost of diabetic complications.

Background

Diarrhea is one of the most common health care problems in both developing and developed countries. Infectious diarrhea has been noted to constitute 10% of US pediatric outpatient visits; its estimated costs total nearly $1 billion annually. World Health Organization (WHO) statistics indicate that diarrhea is the second leading cause of death in the pediatric population, causing about 3 million deaths per year. Although a dramatic decrease in mortality was achieved through the introduction of oral rehydration therapy program in 1979, infectious diarrhea is still a major problem; a causative microorganism is identified in only about half of all such cases. The epidemiology of the microorganisms has not changed significantly over time.

Diarrhea is defined as an excessive loss of fluid and electrolytes in the stool. In newborns and infants, stool volume greater than $15\,g\,kg^{-1}\,day^{-1}$ is considered diarrhea. By approximately 3 years of age, the stool quantity reaches adult output, and from then on, an amount greater than 250 g per day is

considered diarrhea. Diarrhea can be categorized as acute or chronic, according to its duration; chronic diarrhea lasts more than 2 weeks. The etiology of diarrhea can be traced to both noninfectious and infectious agents such as viruses, bacteria, and parasites. Noninfectious etiologies include food allergies, malabsorption, inflammatory bowel disease, drugs, and endocrinopathies.

Pathogenesis of Diarrhea

Most dietary carbohydrates are ingested as di or polysaccharide and are hydrolyzed into monosaccharides prior to absorption. Carbohydrate in the bowel lumen attracts water, and under normal circumstances, water is subsequently absorbed. Whenever there is an excess of luminal carbohydrate, as in the case of malabsorption, net absorption of water is reversed, and diarrhea occurs. Osmotic and secretory diarrhea are differentiated, based on the pathogenesis (see etiology in Tables 1 and 2). Osmotic diarrhea is related to the presence of unabsorbed substances, such as lactose; nonabsorbable sugars, such as lactulose; or laxatives, such as magnesium. These osmotic solutes draw more water through the tight junctions into the gut lumen. Electrolyte absorption continues and is not influenced by intraluminal osmotic solutes. In osmotic diarrhea, the stool fluid has little sodium or potassium; osmolality is high; and the ion gap, calculated by the subtraction of stool osmolality by the doubled value of the sum of $Na + K$, exceeds $100\,mOsm\,kg^{-1}$. This type of diarrhea commonly ceases when fasting. In secretory diarrhea, typically, the amount of stool is voluminous, even when fasting. Stool osmolality is normal, and the ion gap is less than $100\,mOsm\,kg^{-1}$. The most common cause of secretory diarrhea is bacterial enteritis, such as *Escherichia coli* or *Vibrio cholerae*. The increase in net fluid and electrolyte secretion occurs when the pathogens adhere to, or invade, the enterocytes and produce toxins that enhance intracellular second messengers (cyclic AMP, cGMP, and/or Ca/protein kinases). These mediators activate protein kinase, which inhibit NaCl-coupled influx, and increase Cl efflux to the ion channels.

Table 1 Etiology of osmotic diarrhea

Impaired intraluminal digestion
Exocrine pancreatic insufficiency (cystic fibrosis, Shwachman–Diamond syndrome, etc.)
Decrease in bile acid pool (congenital absence of bile acid synthesis, ileal resection, Crohn's disease, etc.)
Congenital lipase deficiency
Congenital lactase deficiency
Adult-type hypolactasia
Sucrase-isomaltase deficiency
Congenital trehalase deficiency
Inflammatory villous atrophy (celiac disease, protein milk allergy, postgastroenteritis)
Malabsorption
Carbohydrate malabsorption (congenital glucose–galactose malabsorption, fructose malabsorption)
Fat malabsorption (abetalipoproteinemia, hypobetalipoproteinemia, etc.)
Laxative abuse
Increased colonic fermentation
Excessive sorbitol
Lactulose abuse
Increased consumption of simple carbohydrate (juice)

Table 2 Etiology of secretory diarrhea

Infection (bacterial toxins)
Enteroaggregative and enterotoxigeneic *E. coli*, cholera
Intestinal obstruction
Partial bowel obstruction, Hirschsprung's disease
Congenital ion transport defects
Congenital chloride transport defect, congenital sodium transport defect
Neuroendocrine tumors
Gastrinoma, VIPoma, somatostatinoma, mastocytosis, carcinoid tumor, medullary carcinoma of the thyroid
Ileal bile acid malabsorption
Nonosmotic laxative abuse
Idiopathic villous atrophy
Congenital microvillous atrophy
Autoimmune enteropathy or vasculitis

Acute Diarrhea

Acute diarrhea is generally associated with an enteric infection. Viral gastroenteritis primarily affects the proximal small intestine. It presents with watery diarrhea and vomiting, leading to dehydration. Enteritis that affects the small intestine, such as that caused by *Vibrio cholerae*, enterotoxigenic and enteroaggregative *Escherichia coli*, *Klebsiella pneumoniae*, *Giardia lamblia*, and *Cryptosporidium*, produces nonbloody, watery diarrhea. Infection with *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, enteroinvasive *E. coli*, and amoeba manifests with fever, abdominal cramps with tenesmus, and bloody mucoid stool. *Clostridium difficile*-associated diarrhea usually follows the use of broad-spectrum antibiotics. Usually, the course of the infectious diarrhea is self-limited and lasts no longer than 14 days.

Infectious Diarrhea

Viral Diarrhea

Rotavirus infection is the most common cause of dehydration in early infancy, particularly between 6 months and 2 years of age. The pattern of viral shedding spreads from shortly before, to possibly 2 weeks after, onset of illness. The infection is most common

during the winter in temperate climates. The viruses spread predominately via the fecal–oral route. Symptoms of rotavirus infection begin with fever, nasal congestion (30–50% of children), and emesis, followed by watery diarrhea without blood or mucus, which can last up to 5–7 days. Vomiting and fever typically disappear within 48 h of onset. Severe dehydration and death can occur in children with underlying malnutrition and short bowel syndrome. In tropical countries or endemic areas, rotaviruses are a cause of traveler's diarrhea. Severe and protracted diarrhea is seen in children with T-cell immunodeficiency and severe combined immunodeficiency (SCID), but rotavirus is not a common cause of diarrhea in children with human immunodeficiency infection. Asymptomatic infants, older children, and adults may shed the virus in their stools.

Diagnosis of rotavirus diarrhea is considered in young children with acute onset of vomiting and watery diarrhea. Viral particles can be detected in the stools by electron microscopy. A simple and inexpensive tool with enzyme-linked immunosorbent assay (ELISA) or latex agglutination can detect viral antigen in the stools.

Management of rotavirus diarrhea focuses on rehydration and contact isolation. Mild to moderate dehydration requires oral rehydration solution therapy. Intravenous fluid therapy is used in children with severe dehydration, recurrent emesis, and failed oral rehydration. Antibiotics and antidiarrheal drugs should not be given. Oral administration of human milk or human immune globulin-containing protective rotavirus antibody is indicated in low-birth-weight infants as passive prophylaxis and in children with immunodeficiencies who develop protracted rotavirus diarrhea.

Astroviruses are the second most important group of viral agents that cause diarrhea in young children. Transmission tends to occur from person to person through the fecal–oral route. Occasionally, contamination with water or shellfish has been reported. Most such infections have occurred in children younger than 4 years of age. Diagnosis is made with direct visualization by electron microscopy, but may not be as sensitive as for rotavirus. ELISAs are available in reference and research laboratories.

Enteric adenovirus diarrhea, which occurs year-round, mostly affects children younger than 2 years of age. Caliciviruses (or Norwalk viruses) and calicilike viruses are a common cause of water- and food-borne outbreaks of acute nonbacterial gastroenteritis, and are particularly associated with ingestion of shellfish and salads contaminated by infected kitchen-workers during food preparation. Transmission occurs from person to person via the fecal–oral route. Viral shedding lasts 5–7 days after the onset of illness but can extend up to 2 weeks, and may persist 4 days after the cessation of symptoms. The illness is indistinguishable from other viral gastroenteritis in children. Adults tend to have an abrupt onset of symptoms similar to those of staphylococcal food poisoning. Several other viruses cause gastroenteritis in children, including picornaviruses, coronaviruses, toroviruses, parvoviruses, parvo-like viruses, and unclassified small round viruses. Some of these viruses are occasionally responsible for outbreaks.

Bacterial Diarrhea

Bacterial infection in the gastrointestinal tract has a variety of manifestations, such as acute food poisoning, nonbloody, watery diarrhea; and dysentery. Antibiotic therapy is recommended in infections by certain bacterial pathogens, as shown in Table 3.

Salmonella Salmonellae are Gram-negative bacilli that are classified into groups A–E. *S. typhi* (group D)

Table 3 Recommended antimicrobial treatment for bacterial diarrhea

Diseases caused by pathogenic bacteria	*Antibiotic treatment*
Cholera	1. Tetracycline 50 mg kg^{-1} day^{-1}; maximum 2 g day^{-1} in four divided doses for 3 days (drug of choice for *V. cholera* 01 and 0139 Bengal): use of tetracycline under the age of 8 years may outweigh the side-effect of developing tooth coloring in resistant strain to other antibiotics 2. Doxycycline 6 mg kg^{-1}, maximum 300 mg, as a single dose 3. Trimethoprim-sulfamethoxazole (TMP-SMX) 8 mg kg^{-1} day^{-1} of trimethoprim if the strain is resistant to tetracycline
Shigellosis	Ampicillin, TMP-SMX, for 5 days
Enteropathogenic *E. coli* diarrhea	TMP-SMX For infants with mild diarrhea, nonabsorbable agents, such as neomycin and gentamicin, given three or four times a day for 5 days
Enteroinvasive *E. coli* diarrhea	TMP-SMX
Yersinia enteritis	Aminoglycosides, cefotaxime, tetracycline (< 8 years old), chloramphenicol, TMP-SMX
Salmonellosis or typhoid fever	Ampicillin, amoxycillin, cefotaxime, ceftriaxone, chloramphenicol, TMP-SMX
Pseudomembranous colitis (*C. difficile*)	Metronidazole 30 mg kg^{-1} day^{-1} in four divided doses for 7–10 days

and many other *Salmonella* serotypes cause bacteremia and typhoid fever, typically with gradual onset of fever, malaise, headache, and abdominal tenderness. Nontyphoidal salmonellosis can present with gastroenteritis ranging from a small volume of stools, to profuse bloody diarrhea and to severely watery stools. Most *Salmonella* infections are sporadic, but transmission occurs from person to person; via contaminated water and food of animal origin (e.g., poultry, red meat, eggs, and unpasteurized milk); and by contact with infected reptiles, such as pet turtles and iguanas. *Salmonella* infection frequently occurs in the extreme ages (younger than 5 and older than 70 years of age), and peaks early in the first year of life. Diagnosis is made by isolation of salmonellae from stool, urine, or blood specimen. Antimicrobial therapy is not recommended in uncomplicated cases of gastroenteritis. Infants less than 3 months of age, and children with complicated and invasive disease, malignancy, hemoglobinopathies, HIV infection, immunosuppressive state, or severe colitis, should be treated with antibiotics. A small number of persons infected with *Salmonella* can develop Reiter's syndrome.

Shigella Shigellae are Gram-negative, aerobic, nonmotile bacteria. Shigellae are easily transmitted from person to person and by the fecal–oral route. Ingestion of 10 shigellae can cause dysentery in adults. The bacteria can survive in water for up to 6 months. The infection tends to occur in children younger than 4 years of age. However, newborn infants can have a subclinical infection, and carriers are commonly found in developing countries. Day-care centers are sources of outbreaks in the developed world. Shigellosis often occurs during the rainy season. *Shigella flexneri* is the most common group in developing countries. The rectosigmoid and distal colon are more affected than the proximal part, which leads to bloody mucoid stools; however, some children present with high fever and watery diarrhea in the first 48 h, followed by abdominal cramps, tenesmus, and a small volume of blood and mucus in the stools. Complications with hyponatremia and hypoglycemia are commonly found in shigellosis. Lethargy and febrile seizures can precede diarrhea. Toxic megacolon, intestinal perforation, hemolytic uremic syndrome, pneumonia, and malnutrition can lead to death. Extraintestinal manifestations rarely occur in shigellosis. Sepsis and disseminated intravascular coagulation are infrequent complications but have high mortality rates. Shigellae can be isolated by a common stool culture, followed by biochemical and serologic tests to identify subgroups and serotypes.

Campylobacter *Campylobacter* is a group of spiral-shaped, motile, flagellated, Gram-negative bacilli that can be transmitted through food and water contaminated with material from infected animals or humans. *Campylobacter* is the most common bacterial cause of diarrheal illness in the USA; the majority of these cases stem from cross-contamination or consumption of raw or undercooked poultry. Most such human illness is caused by one species, *C. jejuni*. The bacteria adhere to the intestinal epithelium and produce enterotoxins, leading to secretory diarrhea. They can penetrate the cells and cause cellular damage and cell death, with subsequent bloody stools. The incubation period can last from 1 to 7 days. Symptoms start with nausea, vomiting, and abdominal pain with fever and myalgia, followed by watery diarrhea or bloody stools. Abdominal pain frequently resembles appendicitis in children older than 2 years of age. The diarrhea can last as long as 2 weeks. Extraintestinal manifestations associated with *C. jejuni* include Guillain–Barré syndrome. Direct examination of stools may demonstrate spiral-shaped organisms and fecal leukocytes. *Campylobacter* is microaerophillic, requiring special culture media and conditions. Correction of fluid and electrolyte imbalance is the sole therapy in this infection. The role of antibiotics is still controversial in complicated cases.

Clostridium difficile Pseudomembranous colitis is associated with a Gram-positive, spore-forming anaerobe that grows when the normal colonic flora is suppressed as a consequence of the use of broad-spectrum antibiotics. This organism produces toxins, particularly toxin A. Usually, it manifests with watery, nonbloody diarrhea and abdominal cramps. Occasionally, bloody mucoid stools may develop. Pseudomembranes may be seen on sigmoidoscopy. A fulminant colitis and toxic megacolon may develop, requiring surgical intervention. *C. difficile* can be found in the stools of young infants without causing any symptoms. Diagnosis is made by detection of toxin A in the stool. It has been seen, however, that in certain infections, toxin A is negative, but toxin B is positive; therefore, stools should be tested for this toxin as well.

***Aeromonas* species** *Aeromonas* species are Gram-negative, oxidase-positive bacilli that may be found in about 2% of children with diarrhea. The diarrhea is usually watery and self-limited; however, bloody stools and persistent diarrhea may occur.

Escherichia coli (E. coli) *E. coli* is part of the normal bacterial flora of the human gut. A few strains can cause gastroenteritis.

Enteropathogenic Escherichia coli *(EPEC)* EPEC consists of 12 serogroups. The EPEC strains do not

produce enterotoxins, but certain strains make Shiga-like cytotoxin. Children younger than 2 years of age are usually affected by EPEC and present with acute or chronic diarrhea, especially in developing countries. Diarrhea can be severe and, if untreated, can last up to 2 weeks. Vomiting and fever occur in 60% of children. Diagnosis can be made with commercial *E. coli* typing sera. Treatment consists of fluid replacement and correction of electrolyte imbalance and antibiotic therapy. Trimethoprim-sulfamethoxazole (TMP-SMX) is administered orally. Intravenous aminoglycoside is added if resistance to TMP-SMX is known. Fluoroquinones are not approved for use in children.

Enterotoxigenic Escherichia coli *(ETEC)* ETEC first adheres to the small intestinal mucosa, and then releases both heat-labile and heat-stable enterotoxins. ETEC is a common cause of nonbloody, watery diarrhea in children, and of traveler's diarrhea in developing countries. Adults in endemic areas do not tend to acquire this infection, probably because of the development of protective immunity. Children can present with rapid dehydration. Mortality is higher among malnourished patients. Patients rarely have fever, and stools do not contain blood or fecal leukocytes. The definitive diagnosis is made by isolation of *E. coli*, which produces enterotoxin and contains a gene encoding for enterotoxin production.

Enteroinvasive Escherichia coli *(EIEC)* EIEC is one of the causes of dysentery in developing countries. Occasionally, there are foodborne outbreaks in the developed world. The Shiga-like EIEC produces a clinical manifestation similar to shigellosis. These strains have the same biochemical characteristics and gene encoding for tissue invasion as *Shigella*. These bacteria invade colonic epithelium and cause ulcers that lead to blood and mucus in stools.

Enterohemorrhagic Escherichia coli *(EHEC)* EHEC infection has a unique presentation, with grossly bloody diarrhea, which is associated with *E. coli* serotype O157:H7. Most of these outbreaks have been related to consumption of contaminated beef. After ingestion of the contaminated food, the organisms adhere to the epithelium and produce cytotoxins, called Shiga-like toxins or verotoxins, which inhibit protein synthesis and result in cellular destruction. Children usually present with watery diarrhea, low-grade or no fever, and severe abdominal cramps. The diarrhea may become bloody. *E. coli* O157:H7 infection may cause hemolytic uremic syndrome in children, and thrombocytopenic purpura in adults. Treatment with antibiotics is not recommended, as some data suggest that antibiotic treatment will increase the incidence of hemolytic uremic syndrome.

Enteroaggregative Escherichia coli *(EAEC)* The EAEC organisms produce one or more enterotoxins that cause injury to the intestinal mucosa. The course may be acute, or it may be chronic, especially in infants. The diarrhea tends to be watery; however, bloody diarrhea may occur occasionally.

Yersinia enterocolitica *Yersinia enterocolitica* can cause inflammation in the ileum and colon and mesenteric adenitis, which mimics appendicitis. The infection occurs most frequently in children between 5 and 15 years of age. Clinical presentation is similar to other acute gastroenteritis. Bloody mucoid stools are found in some patients. This is a self-limiting infection, which, in uncomplicated cases, does not require antibiotics.

Vibrio cholerae Infection with *Vibrio cholerae* is manifested as an afebrile, painless, high-output, watery diarrhea that causes rapid dehydration and electrolyte imbalance, leading to hypovolemic shock within 4–12 h if no treatment is implemented. Stools are colorless with some mucus, and resemble rice water. Transmission occurs via consumption of raw or undercooked shellfish and dried fish. The incubation period is usually 1–3 days. Direct contact has not been described. Drugs of choice include tetracycline and doxycycline. TMP-SMX, erythromycin, or furazolidone may be considered in resistant strains.

Parasitic Infection

Except for giardiasis and cryptosporidiosis, intestinal parasitic infection is an uncommon problem in the developed world. The common mode of transmission is the fecal–oral route and ingestion of contaminated water or food. Infection with *Giardia lamblia* can be asymptomatic or present with nonbloody, watery diarrhea and steatorrhea. Normal hosts with *Cryptosporidium* and *Isospora belli* may present with nonbloody, self-limited diarrhea, whereas persistent diarrhea and malnutrition occur in immunocompromised hosts. The clinical spectrum of *Entamoeba histolytica* infection ranges from mild diarrhea to fulminant rectocolitis, and subsequently with frequent bloody mucoid stools. Roundworm infestation may cause watery diarrhea in tropical and subtropical regions Table 4.

Management Dehydration is the major complication in individuals with diarrhea who need fluid and electrolyte assessment. Rehydration and correction of concurrent fluid loss and electrolyte imbalance are

Table 4 Summary of parasitic infection and management

Disease and/or agents	*Endemic areas*	*Modes of infection*	*Diagnostic tests*	*Manifestations*	*Therapy*
Giardia lamblia	World-wide	Ingestion of contaminated water with feces containing cysts	Microscopic examination, *Giardia* antigen	Acute or recurrent abdominal pain, flatulence, anorexia, failure to thrive	Metronidazole, albedazole, furazolidone
Cryptosporidium parvum	World-wide	Fecal–oral route, ingesting water contaminated with oocysts	Microscopic examination, antigen by EIA	Watery diarrhea, abdominal cramps, vomiting, fever	Human serum immunoglobulin in immunocompromised host
Microsporidia	World-wide	Fecal–oral route, ingesting water contaminated with spores	Microscopic examination	Watery diarrhea in immunocompromised host	Albendazole, metronidazole, atovaquone, but recurrence of diarrhea after therapy is stopped
isospora belli	Tropics, subtropics	Fecal–oral route, ingesting water contaminated with oocysts	Microscopic examination	Protracted, foul-smelling, watery diarrhea, fever, vomiting in immunocompromised hosts	TMP-SMX, pyrimethamine
Cyclospora cayetanensis	World-wide	Fecal–oral route, ingesting water contaminated with oocysts	Microscopic examination	Protracted, watery diarrhea, fever, vomiting in immunocompromised hosts	TMP-SMX for 7 days
Entamoeba histolytica	World-wide	Fecal–oral route, ingesting water contaminated with cysts	Microscopic examination, PCR, isoenzyme analysis, antigen detection, serum antibody test	Watery diarrhea, then bloody mucoid stools, fever, liver abscess	Metronidazole, luminal amebicide with iodoquinol, paromomycin, or diloxaanide furoate
Dientamoeba fragilis	World-wide	Fecal–oral route, ingesting water contaminated with protozoa	Microscopic examination	Intermittent diarrhea, abdominal pain, anorexia	Iodoquinol, paromomycin, or tetracyclin
Balantidium coli	World-wide	Fecal–oral route, ingesting water contaminated with cysts	Microscopic examination, scraping lesions during sigmoidoscopy for histology is more sensitive	Recurrent bloody or mucoid diarrhea	Tetracyclin, or iodoquinol and metronidazole as alternatives
Blastocystis hominis	World-wide	Believed to be fecal–oral route, ingesting water contaminated with cysts	Microscopic examination	Associated with symptoms of bloating, abdominal pain, nausea, mild to moderate diarrhea	Metronidazole or iodoquinol
Trichuris trichiura	Tropics, subtropics	Eating embryonated eggs, from soils or food	Microscopic examination	Protracted diarrhea, rectal prolapse	Mebendazole 100 mg twice a day for 3 days
Strongyloides stercoralis	Tropics, subtropics	Penetration of the skin by infective larvae either from contact with infected soil or autoinfection	Microscopic examination, eosinophilia	Rash, cutaneous larva currens, mucoid voluminous stools, malabsorption, steatorrhea, pneumonitis	Thiabendazole 25 mg kg^{-1} per dose twice a day for 2 days
Trichinella spiralis	World-wide	Eating meat containing encysted larvae	Eosinophilia, bentonite flocculating test, muscle biopsy	Diarrhea, muscle tenderness, subungual petechial hemorrhages	*Trichinella spiralis*

Orange juice	< 1	50		50	120	
Chicken broth	250	8		0	0	500

Gatorade, colas, and juices are demonstrated for comparison, not advised for rehydration.

the mainstay of the therapy. Oral rehydration solution (ORS) therapy was successfully developed for this purpose in children who can tolerate enteral intake (Table 5). The principle is that glucose and amino acids are transported across the apical membrane of the enterocyte by contransporters. Unlike apical sodium–hydrogen exchange, nutrient–sodium cotransport is not affected by increased intracellular cyclic AMP levels, particularly in bacterial toxin-induced diarrhea. Inadequate potassium replacement can cause muscle weakness, paralytic ileus, and cardiac arrhythmia. Current oral rehydration therapy is safe and effective in children with mild to moderate dehydration and electrolyte imbalance. In severe dehydration, when the patient's vomiting is uncontrollable, or whenever there are associated conditions that interfere with oral intake, intravenous fluid rehydration may be required.

Feeding Feeding should be resumed as early as possible. Breastfeeding during diarrhea results in a shorter recovery period and improved nutritional status compared with fasting. Early and rapid reintroduction of a normal diet is recommended to maintain nutritional status, especially in malnourished children. Multiple studies have demonstrated that most eutrophic children do not need to have lactose eliminated from the diet, have the formula diluted, or undergo slow regrading of formula. Liquids that contain a high amount of simple sugars, such as fruit juices, should be avoided, because of their high osmolality. Although lactose malabsorption is rare in well-nourished infants, in some cases, lactose intolerance may delay recovery, especially in children with malnutrition, severe dehydration, or recent episodes of gastroenteritis. In these cases, a lactose-free formula may be beneficial. The addition of age-appropriate food has been shown to be well tolerated by infants and children with diarrhea.

Medications Antimicrobial agents are imperative in those who have infectious diarrhea, as described above. Agents such as loperamide and diphenoxylate, which reduce gut motility, do not alter fluid and electrolyte net balance, and are not recommended. Bismuth subsalicylate may decrease intestinal secretion, but bismuth and salicylate toxicity are worrisome. Clay adsorbents alter the appearance of the

stool without changing the water and electrolyte balance. Probiotics have been shown to shorten the duration of rotaviral diarrhea and prevent antibiotic-associated diarrhea. Zinc supplementation in malnourished children may reduce the duration and severity of diarrhea. Vitamin A and other micronutrients have yet to be proven efficacious for the treatment of diarrheal patients. Hyperimmune bovine antirotavirus colostrums may be given in selected cases to immunocompromised children.

Prevention Individuals who travel to high-risk areas or developing countries should avoid inappropriately prepared drinks, raw fruit and vegetables, and certain foods. Routine antibiotic use is not generally recommended, because of the risks of drug reaction, antibiotic-related colitis, and an increase in the incidence of resistant bacteria. Vaccines are being developed for better immunogenicity and fewer side-effects.

Chronic, Persistent, or Protracted Diarrhea

When the course of diarrhea continues over 14 days, it is considered to have become chronic. Chronic diarrhea can be caused by pathogenic organisms such as viruses, bacteria, or parasites acting on an individual who usually has risk factors such as malnutrition, associated illness, impaired immune status, intestinal mucosal injury, and/or bacterial overgrowth.

Chronic diarrhea may be congenital or acquired.

Congenital Microvillus inclusion disease (congenital microvillus atrophy), although rare, appears to be the most common cause of congenital intractable watery diarrhea. Diagnosis is based on intestinal biopsy demonstrating villous atrophy, crypt hypoplasia, and, on electron microscopy, microvillus inclusion in the enterocytes. Infants with this disease require total parenteral nutrition.

Tufting enteropathy presents in the first weeks of life with intractable watery diarrhea, but its onset is somewhat later than in microvillus inclusion disease. The remarkable finding is that the majority of the epithelial surface contains focal epithelial tufts (teardrop-shaped groups of closely packed enterocytes with apical rounding of the plasma membrane).

Congenital glucose–galactose malabsorption is a rare disorder with a defect of the glucose–sodium cotransporter system, leading to an increase in osmotic load in the intestinal lumen. Affected individuals, however, are capable of absorbing fructose, which becomes the source of dietary carbohydrate.

Congenital chloride diarrhea is a rare autosomal recessive condition. Maternal polyhydramnios is common. At birth, the infant develops rapid dehydration with marked abdominal distention. Stool chloride is $120\,\mathrm{mmol\,l^{-1}}$, and there is metabolic alkalosis. In congenital sodium diarrhea, clinical manifestations are similar to those of congenital chloride diarrhea, except for the fact that stool sodium is as high as $145\,\mathrm{mEq\,l^{-1}}$, and stool pH is alkaline as opposed to what is found in congenital chloride diarrhea.

Primary bile acid malabsorption is another extremely rare transport defect in the distal part of the ileum. Intractable diarrhea begins early after birth, followed by failure to thrive and fat malabsorption.

Hypobetalipoproteinemia is clinically indistinguishable from abetalipoproteinemia (Bassen–Kornzweig syndrome) and manifests itself with steatorrhea, failure to thrive, hypolipidemia, and acanthocytosis, which are present since infancy. The defect is an incapacity to form micelles, an important mechanism for fat transport into the enterocytes. Chylomicron retention disease may manifest similarly with steatorrhea and failure to thrive. Children with intestinal lymphangiectasia can suffer from steartorrhea, protein-losing enteropathy, and lymphopenia.

Disaccharidase enzyme deficiency can be diagnosed with a breath hydrogen test and confirmed by intestinal biopsy demonstrating normal histology and almost absent disaccharidase activity. Congenital sucrase–isomaltase deficiency becomes evident when sucrose or starch is introduced to the diet. Congenital lactase deficiency is a rare condition. Congenital glucoamylase deficiency has been reported in children with chronic diarrhea, which worsened with an oral starch challenge.

Impaired fat digestion tends to cause frequent bowel movements. Stools are foul-smelling, bulky, greasy, and float on the surface of the toilet water. This is one of the most common causes of failure to thrive in children. A sweat chloride test confirms the diagnosis of cystic fibrosis in some of these children. However, exocrine pancreatic insufficiency may occur in other diseases as well.

Acquired Chronic nonspecific diarrhea, or toddler's diarrhea, is seen in children between 6 and 36 months of age. Except for the history of watery stools, the children are healthy, and experience normal growth and development without abdominal pain. Diarrhea has been associated with initiation of broad-spectrum antibiotics, which change the normal intestinal flora, excessive fluid intake, and fruit juice (particularly apple juice) consumption.

Secondary lactase deficiency can be seen after acute gastroenteritis, particularly in malnourished individuals and those with recurrent episodes of diarrhea in the recent past. Acquired or late-onset lactase deficiency may begin in childhood or preadolescence, mainly in the nonCaucasian population, but it occurs

in many Caucasians as well. Reduction of lactase production is determined by genetic background and may lead to lactose intolerance, causing abdominal pain and/or diarrhea.

An abnormal intestinal villous surface prevents the absorption of digested nutrients, and leads to osmotic diarrhea and steatorrhea. Hypersensitivity to cows' milk or soy protein may cause partial villous atrophy in young infants. Frequent bloody mucoid stool, dehydration, and failure to thrive are not uncommon features. Total villous atrophy is found in celiac disease in infants who consume a diet containing gluten. Intestinal biopsy is the gold standard to make the diagnosis. Partial villous atrophy may be associated with intestinal infection such as *Giardia lamblia*, particularly in individuals with secretory IgA deficiency. Chronic diarrhea occurs often in individuals with congenital hypogammaglobulinemia, combined immunodeficiencies, and acquired immunodeficiency, at times associated with opportunistic infections. Crohn's disease and ulcerative colitis may present with chronic watery or bloody diarrhea. Crohn's disease presents systemic symptoms more often than ulcerative colitis. Enteroenteric and enterocolonic fistula may complicate cases of Crohn's disease with malabsorption and bacterial overgrowth. Infectious diarrhea can mimic exacerbation of inflammatory bowel disease.

Autoimmune enteropathy is a poorly understood syndrome with malabsorption and chronic diarrhea, which usually develops after 6 months of age and does not respond to a gluten-free diet. The presence of specific antienterocyte antibodies in serum can confirm this disorder.

Children with altered intestinal motility, such as partial obstruction or pseudoobstruction, may present with chronic diarrhea. Bacterial overgrowth also leads to diarrhea.

Certain tumors such as gastrinoma, VIPoma, ganglioneuroma, and ganglioneuroblastoma produce neurotransmitters that can cause secretory diarrhea. Tropical sprue can be seen among children who live in certain Caribbean countries, northern South America, Africa, and parts of Asia. Patients develop a diffuse lesion in the small intestine, which leads to malabsorption. Symptoms usually begin with fever, malaise, and watery diarrhea, which then subside. Subsequently, malabsorption and intermittent diarrhea follow and cause malnutrition. Small bowel biopsy demonstrates villus atrophy, an increase in crypt length, and chronic inflammatory cells in the lamina propria. Symptoms respond well to nonabsorbable sulfonamides or tetracycline for 3–4 weeks, folic acid and vitamin B_{12} therapy. When the investigation is thorough, but the etiology is still unknown or the resultant data are inappropriate, one should look for a condition of self-induced diarrhea. The use of stool laxatives can mimic chronic osmotic diarrhea. Determination of stool electrolytes, magnesium, and sulfate can be helpful in making the diagnosis. Creatinine may be detected in the stool in cases when urine is added to the stool by the patient or a caretaker to simulate diarrhea. A low stool osmolality suggests addition of water to the stool.

Management Treatment should be approached according to the pathophysiology of the diarrhea. The main goal is to prevent dehydration, malnutrition, its complications, and associated illnesses. Infection should be investigated and aggressively treated with appropriate antimicrobial agents. Empirical therapy for chronic diarrhea is considered when no specific treatment is available, based on the etiology of chronic diarrhea. Empirical trials of antimicrobial agents may be judiciously used in patients who have a high possibility of a condition leading to bacterial, viral, or protozoal infection. Bile acid-binding agents such as cholestyramine may decrease diarrheal output in children with primary bile acid malabsorption or high bile acid output-induced diarrhea. Reducing the intestinal transit time is helpful to allow the enterocytes to reabsorb fluid and electrolyte. Therefore, opiates are considered as antidiarrheal agents in those patients with noninfectious chronic diarrhea. Octreotide, a somatostatin analog used in tumor-induced secretory diarrhea, has been shown to decrease secretions. Parenteral nutrition should be the last resort for those who are unable to meet nutritional requirements with the enteral approach.

DIETARY FIBER

Contents

Properties and Sources

R Mongeau, Ottawa, Aylmer (Quèbec), Canada
S P J Brooks, Ottawa, Canada

Background

Although dietary fiber has been known for more than 2000 years under various terms (e.g., bran, roughage), the term 'dietary fiber' first appeared in 1953 and referred to hemicelluloses, cellulose, and lignin. The term 'fiber' is somewhat misleading since only a fraction (cellulose) of dietary fiber is fibrillar in nature. To correct this misnomer, other terms (e.g., plantix) have been proposed, but despite these efforts, the term 'dietary fiber' has survived.

This section deals with several different aspects of dietary fiber, including its determination and many of its physiological effects. Most of this information is relatively new and is the result of progress in research brought about in the last 30 years. The first part of this article will focus on the nature and composition of dietary fiber, its properties, and examples of sources of dietary fiber. This is followed by a definition of dietary fiber. Although this should be a relatively straightforward description, there are many different viewpoints concerning the nature and physiological effects that dietary fiber should have. These will be discussed in relationship to the physiological effects of dietary fiber.

Chemical Structure

The composition and structure of dietary fiber differ from plant to plant. It is also a function of the portion of the plant that is edible and the stage of maturation and is largely composed of the cell wall (structural) components that give the plant physical stability. As such, it is made of highly interlinked sugar-based and phenolic-based polymers (hemicelluloses, pectic substances, phenolics, glycoproteins, and proteoglycans) in a matrix of amorphous structure with some enmeshed cellulose microfibrils. The cell-wall components are intimately linked together

through various linkages including protein–sugar bonds.

Polysaccharide Fiber Components

Dietary fiber comprises carbohydrate and noncarbohydrate polymers; most of these are structural components. The carbohydrate polymers are often described as nonstarch polysaccharides (NSP) to differentiate them from the (relatively) easily digested starch components of food. Figure 1 shows the proportion of the monomer constituents of fiber polysaccharides from three food categories (11 cereals, 13 fruits and 11 vegetables) and from canned mushrooms, peanuts, and baked white beans. As can be seen, arabinose is a major NSP component of cereals, peanuts, and beans. Xylose is present in large amounts only in cereals. Pectic substances (uronic acids) represent a substantial part of fruit, vegetable, peanut, and bean NSP. Mushroom NSP is formed mostly of glucose residues. These results were based on the analysis of composites made of up to 20 individual foods purchased over a 30-month period using the Englyst gas–liquid chromatography method. A more recent version of this method would have given a higher proportion of xylose relative to glucose.

The different monomeric residues of Figure 1 are the basic units that form the major NSP macromolecular constituents shown in the upper part of Table 1. Cellulose and β-glucans are generally unbranched polymers containing mostly glucose residues. The β-glucans have mixed β-1,3- and β-1,4-inter residue linkages and are a constituent of dietary fiber from barley and oats. The glucose residues of cellulose are joined by β-1,4-linkages. In addition to their resistance to the enzymes of the human digestive tract, these linkages allow greater inter- and intrapolymer hydrogen bonding than do the α-1,4-linkages of starch. This allows the formation of tightly condensed crystalline regions within the cellulose microfibrils. Cellulose includes structurally amorphous regions where the presence of other sugars can be found. The final cellulose structure is a function of the glucose and nonglucose content: the degree of cellulose crystallization is inversely proportional to the nonglucose residue content. Cellulose is a minor fraction of total cereal dietary fiber but is a major fraction of dietary fiber in other foods. The proportion of cellulose in the dietary fiber of a food is not reflected by the glucose content of the NSP fraction, since glucose is also a major component of other fractions such as β-glucans and hemicelluloses.

Xylose is a part of the primary chain of hemicelluloses and gums, and the secondary chain of gums and pectin. Arabinose is in the primary chain of gums and the secondary chain of hemicelluloses and pectin. Hemicelluloses constitute a major fraction of dietary fiber; this fraction is largely made of arabinose and xylose in cereals and of xylose and glucose in fruits and vegetables (Table 1). Pectic substances are prevalent in citrus fruits. They are also present in vegetables, legumes, and cereals in small amounts (Table 1). Other polysaccharide constituents are mainly represented by galactose, or mannose in bananas. Nonstructural NSPs represent a small portion of dietary fiber. The monomer NSP composition is of limited usefulness in predicting the properties and functions of dietary fiber. This is because the structural architecture of dietary fiber plays a large role in many of its physiological properties, and this structure cannot be predicted by its composition. Indeed, two dietary fibers with a similar component profile (e.g., wheat

bran and corn bran) can have clearly different structures, even under optic microscopy, and can show different behaviors in the gastrointestinal tract.

Nonsaccharide Fiber Components

Minor components of dietary fiber that are not polysaccharides and, hence, not NSPs also play an important structural role. Table 1 shows the distribution of the nonsaccharidic polymers that are intimately associated with dietary fiber structure. These polymers include glycoproteins (fruits, vegetables, and legumes), protein (cereals), phenolic esters (cereals), and lignin (lignified tissues of fruits, vegetables, and cereals). Lignin is of special interest because of its role in slowing down the fermentation of dietary fiber. It is a complex group of phenyl-propane polymers formed by the condensation of aromatic alcohols and is especially important in conferring structural stability. As such, highly lignified tissues are found in the stems of plants such as trees and bushes as well as in the stalks of cereals. Lignification occurs at the expense of water and pectin as cells differentiate and mature. This increases cell-wall rigidity in critical areas. Since edible plant tissues are consumed when relatively immature, their cells are largely undifferentiated and, largely, unlignified. Wheat bran and the small seeds covering strawberries are examples of lignified tissues. In most fruits and vegetables, lignin represents only a small part of dietary fiber, although it can be as high as 4% of dry matter in mature pears.

Cutin, waxes, or suberin may also be present in some tissues. These compounds are mixtures of lipids, proteins, and carbohydrates that form the waterproof covering and cuticle on the outer cell wall of plants. They are especially resistant to digestion and fermentation. As such, they impair the digestibility of other cell-wall components and are usually found in the feces.

Structure

Models of primary cell walls of plants were often obtained from nonfood material such as wood and tobacco. Because the cell-wall material forms a large part of these plants, the models provide a wealth of information on the interactions between cell wall components such as carbohydrates and lignin as well as protein and carbohydrates. More recent reports have provided some structural information on the cell walls of plant foods. These reports have shown that, in carrots, protein–protein or protein–polysaccharide linkages may contribute to the formation of a rigid, inextensible cell wall. Other data have shown that protein may form up to 10% of cell walls in immature plants and appears to be important for structural cohesion. The major part of the flesh of fruits and vegetables contains undifferentiated types of cell wall that have significant amounts of highly branched hemicellulosic types of polysaccharides. The cellulose content is usually low, and cellulose is laid down in a more oriented arrangement in the matrix. This may reflect stresses on the plant. The cell walls are often rich in pectic substances and contain approximately 10% protein, as described above. These cell walls are thin and elastic with cell form maintained by osmotic pressure.

In contrast, the outer layers of many seeds and nuts contain thick lignified cell walls that are difficult to break. These serve as mechanical protection to the seed within and as a vapor barrier to prevent desiccation.

Physical Properties

Soluble and Insoluble Dietary Fiber

It is possible to separate total dietary fiber into soluble and insoluble components based on solubility in water, but quantifying the amount of soluble fiber remains problematic. This is because the conditions utilized to measure the proportion of soluble fiber differ among laboratories (e.g., time, temperature, pH, and type of buffer; (see Definition section). It should be noted that the distinction between soluble and insoluble fibers is somewhat artificial, since it is difficult to predict the actual fiber solubility in the gastrointestinal tract.

For many years, it was thought that soluble fiber was not commonly found in foods. Reports on pectin, guar, legume fiber, and oat bran appeared in the early 1960s, and currently, it is estimated that about a third of the daily total dietary fiber intake is soluble fiber. Pectic polyuronides are the major soluble dietary fiber components of vegetables and fruits, but the exact composition varies from plant to plant. When measuring dietary fiber, one must also take into account the method of food preparation because the soluble fiber content of a fiber source is influenced by the method of food preparation. For example, some polyuronides are susceptible to depolymerization at the high temperatures used to cook the foods. Similarly, some insoluble fiber is susceptible to depolymerization at higher temperatures and may be found in the soluble fiber fraction.

In addition to the distinction between soluble and insoluble fiber, viscosity may also be an important fiber characteristic. This is because viscous fibers modestly lower blood cholesterol and triacylglyceride concentrations as well as attenuate the postprandial glucose response. It is thought that the increased viscosity of the intestinal lumen reduces the rate of diffusion of glucose, cholesterol, and triacylglycerides

to their respective receptors along the intestinal wall reducing absorption. The results of a recent meta-analysis using several different clinical studies showed a statistically significant lowering of plasma triacylglycerides and cholesterol in subjects fed for at least 14 days with a diet supplemented with oats, psyllium, pectin or guar gum, but the effect was modest: a decrease of approximately 1 mg per deciliter per gram of soluble fiber was observed. If we consider that an individual with moderately higher blood cholesterol has a total serum cholesterol value of approximately 300 mg dl^{-1}, the change brought about from consumption of viscous, soluble fibers is on the order of 0.3%. Considering that oat bran contains about 20% fiber by weight and only half of this is soluble, one can calculate that 10 g of oat bran per day is needed for each 0.3% change in total cholesterol.

Insoluble dietary fiber is, by definition, the fraction of total dietary fiber (TDF) that is not soluble in hot buffer solution. However, the measured proportion of insoluble fiber can vary depending on the dietary fiber methodology. Insoluble dietary fiber consists primarily of hemicellulose, cellulose, and lignin (*See* **Dietary Fiber**: Determination). It is often incorrectly believed that insoluble fiber is not fermented to any great extent by the bacteria present in the large bowel. However, actual measurements of fiber fermentability have shown that a significant proportion of insoluble dietary fiber is fermented. This is true even for wheat bran, which has a relatively lower insoluble fiber fermentability of between 30 and 40% (approximately 90% of the wheat bran TDF is insoluble dietary fiber). The fermentability of oat bran is even greater – up to 80% of the insoluble fiber (approximately half of the TDF) is fermented in the human large intestine. The degree of fermentability is a property unique to each dietary fiber and depends largely on the nature and the structural arrangement of the fiber components, and also on other physical characteristics such as particle size. For example, the structure of coarse wheat bran favors a high water-holding capacity (see below) and a slow rate of fermentation. This permits the microtrapping of slowly released fermentation gasses, increasing fecal bulk and stimulating defecation.

Water-holding Capacity

Dietary fiber holds water by adsorption and absorption. Some water is also retained outside the fiber matrix (free water). The particle size, chemical composition, and structure of dietary fiber influence the water-holding capacity. The *in vitro* water-holding capacity cannot be used to predict the impact of highly fermentable fiber on colonic function.

Table 2 Effect of grinding on the properties of wheat bran insoluble fiber[a]

Mesh sieve	*Aperture*[b] *(μm)*	*MPS (μm)*[c]	*WHC*[d]	*Glycocholate binding*[e]

[d]WHC, water-holding capacity, grams of water per gram of insoluble fiber, using the centrifugation method: mean ± SEM of three measurements.
[e]Grams of glycocholate bound per 0.2 g of insoluble fiber; mean ± SEM of four measurements.

Although lettuce fiber isolates retain much water, the water-holding capacity expressed in grams of water held by fiber per gram of edible portion of food has been found to be higher for wheat bran fiber (4.5 g) and carrot fiber (2.1 g) than for that of lettuce and various other foods (0.3–1.3 g). The water-holding capacity of fiber from the brans of ready-to-eat breakfast cereals is positively correlated ($r \geq 0.85$, $P < 0.05$) with its mean particle size (MPS): the water-holding capacity of 160-μm MPS wheat bran fiber is 59% of that of 800-μm MPS wheat bran fiber (Table 2). A large portion of the water held by wheat bran fiber appears to be free water.

The water-holding capacity has a significant effect on fecal output and stool hardness, as discussed above. These factors are important physiological effects of wheat bran and contribute significantly to its laxative effects.

Bile Salt Binding and Serum Cholesterol Reduction

There is considerable interest in the cholesterol-reducing properties of dietary fiber. This is because the influence of serum cholesterol (low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol, in particular) on cardiovascular disease is considerable. Three different mechanisms have been proposed to account for the serum cholesterol-reducing properties of dietary fiber. As discussed above, a certain soluble viscous fiber may modestly lower cholesterol by increasing luminal viscosity and preventing cholesterol (re)absorption. Acetic and propionic acids, produced by the fermentation of dietary fibers in the gut, are thought to inhibit liver cholesterol synthesis at the metabolic level. Dietary fibers also have the ability to bind cholesterol directly: deconjugated bile salts are bound to pectic substances by hydrogen bonding, and lignin appears to bind bile salts through hydrophobic interactions. The actual

in vivo mechanism is unknown, and it is likely that different fibers operate through different combinations of all three mechanisms to influence blood cholesterol levels.

In vitro evidence suggests that the physical form of the fiber may also play an important role in binding bile salts. In commonly ingested ready-to-eat cereals, glycocholate ($r = 0.90$, $P < 0.001$) and taurocholate ($r = 0.86$, $P < 0.05$) binding have been positively correlated with the MPS of the neutral detergent fiber (NDF; see Determination). Reducing the particle size of wheat bran NDF from 800 to 160 μm reduces its glycocholate binding by 19% (Table 2). The bile salt binding capacity of fiber isolates, although method-dependent, may reflect events in the terminal small intestine. Purified fiber fractions may be poor (cellulose) or strong (lignin) binders. Some rice brans appear to have a high capacity to bind bile salts.

Human cholesterol-lowering studies have linked the consumption of dietary fiber with lower total plasma cholesterol and increased LDL/HDL ratios in addition to reductions in serum triglycerides. Studies such as these have suggested that cardiovascular risk may be reduced by consuming particular types of foods high in dietary fiber, most notably whole cereal grains. However, it should be noted that coronary heart disease (CHD) is a complex disease and is affected by many factors. For example, the reduction in CHD observed in a recent study was larger than would be expected from the beneficial effects of soluble dietary fiber on serum cholesterol levels only. Thus, reductions in CHD are likely to be the result of many factors, one of which is total dietary fiber intake.

Cation-exchange Capacity

Cation exchange is partly dependent on the presence of uronic acid in the nonesterified form. The preparation of the fiber material may decrease the number of nonesterified carboxyl groups and the apparent cation exchange capacity. Wheat bran contains little uronic acid, and its cation exchange capacity is mainly due to diffusion within the dietary fiber network. The cation exchange capacity of fiber from different sources is difficult to compare, unless it is expressed per edible portion. According to the affinity of minerals for carboxylic acid groups, cabbage and coarse wheat bran show a high cation-exchange capacity compared with pectin.

There has been some concern that the ability of dietary fiber to bind minerals (as measured *in vitro*) may lead to mineral deficiencies in individuals consuming high-fiber diets. In North American diets, calculations show that mineral intakes far exceed the potential binding capacity of dietary fiber so that no need for concern arises. In addition, minerals that are bound to fibers or that are trapped in the (as yet, undigested) cell-wall matrix may not be absorbed in the small intestine but could be partially released and absorbed in the colon when the fiber is degraded by bacteria. Absorption of minerals in the colon has been suggested as a mechanism for accounting for increased mineral absorption in rats fed fructooligosaccharides. This may explain why cation adsorption has not been consistently related to mineral bioavailability. However, wheat bran fibers can permanently bind heavy metal ions to decrease their toxicity.

Viscosity and Gelling Properties

As mentioned above, certain soluble fibers, such as oat β-D-glucans, are viscous when dissolved in water, while others, such as pectins, show gelling properties. These fibers influence gastric emptying and absorption rates in the small intestine. Direct measurement of the viscosity produced by concentrations of fiber likely to be used in diets has shown little effect of low methoxy pectin, a slight increase with wheat bran, and a significant increase with high methoxy pectin. Some of the nonstructural dietary fiber components can also increase viscosity.

Microbial Degradation (Fermentability)

Most dietary fiber remains undegraded until it reaches the large intestine, where the extent of fermentation depends on the source as well as several other factors, including the physical structure of the fiber, the presence of specific components in the fiber matrix, the nitrogen source, bacterial adaptation, and transit time. It is generally accepted that soluble fiber is almost completely fermented in the large intestine, but unfortunately, it is also generally believed that insoluble fiber is not fermented. Actually, both insoluble and soluble fiber are extensively fermented. On average, 70–80% of the total dietary fiber from mixed diets (e.g., fruits, vegetables, legumes, and most cereals) is degraded by colonic bacteria. Since insoluble dietary fiber is the major dietary fiber fraction, representing approximately two-thirds of total dietary fiber in Western diets, this means that insoluble fiber is highly fermented. Indeed, as indicated above, 70–80% of the insoluble fiber from oat bran and up to 40% of the insoluble dietary fiber from wheat bran are fermented.

There is some indication that fermentability depends on particle size, with small particle sizes being more readily fermented, but this has not been consistently reported, and the effect appears modest. In rats fed purified diets containing 15% hard red wheat bran, NDF fermentability was largely unchanged (34–36%) when the MPS varied from 1275

to 394 μm. Similar trends were observed when American Association of Cereal Chemists soft and hard wheat brans were fed at various MPS. In these experiments, 37.3–37.6% and 30.0–32.8% of the NDF was fermented, respectively.

Interaction between Structure and Physiology

Food Processing

The physicochemical properties of dietary fiber *per se* are dependent on the chemical composition and the structural characteristics of the fiber. However, as noted above, knowing the former does not allow one to predict the latter. When considering the potential *in vivo* effect of dietary fiber, one must also take food-processing practices into consideration. Many different types of food processing practices are currently employed. Foods can be boiled, canned, frozen, blanched, parboiled, extruded, adiabatically extruded, and milled. All processes can have an effect on dietary fiber content, as measured by current methodologies. For example, heat treatment can break glycosidic linkages in dietary fiber polysaccharides. This can solubilize some of the insoluble fiber as well as reduce the TDF content if the polymers are broken down into small molecular mass fragments. Heat treatment can also reduce the overall length of the polysaccharide chains to lower viscosity and the water-holding capacity of the fiber. The pentosans in dietary fiber can react with amino acids such as lysine (Maillard reaction) and form new polymers that do not behave physiologically like dietary fiber. The boiling of vegetables increases the apparent TDF content, but this seems to be due to the loss of nonfiber components to the water.

It is often difficult to predict before hand the effect of a food-processing method on TDF and the distribution between insoluble and soluble fractions. For example, extrusion cooking of some cereal brans apparently increases its water-holding capacity *in vitro*, although this does not translate into a change in fecal water holding capacity *in vivo*. Extrusion cooking of wheat bran causes small decreases in TDF and insoluble dietary fiber but also gives rise to small increases in soluble dietary fiber. Processing of rice (abrasion or parboiling) removes the seed coat and the majority of the dietary fiber. Some collapsing of the fiber structure also occurs during food preparation and/or mastication due to the reduction of particle size, and the fiber structure of sources such as spinach may be modified by cooking.

Milling is known to significantly affect TDF fermentation in the human colon. Cereal grains have a tough outer seed coat that would be completely resistant to digestion if the cereals were not milled prior to consumption. After milling, the thin-walled dietary fiber structures from the endosperm are partly disrupted and, thus, easily broken during fermentation. Milling, therefore, makes the endosperm accessible to the digestive enzymes in the upper digestive tract but also makes the dietary fiber more accessible to colonic bacteria. However, milling can also negatively affect the physiological properties of the dietary fiber in grains. While coarse grinding and adequate mastication appear to be sufficient for digestion of cereals, fine grinding disrupts much of the cell-wall architecture, and further milling can even interfere with its determination by gravimetric methods. Table 3 shows the effect of milling on the dry bulk volume of wheat bran, as measured in a volumetric cylinder. The volume of the coarse bran was reduced from 5 ml g^{-1} to less than 2 ml after grinding in a M5 Wiley mill using a 0.5-mm screen. Fiber from different sources ground under the same conditions may behave differently during milling, so that their resulting particle sizes may be different.

Table 3 Effect of grinding on dry bulk of wheat brans (ml g^{-1}): duplicate measurements

Sieve aperture [a]	*Bran A* [b]	*Bran B*	*Bran C*	*Bran D*
As is	3.1	3.4	5.1	3.5
2.0 mm (10 mesh)	2.7	2.4	2.8	2.1
1.0 mm (18 mesh)	2.2	2.1	2.4	2.0
0.5 mm (35 mesh)	1.8	1.8	1.9	1.7

[a]Using a MS Wiley mill. Mesh sieve equivalence is indicated in parentheses.
[b]Bran A was American Association of Cereal Chemists-certified soft white wheat bran; brans B–D were soft or hard wheat brans from other sources.

As discussed above, the particle size of unfermented wheat bran fiber may be related to colonic function and fecal characteristics in humans and laboratory animals. Finely ground cellulose or even wheat bran, for example, may have a constipating effect, whereas coarsely ground wheat bran prevents constipation. The influence of particle size on fecal bulking has been measured directly in rats. When rats were fed diets containing 12% hard wheat bran, the fecal wet density was 0.796 ± 0.010 (mean $\pm$ SEM, $n = 12$) in the coarse bran group (geometric MPS: 850 μm) but increased to 0.888 ± 0.013 in the fine bran group (MPS = 308 μm). This increased density was not due to a change in fecal weight but was due to a decrease in fecal volume, paralleling the effect demonstrated for bran in Table 3. In ready-to-eat breakfast cereals, the fiber MPS has been found to vary between 350 and 2000 μm. Increased particle size normalizes gastrointestinal transit time, delays gastric

emptying, and may also affect the extent of insoluble fiber fermentation. Although dietary fiber has many positive effects on the digestive tract, excessive milling of dietary fiber to produce small particles in the range of 7–70 μm may have negative effects. Smaller particles do not exhibit the transit time normalization associated with larger bran particles, and the persorption of a small amount of very fine fiber particles may occur in some regions of the intestinal wall. Contrary to persorbed starch granules, persorbed fiber particles are not degraded in the blood and may impose an increased workload on the kidneys. Data on persorption are scarce, and much work is needed on this subject.

Studies with apples, apple purée, and apple juice have highlighted the link between the physical integrity of the cell wall and the beneficial effects of unprocessed dietary fiber, in this case, a lowering of the glycemic index of a food (the rise in blood glucose that accompanies ingestion and digestion of a carbohydrate-containing food). Only the unprocessed apple had a reduced glycemic index; the apple purée, containing the physically degraded dietary fiber was similar to apple juice in response. This demonstrates the importance of the physical encapsulation of available macronutrients within the fiber matrix. This effect has also been observed with rolled oats where higher glycemic indices were observed with more finely cut oats. Studies such as these show that the integrity of the cell wall is important in bringing about beneficial physiological effects, even in the presence of viscous, soluble fiber types (β-glucans in the cell wall; *see* section Bile Salt Binding and Serum Cholesterol Reduction).

In vitro Measurements

In vitro properties of fiber isolates have been used to estimate their potential *in vivo* effect. However, *in vitro* data should be used with caution. The measurements are influenced by the methods used to follow digestion *in vitro* as well as by the methods used to prepare the fiber. Other confounding influences are also present: the fiber residue obtained *in vitro* may have been altered by heat or chemicals or may still contain residual digestible materials. For these reasons, *in vivo* conditions generally result in a more extensive digestion than that measured *in vitro*.

Digestive Events

An important consideration when examining the physiological effect of dietary fiber is the fact that dietary fiber is concentrated and denuded only in the terminal small intestine. This means that the dietary fiber that is partially associated with digestible materials in the jejunum and duodenum may have different physical properties from those of an entirely denuded fiber matrix at the terminal ileum. In the large intestine, most of the soluble fiber and a large but variable portion of insoluble dietary fiber are degraded by the colonic microflora. As already discussed, fermentation plays an important role in mediating many of the physiological effects associated with dietary fiber.

Definition (Based on Function and Structure)

In the early 1970s, it became evident that cellulose represents only a small part of the total dietary fiber content of foods. Prior to this, there was a tendency to equate dietary fiber with cellulose because that is what was measured using the old crude fiber method. While this helped reinforce the use of the term dietary fiber (cellulose has a fibrillar structure), cellulose represents only a small part of the total dietary fiber content of foods. Thus, at that time, new methodologies were emerging, and it was clear that there was a need for a dietary fiber definition that was linked to the actual physiochemical composition of dietary fiber.

It is in this context that the dietary fiber hypothesis appeared, a few years after Cleave's hypothesis in 1956, which related refined foods and Western diseases. The dietary fiber hypothesis thus appeared as a refocusing of Cleave's original ideas, reversing the original emphasis to become: a diet high in unrefined edible plant material is protective against Western diseases of the bowel. The dietary fiber hypothesis is important in understanding the 'dietary fiber concept,' since it links botanical structure to digestive processes and health outcomes – mainly noninfective colonic diseases such as constipation, diverticular disease, irritable colon, ulcerative colitis, appendicitis, hemorrhoids, polyps, and cancer of the large bowel. It is this link to these and other health outcomes that has characterized much of the work in the dietary fiber field over the last 30 years. The first dietary fiber definition in 1972 sought to describe the plant structures and components that were responsible for mediating these health benefits: "that portion of food which is derived from the cellular walls of plants and is digested very poorly by human beings... Fibre is composed largely of cellulose, ... hemicelluloses, pentosans, pectin and lignin."

There are many different definitions of dietary fiber. However, they all include certain specific and critical aspects. First and foremost, a definition must include the fact that dietary fiber corresponds mostly to the structural material in the edible part of plant foods in the usual human diet. This has been consistently

reflected throughout decades by the inclusion of the terms 'plant cell wall' when referring to dietary fiber (Table 4). The term 'dietary fiber' itself is something of a misnomer, since dietary fiber is not fibrillar (except for cellulose). To reflect this fact, many other terms have been proposed over the years, including unavailable carbohydrate and plantix. None of these terms has succeeded in replacing 'dietary fiber.'

Another important aspect of any dietary fiber definition is that it be resistant to human digestive secretions (including enzymes) and not absorbed in the small intestine. The observation that dietary fiber increased fecal weight initially gave the impression that dietary fiber was resistant to both human digestive secretions and to bacterial digestion in the lower gut (fermentation). While it is true that dietary fiber is not digested and absorbed in the small intestine, a large proportion of dietary fiber is fermented in the colon. The extent of this fermentation is a function of several different factors (see Microbial Degradation (Fermentability) Section), meaning that the extent of fermentation cannot be use as a criterion to define dietary fiber.

Using 'resistance to endogenous digestive secretions' alone as a criterion may be confusing. For example, some dietary fiber may be partly degraded by acids in the stomach, while some small intestine-digestible material can reach the colon where bacterial fermentation occurs. In addition, a definition based on the resistance to digestibility by endogenous digestive secretions could be problematic if the material is not specified as coming from the edible part of plant foods. Indeed, such a definition could be erroneously interpreted as meaning that dietary fiber is any material resistant to *in vivo* digestion or, even as any material measured as dietary fiber by a specific dietary fiber method. Among the materials to be excluded from the dietary fiber definition are 'ruminant fiber' and the products formed during processing and/or cooking. There have been requests to include some other plant components as well as manufactured polymers, and this is a subject of much debate. Among the criteria that could be used to accept or reject a material as dietary fiber, only 'edible plant cell wall' is specific enough to allow an absolute definition. In addition, it links current dietary fiber

definitions to the original 'dietary fiber concept,' which recognized that a diet high in minimally processed edible plant foods provided many health benefits. Confusion often arises because of the overlapping characteristics and physiological effects of the different 'candidate' materials with those of a dietary fiber 'reference.' Examples of 'candidates' are polydextrose (a randomly bonded synthetic glucose polymer), inulin and fructooligosaccharides (naturally occurring glucose-fructose oligomers and polymers), and resistant starch (formed by food-processing methods and largely undigested in the small intestine). This overlapping means that it becomes virtually impossible to distinguish between fiber and nonfiber material based on resistance to digestion alone. Debates such as this started shortly after dietary fiber became popular in the 1970s. They are still ongoing, as demonstrated by the publication of a recent international survey of 147 professionals. While a complete discussion of the merits of either side is beyond the scope of this chapter, it is important to remember the origins of the dietary fiber definition and the dietary fiber hypothesis that firmly linked fiber to physiological outcome.

The definition of dietary fiber was first centered on the 'original dietary fiber concept' that linked the consumption of 'plant cell walls' in unrefined, traditional foods to positive physiological outcomes. Table 5 shows two definitions that were proposed after the turn of the millennium. These two definitions have taken the original ideas of the dietary fiber hypothesis into account as well as included a reference to some specific physiological effects in humans.

While the newer definitions of dietary fiber specifically mention the fact that dietary fiber has physiological benefits, the list is rather specific and deals primarily with effects observed with viscous fibers (lowering post-prandial serum glucose and lowering serum cholesterol) or effects brought about from partial fermentation and water holding capacity (laxation). These effects are well supported by clinical experiments with laboratory animals and with humans. However, the original dietary fiber concept related dietary fiber intake to the diseases of Western man, including heart disease, cancer and obesity. As mentioned above, the link between viscous dietary fiber and heart disease is supported in the literature through its effect on serum cholesterol and triglycerides but the link with other Western diseases has been much harder to demonstrate. It has been well established that eating patterns that favor foods high in dietary fiber and low in red meat consumption significantly reduce the risk of cancer, heart disease and obesity. However, it has been relatively difficult to isolate this effect to dietary fiber consumption *per se*. Part of the problem comes from the almost exclusive reliance on epidemiological studies to demonstrate any association. There are several reasons why epidemiological studies are generally favored. First, these studies provide data on free-living humans rather than in-bred laboratory animals. Second, these studies follow the long-term effect of dietary fiber consumption on health outcomes. Third, the sample size can vary from a few hundred (case control studies) to many thousands of individuals (prospective cohort studies). This gives the studies good statistical power and lends weight to the conclusions. However, epidemiological studies also suffer from a number of shortcomings including: problems with assessing food intake for the past 2–3 years (case control studies), or with monitoring food intake 2–3 times over a period of 5 years and using this to predict disease outcome 15 years later (prospective cohort studies), problems that arise from the use of incomplete dietary tables to calculate dietary fiber intake, and problems arising from the use of inappropriate methods for correcting for energy intake.

The most striking conclusion from epidemiological studies is a failure to provide support for an inverse correlation between dietary fiber intake and colon cancer. This concept has long been entrenched in the literature largely because of studies with laboratory animals that have provided much data in favor of

a protective effect of dietary fiber. The animal studies are supported by plausible physiological and biochemical mechanisms that can account for the observed results. However, the epidemiological data is inconsistent in its support for an inverse relationship between colon cancer and dietary fiber intake and clinical trials that examined the effect of diet on the re-appearance of colon polyps (colon cell growths that have a 1/20 chance of forming a cancerous tumor) found no protective effect of dietary fiber. Even though the link between adenomatous polyps and cancer is not straightforward, these studies show that more research is needed to elucidate the relationship between the known physiological benefits of dietary fiber and cancer.

Sources of Dietary Fiber

The total dietary fiber content of a food depends on many factors, including (1) the plant variety, (2) the stage of maturity when harvested, (3) the plant growing conditions, and (4) the method of food preparation. Although not all the methodological issues have been completely resolved with respect to measuring dietary fiber, there is now general consensus on the total dietary fiber content for a majority of foods.

The names of 49 common dietary fiber sources are provided in Table 6. The foods are classified according to their TDF content expressed on an 'as is' basis. Since some methodological variability is inevitable, the letters 'E,' 'M,' and 'P' in the right-hand column designate which methods would give TDF values in the range shown. Other methods not included in the comparison are likely to agree with these values. The letter 'E' refers to NSP as measured by the Englyst GLC procedure and includes a lignin value measured separately with potassium permanganate. The letter 'M' refers to the Mongeau rapid method, and the letter 'P' refers to the Prosky method. The last two methods are gravimetric and include lignin in the final determination. Table 6 shows a considerable agreement between methodologies: 33 of 49 foods are designated 'EMP,' meaning that all three methods give similar values. In addition, three foods are designated 'MP' and 13 foods as 'M' only because sample size limitations precluded measurement with other methods. The TDF values are based on winter and summer collections of up to 20 individual foods over 30 months in different locations.

Most fruits and vegetables contain low amounts of dietary fiber (1.0–2.2% TDF) on an 'as is' basis. Legumes contain intermediate amounts of dietary fiber (around 4% TDF), and cereals contain between 1–2.2% TDF (corn kernels) and 15.5–15.8% TDF (oat bran). The dietary fiber content of foods is greatly influenced by the moisture content. Thus, cereal TDF values are high because these foods contain little moisture (up to 10% at most), whereas fruits and vegetables contain 80–90% moisture on an 'as is' basis. The values of Table 6 are reported as a percentage of weight, but when calculating dietary fiber intake, it is important to factor in the serving size (30 g for breakfast cereals, 50 g for lettuce and raisins, and 125 g for vegetables and fruits). For example, 1 serving of Bran flakes will provide approximately 4 g of dietary fiber, 1 serving of lettuce will provide 0.35 g of TDF, 1 serving of raisins will provide about 1.8 g TDF, and 1 serving of corn will provide about 2 g of TDF.

Table 6 Sources of dietary fiber

TDF[a]	*Foods*	*Methods*[b]
0.1–0.5	White rice, cooked	M
	Orange juice from concentrate	M
0.6–0.9	Lettuce	M
	Cucumbers	EMP
	Pineapple, melons (cantaloupe)	EMP

Glossary

- Digestive secretions: enzymes and other secretions produced by the digestive organs (e.g., salivary glands and exocrine pancreas, stomach and small intestinal mucosa, and liver); this excludes enzymes produced by intestinal bacteria.
- Digestibility: degradation of ingested food components by endogenous digestive secretions in the upper gastrointestinal tract.
- Fermentability: degradation of undigested food components (e.g., dietary fiber) by the intestinal microflora, mostly in the large intestine.
- Pectic substances: mixtures of acidic and neutral polysaccharides that can be extracted with water from plant tissues and are rich in galacturonic acid; together with hemicelluloses, they form the cell wall matrix in which are enmeshed cellulose fibers.
- Persorption: the paracellular passage of small amounts of solid food components from the lumen of the intestine into the lymphatic and blood circulation, this being without structural changes.

Determination

R Mongeau, Ottawa, Aylmer (Quèbec), Canada
S P J Brooks, Ottawa, Canada

Introduction

This chapter presents a brief overview and comparison of commonly utilized methods for quantifying dietary fiber in food. There are, fundamentally, only two types of methods. Both rely on the removal of nonfiber components by a combination of physical, chemical, and enzymatic procedures prior to measurement of dietary fiber. The gravimetric methods measure dietary fiber by weighing the residue and the gas-liquid chromatographic (GLC) methods measure dietary fiber by hydrolyzing a treated sample with acid to sugar monomers prior to quantification

by GLC. Although, on the surface, both types of methods appear similar, there are fundamental practical differences that have come about because of variations in the individual method steps and differences in the choice of reagents and enzymes. These practical differences have significant consequences since they determine the final composition of dietary fiber as measured by each method.

Procedures have been described for isolating and analyzing dietary fiber in specific foods as well as analyzing carbohydrate polymers that are not digested in the small intestine and are not identified as dietary fiber by the current Association of Official Analytical Chemists (AOAC) methods. The present article, however, will focus on practical methods that are applicable to the routine analysis of a wide range of foods. Most total dietary fiber (TDF) methods also allow for the quantification of different fiber fractions such as soluble fiber, insoluble fiber, hemicelluloses, cellulose, lignin, etc. In this article, only the methods that measure TDF are reviewed. This is partly because of space limitations and partly because the individual fiber components have not yet been positively associated with human physiological effects. For example, soluble and insoluble fiber can be readily measured but these designations have little physiological meaning since the digestive properties and physiological benefits associated with some soluble fiber can be found in some insoluble fibers and the physiological benefits associated with insoluble fibers are also found with some soluble fibers. In addition, some processing techniques can also partly depolymerize insoluble fiber that may then be found in the soluble fiber fraction.

The early work of Van Soest focused on measuring ruminant fiber (mainly hemicellulose, cellulose, and lignin) but these procedures could not be used to measure TDF because they would have underestimated the TDF content of human foods by missing a significant proportion of the soluble dietary fiber. All the modern methods incorporate steps to measure soluble fiber. This is important since it can represent a significant proportion of the TDF of a food. The chemical complexity and physical variability of the dietary fiber fraction in various foodstuffs as well as the various food-processing techniques have contributed to the difficulties encountered in devising adequate dietary fiber methods. Many of the present-day TDF procedures are based on the pioneering work of Southgate.

Ideal reference standards do not exist for dietary fiber analysis. Purified fiber components and unpurified standardized 'reference samples' are both used as standards of analysis, but the former group rarely represents the complex dietary fiber matrix found in foods and the latter group remains variable in composition, structure, and properties.

Historical Perspectives on Dietary Fiber Values

Several different measures of dietary fiber and dietary fiber fractions have been reported for foods over the last 150 years. It is important to put these values into some sort of context to understand the differences between these measurements and the implications for human dietary fiber research.

The crude fiber method was standardized in the late 19th century in Germany. It was initially developed to analyze ruminant feeds and silage. It is a highly empirical method that uses sequential extractions with hot dilute acid and alkali. The crude fiber residue contains no soluble fiber and retains only about 15% of the total hemicelluloses, 50–100% cellulose, and 10–50% lignin. The variability in the method and the variable losses of various dietary fiber fractions mean that crude fiber values are of little value in human nutrition. (*See* **Cellulose**; **Hemicelluloses**; **Lignin**.)

Acid detergent fiber (ADF) represented the first method that reproducibly maintained specific dietary fiber fractions. ADF is obtained by refluxing in $1\,\mathrm{N\ mol\,l^{-1}}$ sulfuric acid containing cetylmethylammonium bromide detergent followed by filtering and washing. This fraction contains mostly cellulose and lignin.

Neutral detergent fiber (NDF) represents the insoluble fraction of TDF. It is obtained by refluxing in a solution of sodium lauryl sulfate followed by filtration and washing. NDF includes most of the cell wall material but excludes the soluble β-glucans and soluble hemicelluloses. It includes the ADF fraction as well as the insoluble hemicelluloses. It thus underestimates TDF because it does not measure soluble dietary fiber.

In some older tables, TDF values are reported as the sum of NDF and pectin (estimated TDF) but, as shown in Figure 1, this value is not always accurate. Figure 1 also presents the relationship between insoluble dietary fiber (essentially NDF but using porcine pancreatic α-amylase to remove starch; see below) and TDF (as determined by the rapid HPB (Health Protection Branch) method; see below) determined for the same foods. The insoluble dietary fiber underestimates the TDF value by approximately 40% but this is not constant. The differences between TDF and insoluble dietary fiber represent actual differences measured on the same food sample but the differences between the estimated TDF and the actual TDF values were performed at different times with

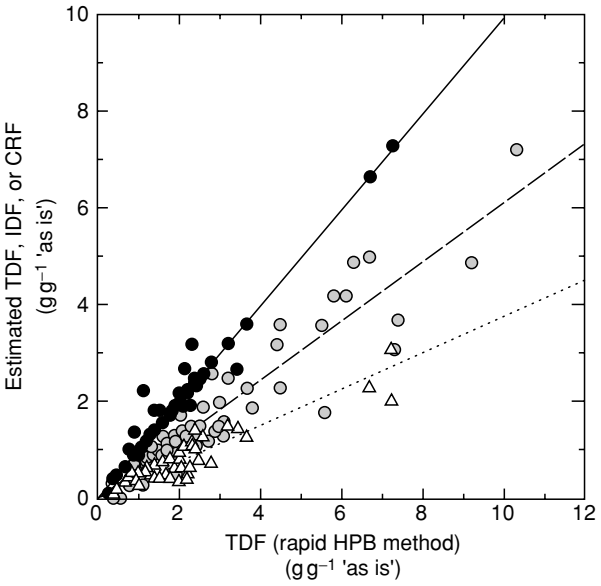

Figure 1 Relationship between crude fiber (CRF; white triangles), insoluble fiber (IDF; gray circles), estimated total dietary fiber (TDF: total of pectin + neutral detergent fiber (NDF), black circles), and TDF values for different types of foods. The TDF and CRF values are from the Canadian Nutrient File (Health Canada 1997) and Mongeau *et al*. (1989). TDF and IDF values were determined by the rapid HPB method (AOAC 992.16, see text). The solid line represents a 1:1 correspondence. The dashed line (IDF) and the dotted line (CRF) are regression lines with the intercept fixed at the origin. Insoluble dietary fiber is essentially NDF but includes a treatment with porcine pancreatic α-amylase. The NDF + pectin values are ultimately from the USDA Nutrient Database (1999).

different procedures and using different food samples so that procedural variations may account for some of the differences. For example, it is known that some previously determined NDF values were measured after incubation at lower (suboptimal) temperatures that may have given higher and more variable values due to incomplete starch digestion.

In addition to the relationships described above, Figure 1 shows the relationship between crude fiber (CRF) and TDF (as determined by the rapid HPB method) for foods from the Canadian Nutrient File. Like the insoluble dietary fiber values, the CRF values significantly underestimate the TDF values; however, in this case, the variability is largely due to the CRF method. Figure 1 shows that no consistent relationship between TDF and CRF or insoluble dietary fiber (and thus NDF). Thus, it is not possible to predict TDF values from either CRF or insoluble dietary fiber: a complete TDF measure is required.

Gravimetric Methods

Gravimetric methods use enzyme and/or chemical treatments to remove material that is digestible in the small intestine. Ideally, these treatments should mimic the digestive processes to arrive at a sample that is representative of the material entering the large intestine of humans. Because dietary fiber represents the structural components of plant cell wall material (*See* **Dietary Fiber**: Properties and Sources), the weight of the residue is corrected for the presence of noncombustible materials (such as minerals) and corrections may also be applied for components that are incompletely digested by the procedure (such as protein). The remaining weight is considered to be dietary fiber. In order to measure the remaining material gravimetrically, it must be filtered through glass crucibles of defined porosities. It is, therefore, important when preparing the sample to insure that it is not too finely ground. The use of a Wiley mill avoids these problems and minimizes particle loss during filtration. Many different gravimetric methods have been published with many variations in reagents, temperatures and incubation times. However, relatively few of these methods have been approved by the Association of Official Analytical Chemists (AOAC) after rigorous testing and interlaboratory verification. Three AOAC approved methods will be discussed in detail in this section: the rapid Health Protection Branch method (rapid HPB method), the Prosky method, and the Lee method. Before presenting these methods, we will first discuss the detergent system.

The Detergent System

When introduced in 1963, the detergent system represented a great improvement over the CRF method and it is still in use today for measuring insoluble dietary fiber. It has been widely used to measure silage and ruminant feed fiber. The system includes the NDF and the ADF procedures, which use hot detergent to remove digestible material and soluble fiber. The detergent system discriminates among the insoluble fibers – hemicelluloses, cellulose, and lignin. A chelating agent in the neutral detergent solution permits the solubilization of insoluble pectin. When NDF and ADF procedures are performed sequentially, the difference in weight between the NDF and ADF extracts is an estimation of the insoluble hemicellulose fraction. The ADF residue contains lignin, cellulose, and (if present) cutin. Lignin can be measured by gently oxidizing the ADF residue with potassium permanganate. A 72% sulfuric acid treatment hydrolyzes cellulose leaving cutin, phlobaphenes, and Maillard products.

NDF and Porcine α-Amylase

Since water-insoluble dietary fibers represent a major fraction of total dietary fiber, the NDF procedure represents a simple method that can form part of an

overall procedure for measuring total dietary fiber in human foods. Nonfiber materials such as starch, most protein, and any fiber-like artifacts remaining in the NDF residue can be efficiently removed by rapid treatment with α-amylase from porcine pancreas (A-3176, Sigma Chemicals Co., St Louis, MO); the rapid treatment consists of 5-min and 60-min incubations at 55 °C and is at least as effective as the 18-h treatment at 37 °C originally proposed by Schaller. The source of the enzyme is specified since pancreatin and other preparations of porcine pancreas α-amylase are much less efficient. Unpurified porcine α-amylase has unique amylolytic and proteolytic activities when applied after the neutral detergent extraction step, making it an ideal enzyme to use for measuring insoluble dietary fiber. (*See* **Enzymes**: Uses in Analysis; **Protein**: Determination and Characterization; **Starch**: Structure, Properties, and Determination.)

The heat-stable α-amylase from *Bacillus subtilis* has also been used to digest starch after the neutral detergent extraction step, but several potential problems arise with this enzyme. It may contain fiber-digesting enzymes that could lead to an underestimation of the cellulose and hemicellulose fractions. On the other hand, it does not completely remove the nonfiber material (such as starch), which will lead to an overestimation of the lignin and possibly the hemicellulose fractions. The final value, therefore, represents a compromise between these two competing factors. Table 1 shows that, for shredded wheat, the NDF residue obtained after treatment with *B. subtilis* α-amylase contained 30% more material than that obtained after treatment with porcine pancreas α-amylase. This residue apparently contained three times more lignin and four times more protein. Both the NDF residue and the apparent lignin content were also higher in samples of bran flakes. Other problems are apparent with the *B. subtilis* α-amylase. For example, toasting wholewheat bread increased the *B. subtilis* α-amylase-measured NDF and lignin values by two- and fivefold, respectively (Table 1), but no such differences were noted with the porcine pancreas α-amylase. The efficacy of the porcine pancreas α-amylase treatment has been verified in various foods and food products and confirmed by other researchers.

In addition to its demonstrated capabilities in avoiding artifactual increases in the estimation of various dietary fiber fractions, porcine pancreas α-amylase enzyme also facilitates rapid filtration in subsequent steps (starch and protein tend to clog the crucibles). The neutral detergent–α-amylase combination is advantageous for research analyses since the neutral detergent solution discriminates well between plant and bacterial cell walls. This is important because bacterial cell walls interfere with the fiber analysis of fecal samples.

Other modifications from the original Van Soest NDF method include the deletion of decalin, 2-ethoxy-ethanol, and sulfite (to maximize the recovery of lignin).

Rapid HPB Method

The rapid HPB method described here is the AOAC No. 992.16 method. In order to obtain a measure of the TDF in a sample, one needs only to combine the insoluble dietary fiber from the NDF + porcine pancreas α-amylase treatment with a specifically tailored method for measuring soluble fiber. In the rapid HPB method, the soluble fiber procedure was devised to maximize the recovery of soluble fiber while excluding protein and other precipitable, nonfiber materials. This latter characteristic is important if one wishes to avoid time-consuming protein determinations that are part of other procedures. The soluble fiber procedure includes a gelatinization step in acetate buffer at pH 4.5 (121 °C) followed by a treatment with heat-stable α-amylase (100 °C) to remove any starch. Starch gelatinization is important to insure complete starch hydrolysis. The soluble material is separated

from insoluble fiber by filtration and is treated at 60 °C with amyloglucosidase (to finish starch digestion by hydrolyzing branched residues), and then with protease (to hydrolyze the peptide bonds of protein). The soluble fiber is then precipitated in 80% ethanol at room temperature; the sugar and amino acid residues remain soluble in ethanol.

Acetate buffer at pH 4.5 favors the exclusion of protein and appears to prevent the degradation of fiber components that may occur at high temperatures. This does not occur as readily at the relatively higher pH values used by other TDF procedures (e.g., phosphate buffer at pH 7). The heat-processed reference standards extracted from apple and carrot, and used in some collaborative studies, may show lower TDF values due to the loss of pectin during analysis. The differences are less apparent when expressed on a 'per g fresh weight' basis. Without a method for accurately measuring all cell wall components it is difficult to provide an absolute compositional measure of the constituents of dietary fiber as measured by different methods. However, the use of differential procedures to obtain fiber fractions (ADF, NDF), coupled with sulfuric acid digestion, permanganate oxidation and total nitrogen analysis, allows an estimate of the relative contribution of several plant components to the final TDF value.

Figure 2 shows a comparison between several methods for measuring dietary fiber as well as the relative amounts of the components retained by each method. The rapid HPB method retains lignin (a structural polyphenol), the cell wall-associated protein, and a small amount of starch. The significant amount of starch retained by the Prosky method (see below) is readily apparent when TDF values are measured in legumes. Table 2 shows a comparison of four different methods for measuring TDF in green peas. The starch in the residue was estimated by subtracting the values from the total nonstarch polysaccharides (NSPs) + lignin measured by the Englyst procedure. The table also shows the effect of adding porcine pancreas α-amylase.

The method is considered 'rapid' when compared to other fiber methods, particularly when the Fibertec E (for soluble fiber) and the Fibertec I (for insoluble fiber) are used. For example, the maximum number of duplicate determinations using the Prosky TDF method is 20 per week, while 44 duplicate TDF determinations per week are possible using the rapid HPB method. This evaluation takes into account the time required for preparing the reagents and performing the analysis, but not the time required for preparing the samples (freeze-drying, grinding).

Both separate and sequential rapid HPB methods are available and Table 3 presents a comparison between them. In the sequential method, the insoluble residue generated during the soluble fiber determination is treated with neutral detergent and porcine α-amylase yielding the insoluble fiber residue. Thus, a single sample generates both insoluble and soluble fiber measurements to give the TDF value. The separate method requires two samples for analysis. Using a

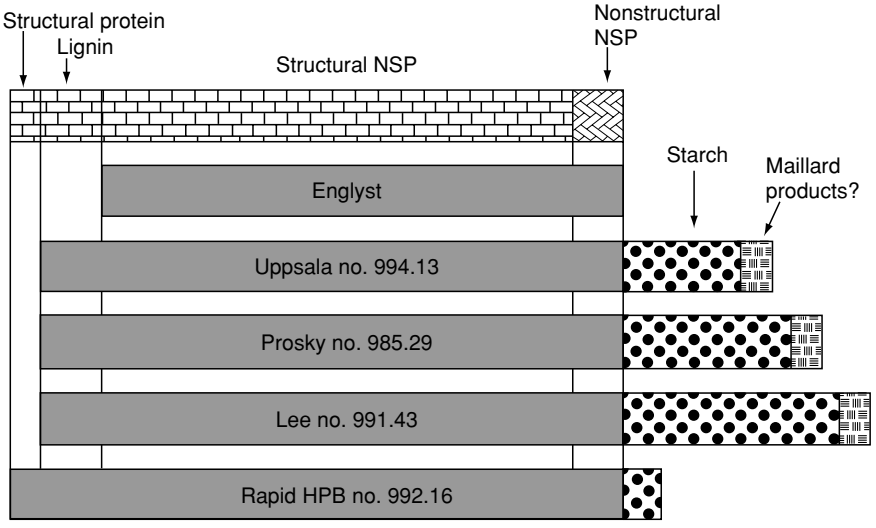

Figure 2 Material measured as dietary fiber by unmodified methods for all food categories. The surface area of the box is proportional to its total dietary fiber (TDF) value. It shows whether the method includes lignin and structural fiber protein or if it excludes starch and Maillard products. The cell wall material corresponds to the structural nonstarch polysaccharides (NSP), lignin, and structural protein. The larger amounts of starch retained by the Theander, Prosky, and Lee methods are most evident when measuring TDF in legumes. AOAC numbers for each procedure are indicated. [b]NSP as determined by the Englyst GLC method.
[c]TDF as determined by the Prosky method and the rapid separate and sequential methods.
[d]The separate method required analyzing two separate samples to obtain the TDF value.

single sample to measure TDF gives a more accurate and reliable measurement because it eliminates potential cross-contamination that could give rise to falsely high TDF readings. For example, if the insoluble fiber fraction contains some small amount of soluble fiber, it will be counted twice in the final value (once in the insoluble fraction and once in the soluble fraction). The far right column of Table 3 shows that the TDF values are comparable when measured by either procedure and demonstrates the variability in the procedure.

In a comparison of 28 foods from various categories, the rapid sequential HPB method agreed well with the Prosky TDF method (slope = 0.99, intercept = −0.11, $r^2 = 0.985$) and with the Englyst GLC method (slope = 1.03, intercept = 0.15, $r^2 = 0.989$). For comparison with the Englyst method, it was necessary to measure lignin in each food and add its weight to the total NSP (obtained from the Englyst analysis). This gave a TDF value that was comparable to that measured gravimetrically. The regression parameters indicate that the rapid HPB method and the Prosky TDF method retain similar material in the final fraction (Figure 2). However, the negative intercept shows that the Prosky TDF method gives a higher value than the rapid HPB method when measuring foods containing low amounts of fiber. (*See* **Carbohydrates**: Classification and Properties; **Chromatography**: Gas Chromatography.)

Prosky, Lee, and Asp Methods

The Prosky TDF method has also been referred to as the AOAC method since 1985. The Prosky, Lee, and Asp methods are similar but differ in the sources and types of enzymes as well as in the type and pH value of the buffers. The TDF values from all three methods are comparable (see Table 2 for a comparison between the Prosky and Lee methods for green peas). In the Prosky and Lee TDF methods, duplicate samples are treated with α-amylase, protease, and amyloglucosidase to remove digestible material. Four volumes of 95% ethanol is then added and the precipitate filtered through celite C-211 (Fisher Scientific, Mississauga, Ontario, Canada). The residue

Table 4 Polysaccharide and unidentified material in the Prosky total dietary fiber (TDF) method for selected food groups

	Prosky TDF method residue (g 100 g^{-1} dry matter)		
Food	*Starch*	*Total polysaccharides*	*Unidentified material*
Bread	1.0	5.1	0.8
Other cereals	0.3	3.8	1.0
Green vegetables	1.5	25.6	4.6
Other vegetables	1.8	10.2	7.5
Canned vegetables	2.3	12.9	4.0
Fresh fruit	0.2	8.6	3.5
Fruit products	0.1	2.5	1.5
Nuts	0.4	6.7	2.5

Adapted from Englyst *et al*. (1995): see Further Reading. Values represent TDF measurements after correction for ash and 'protein' (N × 6.25). Part of the unidentified material represents lignin but the values are too large to be accounted for as lignin only.

contains a substantial amount of nitrogen requiring a total nitrogen analysis (N) and subsequent back-calculation to correct for protein content (N content × 6.25). One of the duplicates is also analyzed for ash as in other gravimetric analyses and this, too, is subtracted from the residue weight. It is proposed that the use of this protein conversion factor leads to overestimation of dietary fiber (Table 4). The additional protein determination step prevents this method from being considered rapid. As pointed out above and in Tables 3 and 4, the final insoluble dietary fiber residue can retain significant amounts of starch. In a simplified version of the Prosky method, the protease step is skipped since protein is measured in the final residue. This means that a larger amount of protein is subtracted as compared with the original Prosky procedure and this may contribute to some variability. The nature of the celite used in different laboratories has also been considered as a source of variability. Other modifications have also been proposed to improve the precision of the Prosky method. The method comparisons in Tables 2 and 3 were confined to the results obtained with the original version of the Prosky method.

Complete Polysaccharidic Components (GLC Methods)

Southgate published the original TDF method that required the hydrolysis of fiber into its individual polysaccharidic components. In Southgate's method, TDF represented NSPs plus lignin but the method also provided values for hemicellulose and cellulose content. The method used 85% (v/v) alcohol to precipitate soluble starch residues followed by gelatinization and starch digestion with an appropriate enzyme. The original enzyme used by Southgate (takadiastase) had both amylolytic and proteolytic activities. However, in the 1970s, this enzyme became unavailable and other enzymes were used as replacements. It is apparent that some of these replacement enzymes are often less effective (Tables 2 and 3) but the α-amylase from porcine pancreas appears to be adequate. The original Southgate method measured the NSPs colorimetrically but now more specific methods are available such as GLC (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

The more modern chemical methods use a combination of enzyme and/or chemical treatments to remove digestible material. The residue is then hydrolyzed by acid prior to measurement of the sugar content. The acid treatment needs to be severe enough to assure complete hydrolysis but mild enough to prevent monomer degradation. The neutral fiber polysaccharidic constituents are measured chemically, usually by GLC after derivitization to a measurable form (e.g., by forming alditol acetates). Chemical derivitization is not required when high-performance liquid chromatography (HPLC) is used to measure the residue concentration. Acidic sugars (uronic acids) are measured colorimetrically. The total NSP content is obtained by appropriate calculations and TDF is calculated as the sum of NSPs + lignin. The main GLC methods have been published by Anderson, Englyst, and Theander and their coworkers. Marlett uses a modified Uppsala method. The GLC methods are different in several aspects, including the starch gelatinization step, enzyme treatments, and conditions of acid hydrolysis. This explains why the methods may be in agreement for some foods, but not for others. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Englyst Method

Like all GLC methods, the Englyst method measures NSPs (neutral sugars + uronic acids). However, unlike other methods, the Englyst method is completely applicable to processed foods because it makes use of dimethyl sulfoxide (DMSO) during the gelatinization step to disperse the starch completely. This is followed by treatment with a heat-stable α-amylase and by a mixture of pullulanase-pancreatin

in acetate buffer at pH 5.2. This treatment completely removes all the starch, leaving only the nonstarch polypeptides (Figure 2). The total insoluble and soluble NSPs are then precipitated in 80% ethanol and collected by centrifugation prior to hydrolysis with sulfuric acid. Neutral sugar residues are measured by GLC as alditol acetates and uronic acids are measured colorimetrically. According to Englyst and Cummings, the method can be performed in approximately the same amount of time as the Prosky TDF method. However, the GLC instrument must be equipped with an autosampler for the comparison to be valid. A rapid version of the Englyst method also exists with the sugar components measured colorimetrically but this does not represent a substantial reduction in assay time when compared to the GLC method with an autosampler.

The Englyst method is the only dietary fiber method that does not include lignin. The role of noncarbohydrate components (which include lignin) in *in vivo* fiber digestion may be significant (*See* **Dietary Fiber**: Properties and Sources). There is some debate over whether some of the starch and structural protein should be considered as dietary fiber. (*See* **Dietary Fiber**: Properties and Sources). These components would have to be measured by other methods if they were included in the TDF value.

Uppsala Method

In the Uppsala method, there is a provision for an initial extraction in 80% ethanol if the sample contains very large amounts of mono-, di-, and oligosaccharides. This extraction appears important in reducing any coprecipitation of nonpolymeric sugars and fiber. Starch is digested in acetate buffer at pH 5.0 by incubating with a thermostable α-amylase and then with amyloglucosidase. DMSO is not used and starch may be less efficiently dispersed and, therefore, less efficiently removed (Figure 2). After reprecipitating in ethanol and centrifuging, the residue is hydrolyzed with sulfuric acid. As in the Englyst method, neutral polysaccharides are analyzed as alditol acetates by GLC and uronic acids by decarboxylation with special equipment or by colorimetry.

Unlike the Englyst method, Klason lignin is measured gravimetrically. Potential errors can arise when lignin is measured independently and added back to NSPs. For example, the lignin fraction may include other, nondigested fiber material (such as cellulose) which would then overestimate insoluble fiber. This was apparently the reason behind an apparent lignin value of 0.9–3.5% (dry weight basis) measured in apples, peas, or a food composite. This value is suspect because low permanganate lignin values (obtained after treatment of the insoluble fiber residue with porcine pancreas α-amylase and subsequent workup to obtain an ADF residue) were obtained which were independent of any food-processing method (similar to the values in Table 1). Marlett has discussed the necessity of measuring lignin and the problems related to its measurement.

Anderson Method

As in the Englyst method, the Anderson GLC method uses DMSO to disperse starch prior to hydrolysis. The starch is then digested with porcine pancreas α-amylase in acetate buffer at pH 5.2. After precipitation with four volumes of ethanol, the residue is extracted with water at 100 °C to obtain soluble and insoluble fiber fractions. Following centrifugation, the soluble fiber from the supernatant and the insoluble fiber from the pellet are hydrolyzed with sulfuric acid. Klason lignin is measured as the loss in weight of the nonhydrolyzed insoluble residue after ashing.

Comparison of GLC and Gravimetric Methods for Measuring TDF

As already indicated, there is general agreement between the rapid HPB method and the Prosky and Englyst methods. The regression coefficients were 0.985 and 0.989 for the Prosky and Englyst methods, respectively. Other comparisons have also shown good agreement between values. For example, in a comparison of 25 different foods, TDF values as measured by the rapid HPB method agreed with those reported by Anderson and Bridges (modified Englyst method) and with those reported by Marlett (modified Uppsala method). However, more direct comparisons are needed to determine the potential problems with each method.

Table 3 presents a comparison of the TDF values expressed on a 'per g dry weight' basis to magnify differences which may be partly hidden when the values are expressed on a 'per g fresh weight' basis. In order to compare TDF values, the permanganate lignin values need to be added to the NSP values. Three different levels of variability are apparent from the data shown in Table 3. The range of NSP values obtained from three different laboratories (using three slightly different methods and different food samples) illustrates, in part, the intermethod variability. In addition, there is some interlaboratory variability, as shown by a comparison of four laboratories as well as an inherent variability in the samples (including stage of maturation of the product; (*See* **Dietary Fiber:** Properties and Sources). Direct comparisons are only possible for the results in the five right-hand columns. These samples were composites based on winter and summer collections of up to 20 individual

foods over 30 months in different locations. The results show that, when lignin is included in the final TDF value, there is good agreement between GLC and gravimetric methods for the indicated foods.

Nutritional Labeling and Analysis

It is difficult to decide on a single method for measuring the dietary fiber content of all foods. The challenge is to find a single method that works adequately for all food groups and is independent of sample processing. Several candidates are possible but to a large extent, the final decision will reflect the definition of dietary fiber. (*See* **Dietary Fiber:** Properties and Sources). The dietary fiber definition must not be driven by available methodologies but must be arrived at independently of methodological considerations. As shown in Figure 2, it is possible to make a case for including structural protein, lignin, structural, and nonstructural NSPs, as well as some starch. Each method includes variable amounts of all these components. In addition to these complications, it is also possible to separate TDF into insoluble and soluble components. Once again, each method uses different procedures to measure these fractions so that the measured content of insoluble and soluble fiber will differ from laboratory to laboratory. Consumption of these different fiber fractions has not yet been related to definite physiological effects, although there appears to be a role for viscous soluble dietary fiber in reducing the risk factors for cardiovascular disease. The role of starch and other nonstarch polymers not traditionally associated with dietary fiber has yet to be determined as well. Therefore, the following discussion deals only with practical considerations in choosing a TDF method for food labeling.

Equipment

A method requiring simple, inexpensive equipment would be the most widely applicable because it would be more acceptable to nations unwilling or unable to spend considerable sums of money to monitor labeling. In general, the gravimetric methods require simpler equipment and the rapid HPB method is less costly than other gravimetric procedures because it does not require elemental nitrogen analysis. The Englyst colorimetric method can be completed with a simple spectrophotometer, although this method is less robust than the GLC method. Except for the Englyst method, all methods require a muffle furnace for ashing the samples. Although the gravimetric systems require simpler equipment, a hot-water supply is needed and analyses are greatly aided by purchasing semiautomated filtering/refluxing equipment that would increase the cost. However, these pieces of equipment are usually less expensive to maintain than GLCs.

Operator Time

Because it does not include a protein determination, the rapid HPB method requires the least amount of operator time per duplicate determination. Methods that require sugar derivitization and analysis by GLC tend to be longer than the gravimetric methods, especially when lignin measurement is included. The time required for these methods is greatly reduced if the GLC system includes an autosampler. Semiautomatic equipment is available for the gravimetric determinations but filtering time can be slow, especially for samples that contain a considerable amount of starch.

Lignin

The Englyst method is the only one that does not include lignin in the final TDF value. Most researchers consider lignin to be an important dietary fiber constituent (*See* **Dietary Fiber:** Properties and Sources) and, consequently, most methods include a measure of the lignin content. In the GLC methods, the adoption of the Klason method (residue after sulfuric acid digestion) for measuring lignin means that other nonfiber material such as Maillard products may be included in the lignin fraction. This could lead to overestimation of the lignin content and, consequently, overestimation of the insoluble dietary fiber and TDF values. Lignin may be more accurately measured by a combination of NDF + porcine pancreas α-amylase and ADF treatments prior to permanganate oxidation. This would, however, increase the time required for analysis as well as increase the amount of sample needed per assay.

Independence from Food Processing

Different methods include different amounts of starch in the final TDF estimate (Figure 2). The only method that does not include any starch is the Englyst method because it completely solubilizes the starch with DMSO prior to enzymatic hydrolysis. There are several different types of starch, some of which arise from food preparation such as retrograde starch and so the inclusion of starch in a method could be problematic. An example of the potential for problems comes from measuring the TDF values in cooked and uncooked rice and potatoes (high-starch foods) using the Prosky method. The Prosky method gave higher TDF values in the cooked foods. Problems were also noted with roasted peanuts where nonfiber material was included with TDF as well as toasted wholewheat bread (**Table 1**). Lower cooking temperatures (i.e., 95 °C compared to 100–120 °C)

artificially increased the TDF content of white navy beans when the Prosky or Lee methods were used. Some of the problems may have been related to the choice of enzyme used to degrade starch, as was observed for toasted wholewheat bread (**Table 1**).

In general, the Englyst method is independent of the effects of food processing because it uses DMSO to aid in removing starch and nonpolymeric sugars. This helps exclude food preparation artifacts, such as retrograde starch, as well as Maillard products from the final analysis but it also means that lignin is not included. It also means that lignin is excluded from the final analysis. Other methods that rely on GLC identification of NSPs include Klason lignin but this analysis has other problems (see above). Of the gravimetric methods, the rapid HPB method appears to be independent from food processing and, at the same time, includes lignin in the final value.

Precision

Method variability pooled over all foods has been measured in a US Department of Agriculture study using 25 duplicate food samples. Different laboratories were asked to measure TDF in the samples without knowing their composition or source. The coefficient of variation for a single observation was 3.0% with the rapid HPB method, 4.7% with the Prosky TDF method, and 8.4% for the Uppsala method. This represents an estimation of the intralaboratory precision for selected unprocessed and processed foods. More interlaboratory work comparing precision of several methods is needed.

Remaining Problems

The general agreement between the different methods for measuring fiber is encouraging because it opens the door to universal acceptance of a dietary fiber method. However, many problems remain. First, an alcohol precipitation step is used to separate fiber material from nonfiber material. This step usually follows starch digestion and is designed to precipitate sugar polymers. It is possible that some of the fiber components are not completely precipitated and that some sugars released by starch digestion are coprecipitated. This may vary with the method and may be the source of some of the intermethod variability. In addition, the selectivity of this step in separating sugar polymers from nonpolymeric compounds has been questioned. In particular, polymers such as oligofructose (actually a mixture of oligomers and polymers) do not precipitate during the subsequent centrifugation. The 'dietary fiber' nature of these polymers is currently being debated. (*See* **Dietary Fiber**: Properties and Sources.)

Second, structural fiber protein may represent up to 10% of dietary fiber in immature plant tissues. It is impossible, at the present time, to quantify this protein (although the rapid HPB gravimetric method presumably includes it). Except for the rapid HPB method, this fraction is excluded from the reported TDF values.

Third, the colorimetric method for determination of uronic acid values (included in most GLC methods) needs to be reexamined. This is because the uronic acid content of vegetables was shown to be higher when measured by a decarboxylation method.

Fourthly, there are a small number of foods where significant method disagreement occurs. For example, for soya bean fiber isolate the NSP value using the Englyst GLC method is lower than the TDF value measured gravimetrically. The reasons for these discrepancies need to be examined in order to determine the exact TDF composition measured by each method. These comparisons will greatly improve fiber methodology.

Finally, although both acetone and ether have been used to remove fat from the samples prior to analysis, their efficacy is questionable and only the defatting procedure of Bligh and Dyer is efficient enough to defat all food samples completely. Caution is warranted when substituting defatting procedures since TDF methods have been validated with their respective defatting methods and substitutions may produce unexpected results. For example, the degree of lignin removal with the Bligh and Dyer procedure is unknown. There is some question as to the necessity for complete defatting since the methods were validated with a wide variety of food samples, all with different fat contents. It may be necessary to reexamine the importance of fat removal prior to analysis in samples containing high amounts of fat.

Conclusion

Comparable TDF values can be obtained for many foods using any of the methodologies discussed above. Some foods are more problematic and require a careful choice of methodology. Significant causes of error have been identified, including the potential precipitation of incompletely digested starch and the measurement of Klason lignin, particularly in processed foods. The inclusion of Maillard products in Klason lignin may significantly increase the final TDF value. The following treatment is recommended: NDF, porcine pancreas α-amylase, ADF, and permanganate treatment. This procedure gives permanganate lignin values that are independent of food processing and, when added to NSPs determined by GLC, provides a detailed and known measurement of dietary

fiber. The rapid HPB method, including the neutral detergent and porcine α-amylase treatments, has several advantages and would serve as a good method for food labeling.

Physiological Effects

I T Johnson, Institute of Food Research, Norwich, UK

Introduction

The term ‘crude fiber’ was coined in the nineteenth century to describe the material that remained after rigorous nonenzymic hydrolysis of animal feedstuffs.

The possible importance of a similar undigestible residue in human foods was proposed in the early 1970s by the physician and epidemiologist Hugh Trowell, but he also recognized that the crude fiber figures then available for foods had little physiological significance and were of no value in the context of human diets. He therefore used the term 'dietary fiber' to describe the 'remnants of plant cell walls resistant to hydrolysis (digestion) by the alimentary enzymes of man.' Later, he and others redefined it more precisely as 'The sum of lignin and the plant polysaccharides that are not digested by the endogenous secretions of the mammalian digestive tract.' Although some controversy still exists as to the precise definition of dietary fiber, there is no doubt that the term embraces a large and complex mixture of polysaccharides that share few common properties other than resistance to digestion by the endogenous enzymes of the human alimentary tract. The presence of undigested cell wall fragments and dispersed polysaccharides can alter physiological processes throughout the gut, but the effects of different fiber components depend upon their varied physical and chemical properties during digestion, and upon their susceptibility to degradation by bacterial enzymes in the colon. It is important to realize that a single analytical value for the fiber content of a food is a poor guide to its physiological effects. This article will review the main mechanisms of action of resistant polysaccharides in the alimentary tract and their implications for human health.

Fiber in the Alimentary Tract

Food is conveyed through the alimentary tract by rhythmic muscular activity. Digestive enzymes are released into the lumen at intervals to facilitate the breakdown of macromolecules into fragments that can then be absorbed and utilized by the body. The earliest stages of digestion begin in the mouth, where food particles are reduced in size, lubricated with saliva, which also contains the digestive enzyme salivary amylase, and prepared for swallowing. In the stomach, any large particles that remain are broken down by rigorous muscular activity in the presence of hydrochloric acid and proteolytic enzymes. The need to disrupt and disperse intractable food particles and cell walls appears to delay the digestive process significantly. Since cell wall polysaccharides help to determine the texture of many plant foods, and hard foods tend to be chewed more thoroughly than soft foods, the presence of dietary fiber in unrefined foods may begin to regulate digestion at a very early stage. Apples, for example, tend to be consumed more slowly than apple juice, and the absorption of sugar from apples is also slower. Similarly, the rate at which the starch is digested and absorbed from cubes of cooked potato has been shown to be much slower when they are swallowed whole than when they are chewed normally. The nutritional significance of these effects is not entirely clear, but they may limit the rate at which glucose from some foods enters the circulation.

Small Intestine

The small intestine is the largest of the digestive organs, with the greatest surface area, as befits its role as the main site of nutrient absorption. The semiliquid products of gastric digestion are released at intervals into the small intestine and propelled away from the gastroduodenal junction by peristatic movements at about $1\,\mathrm{cm\,min^{-1}}$. The hydrolysis of proteins, triglycerides, and starch continues within the duodenum and upper jejunum, under the influence of pancreatic enzymes. The final stages of digestion occur at the mucosal surface, where the products are absorbed into the circulation, along with water and electrolytes, via the specialized epithelial cells of the intestinal villi. Muscular activity in the small intestinal wall, together with rhythmic contractions of the villi, insures that the partially digested chyme is well stirred. In adults, the first fermentable residues from a meal containing complex carbohydrates enter the colon approximately 4.5 h after ingestion. When a solution containing indigestible sugar is swallowed without food, it reaches the colon about 1.5 h earlier than when the same material is added to a solid meal containing dietary fiber. The presence of solid food residues slows transit, probably by delaying gastric emptying and perhaps also by increasing the viscosity of the chyme so that it tends to resist the peristaltic flow. Soluble polysaccharides such as guar gum, pectin and β-glucan from oats increase the mouth-to-cecum transit time still further.

Carbohydrate Metabolism

In his early work, Trowell proposed that dietary fiber was a major factor in the prevention of the metabolic condition insulin-dependent diabetes. Indeed, he argued that historically, this condition was unknown in western Europe prior to the introduction of mechanized flour milling, because until then, the consumption of unrefined carbohydrate foods had favored slow absorption of glucose, which placed less strain upon the ability of the pancreas to maintain glucose homeostasis. Whatever its merits, this hypothesis has encouraged a great deal of research on the effects of cell wall polysaccharides on the digestion and absorption of carbohydrates, which in turn has shed light on

the potential role of dietary fiber in the control of diabetes. The 'glycemic index' is essentially a quantitative expression of the quantity of glucose appearing in the bloodstream after ingestion of a carbohydrate-rich food. To calculate the index, fasted subjects are given a test meal of the experimental food containing a standardized quantity of carbohydrate. The change in concentration of glucose in the blood is then measured over a period of time. The ratio of the area under the blood-glucose curve in response to the test meal to that produced by an equal quantity of a standard reference food is then calculated and expressed as a percentage. When glucose is used as the standard, complex starchy foods often have glycemic indices lower than 100%.

The physical resistance of plant cell walls during their passage through the gut varies considerably from one food to another, and any cell walls that remain intact in the small intestine will impede the access of pancreatic amylase to starch. Even when enzymes and their substrates do come into contact, the presence of cell wall polysaccharides may slow the diffusion of hydrolytic products through the partially digested matrix in the gut lumen. Pulses tend to give particularly low glycemic index values, probably because legume seeds have relatively thick cell walls, which resist destruction during processing and cooking. This effect of fiber on carbohydrate metabolism cannot be predicted from simple analytical values for total fiber because it reflects the structure, as opposed to the absolute quantity, of cell wall polysaccharides within the food.

Many studies on postprandial glycemia have been conducted using isolated fiber supplements added to glucose test-meals or to low-fiber sources of starch. They demonstrate that, contrary to Trowell's original hypothesis, wheat bran and other insoluble cell wall materials have little effect on glucose metabolism. However certain polysaccharides, such as guar gum, pectin, and oat beta-glucan, which form viscous solutions in the stomach and small intestine, do slow the absorption of glucose. Highly viscous food components may delay gastric emptying and inhibit the dispersion of the digesta along the small intestine, but the primary mechanism of action appears to be suppression of convective stirring in the fluid layer adjacent to the mucosal surface. The rapid uptake of monosaccharides by the epithelial cells tends to reduce the concentration of glucose in this boundary layer, so that absorption from the gut lumen becomes rate-limited by the relatively slow process of diffusion. The overall effect is to delay the assimilation of glucose and hence suppress the glycemic response to glucose or starchy foods in both healthy volunteers and diabetics. A similar mechanism probably inhibits the reabsorption of cholesterol and bile salts in the distal ileum, and this may account for the ability of some viscous polysaccharides to reduce plasma cholesterol levels in humans. (*See* **Carbohydrates**: Metabolism of Sugars.)

Mineral Metabolism

Polysaccharides and phenolic components of cell walls often contain polar groups that can interact with ionized solutes in the gastrointestinal contents. Such molecular binding effects do occur *in vitro* and might, in principle, restrict the availability of nutrients and other substances for absorption in the small intestine. Iron, zinc, and calcium are absorbed relatively poorly from the human diet, and there is a long tradition that high intakes of dietary fiber have an adverse effect on human mineral nutrition. Studies with subjects who, for clinical reasons, have had the colon removed and the small bowel brought to the abdominal surface (ileostomists) suggest that although neutral polysaccharides do not bind minerals, charged polysaccharides such as pectin can displace cations into the colon. However, fermentation of cell walls probably releases iron and calcium into the lumen, whence they may be salvaged by colonic absorption, and there is little objective evidence that dietary fiber *per se* has much of an adverse effect on mineral metabolism. Indeed, highly fermentable oligo- and polysaccharides have been reported to promote mineral absorption in some studies, presumably by stimulating active transfer in the colon.

The effect of phytate (myoinositol hexaphosphate) is generally considered to be more significant than that of fiber. Phytate is often present in close association with cell wall polysaccharides in unprocessed legume seeds, oats, and other cereals. Phytate does exert a potent binding effect on minerals and has been shown to reduce the availability of magnesium, zinc, and calcium for absorption in trials with human volunteers. Phytate levels in foods can be reduced by the activity of endogenous phytase, by hydrolysis with exogenous enzymes, or by fermentation. Dephytinized products may be of benefit to individuals at risk of suboptimal mineral status. (*See* **Phytic Acid**: Nutritional Impact.)

Large Intestine

The large intestine, which is located distal to the small bowel, salvages energy from food residues and from endogenous proteins and carbohydrates that have escaped digestion and absorption. Its other main role is to form and store feces. Fecal microorganisms degrade undigested starch, and many of the polysaccharides that comprise dietary fiber, to yield the

volatile fatty acids butyrate, propionate, and acetate. Whereas the gut of ruminants is adapted to provide a watery, nutrient-rich environment for bacterial fermentation in the foregut, the colon is the main site of permanent bacterial colonization in the human alimentary tract. The proximal colon contains about 200 g of dilute fecal material, portions of which are transferred at regular intervals from the right colon into the transverse and distal segments for partial dehydration and storage. The pattern of motility in the large intestine is similar in principle to that of the rest of the alimentary tract, but the rate of transit is slower. In healthy individuals, stools are passed with a frequency varying from once or twice a day to once every 2–3 days.

The absorption and metabolism of short-chain fatty acids derived from carbohydrate fermentation provide an important route for the recovery of energy from undigested polysaccharides. Butyrate functions as a source of energy for the colonic mucosal cells, whereas propionate and acetate are absorbed and metabolized systemically. The other major breakdown products of carbohydrate fermentation are hydrogen, methane, and carbon dioxide, which together comprise flatus gas. Excess gas production is said to cause distention and pain in some individuals, especially those attempting to increase their fiber consumption, but this is probably caused more by fermentation of oligosaccharides such as stachyose and verbascose, found for example in legume seeds, rather than the cell wall polysaccharides themselves.

Fecal Bulk

The ability of dietary fiber to prevent cancer and various degenerative diseases of the alimentary tract was proposed by Denis Burkitt, who based his hypothesis largely on the concept of fecal bulk. His field observations in Africa, where cancer and other chronic bowel diseases were rare, suggested that populations consuming traditional rural diets rich in vegetables and cereal foods produced bulkier, more frequent stools than persons living in the industrialized West. Burkitt argued that consumption of highly processed cereals in industrialized societies led to chronic constipation, and that this caused prolonged high pressures both within the colonic lumen, and also within the lower abdomen as a result of straining to pass hard stools. This in turn was thought to increase the risk of various diseases of muscular degeneration including varicose veins, hemorrhoids, hiatus hernia, and colonic diverticuli. Furthermore, infrequent defecation was thought to cause prolonged exposure of the colonic epithelial cells to mutagenic chemicals that could initiate cancer. Although Burkitt's overall hypothesis for the beneficial effects of fecal bulk is undoubtedly an oversimplification, it has never been comprehensively refuted.

It is certainly true that the consumption of dietary fiber is a major determinant of both fecal bulk and bowel habit, but the magnitude of the effect depends upon the type of fiber consumed. Soluble cell wall polysaccharides such as pectin are readily fermented by the microflora, whereas lignified tissues such as wheat bran tend to remain at least partially intact in the feces. Both classes of dietary fiber can contribute to fecal bulk but by different mechanisms. The increment in stool mass caused by wheat bran depends to some extent on particle size, but in healthy Western populations, it has been shown that for every 1 g of wheat bran consumed per day, the output of stool is increased by between 3 and 5 g. Other sources of dietary fiber also favor water retention. For example isphagula, which is a mucilaginous material derived from *Psyllium*, is used pharmaceutically as a bulk laxative. Soluble polysaccharides such as guar and oat β-glucan are readily fermented by anaerobic bacteria, but solubility is no guarantee of fermentability, as is illustrated by modified cellulose gums such asmeythylcellulose, which is highly resistant to degradation in the human gut. Fermentation reduces the mass and water-holding capacity of soluble polysaccharides considerably, but the bacterial cells derived from them do make some contribution to total fecal output. Thus, although all forms of dietary fiber exert some laxative effect, the important differences in their properties and behavior make it hazardous to infer the biological effects of any diet from a single analytical measurement of total fiber content.

Fecal Chemistry

Apart from increasing the availability of energy from dietary fiber, the major effect of bacterial fermentation is to regulate the physical and chemical properties of the intraluminal environment. It is now generally accepted that most colorectal carcinomas develop progressively from precancerous lesions called adenomatous polyps. The gradual transition from a normal crypt via a precancerous lesion to a malignant tumor is associated with a progressive loss of differentiation, deregulation of cell growth, and an accumulation of mutations in genes associated with the control of cell proliferation and death. These somatic mutations are assumed to be caused primarily by mutagenic chemicals in the feces, much as mutagens in tobacco smoke induce lung cancer. Human fecal water contains a number of different mutagens that have been shown to be carcinogenic in animals. These include heterocyclic aromatic amines created during the cooking of meat at high temperatures, and

N-nitrosamines derived from dietary proteins. It has not been established conclusively that these substances cause colorectal carcinogenesis in humans, but there is strong circumstantial evidence that they do, and it would seem prudent to adopt nutritional strategies to reduce their concentration in the colon. The fecal bulking hypothesis provides the principal rationale for the current Dietary Reference Values for nonstarch polysaccharides in the UK, which recommend that adults should consume an average of 18 g of fiber per day. Epidemiological studies provide only weak evidence for a protective effect of dietary fiber against bowel cancer *within* the populations of industrialized Western countries such as the USA, perhaps because the overall range of fiber intakes is relatively low. However, there is stronger evidence for a protective effect of fiber intake and fecal weight against bowel cancer when different populations with a broader range of fiber intakes are compared.

The realization that colorectal carcinogenesis is a prolonged multistage process involving changes to a complex array of genes raises new questions about interactions between the colonic epithelial cells, dietary fiber, and other constituents of the fecal stream. Bile acids, which are produced by the liver and secreted into the gut lumen, where they facilitate the digestion and absorption of fat, are known to increase the rate at which colonic mucosal cells divide. It has been proposed that this effect causes bile salts to act as tumor promoters in the human colon, and thereby helps to accelerate the carcinogenic process initiated by fecal mutagens. High-fat diets tend to stimulate the release of bile acids and increase their concentration in the feces, and this may explain at least partially the fact that high fat consumption is a risk factor for bowel cancer in human populations. However, increased fecal bulk will tend to dilute the concentration of bile salts and reduce their residence time. The nonfermentable particulate components of plant cell walls may also provide a finely dispersed solid phase on to which bile acids can bind, so that their concentration in the aqueous phase of the feces is reduced still further. (*See* **Cancer**: Diet in Cancer Prevention.)

Cellular Physiology

Fermentation of carbohydrates lowers the pH of the feces and increases the concentration of short-chain fatty acids in contact with the mucosal cells. There is increasing evidence that these changes modify the intraluminal environment in such a way as to regulate the birth and death of the mucosal cells. Programmed cell death (apoptosis) is a mechanism whereby damaged cells are removed selectively from a tissue in an orderly manner that does not cause inflammation or general tissue desruction. This may well provide a defense against the survival of cells carrying tumorigenic mutations. Apart from the role of butyrate as an essential source of energy for the colonic mucosa, it also suppresses proliferation, increases differentiation, and induces apoptosis in many types of tumor cell grown *in vitro*. Tumor cell lines established from adenomatous polyps and carcinomas from human colon undergo increased apoptosis in the presence of butyrate, at concentrations close to those that occur *in vivo*. Moreover, cells from fully developed carcinomas have been shown to be less responsive to butyrate than those from early lesions, which perhaps implies that abnormal cells that survive and evolve into malignant tumors also acquire an adaptive resistance to butyrate. Unabsorbed starch and fermentable components of cereal fiber may provide a source of increased butyrate, which helps to suppress the proliferation of tumor cells and increase the likelihood of their deletion from the tissue by apoptosis. If so, much may depend on the rate of fermentation. Sugars and small oligosaccharides probably disappear too rapidly after entering the colon to provide a supply of butyrate to the distal colorectum, whereas lignified plant cell walls and some types of resistant starch that are slowly fermented may deliver butyrate efficiently to more distal regions of the colonic mucosa.

Adverse Physiological Effects

There are few well-authenticated adverse effects of dietary fiber. Some cases of pediatric malnutrition caused by very high fiber intakes have been reported, but this problem appears to be confined to grossly unbalanced diets. Similarly, the few cases of gastrointestinal obstruction in the literature appear to stem from very abnormal intakes of wheat bran or from swallowing nonhydrated supplements of viscous polysaccharides intended for consumption as a drink. There is some evidence that patients with a history of gastrointestinal surgery are at increased risk of obstruction due to abnormally high intakes of cereal bran. (*See* **Inflammatory Bowel Disease**.)

Sources of Fiber

It should now be obvious that although all plant foods provide some form of dietary fiber, not all components of fiber have the same physiological effects. In the UK, about 47% of total fibre intake is obtained from bread of various types and from breakfast cereals. The level of fiber in bread depends upon the extraction rate, which is the proportion of the original grain used to make flour. White flour has an extraction rate of about 70% and contains about 3%

nonstarch polysaccharides (NSP), whereas 'wholemeal' (100% extraction) flour contains about 10% NSP. Wheat bran, which contains about 40% NSP, can be added to the diet as a supplement, but it is relatively unpalatable. One of the lasting effects of the dietary fiber hypothesis has been to increase the variety and palatability of high extraction cereal products in the market place. Such products tend to contain primarily insoluble, poorly fermentable polysaccharides, and their consumption is a very effective way of increasing fiber intake to increase stool bulk. Oats, rye and barley contain higher quantities of soluble fiber than wheat. Oat bran is an important source of β-glucan, a soluble viscous polysaccharide that has been shown to slow down glucose absorption and reduce plasma low-density lipoprotein cholesterol levels in humans. A further 45% of total fiber intake in the UK comes from fruits and vegetables. Typically, the levels of NSP in fruits and vegetables are between 1 and 5% of fresh weight, and the polysaccharides are mostly soluble pectins and arabinoglactans, which are readily fermentable in the large bowel. For reasons described earlier, soluble fiber from vegetables and fruit does not have the bulk laxative effect of cereal bran, but it does provide fermentable carbohydrate for fermentation in the colon. Moreover, there is strong evidence that fruit and vegetables protect against cancer through other mechanisms, including the provision of biologically active phytochemicals. Effects of Fiber on Absorption

L Prosky, Prosky Associates, Rockville, MD, USA

Background

Although dietary fiber is not in itself a nutrient, in many countries, it is considered among the six groups of major nutrients along with proteins, carbohydrates, fats, vitamins, and minerals. Its required listing on the nutrient food label in most countries that have labeling procedures begs the question: what is the function of dietary fiber? Among these concerns is: how does the speeding up of the passage of food through the gastrointestinal tract and increase in the stool weight caused by the ingestion of diets high in dietary fiber affect the absorption of nutrients and other substances in the gastrointestinal tract?

Effects on Mineral Absorption

In vitro studies have shown that particular fibers bind minerals such as iron and zinc, suggesting interference of fibers on mineral absorption. Iron deficiency, which is one of the most prevalent deficiency disorders in the world, is present in Western cultures where there is no lack of food. There would also be concern for many of the other minerals for which there is only a marginal dietary intake. Some reports have implicated bran as a very strong iron absorption inhibitor, the action of which could be reversed with ascorbic acid or dietary meat (**Table 1**). High intake of phytate-rich, fiber-rich foods could inhibit zinc absorption, but again, this could be reversed by ingestion of animal protein. This would seem to indicate that there are many other factors involved in the absorption of minerals. In addition, several reports have revealed a tendency for reduced absorptions and retentions to occur for calcium, magnesium, phosphorus, and copper. It should be noted that no reliable method exists for measuring the bioavailability of an ingested mineral that separates this exogenous intake and its associated biological response from the amount of endogenous mineral in the body being reabsorbed and reutilized. Further, it has remained a challenge to detect a biological response sensitive enough to measure a change in the body's storage or use of a mineral that reflects the true amount of a specific dietary mineral absorbed or utilized. These problems are further compounded when the interactions among minerals are considered. The drawback to many of the studies was the relatively short period of observation and the often excessively high

dosage of the particular experimental component. The intakes of dietary fiber foods often bear little relationship to human dietary situations (as much as 60 g per day of bran supplements in some studies). It also has been demonstrated that there is an adaptation to decreased mineral intake. Ingesting 50–60 g of dietary fiber derived from whole maize meal, brown bread, and beans with a mean daily intake of 275 mg of calcium resulted in calcium absorption varying from 61 to 83%. This is far higher than the usual 20–30% absorption that occurs with Western subjects ingesting much lower dietary fiber diets. The results showed that the subjects were in balance with regard to calcium, magnesium, and iron, and that the drawbacks of habitually high dietary fiber intakes and low calcium and other mineral salt intakes of Third World people may be of less significance to health than might be expected. While the nutritional policies of Western societies should not do anything to restrict, at this time, the intake of dietary fiber-containing food, it is apparent that as the world population increases, there will be a greater reliance on plant foods. This is because it is far more economical to use land to produce plant products than to produce meat products. More work will obviously have to be done to establish the mineral absorption effects and the factors that affect them (i.e., phytate, etc.), but for now, the benefits of ingesting dietary fiber far outweigh any negative effects of decreased mineral absorption. Also included in Table 1 are the mineral absorption effects of four food components; the methods for these food components were approved recently by the Association of Official Analytical Chemists (AOAC). These food ingredients are not measured as dietary fiber by the standard AOAC methods for dietary fiber but are carbohydrate polymers of DP-3 and higher and are resistant to hydrolysis and absorption in the human small intestine. Updated definitions of dietary fiber include these components (*See* **Minerals – Dietary Importance**.)

Effects on Vitamin Absorption

There is a paucity of information on the availability of vitamins in relation to the dietary fiber content of the diet. Further, what is available is mainly from animal studies, and the extrapolation of its effects to humans may be difficult.

In previous studies, methyl cellulose or pectin did not affect the utilization of vitamin A in rats, but a combination of the two did appear to decrease liver vitamin A stores. Lignin given with a test meal did not affect serum vitamin A of human subjects, but carotene, which is bound to plant cell walls, is less available than pure or added carotene. (*See* **Carotenoids**: Physiology; **Retinol**: Physiology.)

Dietary methyl cellulose had no effect on the growth of thiamine-deficient or normal rats. Riboflavin and niacin may be less available from wholemeal bread than from enriched white bread. Several fiber sources (course bran, fine bran, cellulose, and cabbage) improved absorption of a load dose of riboflavin in humans. Nicotinic acid, which is bound to fiber in cereal brans and is not available unless released by alkaline hydrolysis or treatment with limewater, was rendered effective in promoting weight gain in animals, made deficient by feeding maize with bound vitamin. The binding was probably due to cellulose or hemicelluloses. (*See* **Niacin**: Physiology.)

A lower bioavailability of vitamin B_6 from cereal than from nonfat dry milk was reported for rats. Vitamin B_6 was available to a lesser degree from soybeans than from beef, and the addition of wheat bran to a diet increased vitamin B_6 availability in human subjects. Fibers digestible by intestinal bacteria (xylan, guar gum, and pectin) intensified the symptoms of B_{12} depletion in rats as compared with the nondigestible fibers (cellulose, lignin, alginate, and wheat bran). (*See* **Vitamin B_6**: Physiology.)

In two additional studies, fiber (in the form of white bread, wholemeal bread, or cellulose) was found to have no effect on urinary folate excretion, but in another study, fiber (maize, rice, and bread) decreased the elevation in serum folate as compared with the vitamin alone. (*See* **Folic Acid**: Physiology.)

From these inadequate data, it appears that in general, the availability of unbound vitamins is not affected by the presence of dietary fiber, but the situation with the bound vitamins will have to be explored further.

Effects on Lipid Absorption

Dietary fiber can influence lipidemia and atherosclerosis by affecting the absorption and metabolism of the lipid components in the blood. Soluble fibers, such as pectin, do affect the lipid uptake and glycemia. Oat bran, which contains β-glucans (soluble fibers), will lower the level of serum cholesterol. It is now established that, whereas insoluble dietary fibers (wheat bran, cellulose) do not influence serum lipids, soluble dietary fibers (guar, pectin, psyllium) exert a hypocholesterolemic effect (Table 2). The mechanism by which this hypocholesterolemic effect is exerted involves increased viscosity of the stomach and small intestine contents, and may also influence bile acid metabolism.

Cereal fibers and fractions (oat, rice, and barley) contribute significantly in reducing total cholesterol in a variety of animal species and in hypercholesterolemic subjects. Long-term population studies (Framingham, LRC, and Helsinki) have demonstrated that for each 1% reduction in total cholesterol, there is a two- to fourfold decrease in atherosclerosis in otherwise healthy individuals. A 6-year prospective study of male health professionals diagnosed free of cardiovascular disease showed that cereal fiber was found to be most strongly associated with a reduced risk of myocardial infarction. Adding oat and barley, in addition to other soluble dietary fiber foods, proved efficacious in lowering cholesterol even further. The data generated by some 60 feeding studies with psyllium convinced the US Food and Drug administration to approve a health claim for psyllium, which allows foods and supplements with at least 1.7 g of soluble dietary fiber from psyllium to claim 'soluble fiber from psyllium per serving, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease.' Although the effects of cereal fiber are less pronounced in normo-cholesterolemic individuals, these changes would have a significant impact on reducing cardiovascular risk for the whole population. Table 3 shows the effects of feeding various dietary fibers on serum and liver cholesterol and serum triglycerides in a rat model. Of particular interest is cellulose, which has no effect on cholesterol and triglycerides, and wheat bran, which has little effect on serum and liver cholesterol but plays a role in reducing serum triglycerides.

To date, the FDA has approved health claims for three substances, oats, psyllium and soy, with regard to their cholesterol-lowering ability in combination with a diet that is low in saturated fat and cholesterol. This reinforces the abundant data available showing the cholesterol-lowering properties of specific dietary fibers. A study was done to compare a soluble fiber, soy-enhanced diet with a diet containing low-fat dairy foods but low in soluble dietary fiber on the level of serum lipids. The test diet reduced the total cholesterol:high-density lipoprotein (HDL)-cholesterol ratio and reduced the risk of coronary heart

disease (CHD). (*See* **Cholesterol**: Factors Determining Blood Cholesterol Levels.)

In a study of the relationship of dietary fiber and serum lipids among true vegans, lacto-ovo-vegetarians, nonvegetarians, and the general public, only the true vegans showed a significant lowering of cholesterol. The only difference in the dietary fiber intakes among the four groups was a higher intake of pectin in the true vegans.

The digestion of dietary fat begins in the stomach, where it is coarsely emulsified and partially hydrolyzed. No further emulsification occurs in the duodenum, but subsequently, under the action of pancreatic lipase, phospholipids and cholesterol esters are cleaved enzymatically. The activity of pancreatic lipase *in vitro* can be reduced by several of the soluble dietary fibers, including pectins, oat bran, psyllium, and sugar beet fiber, with part of the loss being due to the binding of the fiber to the enzymes. The inhibitory effects of insoluble dietary fibers, wheat bran, and wheat germ can also produce this reduction of pancreatic lipase. Because the mechanism by which soluble dietary fibers alter the breakdown of fat is not well understood, some investigations of the physicochemical aspect of the process were studied. It is well known that emulsification is a key step in fat digestion, because gastric and pancreatic lipases act at the fat globule–water interface, and that the size of the fat globule is a parameter governing the activity of gastric and pancreatic lipases. Could dietary fiber intefere with the normal process of fat emulsification? The two parameters studied were viscosity and electric charge. Five sources of fiber with different properties were studied, namely gum arabic (not viscous), two differently charged pectins, and three uncharged guar gums (of varying viscosity). Under gastric conditions (pH 5.4), the degree of emulsification was not affected by any of the fibers, but the viscous fibers did increase the size of the emulsified droplets, and the effect was more pronounced as the concentration of these fibers increased. Only viscous fibers significantly increased droplet size and reduced droplet surface area. Overall, the droplet size was positively correlated, and the droplet surface area was negatively correlated with the concentration of the medium viscosity guar gum in the range 0–20 mPa.s. The high-viscosity guar gum significantly reduced (by 32%) the triglyceride lipolysis of such emulsions by human gastric lipase, compared with control and low- and medium-viscosity fibers (Table 4).

In duodenal conditions (pH 7.5 and addition of bile), the quantity of emulsified lipids was reduced, and raising the concentration of viscous fibers increased the size of the droplets. The extent of the emulsification, the droplet size, and, consequently, the droplet surface area were strongly correlated with the concentration of the medium-viscosity guar gum in the range 0–4 mPa.s. (and also 0–20 mPa.s.). The high- and medium-viscosity guar gums and one type of pectin significantly reduced the extent of triglyceride lipolysis catalyzed by pancreatic lipase only. Overall, the extent of triglyceride lipolysis was negatively correlated with the viscosity of the duodenal medium. These findings indicate a mechanism by which soluble, highly viscous fibers can alter lipid assimilation by lowering the emulsification of dietary lipids in the stomach and duodenum.

This hypothesis was tested *in vivo* in rats. A coarsely emulsified lipid mixture with and without 0.3% high-viscosity guar gum was intragastrically intubated. After 30 min of digestion in the stomach, the median droplet diameter of the emulsion in the presence of guar gum was about two fold larger. The specific surface area displayed by the emulsion was about half that of the controls. In the presence of the guar gum, the extent of triglyceride lipolysis was about threefold lower in the stomach content and about twofold lower in the duodenum content. Thus, dietary fibers that raise viscosity in the stomach and duodenum contents reduce the extent of emulsification and subsequent triglyceride lipolysis.

Table 4 Influence of dietary fiber charge and viscosity on droplet size, droplet area, and triglyceride lipolysis under gastric and duodenal conditions

The lipid products of the digestion process (i.e.,mainly monoglycerides, free fatty acids, lysophospholipids, and free cholesterol) are absorbed by the small intestine, where they are rapidly used as substrates for the *de-novo* synthesis of triglycerides, phospholipids, and cholesterol esters. They are then packaged and secreted as chylomicrons into the lymph and finally into the blood.

Other mechanisms can contribute to the absorption of lipids. The binding or entrapment of lipolytic products as well as bile salts in the presence of viscous fibers such as oat bran, guar gum, and pectin can counteract the building of vesicles and mixed micelles in the aqueous phase of the small intestine contents. The limiting step in lipid absorption is the transport across the unstirred water layer associated with the enterocyte brush-border membrane. Highly viscous fibers have been observed to increase the thickness of the unstirred layer, reducing the rate of diffusion and absorption of cholesterol and free fatty acids. These effects have not been observed in the presence of slightly viscous soluble fibers (hydrolyzed guar gum, or chitosan) or insoluble fibers such as cellulose or some hemicelluloses. Changes induced in the intestinal lumen by feeding viscous fibers have been shown to result in reduced recovery of fatty acids and cholesterol in the lymph.

Augmented ileal excretions of lipids have been repeatedly demonstrated in ileostimized human subjects after ingesting meals containing citrus pectin, alginate, oat bran, or β-glucan, and barley fiber. Some investigators have also reported increased fecal or ileal lipid excretions after their subjects' diets were enriched with wheat bran or wheat germ. The ileal or fecal excretion of cholesterol and/or bile acids is markedly increased after addition of various kinds of dietary fibers are added to the test diets. Soluble and viscous fibers such as β-glucans, pectin, or psyllium are particularly efficient in increasing cholesterol excretion,

A principal feature of the postprandial state is a striking increase in triglyceridemia, owing to the secretion of chylomicrons (which transport absorbed dietary lipids and cholesterol) by the small intestine into the circulatory system. Studies with a variety of diets, either supplemented or not supplemented, has shown that different kinds of dietary fibers (wheat fibers, legume fibers, guar gums, pectins, oat bran, β-glucans, psyllium, and mixed fibers, especially those rich in soluble fibers) can reduce the postprandial rise in triglyceridemia. This results from reduced bioavailability of fatty acids and cholesterol induced by the viscous dietary fibers, making the small intestine mucosa less efficient in lipid synthesis and in secreting chylomicrons into the lymph and finally into the circulatory system.

Partially hydrolyzed guar gum lowers total cholesterol, triglycerides and LDL with no change in the HDL in human subjects. Hemicelluloses from soft winter wheat, hard red spring wheat, corn bran, soy hulls, apples, and carrots lowers triglyceride levels, but only the hemicellulose from soft winter wheat had no effect on serum cholesterol. This indicates that the effects may be dependent of chemical interactions with other nutrients in the foods.

Several of the carbohydrate dietary components that are not measured as dietary fiber in any of the accepted methods, but which are not digested or absorbed in the small intestine, appear to have the physiological effects that we have come to identify as

Table 5 Effects of food constituents on lipid parameters

fiber effects and have received much attention recently. They have the following properties with regard to lipid absorption (Table 5).

Effects on Carbohydrate Absorption

The rate of delivery of glucose by the gut to the portal vein and the peripheral tissues is influenced by many factors other than the amount of α-linked glucose polymers in foods. The amylose:amylopectin ratio in starchy foods influenced postprandial glycemia, because amylopectin had a much faster rate of hydrolysis by pancreatic α-amylase. Food that was not chewed resulted in a much flatter glycemic response than food that was chewed well before swallowing. Similar responses could be found when food was altered through milling of cereals, indicating the importance of structure and particle size affecting the α-amylase access to the starch substrate and the effects of surface area. Food constituents such as dietary fiber, which form viscous solutions, may slow the rate of starch digestion and hence glucose absorption. The mechanism of the effects of a viscous solution might happen because of (1) delayed gastric emptying; (2) reduced hydrolytic activity; (3) poor mixing of the intestinal contents with the secreted enzymes; and/or (4) increased thickness of the unstirred water later, slowing down the diffusion of glucose.

The concept of a glycemic index (GI) was introduced in 1981 as a measure of the rise in postprandial glucose of various food carbohydrates. Low-GI foods were found to be slowly or incompletely digested in the small intestine, or found to contain fructose, which is only partially converted to glucose. On the basis of this determination, foods such as unripe bananas (rich in amylose) and over-ripe bananas (rich in fructose) had a lower GI than fresh white bread, which is the standard against which the GI of other foods is measured.

Starch in freshly cooked potatoes is readily hydrolyzed by α-amylase and results upon feeding in a high glycemic and insulinemic response. Repeated cooking and cooling of these potatoes increases the amount of starch resistant to the α-amylase of the small intestine. The result of feeding freshly cooked potatoes and potatoes that had been cooled and cooked several times was a higher postprandial peak for plasma glucose and serum insulin in the former group. (*See* **Starch**: Functional Properties.)

In subsequent years, interest has been shifted to the effects of viscous fibers on glucose absorption by the small intestine and insulin release by the pancreas. It has been shown that insoluble fiber sources such as wheat bran had little effect on glucose tolerance and postprandial insulin response. The effects of viscous fibers were striking and depended on the viscosity of the fiber. Oat β-glucan clearly showed this effect, which was similar to sipping glucose over 3 h, rather than ingesting it as a bolus in 5 min. The nibbling versus gorging effect has been shown to be of benefit in diabetes.

The chemically resistant starches have no effect on the glycemic response of the available starch. These starches are chemically resistant and require solubilization with potassium hydroxide prior to analysis. Entrapped starch, which may be physically trapped in, or by, the fiber reacts as a slow-release carbohydrate. This starch simply needs to be released from its bound physical matrix and made available by good mastication or fine grinding of the food ingredient.

Fructooligosaccharides have no major effects on the glycemic response of the accompanying carbohydrate and have no effect on the glycemia *per se*.

Dried legumes peas, beans and lentils, pumpernikel rye bread, and bulgur or cracked wheat have been shown to reduce the rate at which these foods are digested, and therefore improve the glucose tolerance. The structure of the food may also influence the rate at which the foods are digested.

Paradoxically, insoluble dietary cereal fiber have been shown to offer protection from diabetes in several large cohort studies. Low-GI diets or diets with a low glycemic load (dietary GI × dietary carbohydrates) were also found to be related to the development of Type 2 diabetes over a 6-year period. It is not easy to explain why cereal fiber has an effect in reducing Type 2 diabetes, unless it is through associated nutrients such as magnesium or antioxidants. While the effects of wheat bran on glycemia are not striking, it is possible that the phenolics in the bran may be useful antioxidants of importance in the prevention of diabetes.

The early promise shown by viscous soluble dietary fibers in the treatment of diabetes has suffered because of the unavailability of palatable soluble dietary fiber diets. Studies using the insoluble dietary fibers from cereal have not been followed up successfully in more recent studies.

Table 6 Effects of food constituents on postprandial carbohydrate parameters

Product	*Blood glucose*	*Insulin*	*Glucagon*
Partially hydrolyzed guar gum (Sunfiber®)	↓	↓	
Inulin and oligofructose	ne	ne	ne
Polydextrose	↓	ne	
Galactooligosaccharides	–	–	–
Resistant maltodextrin (Fibersol-2®)	↓	↓	↓

ne, no effect; –, no experimental evidence.

Table 6 lists the effects of five food constituents on postprandial carbohydrate parameters. Only the partially hydrolyzed guar gum and resistant maltodextrin measure as dietary fiber by the AOAC method.

Effect on Protein Absorption

The effects of dietary fiber on protein absorption have mostly been ignored. Studies have shown that the increased intake of dietary fiber results in increased nitrogen loss. The form in which the nitrogen occurs in the feces is of considerable importance, if one is trying to deduce the effects of a dietary component on digestion.

Investigations in which the fecal nitrogen was fractionated imply that most of the nitrogen is in the bacterial mass or metabolic products, such as bacterial products, unabsorbed intestinal secretions, or mucosal cell debris. The proportion derived from unabsorbed dietary components represents a loss to the body, which is probably an effect of absorption of protein. There is also evidence that some bacterial nitrogen is derived from urea secreted in the large bowel and some fixation of nitrogen occurs in the large bowel. These uncertainties emphasize the limited value of fecal data for deducing what are essentially intestinal events. The probable solution to this problem would be to carry out ileostomy studies. To date, ileostomy studies centered on protein absorption have not been carried out.

Bran

A Zitterman, University of Bonn, Bonn, Germany

Definition and Characteristics of Bran

Bran is the outer coating or shell on grain that is removed while processing white flour. Bran consists of the pericarp, the seed coat, and the aleurone layer. The pericarp itself consists of three layers of differentiated types of cells (**Figure 1**). Wheat, oat, rice, and rye are common sources of bran. The bran content of wheat is approximately 15% of the whole grain. In rice, where the beard is coalesced with the corn, the bran content is only 8%. Typical commercial oat bran products contain large amounts of adhering starchy endosperm, because the endosperm tissues in the oat grain do not separate cleanly and efficiently from the outer layers. Bran has very little taste.

Chemical Composition of Bran

Bran is not a chemically defined substance. The composition of bran depends upon many different factors: species and variety, e.g., grain, kernel seize, shape, maturity, size of germ, and thickness of the outermost layer, length of time and condition of grain storage, system of grain conditioning before milling, the milling system itself, and, above all, the type of flour produced. The lower the extraction rate of the flour, the more endosperm passes to the bran.

Bran is an excellent source of dietary fiber (**Table 1**). However, it is important to recognize that bran is not dietary fiber as such. Bran is also a good source of

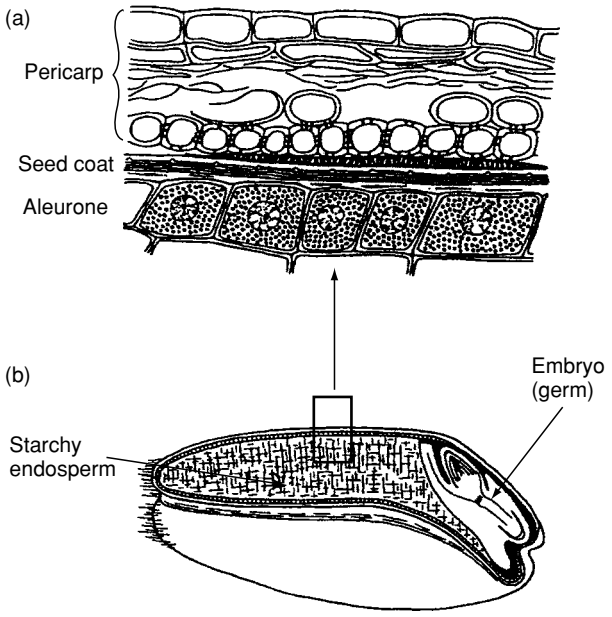

Figure 1 (a) Longitudinal section of the bran layers of a wheat grain showing the different cell types. (b) Longitudinal section through a wheat grain: the rectangle indicates the location of the section shown in (a). From Ferguson LR and Harris PF (1999) Protection against cancer by wheat bran: role of dietary fibre and phytochemicals. *European Journal of Cancer Prevention* 8: 17–25, with permission.

Table 1 Chemical composition of wheat and rice bran

Grams per 100 g dry weight	*Wheat bran*	*Rice bran*
Protein	13–18	12–20
Fat	3–6	3–22
Ash	6–7	9–13
Total dietary fiber	35–58	24–29

Insoluble dietary fiber	32–53	20–24.5
Cellulose	6–12	6–12.8
Hemicellulose	19–31	8.7–17
Lignin	2–8	3–4

certain nutrients. It is rich in protein, which is primarily located in the aleurone layer. Rice bran is a particularly good source of fat (Table 1), mainly oleic acid (40%), linoleic acid (34%), and palmitic acid (17%). Moreover, approximately 70% of the mineral content and between a third (thiamine) and two-thirds (pyridoxine) of the B vitamins of cereal grains are located in the bran fraction. Bran also contains nonessential ingredients like phytic acid and ligans, substances for which the effects on human physiologic functions have not yet been clearly established. (*See* **Fatty Acids**: Properties; **Vitamins**: Overview.)

Dietary Fiber

The high amount of insoluble dietary fiber in cereal brans (Table 1) comes primarily from plant cell walls. The cell walls consist of heterogeneous mixtures of cellulose, noncellulose polysaccharides, and lignin cross-linked to varying degrees to form a complex matrix. Lignocellulose materials and insoluble arabinoxylanes (hemicellulose) constitute most of the mature cell wall of the plant materials such as cereal brans. In addition, cell walls of the seed coat contain cutin, a three-dimensional polyester, which has similar properties to lignin. Moreover, ferulic acid, the predominant phenolic acid in wheat bran, is bound to the cell wall. (*See* **Phenolic Compounds**.)

Cereal brans can also contain varying amounts of *soluble* arabinoxylanes and β-glucans, but no pectins. β-Glucan is a soluble polysaccharide that is formed exclusively by glucose residues. In contrast to the insoluble cellulose, β-glucans are formed not only by β-1,4 but also by β-1,3 glycosidic bonds. The ratio of β-1,3 and β-1,4 glycosidic bonds is approximately 3:7. Normally, blocks of two to 10 β-1,4-glycosidic glucose residues are interrupted by β-1,3-glycosidic bonds. High amounts of β-glucans are found in the aleurone layer and in the adhering endosperm of some cereal brans. Similar to pectin, the physiologic effects are related to the viscosity of β-glucans. (*See* **Carbohydrates**: Classification and Properties.)

Like wheat bran (Table 1), barley bran contains up to 55% of dietary fibers, of which normally 90% are insoluble. Barley bran contains approximately 5% of β-glucans. Special barley subspecies like 'Prowashonupana' contain up to 15% β-glucans. The dietary fiber content of rye bran is 28–36% and is thus lower than that in wheat bran. However, the amount of soluble arabinoxylanes in rye bran (15–25%) is relatively high compared with wheat bran (1–1.5%). In oat bran, the total amount of dietary fiber is 15–18% with about 50–60% insoluble and 40–50% of soluble dietary fibers. Oat bran normally contains 5–8% β-glucans.

The rice bran produced under normal milling conditions is unpalatable. When brown rice is milled to white rice, the oil in the rice bran comes into contact with a potent lipase also present in the bran, resulting in rapid degradation of the oil to glycerol and free fatty acids. However, if the bran is subject to a short-term high-temperature heat treatment immediately after milling, the lipase activity is destroyed, and a stabilized bran is produced. In contrast to other cereals, the rice grain has the ability to enrich silicium. Therefore, the industry standard for rice bran is a maximum of 0.1% silicium dioxide.

Phytic Acid

Phytic acid, the hexaphosphate of myo-inositol, is an abundant component of bran, where it occurs as a magnesium–calcium salt. The phytic acid content of

different types of bran can vary widely. Rice bran contains approximately 10% phytic acid, whereas wheat bran and rye bran contain only 5%. The phytic acid content of different cereals depends on the botanic subfamily to which the grain belongs. Wheat and rye are members of the Hordeae subfamily, whereas rice is a member of the Oryzeae. The phytic acid content of oat bran (subfamily: Aveneae) is approximately 6%.

Phytic acid can strongly chelate multivalent metal ions, especially the positively charged ions zinc, calcium, and iron. The chelates are named phytates. Such chemical bonds with multivalent cations can be formed intra- and intermolecularly by one or several phosphate groups of the pyhtic acid molecule (Figure 2). These complexes are insoluble.

The distribution of phytic acid in different morphologic layers of seeds can vary significantly. In cereal grains from the Hordeae subfamily, phytic acid is normally concentrated in the aleurone cells and, to a lesser degree, in the germ. The aleurone layer of wheat grain, for example, contains 85% of the phytic acid, the embryo 13%, and the endosperm 2%. In contrast, 80% of the phytic acid content of rice and maize is concentrated in the pericarp and embryo, respectively.

Inositol-6-phosphate and inositol-5-phosphate show the strongest inhibiting effect on mineral bioavailability, whereas the effect of inositol-4-phosphate and inositol-3-phosphate, two products of inositol-6-phosphate hydrolysis, is markedly lower. Phytic acid is hydrolyzed by the enzyme phytase. This enzyme was first described in rice bran. In wheat bran, the highest phytase activity is present in the aleurone layer, where more than 40% of the phytase activity is located. Approximately 34% is present in the endosperm, 15% in the scutellum, and 3% in the germ. In rye bran, the phytase activity is 10–20 times higher than in the rye flour. The total amount of cereal phytase activity varies depending on the food origin: phytase activity is high in wheat and rye grains, medium in barley, and low to very low in oat and maize grain. (*See* **Phytic Acid**: Properties and Determination; Nutritional Impact.)

Lignans

Lignans are phenolic dimers possessing a 2,3-dibenzylbutane structure. Such compounds are known to exist as minor constituents of many plants, where they form the building blocks for the formation of lignin in the plant cell wall. The compounds occur mainly in the glycosidic form. In rye, lignans are predominantly present in the bran fraction (Table 2). The glycosides are converted by fermentation in the proximal colon to mammalian lignans. The two major mammalian lignans, enterodiol and enterolactone, are the products of colonic bacterial metabolism of the plant lignans secoisolariciresinol and matairesinol.

Table 2 Lignan content of whole grains and bran[a]

	Secoisolariciresinol (μg per 100 g dry weight)	*Matairesinol (μg per 100 g dry weight)*
Wheat bran (whole grain)	33	3
Wheat bran	110	0
Rye meal	47	65
Rye bran	132	167
Oat meal	13	0
Oat bran	24	155
Barley (whole grain)	58	0
Barley bran	63	0

Physiologic Effects of Bran

Stool weight

Stool weight is significantly increased by adding sources of insoluble fiber to the diet. The physiological effect of dietary fiber is largely determined by the size of the particles. One gram of fine wheat bran increases the stool weight by 3.1 g, and 1 g of coarse bran increases the stool weight by approximately 6.2 g. Barley bran is more effective in increasing stool weight than fine wheat bran but less effective than coarse wheat bran. Comparable amounts of fiber provided by wheat and oat bran have the same effect on daily stool output, even though > 90% of wheat bran fiber and only 50–60% of oat bran fiber are insoluble. Wheat bran increases the fecal concentration of sugars and mass of plant material more than oat bran, whereas oat bran increases the fecal bacterial mass more. Oat bran increases the stool weight by providing rapidly fermented soluble fiber in the proximal colon for bacterial growth, which is sustained until excretion by fermentation of the insoluble fiber. Bacteria and lipids are major contributors to the increase in stool weight with oat bran consumption, whereas ingested plant fiber is responsible for much of the increase in stool weight with wheat-bran consumption.

Constipated subjects should start increasing dietary fiber by 2–4 g, e.g., with 1–2 tablespoons of bran. Plenty of liquid should be taken with bran, as it may cause irritations in the digestive tract. Intake can be increased to three times a day with a meal. Bran should be mixed with food in order to absorb water and increase stool volume. Coarse bran holds water better than fine bran. Depending on the severity of constipation, improvement may take a few days to several months.

Sterol Metabolism

Bile acids Soluble dietary fiber can adsorb bile acids. Accordingly, oat bran and rye bran increase fecal excretion of total bile acids, whereas wheat bran has no or only modest effects. Moreover, oat bran and rye bran influence the metabolism of bile acids. Rye bran increases the daily excretion and percentage of conjugated primary bile acids (cholic acid, chenodesoxycholic acid) and lowers the percentage of free secondary bile acids (desoxycholic acid, lithocholic acid). Rye bran thus decreases the ratio of secondary bile acids to primary bile acids. Rye bran, but not wheat bran or barley bran, reduces the ratio of lithocholic acid to desoxycholic acid. Oat bran enlarges the cholic acid pool, increases the relative proportion of chenodeoxycholate in bile, and reduces the relative proportion of desoxycholic acid, whereas cholate remains unchanged.

Blood cholesterol levels Since the first study performed in 1963 in humans with fiber-rich rolled oats, several studies have reported a beneficial effect of oat bran or oat meal-enriched diets on plasma cholesterol levels in healthy subjects or mildly hyperlipidemic subjects. The daily intakes ranged from 17 to 100 g oat bran, and the duration was 2–12 weeks. Oat bran and oat gum (80% β-glucan) has been served in drinks and instant whips, or baked in bread and muffins. The majority of controlled studies performed in hyperlipidemic subjects showed a decrease in plasma total cholesterol, with most decreases in the range of −4 to −10%. It is noteworthy that decreases in plasma cholesterol are related to decreases in LDL cholesterol, whereas while HDL cholesterol does not generally noticeably change. Consequently, oat bran causes a modest reduction in blood cholesterol level. Larger reductions are seen in subjects who have initially higher blood cholesterol levels ($> 5.9\,\text{mmol}\,\text{l}^{-1}$ or $229\,\text{mg}\,\text{dl}^{-1}$). Studies have shown clearly that soluble β-glucan in oat fiber has a cholesterol-lowering effect in animals and humans. About 3 g of β-glucan per day causes a 10% drop in LDL cholesterol. In bread and muffins, the baking process can decrease the solubility and/or molecular weight of β-glucans, resulting in a weak serum cholesterol-lowering effect. Approximately 100 g of oat bran should be ingested daily to have any effect on plasma cholesterol levels. Oat β-glucan also improves glucose and insulin regulation. The mechanisms of action of viscous polysaccharides like β-glucans in the human gastrointrestinal tract are not completely understood. Increased luminal viscosity is believed to cause delayed gastric emptying and reduce the rate of absorption of nutrients in the small intestine, thereby attenuating the postprandial glucose and insulin response to an oral carbohydrate load. Viscous gums alter bile acid- and cholesterol metabolism, reduce and alter the site of lipid absorption, and undergo fermentation in the colon to short-chain fatty acids. All of these effects might contribute to a reduction in serum cholesterol levels in humans. Full-fat rice bran leads to a similar reduction in serum LDL cholesterol compared with oat bran. Rice bran contains low amounts of soluble fiber, but rice bran oil has a hypolipidemic effect. Essentially all human studies performed since 1969 have shown no effects of wheat bran on fasting blood total cholesterol as well as LDL cholesterol in healthy or hyperlipidemic subjects following a chronic intake of 14–77 g of wheat bran per day. Moreover, in rats, wheat bran essentially does not change fasting blood lipid parameters.

(*See* **Cholesterol**: Properties and Determination; Absorption, Function, and Metabolism.)

Female sex hormones A daily intake of 15 g of wheat bran can significantly reduce circulating levels of estradiol and estrone in premenopausal women by approximately 15–20%. The mechanism by which wheat bran modulates serum estrogen levels most likely involves their enterohepatic circulation. Estrogens are conjugated in the liver to form glucoronides and sulfoglucoronides, and 20–50% of estrogen metabolites are excreted in the bile as these polar biologically inactive substances. Approximately 80% of the estrogens in the gut are reabsorbed, a process that requires deconjugation by bacterial enzymes. Wheat bran intake may lower fecal β-glucoronidase activity. An additional mechanism may be the binding of unconjugated estrogens to fiber in the gut, thus impeding their reabsorption. Oat bran causes reductions in fecal β-glucuronidase activity to a lesser extent than wheat bran. Maize bran has no significant effect on this enzyme.

Vitamin D A high intake of wheat bran can also influence the metabolism of vitamin D, another steroid substance: an additional intake of 20 g of dietary fiber per day from wheat bran can reduce the plasma half-life of tritium-labeled 25-hydroxyvitamin D by approximately 30%. A dietary fiber-induced decrease in vitamin D status may diminish active absorption of dietary calcium. The occurrence of rickets and osteomalacia in Asians living in the UK has been partially associated with a high intake of fiber-rich chapatties (unleavened bread). However, such an adverse effect may only be of clinical importance in subjects with marginal or insufficient vitamin D status and low dietary calcium intake. (*See* **Vitamins**: Overview.)

Effects of Bran on Mineral Metabolism

It has been demonstrated in several human studies that wheat bran and high-fiber diets decrease intestinal Ca absorption. Wheat bran alters the usual inverse relationship between calcium load and fractional absorption in humans. This effect is the result of the high Ca-binding capacity of wheat bran. At pH 8.0, 1 g of wheat bran can bind approximately 0.45 mmol of calcium. This amount is slightly higher than the calcium binding of rye bran (0.38 mmol of Ca per gram of bran) and slightly lower than the calcium binding of rice bran ($0.49\,\text{mmol}\,\text{g}^{-1}$), whereas soy bran only binds 0.19 mmol of calcium per gram at pH 8.0. In wheat bran, phytic acid and dietary fiber are both present in high quantities. Theoretically, each mole of phytic acid can maximally bind 6 moles of calcium. Phytic acid can form insoluble calcium salts resulting in a low bioavailability of calcium, but wheat bran can bind more calcium *in vitro* than expected from the molar binding ratio of bran phytate:calcium. *In vitro* calcium binding to wheat bran is linear over a wide range. Thus, the amount of calcium binding by wheat bran cannot be explained by the content of phytic acid alone. Other bran constituents may influence calcium bioavailability. Although neutral cellulose has little affinity to cations, lignin strongly binds calcium. The lignin in wheat bran is indigestible during the gastrointestinal transit. However, as the result of an adaptation process, wheat bran intake is also associated with a reduced renal calcium excretion. Consequently, a high bran intake does not necessarily increase the risk of a negative calcium balance.

Intakes of high (> 15 g) amounts of bran (wheat, oat, barley) can reduce zinc absorption and decrease iron availability. Measures to reduce the phytate content of cereals like malting and soaking (activation of endogenous phytase activity) can significantly improve zinc and iron absorption. Nevertheless, in diets that provide sufficient amounts of trace elements, decreased absorption does not necessarily influence the trace element balance and status of human subjects. A reduced endogenous fecal excretion can compensate for the lower absorption. However, if zinc and iron intakes are marginal or inadequate, the additional consumption of a fiber concentrate may contribute to the development of trace element deficiencies.

In animal diets, supplemental phytases of microbial and cereal sources improve dietary phytate phosphorus utilization. Such a measure is environmentally advantageous in order to replace the content of inorganic phosphorus in those diets.

Beneficial Health Effects of Bran and its Components

In animals, wheat bran causes a significant reduction in incidence of mammary cancer. A suggested protective effect of wheat bran on breast cancer in humans may be due, at least in part, to the effect on circulating estrogen concentrations and their bioavailability. Moreover, the lignans especially present in the aleurone layer of some cereals (Table 2) may exert antiestrogenic effects in humans.

Wheat bran and its component phytic acid have both been shown to decrease early markers of colon carcinogenesis like certain indices of cell proliferation and certain aberrant cryt foci parameters. Wheat bran, dephytinized wheat bran, and phytic acid induce cell apoptosis, increase cell differentiation,

and favorably affect colon morphology, thus indicating that phytic acid as well as other components of bran may be preventive against colon cancer. A lower concentration of the co-carcinogenic secondary bile acids and a high bacterial production of butyrate may contribute to a normal metabolism and proliferation of the colon epithelial cells after bran intake.

Phytic acid inhibits *in vitro* and *in vivo* the enzymatic degradation of starch and reduces the glycemic index owing to complexation of the starch molecule, amylase, and calcium ions, which are essential for the amylase activity. The reduced rate of glucose absorption and reduced postprandial increase in blood glucose may both be beneficial in prophylaxis and treatment of diabetes mellitus. Protective effects of phytic acid against lead toxicity have been demonstrated in the presence of calcium ions. Acute toxic effects of 1 g of lead per kilogram of diet can be reduced by 20 g of calcium phytate per kilogram.

Commercial Products

Both fine wheat bran and coarse wheat bran are available for the consumer. One tablespoon of bran contains approximately 2 g of dietary fiber. Bran may be used alone as a cereal, mixed with other cereals, sprinkled on cereals or included in bran muffins, hamburgers, etc. Bran is legally regarded as a food. Moisture should not exceed 14%, and the amount of starch in wheat bran should not exceed 15% of the dry weight. Since especially the bran fraction of wheat can accumulate relatively high amounts of cadmium, the cadmium content should not exceed 50–60 $\mu g\,kg^{-1}$. Wheat bran tablets are also obtainable – one tablet equals approximately 2 g of dietary fiber. Moreover, breakfast cereals with a bran content up to 85% are in the market (such as Kellogs All-Bran Plus™). These products contain 11 g of dietary fiber per 40-g portion. Several baked goods are enriched with wheat bran to increase the fiber content. Enrichment should at least result in a doubling of the dietary fiber content, and a good source of dietary fiber should contain 2 g per portion. Although coarse wheat bran increases the stool weight more efficiently than fine wheat bran, the latter is often used to enrich baked goods, as it is easier to process and is preferred by the consumer.

Pure oat bran flakes are also commercially available. One portion (25 g) of oat bran contains approximately 2.3 g of insoluble and 1.95 g of soluble dietary fiber. Moreover, oat bran-enriched breakfast cereals and oat flakes containing 80% oat bran are obtainable, and oat bran can be used as a fat replacement in sausages like Frankfurters (6% oat bran, 30% water).

Protex™ (Food Engineering International, Inc.) is a specially processed rice bran derivative that may be used in baked goods, breakfast cereals, macaroni and noodle products, and milk-like beverages.

New Potential Sources

Psyllium is a new source of dietary fiber. It is made from ground husks of psyllium seeds and has the ability to hold water and form bulk. Psyllium contains up to 85% soluble fiber. Psyllium holds water better than bran, so smaller amounts are needed to be effective. Moreover, psyllium effectively lowers serum LDL cholesterol and blood glucose and insulin levels. In 1998, the US Food and Drug Administration ruled that psyllium, like oat bran, may reduce the risk of heart disease. Psyllium has several advantages over oat bran. It is more versatile, since it is a far more concentrated form of fiber. The US Food and Drug Administration allows the addition of psyllium to breakfast cereals, and FDA officials expect more psyllium-containing foods, from waffles to biscuits, to hit the market.

Soy bran is a dietary fiber concentrate that is obtained during the production of soy protein, and the insoluble portion is separated by centrifugation. The concentrate is defatted and contains the soy hulls. The dietary fiber content is approximately 67–80% (Table 3). Soy bran is sold in competition with other dietary fiber concentrates. It is effective in increasing stool weight (Table 2), and 25 g of soy fiber significantly reduces total serum cholesterol levels, especially in patients with blood cholesterol concentrations above 7.7 $mmol\,l^{-1}$ (300 $mg\,dl^{-1}$).

Several other food residues with a high dietary fiber content are obtained during food processing (Table 4). They can be used by food technologists, e.g., for the fiber enrichment of bread (beer draff) or for the processing of fiber and β-carotene-rich fruit juices (carrot husks).

Wheat fiber (fiber content 97%) is a concentrate of cellulose and hemicellulose that is free of phytic acid

Table 3 Effect of bran and other fiber-rich foods on stool weight

	$\text{Efficiency index} = \frac{\text{increase in stool weight (g)}}{\text{fiber intake (g)}}$
Wheat bran, fine[a]	3.1
Wheat bran, coarse[a]	6.2
Bread, whole wheat grain, fine[a]	5.6
Bread, whole wheat grain, coarse[a]	8.2
Barley fiber concentrate[a]	4.2
Oat bran[a]	4.54
Soy bran[b]	1.5–2.3
Carrots, raw[a]	3.6

[a]Daily intake of 14 g of fiber; [b]daily intake of 30–65 g of fiber.

Table 4 Different fiber concentrates of food residues

Concentrate	*Dietary fiber content (g per 100 g dry weight)*
Beer draff	60–82
Maize bran	42–79
Soy bran	67–80
Pea seeds	83–90
Sugar-beet fiber	67–72
Citrus fiber, orange fiber	50–60
Cacao seeds	55
Carrot husks	60–68

and gluten. This insoluble wheat fiber can be used for the production of common foods and also for the preparation of dietetic foods (e.g., for patients with celiac disease).

The drying of apples results in a dietary fiber concentrate that is rich in soluble fiber (pectins). The combination of wheat and apple fiber influences the ratio of insoluble to soluble dietary fiber in processed foods.

Energy Value

S Brooks, 3W Banting Research Centre, Ottawa, Canada
R Mongeau, Ottawa, Aylmer (Quèbec), Quebec, Canada

Caloric Value in Human Nutrition

All food contains energy, which is needed by the body to fuel metabolic processes. This energy is obtained though the oxidation of macronutrients (carbohydrate, fat, and protein) and is partly captured as chemical energy in compounds such as adenosine triphosphate (ATP). These 'high-energy' compounds are used to drive many processes, including the biosynthesis of cellular components, the maintenance of ion concentrations across membranes, the initial phases of catabolic pathways, cell replication, mechanical function, etc. The large amount of energy released by the hydrolysis of ATP (approximately $7\,\text{kcal}\,\text{mol}^{-1}$ under cellular conditions) is captured by coupling its hydrolysis to other chemical reactions to drive them to completion.

The energy captured as ATP equivalents is one end of a long chain of digestive and metabolic processes that starts as the gross energy of the macronutrients in ingested food (**Figure 1**). Significant losses in energy occur during the digestive process. These can be identified and quantified as losses due to incomplete digestion and absorption (loss in fecal energy to give apparent digestible energy; DE_{app}), losses to fermentation gases and urinary nitrogen energy (to give apparent metabolizable energy), as well as losses associated with the digestive process itself and with the absorption and storage of food (to give net energy). Calculating the metabolizable energy from a food requires the collection of all excreta (including methane and hydrogen gasses). For substances that are fermented, extra information is also required as discussed later in this chapter. Net energy values are more difficult to estimate and require some assumptions about digestive processes (see section on Factorial Models of Fermentation, eqn (19)).

Metabolizable energy values are the commonly reported food energy values found on product labels. These were initially determined in the 1900s by a German scientist who was a pioneer in this area. To honor his name, these factors are commonly referred to as 'Atwater factors.' Both general and specific Atwater factors exist. The specific values were measured in individual foods. The general values (4 for carbohydrate, 9 for fat, 4 for protein, and 7 for alcohol) were calculated from the specific Atwater factors using

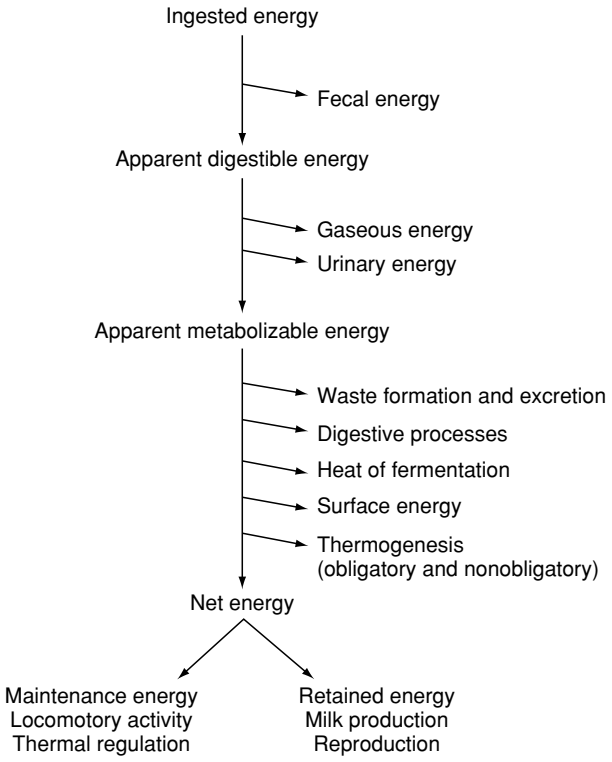

Figure 1 Diagrammatic representation of the energy losses associated with various stages of digestion and the resulting determined energy values.

average intakes of mixed diets. The more modern food energy values, as contained in tables such as the US Department of Agriculture Handbook #8, represent specific Atwater factors as modified by Merrill and Watt. Although we refer to these factors as metabolizable energy values for macronutrients, the values for carbohydrate and fat are, in reality, DE_{app} values. This is because urinary and gaseous energy losses were considered as insignificant for these macronutrients. In the case of the protein Atwater factors, urinary energy losses were taken into account, but gaseous energy losses were, again, assumed to be negligible. The Atwater factors for fat, protein, and carbohydrate represent the total energy available for metabolism, and this heat should be equivalent to the energy measured with a whole-body calorimeter.

Digestible sugars, fats, and protein are readily absorbed in the small intestine by physiological and biochemical processes that capture the maximum energy from these food components. These macronutrients are virtually completely absorbed by the small intestine with little energy finding its way into the large intestine. In fact, with diets high in digestible sugars, fats, and protein, most of the energy entering the large intestine comes from small intestine secretions and from the sloughing off of dead intestinal cells. It is the relative simplicity of the digestive process coupled with the high degree of absorption that allows the comparatively easy metabolic energy calculation for these macronutrients.

Not all food components are readily digested and absorbed in the small intestine. Nonstarch long-chain polysaccharides such as those associated with plant cell walls are not digested by human enzymatic secretions. Many other carbohydrates are not well absorbed by the small intestine. These pass into the large intestine where they are anaerobically fermented by the bacterial population that resides there. For sake of clarity, the terms 'undigested' and 'resistant' will be used here to refer to the degradation processes occurring in the upper gastrointestinal tract (mostly by host digestive enzymes), and the term 'fermentation' and related words will be used to refer to the bacterial degradation processes occurring in the lower gastrointestinal tract. The energy losses associated with fermentation are not as readily measured, and so calculation of the metabolizable energy for fermentable food components is not as straightforward as it is for sugars, fats and protein. The present chapter outlines different methods for obtaining the metabolizable energy of food components not digested and absorbed in the small intestine.

A short note about the methods used to determine macronutrient content of foods is in order. In some countries like the USA and Canada, the carbohydrate content is determined by subtracting the fat, protein, water, and ash content of the food from the total weight (difference method). This measurement includes both 'available carbohydrate' (i.e., carbohydrate that can be digested in the small intestine) as well as dietary fiber. Other countries, such as Great Britain and Australia, measure 'available carbohydrate' directly using chromatographic methods. The carbohydrate values from this latter method do not include dietary fiber. Specific Atwater factors used in the USA and Canada take into account some (but not all) of the energy losses associated with dietary fiber because they rely on the apparent digestibility of carbohydrate to calculate food energy. This approach overestimates energy availability from mixed diets. In Europe, the general Atwater factor for carbohydrate ($4\,kcal\,g^{-1}$, $16.7\,kJ$) is used to calculate carbohydrate energy after subtracting the dietary fiber content. This method underestimates the energy of mixed diets. When 'available carbohydrate' is measured directly, one must also measure dietary fiber and use a dietary fiber-specific energy value to calculate the energy contribution from dietary fiber.

Digestible Energy and Metabolizable Energy: Calculations

Digestible Energy

As noted above, the digestible energy of a substance is the difference between the ingested energy and the energy excreted in the feces. This is, in principle, a simple definition but gives rise to two different digestible energy values depending on how the measurement is made: the apparent digestible energy and the partial digestible energy. We begin by defining IM_s as the ingested mass of a measured substance FM_s as the amount of the substance of interest. This substance can represent any dietary material but for the purposes of this article, we will assume that it escapes digestion in the small intestine and reaches the large intestine where it may (or may not) be fermented. If we further define recovered in the feces, the apparent digestibility (D_{app}) can be calculated as:

$$D_{app} = (IM_s - FM_s)/IM_s. \quad (1)$$

The apparent digestible energy value (DE_{app}) is simply the apparent digestibility multiplied by the heat of combustion (ΔH_c) of the material:

$$DE_{app} = D_{app} \times \Delta H_c. \quad (2)$$

The DE_{app} takes into account only the energy loss associated with incomplete digestion of a single food component and not any potential interaction of the component with macronutrients. If the food component is fermented, part of its energy value will be captured and utilized by the host, part of the remaining energy will appear in the feces, and part will be lost to other processes (discussed below). Thus, the DE_{app} overestimates the true digestible energy.

Partial digestible energy values (DE_{part}) describe the influence of a dietary substance on the energy digestibility of the whole diet. As such, they represent a more complete picture of the energy intake and excretion associated with ingestion of a particular food component. Calculating DE_{part} values requires measurement of overall energy balance. The first step is to define the energy digestibility (D_{energy}) of the overall diet as:

$$D_{energy} = (IE_T - FE)/IE_T, \quad (3)$$

where IE_T is the total ingested energy, and FE is the fecal energy. Partial digestible energy values are determined by adding a varying amount of a food component (as a supplement) to an unchanging basal diet. The energy digestibilities of the unsupplemented and supplemented diets are then determined (eqn (3)) and are plotted as a function of the fraction of ingested energy that is derived from the supplement (IE_S/IE_T). If the supplement has a lower digestibility than that of the overall diet, the graph should be a straight line with a negative slope – the energy digestibility of the overall diet will decrease with increasing amounts of the supplement. The partial indigestibility of the supplement (S_D) is given by:

$$S_D = \Delta D_{energy}/\Delta(IE_S/IE_T) + (1 - D_{energy,0}), \quad (4)$$

where $D_{energy,0}$ is the energy digestibility of the basal (unsupplemented) diet. The DE_{part} is obtained by multiplying the partial digestibility (1 − the partial indigestibility) of the supplement by its heat of combustion.

$$DE_{part} = \Delta H_c \times (1 - S_D). \quad (5)$$

Partial and apparent digestibilities can differ by a considerable amount. In general, $DE_{part} < DE_{app}$ because DE_{part} includes energy losses that are not accounted for by DE_{app} measurements. This is illustrated by an experiment that compared the DE_{app} and DE_{part} values for the fiber component of hard red wheat bran (bran is approximately 40% fiber). Measurement of the diet and fecal fiber content as well as the diet and fecal energy content gave a $DE_{app} = 1.82 \pm 0.17\,kcal\,g^{-1}$ ($7.6\,kJ\,g^{-1}$) and a $DE_{part} = 0.45 \pm 0.10\,kcal\,g^{-1}$ ($1.9\,kJ\,g^{-1}$). The DE_{app} value shows that, for every gram of wheat bran fiber ingested, $4.15 - 1.82 = 2.33$ kcal (9.7 kJ) of energy was lost to feces in the form of fiber. The DE_{part} value shows that $1.82 - 0.45 = 1.37$ kcal (5.8 kJ) of extra energy was lost to the feces in addition to that lost from fecal fiber excretion. Thus, only $0.45/1.82 \times 100\% = 25\%$ of the energy of the fermented wheat fiber was potentially retained by the rats (see below for other calculations on the metabolizable energy value of wheat fiber). These calculations show the importance of determining the total energy losses in a digestion experiment involving fermentable substances.

Metabolizable Energy

Like digestible energy values, it is possible to define two different metabolizable energy values. Livesey (1993) calls the Atwater metabolizable energy values 'apparent metabolizable energy' values (ME_{app}) because they do not take into account all the energy losses normally associated with metabolizable energy measurements:

$$ME = IE - (FE + UE + GE) \quad (6)$$

where UE is the urinary energy and GE is the gaseous energy. If a strict parallel between digestible energy and metabolizable energy is to be made, one could also define ME_{app} as $DE_{app} - (UE + GE)$. In essence,

this is the definition used by Atwater with some assumptions. For fat and carbohydrate, it was assumed that GE and UE were negligible. For protein, it was assumed that GE was negligible but UE was not.

Partial metabolizable energy values (ME_{part}) can also be calculated in a fashion analogous to DE_{part} values. In this case, we define the total energy loss as:

$$\sum E_{losses} = FE + GE + UE. \quad (7)$$

Once again, we define the energy metabolizability of the total diet as:

$$M_{energy} = (IE_T - \sum E_{losses})/IE_T \quad (8)$$

and use this value to define a partial energy 'non-metabolizability' (S_M).

$$S_M = \Delta M_{energy}/\Delta(IE_s/IE_T) + (1 - M_{energy,0}), \quad (9)$$

where $M_{energy,0}$ is the energy metabolizability of the basal (unsupplemented) diet. The ME_{part} is then given by:

$$ME_{part} = \Delta H_c \times (1 - S_M). \quad (10)$$

Equations that minimize the error structure for experimentally determining DE_{part} and ME_{part} are also available.

Like DE_{part} values, ME_{part} values describe the influence of a part of the diet on the energy metabolizability of the whole diet. For protein and fat, it is thought that $ME_{part} > ME_{app}$ because fecal excretion of bacterial nitrogen and fat will decrease the ME_{app} value. Note that energy losses to bacterial fat and nitrogen are not simply due to the loss of macronutrient mass. Energy is required for the *de novo* bacterial synthesis of fat- and protein-containing macromolecular structures, which are then excreted in the feces. This energy is also lost. For carbohydrates, it is thought that ME_{part} and ME_{app} are equivalent since bacteria do not contain appreciable amounts of carbohydrate. For carbohydrates that escape digestion in the small intestine and are partially or completely fermented, like those in dietary fiber, $ME_{app} > ME_{part}$ because of the extra energy losses that occur during fermentation. This energy loss is the subject of this chapter.

Metabolizable or Net Energy?

The discrepancies between ME_{app} and ME_{part} energy values mean that a more accurate system for measuring food metabolizable energy must be employed for diets containing appreciable amounts of undigested and fermented carbohydrates as the greatest differences occur with these food components. Many methods can be used to obtain the ME values of food components that are not digested by the small intestine. Whole-body calorimetric measurements (in a chamber where an individual can be placed for experimentation) can be used to determine the energy value directly, estimates of the metabolizability can be obtained from mixed diets, body energy measurements can be made in laboratory animals and related back to the metabolizable energy of the food, and theoretical calculations can provide a general model for estimating metabolizable energy.

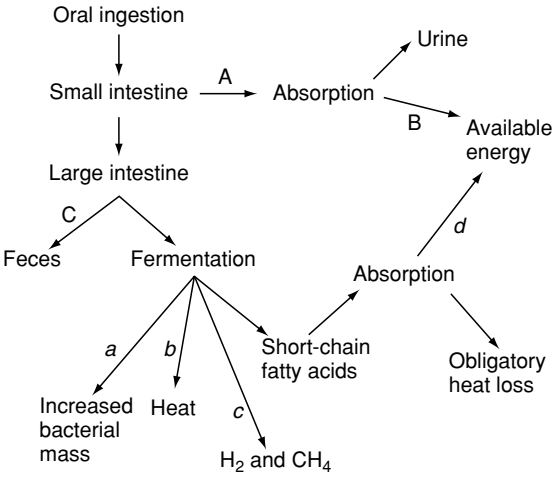

Figure 2 Scheme showing various stages of digestion of a macronutrient that is partially digested in the small intestine and partially fermented in the large intestine. The letters represent fractions of the initial amount that proceed down various pathways (see text).

Large differences exist between the energy losses associated with the digestion of macronutrients (fat, carbohydrate, and protein) and undigested and fermented carbohydrates. Figure 2 shows an example of the various processes that occur in the gastrointestinal tract during the consumption of a partially digested and partially fermented food. Because the final energy value is net of all major losses of energy, many researchers have called it a net metabolizable energy (NME). This should not be confused with the net energy values used for livestock, which represent different energy measurements. Also, it is not the net energy of Figure 1, which incorporates many more energy losses. The NME is a more practical measure of food energy for undigested and fermented substrates because it takes into account energy losses that do not occur for fat, carbohydrate, and protein. Use of this value would allow comparisons between the energy values of different food components.

Mathematical Models for Undigested and Fermented Compounds: Sugar Alcohols

It is technically difficult and expensive to measure all stages of the fermentation process and determine the

energy losses associated with each step. This is true of human whole-body calorimetric measurements since analysis requires a complete energy balance profile for each subject (see below). A more simplistic approach involves the construction of a mathematical model of the digestive events in the large intestine. This approach has most commonly been applied to the energy value of sugar alcohols but can also be extended to other partially or completely fermentable carbohydrates.

Common dietary sugars (such as glucose, galactose, and fructose) have a ketone or aldehyde group that allows cyclization to a hexose or pentose ring structure. Reduction of this carbonyl group to an alcohol produces a sugar alcohol that cannot cyclize. The resulting sugar alcohols are not well absorbed in the small intestine so that a significant percentage can pass intact into the large intestine. Isomalt (Palatinit®), an equimolar mixture of two disaccharide alcohols (α-D-glucopyranosyl-1,1-D-mannitol and α-D-glucopyranosyl-1,6-D-sorbitol), is an example of a sugar alcohol that is virtually unabsorbed in the small intestine. It passes intact into the large intestine, where it is rapidly and completely fermented by the bacterial population that resides there. As such, it represents a model for a theoretical dietary fiber that is completely fermented in the large intestine and can be used as a basis for constructing a mathematical model.

A good mathematical model seeks to define all losses that occur during fermentation of ingested material and assign reasonable factors to these losses. Figure 2 presents the scheme for such a model. Fermentable substances provide carbon units for bacterial growth and reproduction and serve as metabolizable substrates to meet the colonic bacterial population's energy requirements for maintenance and growth. Four major products result from anaerobic colonic fermentation: increased bacterial mass (factor *a*, Figure 2), heat energy loss due to fermentation (factor *b*, Figure 2), methane and hydrogen gas (factor *c*, Figure 2), and short-chain fatty acids (SCFAs). Humans can only use SCFAs as an energy source. Thus, the metabolic energy yield of the sugar alcohol has been reduced by the losses to bacterial mass, as well as the heat and gas produced during fermentation. It has also been reported that SCFAs may produce significantly less ATP per gram of absorbed SCFA than glucose, so an additional energy loss to this difference in metabolic efficiency should also be included (factor *d*, Figure 2).

The fermentation model of Figure 2 can be expressed as an equation that incorporates the four major processes by which energy is lost during fermentation. The equation describing the scheme of Figure 2, as it applies to sugar alcohols, was first developed for the Nutrition Council of Holland and has been recognized by several authors as an alternative method for calculating the energy value of sugar alcohols. For partly fermentable substances, it can be written as:

$$\mathrm{NME} = \Delta H_c \times [(A \times B) + \alpha \times (1 - A - C) - \beta], \tag{11}$$

where, ΔH_c is the heat of combustion of the substance in question, A represents the fraction of the ingested substance absorbed in the small intestine, B represents the fraction of absorbed substance that is metabolized, and C represents the fraction of the ingested substance that is excreted intact in feces (Figure 2). The factor α represents the proportion of energy derived from fermentation of the substance. It can be calculated from eqn (12):

$$\alpha = (1 - a - b - c) \times d. \tag{12}$$

The factor β was not present in the original equation and represents the extra energy lost due to the presence of the fermentable carbohydrate. This can come about through binding to macronutrients, changes in osmotic balance, alterations in transit time, changes in intestinal viscosity, inhibition of digestive enzymes, inhibition of macronutrient uptake, or increased sloughing of intestinal cells. As discussed above (see section on DE_{part} and ME_{part}), measuring the appearance of an undigested food component in the feces is not sufficient to account for all of the energy losses that can occur when a diet is supplemented with a fermentable carbohydrate. In a practical sense, it is impossible to differentiate between any 'extra' energy lost to the feces (β) and the energy lost due to increased bacterial mass that results from fermentation (factor *a*). The solution is to set $\beta = 0$ in eqn (11) and measure total fecal output.

Using the mathematical model of eqns (11) and (12) requires a knowledge of factors A, B, and C, which are obtained from experimental evidence. For sugar alcohols, values for factor A have been obtained from ileostomy patients or by direct sampling using multiple lumen tubes. Factor B (the amount of sugar alcohol metabolized) has been estimated indirectly by measuring urinary sugar alcohol content (the amount of sugar alcohol not metabolized).

In the original factorial model paper, the Nutrition Council of Holland held α to be constant for all sugar alcohols and estimated it at 0.5. This value included fermentation energy losses resulting from increased microbial mass excreted in the feces ($a \approx 0.2$), loss of H_2 and CH_4 ($c = 0.03$–0.08), heat produced by microbes ($b = 0.02$–0.05), and higher heat loss during utilization of short-chain fatty acids as compared

Table 1 Potential error associated with oxidation of 50 g of a carbohydrate versus fermentation and oxidation of the released short-chain fatty acids[a]

Substrate	*RQ*	*Oxidation substrates (mol)*[b]	*O_2 consumed (mol)*	*H^{eq}*[c]	*kcal per 50 g*
50 g of sucrose	1.00	0.146 CHO	1.753	5.012	250.6
50 g of lactitol	0.943	0.409 (CHO) + 0.099 (fat)	1.113 (CHO) + 0.269 (fat)	4.981 (CHO) + 4.682 (fat)	153.1
50 g of lactitol	0.943	0.508 SCFA	1.382	4.663	144.5

[a]The table illustrates the potential error involved in measuring the apparent metabolic energy value of a completely fermentable supplement (lactitol) by indirect calorimetry. This was done by calculating the apparent metabolic energy value using two different methods. It was assumed that lactitol was fermented to a mixture of SCFAs followed by complete oxidation to CO_2 and water plus fermentation gases. In an indirect calorimeter, oxidation of SCFAs can be mistaken as oxidation of fat and carbohydrate in a 0.195:0.808 ratio. Oxidation of these substrates would give 153.1 kcal per 50 g. Oxidation of the SCFA directly would give 144.5 kcal per 50 g of original lactitol. Thus, an error of approximately 6% can occur when indirect calorimetry is used to measure the metabolic energy value of lactitol. The yield of SCFAs from lactitol and the proportion of acetate, propionate, and butyrate (115.1:35.38:24.5 per 100 mol of glucose) represent weighted averages of literature values for ruminants. As such, these calculations approximate the actual error associated with indirect calorimetry, which varies from individual to individual.

[b]Equivalent mol of sucrose or SCFAs obtained from 50 g of substrate.

[c]H^{eq} values from Livesey G and Elia M (1988) Estimation of energy expenditure, net carbohydrate utilization, and net oxidation and synthesis by indirect calorimetry: evaluation of errors with special reference to the detailed composition of fuels. *American Journal of Clinical Nutrition* 47: 608–628. The H^{eq} value for glucose was used for carbohydrate and the H^{eq} value for the fat mixture of an omnivore diet were used for fat. The H^{eq} value for SCFAs represents a weighted average.

with glucose ($d = 0.80$–0.85). Summing these factors gives a value of 0.40–0.53. The value of 0.5 was adopted because the Nutrition Council of Holland did not want to suggest that the value was known with high precision (they could have used 0.46–0.47 as the average) and because they wanted to include some energy lost to increased cell proliferation in the large intestine caused by increased fermentation. Thus, the slightly higher value of 0.5 was chosen as an estimate of the total losses during fermentation. In a later review of the value of α, it was determined that the individual factors that contribute to α should give a value closer to 0.6. However, in the same review, the author noted that the factorial procedure overestimates energy values to the extent that it takes no account of osmotic effects of the sugar alcohol. Thus, the results of energy values calculated by the Dutch method are probably fairly accurate. Many researchers agree that the value of 0.5 represents a reasonable estimate of the fermentation process.

For completely fermentable substrates that are not absorbed by the small intestine, like sugar alcohols, the MNE value is $0.5 \times \Delta H_c$ because $A = 0$ and $C = 0$. As indicated above, the value of β is set to 0, and any 'extra' energy lost due to ingestion is incorporated into the factor α, which has been estimated at 0.5. Thus, for the sugar alcohol isomalt (which is completely fermented and not absorbed by the small intestine), the energy value is approximately 1.9 kcal g^{-1} (8 kJ g^{-1}, approximately half the heat of combustion). For completely fermentable dietary fibers, the $0.5 \times \Delta H_c$ rule of thumb represents an upper limit of the NME since dietary fiber is known to bind fats and cholesterol as well as inhibit carbohydrate absorption. Thus, dietary fiber may interact with other macronutrients to decrease their metabolizable energy values. This will give a lower NME value for dietary fiber since there will be a higher excretion of fecal energy.

When all the energy losses are included, the energy value of dietary fiber can be small compared with the ingested value. For example, measurements with hard red spring wheat fiber give NME values of approximately 0.3 kcal g^{-1}, even though the total ingested energy is approximately 4 kcal g^{-1}. In the case of hard red spring wheat bran, much of the energy is lost to excretion; wheat bran dietary fiber is incompletely fermented so that approximately 60% is lost directly to the feces. In addition, a significant loss of energy comes from dietary fiber interactions with macronutrients plus other losses due to the presence of wheat bran fiber (β). Finally, energy is lost during the fermentation process itself. The energy value of hard red spring wheat fiber is not typical of other dietary fibers, as shall be shown in the following sections (Table 1).

Whole-body Calorimetric Measurements: Lactitol as a Model

Indirect calorimetry (a type of whole body calorimetry where all gas consumption and gas exhalation are continuously monitored) can be used to determine energy expenditure through the use of equations relating total O_2 consumption, CO_2 expiration, and urinary nitrogen excretion to energy utilization. One such equation is:

$$\text{Heat production} = 16.175\,O_2 + 5.021\,CO_2 - 5.987\ \text{urea N} - 4.5\,H_2. \quad (13)$$

In addition to total energy production, indirect calorimetry provides information on macronutrient utilization through the nonprotein respiratory quotient

(RQ). The RQ is the ratio of CO_2 expired to O_2 consumed during a defined period. The theoretical RQ values are known for fat, carbohydrate, and protein oxidation, making it possible to determine total fat, carbohydrate, and protein oxidation. When protein oxidation is estimated from nitrogen excretion, fat and carbohydrate oxidation can be calculated as follows:

$$\text{Nonprotein RQ} = 1.00 \times \text{carbohydrate oxidation} + 0.707 \times \text{fat oxidation}. \quad (14)$$

However, caution is needed when estimating fuel oxidation from nonprotein RQ values, since the RQ itself can vary considerably depending on the fat and protein mixture being oxidized. In addition to the problem of obtaining an accurate picture of fat and carbohydrate oxidation from nonprotein RQ values, it is also not possible to distinguish between the oxidation of carbohydrate + fat and the oxidation of short-chain fatty acids produced by carbohydrate fermentation. When measuring the apparent metabolizable energy value of a macronutrient that represents a small proportion of the total diet, there is a high potential for error when macronutrient oxidation profiles are measured. However, theoretical calculations show that there is much less error associated with measuring energy loss.

An example of the use of indirect calorimetry for measuring the metabolic energy of completely fermentable substances is the determination of the net energy value for lactitol, a disaccharide sugar alcohol (4-*O*-(β-D-galactopyranosyl)-D-sorbitol). The total energy balance was measured during the experimental period in the calorimeter. The retained energy of each subject was then calculated as:

$$\text{RE (retained energy)} = \text{IE}_\text{T} - (\text{fecal E} + \text{urine E} + \text{gaseous E} + \text{expended E}). \quad (15)$$

The energy needed to maintain energy balance (metabolizable energy for maintenance; ME_m) could then be determined as:

$$\text{ME}_\text{m} = \text{metabolizable energy intake} + \text{negative RE} - 1.11 \times \text{positive RE}. \quad (16)$$

The factor 1.11 represents the cost of depositing body energy and was measured in an earlier experiment. The difference in ME_m on a diet supplemented with sucrose versus one supplemented with lactitol is a measure of the energy lost from lactitol, and can be expressed as the change in ME_m adjusted for the metabolic weight of the individuals ($\text{weight}^{0.75}$):

$$\Delta\text{ME}_\text{m} = (\text{ME}_\text{m}/\text{weight}^{0.75})_\text{lactitol} - (\text{ME}_\text{m}/\text{weight}^{0.75})_\text{sucrose}, \quad (17)$$

and the NME can then be calculated as:

$$\text{NME} = \text{ME}_\text{part} - \Delta\text{ME}_\text{m}/(\text{IS}/\text{weight}^{0.75})_\text{lactitol}, \quad (18)$$

where ME_part is obtained from eqn (10), and IS is the ingested mass of the supplement (lactitol). The ME_m values are divided by the metabolic weight to account for differences in metabolic mass. Using this procedure, a value of 2.4 kcal g^{-1} (10 kJ g^{-1}) for lactitol was obtained. Note that some measure of the energy expenditure is required in this experiment (eqn (15)). The authors relied on diaries and ankle actometers and corrected to equal actometer counts. They acknowledged that this was not very satisfactory; there is a potential 15% error in the final net energy value for lactitol.

Metabolizable Energy Value of Dietary Fiber in Mixed Diets

Up to this point, this article has focused on undigested and fermented food components as a general group of substances. This section will deal specifically with dietary fiber, a partly fermented food component that passes through the small intestine unacted upon by human digestive enzymes. Dietary fiber is a mixture of nonstarch polysaccharides and lignin that are structural components of plant cell walls.

As indicated above, it is not appropriate to use metabolizable energy values for dietary fiber since many more energy losses are associated with fiber digestion as compared with the digestion of fat, carbohydrate, and protein. Equations have been developed to take account of these extra losses and provide a method to calculate the NME value of a fermentable dietary component when the fecal energy losses are known. These equations show that approximately one half of the potential energy is available to the host when undigested carbohydrates are completely fermented. This value is widely accepted.

Knowledge of the energy yield from the fermented portion of dietary fiber is not sufficient in and of itself to allow the calculation of dietary fiber NME since a significant proportion of the 'fermentable' dietary components are not fermented but appear in the feces. In addition, some 'extra' energy (factor β, eqn (13)) may be lost during digestion because of the intimate physical interaction between dietary fiber and the food matrix (*See* Dietary Fiber: Properties and Sources). The aim of these studies is to determine a general NME value for dietary fiber that can be used to calculate the metabolizable energy of mixed human diets. To overcome these problems, two solutions have been employed. The first solution involved determining individual digestibility factors for
