Yeasts are not heat-resistant and are readily destroyed in most heat processes. Other food processes, such as freezing, refrigeration, vacuum packaging, and acidification, will not necessarily destroy yeasts. Vacuum packaging will prevent growth of highly aerobic film yeasts, but not of fermentative types. Lower pH will not necessarily prevent the growth of yeasts, but organic acids may prevent growth of

some yeasts. Sorbic acid and sorbates are particularly effective in preventing yeast growth. Sulfur dioxide can be used to kill wild-type yeasts in dried fruits and in grapes for wine-making. Heating of dried fruits in the package can also be used to kill yeasts and pasteurize the fruit.

Specific Genera of Yeasts

There are a number of genera of yeasts that are important in foods. These include both beneficial and harmful types. The following is a synopsis of 10 genera of yeasts that include the most important industrial yeast, and various spoilage yeasts, including osmophilic yeasts, film yeasts, and asporogeneous yeasts.

Saccharomyces

Saccharomyces is the most important genus from an industrial standpoint. The main species is *S. cerevisiae* and different strains of it are used in many food industries for leavening bread and making ales, beer, wine, alcohol, and other products. It has also been used to produce single-celled protein, and food ingredients such as autolyzed yeast. It is probably the single most important yeast known. *S. cerevisiae* cells are elliptical to ovoid in shape, with some spherical and elongated cells as well. They reproduce by budding, and form ascospores. *S. cerevisiae* can also cause spoilage under certain conditions where its fermentative activity is not desired.

Zygosaccharomyces

Zygosaccharomyces is considered to be a subgenus of *Saccharomyces*, and some authors have reclassified this genus as *Saccharomyces*. The yeasts in this genus are osmophilic and can grow in high concentrations of sugar. They are responsible for spoilage of molasses, syrups, honey, salad dressing, soya sauce, and wine. They reproduce by budding, and form ascospores.

Schizosaccharomyces

Schizosaccharomyces species are found in sugar, molasses, honey, tropical fruit, and soil. They reproduce by fission, forming arthrospores, or by sexual means, forming ascospores. There are either four or eight ascospores per ascus. The spores are oval, spherical, or kidney-shaped.

Debaryomyces

Yeasts in the genus *Debaryomyces* are film yeasts, and they form pellicles of surface growth on meat brines. They also grow on cheese and sausage products. The cells of *Debaryomyces* are round to oval-shaped and they form ascospores. They may also form pseudomycelia.

Hansenula

Yeasts in the genus *Hansenula* are also film yeasts. They are common in olive brines, fruit juice concentrates, citrus fruits, and grapes. Although they are film yeasts that form pellicles, they are somewhat fermentative. They produce spherical to oval elongated cells. They reproduce by budding and by forming ascospores. The ascospores have a characteristic shape, similar to a bowler hat. They may form pseudomycelia.

Pichia

Yeasts in the genus *Pichia* are also film yeasts that form a pellicle on liquids, such as beer and wines. Cells are oval to cylindrical-shaped and form ascospores which are either round or hat-shaped.

Torulopsis

The *Torulopsis* genus may also be called *Torula* and it consists of asporogenous yeasts that are round to oval in shape. They reproduce by budding. These yeasts are common in nature, and contaminate many foods, including refrigerated foods. Species of this genus can ferment lactose and can spoil milk products, such as sweetened condensed milk, as well as fruit juice concentrates and acid foods.

Candida

Candida species are asporogenous yeasts that form pseudomycelia or true mycelia. They are sometimes categorized as Fungi Imperfecti in the family Moniliaceae with other yeast-like genera, particularly *Trichothecium* and *Geotrichum*. They reproduce by budding and fragmentation of the mycelia into blastospores. Members of this genus are common in foods and occur in fresh meat, such as ground beef, cured meats, and butter and margarine. They can spoil foods high in acid and salt, and the lipolytic species *C. lipolytica* can cause rancidity of butter and margarine. Other species have been grown for food and feed. At least one species, *C. albicans*, is responsible for infections in humans and animals.

Trichosporon

Trichosporon species are asporogenous yeasts that reproduce by budding and form arthrospores. They grow at lower temperatures and can be found in many foods, including chilled beef, beer, and maple sap.

Rhodotorula

Yeasts in the genus *Rhodotorula* are sporogenous and reproduce by budding. They sometimes also from pseudomycelia. These organisms are widespread in nature, often found in air and dust, and contaminate many foods. They produce red, yellow, and pink pigments and often discolor foods with red and yellow spots on meats, particularly cured meats, and pink areas in sauerkraut.

Health Implications

Yeasts are generally not associated with foodborne illnesses, but certain yeasts can cause infections in humans and animals. Probably the most common infection caused by a yeast is candidiasis, caused by *C. albicans*. This organism is a common inhabitant of the mucous membranes of the mouth, vaginal canal, and intestinal tract. Yeast infections can occur most readily in persons receiving broad-spectrum antibiotic therapy and those who are immunocompromised. In the immunocompromised subjects, *Candida* species and other yeasts can cause endocarditis, urinary infections, kidney infections, esophageal infections, and septicemia or systemic candidiasis. As the number of immunocompromised persons increases from radiation and chemotherapy, AIDS, and simple aging, it remains to be seen if foodborne yeasts may become a problem for these individuals as opportunistic infectious agents.

Molds in Spoilage

F Ottaviani, State University of Bologna, Italy
M G Ottaviani, CONSAL – Advising in Food Microbiology, Sermide, Italy

Basic Biology of Molds

Molds are eukaryotic organisms widely distributed in nature, and are common contaminants of agricultural commodities, food, beverages, and feed.

In contrast to the simple (prokaryotic) bacteria, molds are complex organisms whose mycelium is composed of individual filaments termed hyphae. The hypha is essentially a tube, consisting of a rigid wall and containing a moving mass of protoplasm; its interior is frequently divided into compartments by cross-walls which, being incomplete or perforated, do not separate the content into individual cells. This coenocytic condition gives molds an advantage over the single-celled bacteria, permitting both a more efficient distribution of nutrients and a better dilution of external stresses over a large number of cells. Organelles inside the hypha are of the eukaryotic type, i.e., more sophisticated than those of the bacterial cell. Nuclei and energy-yielding mitochondria are present.

The hyphal wall is predominantly composed of polysaccharides which give the molds a more defined barrier against environmental stress.

Chitin, a polymer of *N*-acetyl-D-glucosamine, is the more frequently occurring polymer in the walls of fungal spores and mycelia and it does not exist in bacteria or most uncontaminated food and feed products. Glycoproteins such as galactomannan are either

extracellular or bound to the fungal cell wall. Ergosterol is considered the principal sterol of fungi and plays an important role in cell membranes.

All these specific components of fungi are used to estimate fungal activity by rapid chemical, biochemical, and immunological methods even when fungal biomass may have been killed, given that chitin and fungal polysaccharidic antigens are heat-resistant and they can survive after the death of fungal species.

Because of their peculiar structure, molds behave in a different way from bacteria, with regard both to food preservation technologies and to laboratory analytical techniques – they have better control of ionic homeostasis (with regard to pH and water activity (a_w)), and insensitivity to antibiotics commonly used to repress bacterial growth.

With generation times ranging between 2 and 5 h, fungal hyphae extend at their apices with their oldest parts producing branches which fuse between adjacent hyphae. Branched vegetative hyphae form a vegetative mycelium which appears as a light, ill-defined spot on the food or culture medium surface at the beginning of the spoilage or during the initial stage of the colony development. Later, specialized cells emerge from the flat hyphal mass bearing at their ends the staminal components of the molds. These constitute the reproductive mycelium of the mold, whose cells are usually called conidiophores and staminal components either conidia, if asexually formed, or spores, if sexually generated. Sexual formation of spores, which involves genetic rearrangements, greatly contributes to the mold's survival in nature, but it is seldom observed in food and culture media where asexual conidia are more likely to appear. Sexual spores are frequently thick-walled and able to withstand severe environmental conditions, including heat processing, as in the case of the *Byssochlamys* sexual spores which may spoil fruit juices. In common with conidia, which possess a thinner wall, spores differ from vegetative cells in having a thicker tegument, a poorly differentiated cytoplasm, and a low water content, resulting in the ability to survive when environmental conditions become lethal to living cells.

Resting cells, which can withstand many adverse conditions such as drying or oxygen deprivation, may later restore their normal metabolic pathways, eventually giving rise to the first hyphal cell and so commencing the mold life cycle when availability of water, or air, or any other condition suitable to growth, occurs.

Nutrient requirements for mold growth are very simple. A suitable organic carbon source is necessary (this can be simple, such as glucose, or very complex, like cellulose and hemicellulose composing the plant cell wall). Many molds grow on poor substrates containing only inorganic nutrients, e.g., inorganic nitrogen or phosphorus. This explains why molds may actively grow where bacteria cannot proliferate, such as on the apparently hostile substrates of walls, wood, fabrics, etc.

Many molds produce energy by reoxidation of nicotinamide adenine dinucleotide/nicotinamide adenine dinucleotide phosphate (NAD/NADP) coenzymes along an electron transport chain where an inorganic compound serves as a terminal electron acceptor (respiration); usually oxygen is the final acceptor, so molds need an aerobic environment for their growth, but many common strains (e.g., aspergilli) use anaerobic respiration with nitrogen ions as electron acceptors. *Byssochlamys* and a very few other molds may break down sugars by fermentation, in the complete absence of oxygen, initially producing carbon dioxide, which can cause visible swelling of a package. Growth of proteolytic and lipolytic strains of molds is responsible for both the ripening and distinctive flavor of the internally or surface mold-ripened cheese and off-flavors and off-odors resulting from fungal lipase activity, with an increase in the free fatty acid (FFA) values.

Spoilage refers to any change that occurs in food resulting in reduction in sensory quality, i.e., changes in color, flavor, texture, or aroma brought about by the growth of microorganisms in food and feed. Degradative enzymes, such as pectinases and cellulases, are primarily responsible for degradation of the main structural components of vegetables, fruits, and legumes and related transformed commodities, pectin, and cellulose.

Flavor-volatile metabolites produced by molds, such as 3-methyl-butanol, 3-octanone, 3-octanol, and many others, cause adverse changes in flavor and aroma.

Besides the primary metabolic pathways supplying the fungal cells with energy and cellular metabolites necessary for growth, molds may show a range of unusual metabolic processes (grouped as secondary metabolism). These are not concerned with survival and growth and take place when normal development is restricted or the substrate composition is unbalanced (e.g., a very high carbon to nitrogen ratio, as in the case of plant tissues). Some secondary metabolites are of great commercial value (e.g., antibiotics like penicillins) but others, such as mycotoxins, pose a health risk to the consumer in crops and other plant products. (*See* **Mycotoxins**: Occurrence and Determination.) Mold spoilage is so undesirable not solely because of the resulting unesthetic changes, but also because it may constitute a hazard to human and animal health.

Growth Requirements of Molds and Effects of Processing

The metabolism of molds, like that of other organisms, is affected by environmental conditions which may increase or decrease the rate of enzymatic reactions. Physical and chemical conditions which play a major role in controlling the mold's metabolism and growth are temperature, water availability, and ion content.

The nutritional, physical, and chemical attributes of a given food substrate may select molds for predominant growth, these being the most highly adapted organisms, e.g., to reduced water content in high ionic strength (high acidity). Moreover, organisms can survive to some degree in conditions that do not allow growth. Spores and, to a lesser extent, conidia may tolerate extreme conditions in food and environment, retaining for extended times their ability to develop a mold when the substrate becomes favorable again. Mold propagula held on a frozen food may later undergo germination when mixed at room temperature with other ingredients. Although usually repressed by the high osmotic pressure (low a_w) in sugar-preserved or dried commodities, such as in preserves in tanks for industrial use or in pasta in its packaging, spores may give rise to a visible spoilage when water condenses at the mass surface.

Most fungi are mesophilic, so they grow at moderate temperatures, in the range 10–40 °C. Lowering the temperature decreases the rate of metabolism and is often used to slow deterioration. A few fungi grow at very low temperature. *Cladosporium* and *Thamnidium*, sometimes colonizing animal hairs, are important as spoilage agents of improperly dressed meat that is held for long enough (usually more than a month) at subzero temperatures above − 10 °C.

Important intrinsic factors which influence the microflora that develops in food and feed include pH and a_w.

Fungi show a wide range of behavior with respect to water availability, generally being more tolerant of water stress than other organisms, including the majority of yeasts. The lower limit for growth of molds, expressed as a_w, vary from 0.93 for destructive rots of fruits and vegetables like *Rhizopus* and *Mucor*; to 0.87 for toxigenic fusaria; to 0.83 for agents of surface discoloration in fresh cheese and sausage like *Penicillum expansum* or *P. viridicatum*. Xerophilic fungi are characterized as being capable of growth below an a_w of 0.85 and are most commonly associated with intermediate-moisture food such as dried meats, seafood, fruit concentrates, jellies, jams, preserves, and syrups, spices, nuts, and cereals, where their effective growth range can be as low as 0.65. Conditions of reduced a_w lower the final fungal biomass produced because of reduction of the growth rate and of increase of the time required for spore germination up to 3 months or more. Properly dried and stored commodities are inherently resistant to spoilage due to their low a_w; however, temperature differentials, such as in bulk-stored grains, may lead to moisture condensation and possible growth of xerophilic molds. The majority of xerotolerant fungi belong to genera *Penicillium* and *Aspergillus*, including its perfect forms such as *Eurotium* (*Aspergillus glaucus*), *Emericella*, and *Wallemia sebi*. (*See* **Water Activity**: Effect on Food Stability.)

Media and diluents with reduced a_w are necessary for enumerating xerophilic fungi, otherwise vegetative cells and spores may be lysed by osmotic shock or remain dormant when exposed to the relatively high a_w associated with the conventional diluents and media used in microbiological analysis. Addition of humectants, such as 50% glucose to the diluent, and 18% glycerol or 50% glucose to traditional media, especially malt extract agar, lowers a_w levels to about 0.94 and 0.92 respectively. Extended incubation periods, such as 4–6 weeks at room temperature instead of the traditional 5 days time, are required for recovery.

Molds, like yeasts, tolerate a greater pH range than bacteria do. Many fungi can grow over a wide pH range of at least 3–8, while pH values below about 5 negatively affect the metabolism and growth of bacterial cells. Where the food substrate shows a high a_w, it is the acidic environment which plays a decisive role in the competition between bacteria and filamentous fungi. As fruits show pH values of 4.6 or lower, mold growth is more likely. Spoilage thus arises from the intense activity of pectic and proteolytic fungal enzymes that have pH optima between 2 and 5. (*See* **pH – Principles and Measurement**.)

Because of the the acido-tolerant behavior of molds, originally food mycologists relied on low-pH media, such as acidified potato dextrose, Sabouraud, or similar agars to detect fungi in clinical and food specimens. However, in food samples acid pH may adversely affect mold spore germination and give rise to protein coagulation with the formation of artifacts, and, therefore, it is more effective to use media of neutral pH in combination with antibiotics. Antibiotics, such as chloramphenicol, gentamicin, and others, are well-known biomolecules perturbing the cell wall of bacteria which is different from that of fungi.

Molds may alter the pH of the environment in which they grow, by producing ammonium ions that neutralize the substrate acidity and thus allowing

(re)growth of normally repressed, dangerous organisms. Such an example of metabiotic association is given by the persistence of *Listeria* in cheese ripened by selected molds. (*See* ***Listeria***: Properties and Occurrence.)

Molds are aerobic organisms in that they require oxygen and/or a food substrate with a high oxidation-reduction potential (E_h) for growth. Oxidized foods, such as fruits with E_h values betwee0n $+300$ and $+400$ mV, support the growth of molds well, while reduced ones, like yogurt with its E_h value of about -100 mV, do not. In the latter case, molds may develop a mycelium only at the surface in contact with the air. Some fungi (e.g., strains of *Paecylomyces* and *Penicillium*) are microaerophilic, growing in an atmosphere containing only 0.1–0.5% oxygen. A few species, such as *Fusarium oxysporum*, may show a very delayed growth in the complete absence of oxygen. It would appear, therefore, that the degree of anaerobiosis attained under commercial processing conditions is not always adequate to prevent completely the growth of molds.

There is evidence that raising the level of carbon dioxide in the atmosphere above 70–80% greatly reduces the growth rate of most molds, with some notable exceptions, such as *Penicillium roquefortii* or *Byssochlamyis nivea*.

Growth of most molds is restricted – sometimes inhibited – by the use of preservatives at the legally permitted concentrations (between 0.1 and 0.2%) The acids and salts commonly used are propionic, sorbic, and benzoic. Propionates are added to bakery products and to certain processed cheeses. Benzoic acid and its sodium salt are most widely used in highly acidic foods such as fruit products and carbonated beverages. The undissociated acid is the active molecule and therefore the effectiveness increases with decrease in pH while the organic acids exhibit little fungistatic activity in neutral conditions. Inhibition of growth by weak acid preservatives is due to a number of actions, including membrane disruption, inhibition of essential metabolic reactions, stress on intracellular pH homeostasis, and accumulation of toxic anions. Natamycin (pymaricin), a natural antimycotic compound produced by *Streptomyces natalensis*, is commercially available for the surface treatment of cheese. In recent years, strains of preservative-resistant molds (particularly aspergilli) have been reported which tolerate high (0.5–1.5%) concentrations of organic acids due the induction of an active transport system that pumps undissociated acid molecules out of cells. The enzymatic degradation of sorbic acid to pentadien by certain fungal species is well documented. (*See* **Preservation of Food**.)

Most molds possess little heat resistance, and are easily destroyed when food with a_w values above 0.93 are heated at pasteurization temperatures. Vegetative cells and asexual propagules behave in the same manner. Heat resistance of molds is enhanced in the presence of high levels of solutes such as salt and sugar. The decimal reduction time for *Aspergillus niger* conidia heated at 100 °C increases from about 1 ms in a moist substrate ($a_w = 0.98$) to about 1 s in intermediate-moisture substrates (a_w between 0.85 and 0.90, such as cakes and most oven-processed sweet products), and to 10 s when a_w falls below 0.85 because of the addition of sugar (e.g., in fruit preserves). In the latter products, the low pH, usually between 3.2 and 3.5, partially counteracts the protective effect of sugar, thus decreasing the resistance of mold to heat.

The responses of molds to the presence of sodium chloride (salt) is somewhat different from that observed with sucrose. Protection against heat inactivation of molds is increased even at lower a_w values, usually below 0.97, i.e., a salt concentration of about 3%. This should be kept in mind when setting up pasteurization procedures for brines used in cheese and sausage manufacture.

A few molds produce heat-resistant ascospores or sclerotia. Ascomycetous species are widely distributed in soil and cause spoilage in heat-processed food products containing fruits which have been extensively contaminated with soil. Ascospores produced by the two species of *Byssochlamys, B. fulva* and *B. nivea*, and by *Neosartorya fischeri* are the most resistant of all and they are typically associated with spoilage of thermally processed fruit products, mainly canned, where the can center temperature is raised up to 80–90 °C. The decimal reduction time of *Byssochlamys nivea* spores at 80 °C increases from about 35 min ($a_w = 0.95$) to about 4 h in neutral foods with a_w values between 0.85 and 0.86. *Neosartorya fischeri* var *fischeri* has a D_{85} (decimal reduction time at 85 °C) value of 6–10 min with a Z value (Thermal Death Time curve's slope) of 5–7 °C while the *spinosa* variety is more heat-resistant (D_{85} value of 10–96 min with a Z value of 5–7 °C). Symptoms observed with spoiled canned fruits include breakdown of fruit texture, off-odors, gas, and visible mold growth. (*See* **Heat Treatment**: Chemical and Microbiological Changes; **Pasteurization**: Principles.)

Classification of Molds

Only a small proportion of the thousands of genera and species of molds identified in nature are of any significance in foods.

Ranked taxonomically in the separate kingdom of Fungi, molds are subdivided into further taxonomic categories on the basis of ecological behavior, and gross colony and microscopic morphology.

The most important diagnostic factor relies on the morphology of the asexual reproduction system (the so-called anamorphic stage of the mold), best observed under the microscope in slide-mounted cultures. Spores formed through sexual reproduction (the so-called telemorphic stage) are rarely used in identifying foodborne molds, given the difficulty of inducing gametogenesis and sexual fusion *in vitro*.

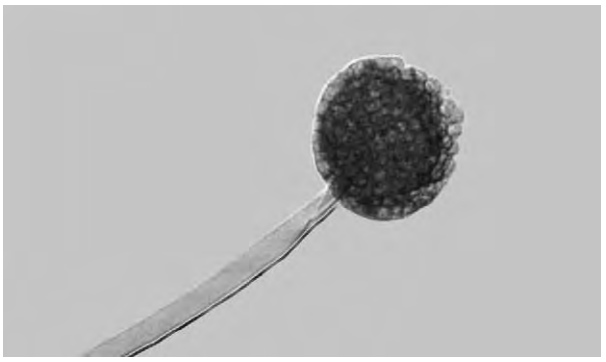
Molecular tools based on the polymerase chain reaction (PCR) may be applied in food mycology for diagnostic purposes. The noncoding ITS (Internal Transcribed Spacer) region of the rDNA unit, and other genes coding for metabolic and structural functions (e.g., the β-tubulin gene), have been investigated to clarify the genetic structure of some species.

Three subkingdoms include genera of significance in food spoilage: Zygomycotina, Ascomycotina, and Deuteromycotina. Most fungi, within the subkingdom Zygomycotina, belong to the class Zygomycetes, which includes, in the order Mucorales, three phytopathogenic genera frequently involved in the spoilage of moist wheat, flour, and cereal products: *Absidia, Mucor*, and *Rhizopus*. Distinctive features of these molds are (1) rapid growth when water availability is above the limiting value of 0.92–0.93, including filling the whole Petri dish with fine white to greyish to blackish aerial mycelium, and (2) asexual spore formation by cytoplasmic cleavage within a large globose cell termed sporangium, from where sporangiospores are liberated by breakage or deliquescence of the wall. Sporangia are located at the end of a supporting hypha (sporangiophore), from where they are separated by a septum forming a protrusion called columella (**Figure 1**).

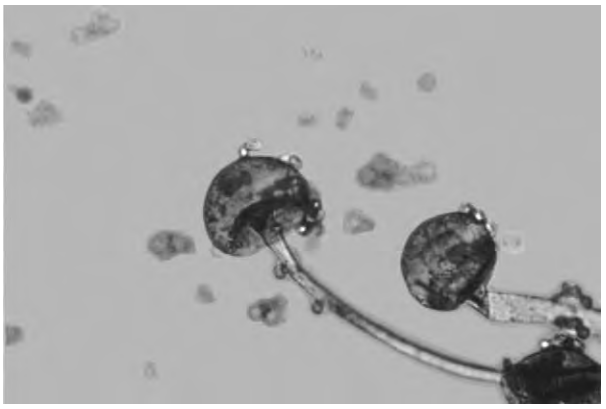
A distinctive feature of the subkingdom Ascomycotina is the development of sexual spores in a cell (sporangium), more specifically termed the ascus (bag). Asexual spores, called conidia, develop in various ways directly from reproductive hyphae. Ascospores of *Byssochlamys* species show a very distinctive heat resistance.

The subkingdom Deuteromycotina is used mainly for convenience to accommodate all those fungi that seldom, if ever, produce sexual stages. In all other respects, however, these fungi are similar to the Ascomycotina, and where sexual stages are discovered they are usually found to belong to the Ascomycotina. In Deuteromycotina systematics the teleomorph (perfect, sexual stage) name should preferentially be used to indicate the species. Unfortunately, the anamorphic name is firmly rooted in the literature and in common parlance. The teleomorphic stage cannot usually be seen in routine examination of fungi unless special cumbersome techniques are used, so the anamorph name is commonly retained: *Aspergillus*, instead of its teleomorphs *Eurotium* and *Emericella*; *Penicillium*, not the teleomorphs *Eupenicillium* and *Talaromyces*, and so on.

The morphology of the fertile hypha is again the most important factor in taxonomic characterization. During development of the mold, asexual propagation occurs which starts with conidiogenesis: asexual propagula, named conidia, are produced from the mother cell (conidiogenous cell). The system composed of a conidiogenous cell and its conidia is known as a conidiophore. Conidiogenous cells are sometimes supported by mono- or pluricellular stipes whose shape may help in mold identification. Differentiation of the conidiophore and conidial arrangements serve as diagnostic features, and we may distinguish the following:



(a)



(b)

Figure 1 (a) Large, round sporangium of *Rhizopus oryzae*. (b) After disintegration of the sporangial wall, small clusters of sporangiospores are released, leaving a naked umbrella-shaped columella. Reproduced from Spoilage, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds) 1993, Academic Press.

1. Arthroconidia: usually square-shaped conidia originating directly by fragmentation of a hypha (e.g., *Geotrichum candidum*, or 'machinery mold' because of its characteristic enrichment in samples from improperly sanitized machinery).
2. Blastoconidia: unbranched chains with dark hila (basal scars) that arise directly from a distinct conidiophore; those of *Cladosporium* are small and typically apiculate (lemon-shaped).
3. Poroconidia: dark-walled (dematiaceous) conidia in chains, each of them developing through a pore in the apex of the preceding conidium. The youngest conidia (smaller) are at the tip of the chain, while the most mature conidia are closer to the conidiogenous cell. The claviform shape, large dimensions, and both longitudinal and transversal septa give a typical appearance to the conidia of *Alternaria* (Figure 2).
4. Phialoconidia: produced in a long chain from an opening of conidiogenous cell called a phialide because of the distinctive amphora (flask) shape.

Both *Penicillium* and *Aspergillus* produce phialoconidia in structures which look different under the microscope because of (1) the presence in the former mold of the typical 'penicillus' (brush), a conidiophore with several terminal branches each bearing a phialide (Figure 3), while (2) in the latter the conidiophore is formed by an unbranched stipe, which enlarges at its end into a vesicle from which phialides arise with their chains of very small conidia (Figure 4). The sickle-shaped, septate phialoconidia of *Fusarium*, a powerful mycotoxigenic mold, are called macroconidia (Figure 5), in contrast to the smaller and usually nonseptate chains of microconidia.

Figure 2 *Alternaria tenuis*. Chains of large brown clavate conidia with transverse septa, blowing out from a conidiophore. Reproduced from Spoilage, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds) 1993, Academic Press.

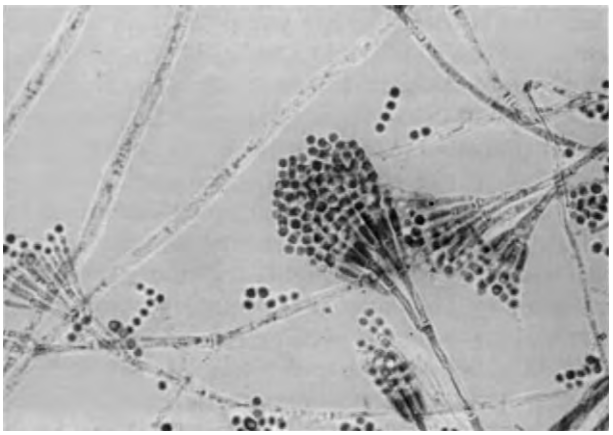


Figure 3 *Penicillium*. Branched conidiophore bearing conidial chains, in the form of a brush ('penicillus'). Reproduced from Spoilage, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds) 1993, Academic Press.

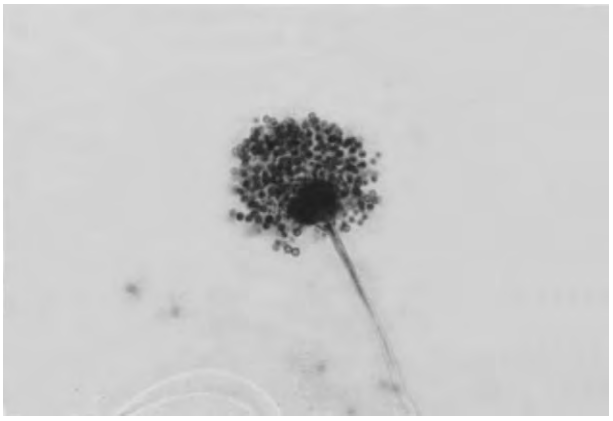

Figure 4 Conidiophore of *Aspergillus* enlarged in a round vesicle covered with a mass of round conidia. Reproduced from Spoilage, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds) 1993, Academic Press.

Contamination and spoilage of food

Factors contributing to the wide distribution of molds in the natural environment are their capacity to utilize almost all carbonaceous substrates, their ability to develop in the presence of very low concentrations of nutrients, and their tolerance to many adverse conditions. Fungal spores are present in dust and dead materials where, because of their ability to utilize cellulose and lignin, they may grow extensively during those materials' decomposition.

During cultivation, grains, and to a lesser extent vegetables and fruits, are exposed to fungal spore contamination from many sources, such as dust,

Figure 5 Sickle-shaped macroconidia of *Fusarium* with three transverse septa. Reproduced from spoilage, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds) 1993, Academic Press.

Table 1 Risk relationships for moisture content against deterioration

Grain	*Minimum moisture level to prevent spoilage (20–30 °C)*
Barley (*Hordeum sativum*)	15–14.5
Corn (*Zea mays*)	14.5–13.5
Cotton (*Gossypium barbadense*)	8.5–8
Rice (*Oryza sativa*)	13.5–13
Soybean (*Glycine soja*)	12–11.5
Wheat (*Triticum vulgare*)	14.5–13.5

Table 2 Overview of molds occurring in field and stored grain

Mold genus/species	*Minimum moisture level for growth*	*Minimum water activity level for growth*
Field molds		
Fusarium spp.	20–22%	0.87–0.89
Fusarium moniliforme		0.87
Fusarium graminearum		0.89
Alternaria alternata	18–20%	0.85–0.87
Cladosporium spp.	18–20%	0.85–0.87
Storage molds		
Penicillium spp.	16–18%	0.80–0.85
Penicillium viridicatum		0.81
Penicillium griseofulvum		0.83
Penicillium citrinum		0.82
Others		
Aspergillus spp.	14–20%	0.72–0.87
Aspergillus flavus		0.85
Aspergillus ochraceus		0.80
Aspergillus glaucus		0.74

insects, and rainfall, so that it is not surprising to find propagule counts on their surface between 10 and 10^2 colony-forming units (CFU) per square centimeter, i.e., between 100 and 10^5 CFU g^{-1}. Invasion of internal tissues is usually prevented by the integrity of the outer skin. During storage, control of relative humidity and temperature and the use of modified gaseous atmospheres (high levels of carbon dioxide) retard germination and growth rate of molds, thus preventing spoilage. Moisture content–deterioration risk relationships for given kinds of grain are shown in Table 1.

Handling and processing may either give mold propagules the chance to invade the body of injured fruits or vegetables or remove them when the grain pericarp is separated from endosperm during milling. Mold counts in flour may therefore be reduced to 10–10^3 CFU g^{-1}.

'Field fungi' include molds that grow on grains in the field, where the a_w is in the range 0.95–1.00, while 'storage fungi' can grow at the lower a_w levels found in grains during storage (0.70–0.90). Most species of the genus *Aspergillus* grow well when the moisture content is in the range of growing grains (i.e., > 18%, or $a_w > 0.85$) as well as when the moisture is that typical of stored grains (i.e., < 18% or $a_w < 0.85$). An overview of field and stored grain molds is shown in Table 2. (*See* **Cereals: Handling of Grain for Storage**; **Controlled-atmosphere Storage: Effects on Fruit and Vegetables.**)

Other dried agricultural commodities, such as spices, may retain their original fungal bioload (i.e., counts between 100 and 10^4 CFU g^{-1}) if sufficient attention is given to protection from dust and water condensation during processing. Unfortunately, most important producers are located in the Third and Fourth World areas, where conditions of harvesting and processing are sometimes primitive, so that mold counts may reach levels as high as 10^5–10^6 CFU g^{-1}, posing a risk of spoilage in foods with which spices are mixed.

Well-slaughtered and dressed meat is contaminated with only a few mold spores, usually less than 10 CFU cm^{-2}, which increase when skin and hide are not completely removed. If the surface of meat becomes dry, because of too long storage in the chiller, yeasts and molds (e.g., *Cladosporium cladosporioides*, agent of the 'black spot') may develop and give visible spoilage. (*See* **Meat: Preservation.**)

Molds are sometimes isolated from egg shells. Their presence is mainly as a result of dust and moisture in the hatchery and the cold store, but their growth is prevented by the low E_h value of the egg.

Molds entering raw milk from soil, bedding, feed residues, manure, and so forth, during milking are so greatly outnumbered by bacteria, and so effectively inhibited by natural antimicrobial substances such as lactoperoxidase and lactoferritin, that their number

never exceeds a few tens of spores per liter. (*See* **Milk**: Processing of Liquid Milk.)

Molds pose a real problem to the food industry mainly as secondary invaders of heat-treated (not aseptically packed) products. These treatments are usually sufficient to inactivate all but the most heat-resistant microorganisms. Airborne mold spores may contaminate products after heating (e.g., baking) and, when chemical and physical properties of the substrate are unsuitable to bacteria, may invade the food and become the main agent of spoilage. The main sources of airborne contamination are (1) crops and trees in close proximity of the factory; (2) areas where dusty raw materials, such as flour, cardboard packages, and woody materials such as pallets are stored; and (3) aerosol-generating operations, such as in waste treatment plants. Molds carried by air movements and/or by the clothes and shoes of people coming from these areas may penetrate processing rooms, where they fall directly on to the product before packaging, and are also deposited over the floor and wall surface. In this case the spores may later recirculate and contaminate the product.

When large volumes of air are needed, e.g., for dehydration or forced cooling of foods, the number of airborne organisms needs to be reduced by suitable filtration. High-efficiency nonabsolute filters, which remove 90–99% of the 1-μm or larger particles, are the minimum requirement for drying and cooling operations. Ultrahigh-efficiency (removing at least 99–99.9% of all particles of 0.1–0.2 μm or larger) or absolute filters (efficiency > 99%), even in the form of hoods or ceilings, are suggested to insure trouble-free production in aseptic or semiaseptic (such as yogurt) packaging lines.

To prevent condensation and subsequent mold growth on surfaces, good ventilation is required, which removes the excess moisture released during processing and storage of certain products, e.g., during cooking, salting, aging, and other common operations.

Possible fallout of airborne mold spores on to the surface of exposed products during high-risk operations such as cooling after baking or during packaging may be prevented by a careful separation between these environments and sources of molds such as storage of raw commodities and packaging materials.

The microbiological condition of packaging materials may directly contribute to the fungal contamination of packed foods, owing to the presence of spores on the material. The high temperatures used in the fabrication of plastic articles cause most of them to be virtually sterile (usually less than 1 mold spore per 100 cm^2). The maintenance of hygiene during handling and storage is therefore important. Materials and containers should be stored in clean and dust-free warehouses, well sealed in their original bags, until the moment of use. At that time, packaging materials should be taken out of their wrapper before entering the processing room, in order to limit the entry of dust and associated fungal spores.

Unless a food has been previously heated and subsequently aseptically placed in a hermetically sealed container, the presence of mold spores arising from raw materials or processing environments has to be considered as 'normal'. Fortunately, the growth of mold colonies on incubated Petri dish does not necessarily imply their development in the food substrate, because food is usually protected through suitable preservation techniques that prevent or delay the mold spores' germination and growth. Cooling and lowering the E_h value of cheese and sausages and drying and storing dry wheat and flour are examples of appropriate means for avoiding overt spoilage by molds.

None the less, molds are involved in the spoilage of both fresh, perishable foods and stored or processed foods. They are the main cause of market disease of fresh fruits and vegetables. Some of the spoilage organisms are true plant pathogens in that they have the ability to invade healthy, viable plant tissue. An example is *Phytophthora infestans*, the causal organism of late blight of the potato. Other fungi are saprophytes in that their development is restricted to dead or damaged plant tissue. Species of penicillia and aspergilli fall into this category. Molds produce enzymes which digest the main fruit and vegetable skin components, i.e., pectinases and esterases for the pectic substance and glucanases and glycosidases (cellulases) for the soluble cellulose. Growth of fungi on fruits and vegetables therefore results in tissue disintegration, i.e., rotting.

The ubiquity of molds in the environments where foods are handled, stored, and processed is such that these organisms will always be found in, and on, items which have not been heat-treated in a sealed container or aseptically packed after heating. Notwithstanding this, molds are involved in the spoilage of foods only under special circumstances. They dominate in spoiled food whose intrinsic properties are suited for their physiology, i.e., moist acidic foods rich in carbohydrates (fruits), those having a tendency to dry out during storage (vegetables), or with added salt (cheese, sausages), and dry foods rich in carbohydrates, such as cereals and flour. Development of grain spoilage molds is usually limited to high-moisture, temperature-abused stored cereals. The water content of flour is usually just below the critical level for mold growth (i.e., under 16–17%), hence flour carries fungal propagules to cereal products rather than undergoing spoilage. When growth is present flour gives a very pungent musty smell.

Infection of the surface of bakery products, particularly bread and cakes, may arise from dispersal of fungal propagules by air when products are cooled after baking. Enough water and a long storage time are required for fungal growth, which appears in the form of colored spots. French-style high-moisture breads, although wrapped and treated with preservatives, spoil very rapidly (i.e., within 2–7 days). Cakes have a longer mold-free life, depending on the individual a_w, processing technology, sanitation, and selection of ingredients.

Herbs and spices often contain large numbers of fungal spores and, even if the proportion of spices in recipes is usually low, under some conditions they contribute to an overt spoilage of the final product. The most important factors in determining the quality of dried herbs and spices are the initial bioload of the source crop and subsequent storage conditions. The desired properties of many spices are lost if storage is too extended or under poor conditions. (*See* **Herbs**: Herbs and Their Uses.)

Under special circumstances, molds may spoil even protein-rich foods, e.g., fresh meat whose surface dries following prolonged cool storage, and long-term ripened cheese whose rind becomes too dry to support the growth of competing bacteria. Penetration of mold mycelium through cracks in the rind and spreading of fungal enzymes across the rind may result in localized off-colored and off-flavored areas in the body of the cheese. Growth of spoilage molds is a problem on all cheeses but it is particularly rapid on soft cheese where cutting for prepacking is involved – even more so where untreated ingredients, pepper, nuts, herbs, and mushrooms are used.

Conversion of an oil-in-water emulsion, i.e., cream, to a water-in-oil emulsion, i.e., butter, makes butter a substrate with such a low a_w that surface molding is seldom a major problem. When present it is manifested by discolored areas, appearing more frequently on the surface of items manufactured from unpasteurized cream (farm-related contamination) or under unsanitary processing conditions (process-related contamination). (*See* **Butter**: The Product and its Manufacture.)

Both fresh and fermented sausages represent an ecological niche where inherent (pH, a_w) and environmental (temperature and moisture in the cellar) factors promote mold growth. Traditionally some salami-type sausages in Europe are mold-ripened. The organisms involved, mainly belonging to the genus *Penicillium*, are chosen on the basis of their ability to develop pleasant flavors during growth with no adverse side-reactions such as the production of mycotoxins. (*See* **Meat**: Sausages and Comminuted Products.)

Yeasts in Spoilage

V Loureiro and M Malfeito-Ferreira, Universidade Técnica de Lisboa, Tapada da Ajuda, Portugal

Background

Yeasts are microorganisms generally perceived as favorable components in food systems, since their roles are well known in the production of foods and fermented beverages – bread, beer, wine, cider, sake,

distilled spirits, etc. More recently, this image has been strengthened by the fact that yeasts can be obtained in capsules, as sources of B-complex vitamins, and are medically prescribed for several conditions. However, yeasts are also responsible for undesirable effects such as food spoilage. This article summarizes the main aspects of the occurrence, effects, and monitoring of yeasts in the spoilage of foods and beverages.

Competition among Bacteria, Molds, and Yeasts

The contaminant microflora of food is constituted, in most cases, of mixed populations of bacteria, molds, and yeasts. Microbial alteration becomes a competitive process among the different groups of microorganisms, prevailing over those which show a better adaptation to the environmental conditions in each product.

In food commodities, under optimal growth conditions, the populations of most bacteria, owing to their faster growth, overtake those of molds and yeasts. While bacteria have typical generation times of less than 1 h and, in some cases, around 10–15 min, mold and yeast populations may take several hours (or days) to duplicate. Thus, molds or yeasts can compete with bacteria only when environmental conditions severely affect bacterial activity. Low pH and low water activity (a_w) favor the growth of molds and yeasts, as they are more acid-resistant and xerotolerant than bacteria. The presence of chemical preservatives, mainly those of an acidic nature, is also less inhibitory towards molds and yeasts.

Yeast activity can lead to subsequent bacterial activity, as in acid-fermented foods; in this case, organic acids can be consumed by film-forming yeasts, leading to deacidification and promotion of bacterial activity. The competition between molds and yeasts depends, to a large extent, on oxygen availability. While the former are obligate aerobes, the latter may be facultative, growing either under aerobic or anaerobic conditions. For this reason, yeasts are found much more frequently on liquids, where good aerobic conditions exist only at the air–liquid interface, whereas filamentous fungi predominate in solid foods.

Concept of Spoilage Yeasts

Of all yeasts isolated from nature, about 500 species are presently recognized by taxonomists. Of these, about a quarter may be readily isolated from foods, but only a few play a significant role in food alteration. Those which do not affect foods are generally called adventitious or innocent yeasts; those responsible for undesirable changes in foods and beverages are called spoilage yeasts. For food technologists, the concept of spoilage yeast generally has a stricter sense. It takes into account only whether a particular species is able to cause deterioration in foods and beverages which have been processed and packaged according to the standards of good manufacturing practice (Table 1). It should be emphasized that the concept of spoilage yeast is conditioned by the type of product and by the moment when the yeasts exert their activity. For instance, in the production of wines, the yeast *Saccharomyces cerevisiae* is

Table 1 Principal yeast species causing spoilage of foods and beverages processed according to the standards of good manufacturing practices

Type of food	*Food product*	*Yeast species*
Fresh fruits and vegetables	Strawberries, figs, tomatoes	*Hanseniaspora*/*Kloeckera* spp.
Refrigerated and frozen foods	Icecreams, frozen peas	*Rhodotorula* spp.
Pasteurized foods	Yogurts, fruit juices, ketchup	*Kluyveromyces marxianus*, *Saccharomyces cerevisiae*, *Zygosaccharomyces bailii*
Preserved foods	Mayonnaise, salad dressings, sauces, soft drinks, chutneys	*Brettanomyces*/*Dekkera* spp., *Issatchenkia orientalis*, *Pichia membranifaciens*, *S. cerevisiae*, *Saccharomycodes ludwigii*, *Schizosaccharomyces pombe*, *Z. bailii*
Fermented foods	Pickles, olive brines, sauerkraut, cheeses, sausages	*Debaryomyces hansenii*, *I. orientalis*, *P. membranifaciens*, *Yarrowia lipolytica*, *Z. bailii*
Alcoholic beverages	Wine, beer, cider	*Brettanomyces*/*Dekkera* spp., *Pichia anomala*, *P. membranifaciens*, *S. cerevisiae*, *S. cerevisiae* var. *diastaticus*, *Sac. ludwigii*, *Sc. pombe*, *Torulaspora delbrueckii*, *Z. bailii*
Concentrated products	Dry fruits, jams, jellies, honey, fruit concentrates, filled chocolates, marzipan	*Candida versatilis*, *D. hansenii*, *P. anomala*, *T. delbrueckii*, *S. cerevisiae*, *Sc. pombe*, *Z. bailii*, *Z. rouxii*, *Z. bisporus*

recommended for its good fermentation characteristics. However, later in the production process, this species is considered a dangerous spoiler in sweet bottled wines, because it is able to ferment residual sugar. (*See* **Wines**: Production of Table Wines; Production of Sparkling Wines.)

Importance of Yeasts in Food Spoilage

The presence of yeasts in food is generally believed to be harmless to public health, although occasional allergies have recently been attributed to them. The absence of pathogenic foodborne yeasts diminished interest compared with bacteria and molds, and so, for a long time, their importance as food contaminant microorganisms has been underestimated. More recently, however, yeasts have been established as important factors in food spoilage, which involves the visible or detectable deterioration of physical and sensorial properties of foods. These undesirable activities are responsible for serious economical losses, which remain mostly unreported due to the confidentiality assumed by the companies involved (e.g., manufacturers, suppliers of raw materials and packaging, retailers).

Among the factors that have contributed to this increasing importance are the use of modern technologies in food processing, the great variety of new formulations of foods and beverages, and the tendency to reduce the use of preservatives, particularly those effective against yeasts (e.g., sulfur dioxide and benzoic acid). Modern technologies tend to utilize less severe processing conditions so as to preserve as much as possible their flavors, tastes, and natural colors. Thus, for instance, in the thermal processing of products of vegetable origin, it is becoming more commonplace to use cold filling, after a gentle pasteurization treatment, which significantly increases the risk of yeast contamination and, consequently, the risk of yeast spoiling. New food and beverage formulations, using juices and concentrated fruits, sugar syrups, sliced fruits, etc., such as the different types of yogurts, have also contributed significantly to the importance of yeasts as spoilage agents. In the same way, low-calorie foods, where preservation no longer depends on the effect of high sugar concentrations, providing low water activities, are good habitats for yeast activity.

Effects and Extent of Yeast Spoilage

The most common spoiling effects occur in sweet acid drinks and are characterized by abundant gas production, which may deform or explode the packages, haziness, sediment or film formation, off-flavors, and off-tastings. Deterioration of food and drinks by yeasts may present other effects, more or less evident, according to the type of food (Table 2). However, in certain cases, yeast spoilage is not so easily defined, mainly in fermented foods and drinks (e.g., wines, artisanal beers, black olives, soy sauce, cheeses), where the metabolites produced contribute to the flavor and aroma. In fact, the distinction between detrimental and beneficial activities is not always clear-cut. For instance, the 4-ethylphenol production by *Brettanomyces/Dekkera* yeasts in red wines is only regarded as spoilage when this secondary metabolite is present at levels above about 700 $\mu g\,l^{-1}$. At levels below 400 $\mu g\,l^{-1}$ it contributes favorably to the complexity of wine aroma.

The level of contamination in foods is not a clear indicator of product deterioration. For instance, in many cheeses, cured meats, and cloudy beers, yeast counts as high as 10^5–10^8 cells g^{-1} do not cause any detectable depreciation; on the contrary, they are supposed to improve aromatic complexity. The reverse

Table 2 Principal spoilage effects of food products resulting from yeast activity

Food product	*Spoilage effect*						
	Color spots/discoloration	*Gas production*[a]	*Haze/ cloudiness*	*Sediments*	*Films*	*Off-flavors/ off-tastings*	*Texture changes*
Fresh fruits and vegetables	X	X				X	X
Brined vegetables	X	X	X	X	X	X	X
Fruit juices, wine, beer		X	X	X	X	X	
Mayonnaise, salad dressings	X	X			X	X	X
Confectionery	X	X			X	X	X
Syrups, honey, fruit concentrates		X	X		X	X	
Butter, cream	X					X	
Cheeses, yogurts	X	X				X	
Sliced bread, unbaked bread dough	X					X	
Sausages, meat products	X	X				X	

[a]Gas production may lead to distortion or explosion of the container or product.

situation also occurs, when counts below 10^5 cells g^{-1} induce spoilage. This is the case of the formation of visible cell clusters, in bottled white wines, or of the development of surface color spots due to yeast colonies, in certain solid foods (e.g., skinless sausages, sliced bread, etc.).

Factors Affecting Yeast Activity

The microbiological stability of foods and beverages can be achieved by complete removal of microorganisms before packaging of the final product, as in sterile filtration of beverages without suspended solids. It can also be achieved by total destruction of contaminant microorganisms, as in heat sterilization, pascalization, or γ-irradiation, or by inhibiting metabolic activity by freezing. However, in most cases, food microbiological stability is dependent upon the inhibition (or reduction) of microbial activity by the creation of one or more adverse environmental factors, such as low water activity (dried, concentrated, and salted foods), low pH (acid foods), low temperatures (refrigerated foods), and the presence of inhibitors (preserved foods). In the case of sterile filtration, heat, pascalization, or γ-irradiation, microbial contamination is possible only when there is process failure or when there is contamination after treatment. When thermal processes, pascalization, and γ-radiation are used, heat-, high-pressure-, or radioresistant yeasts predominate as contaminant organisms. For food preservation based on microbial inhibition through the action of adverse environmental conditions, the spoilage microflora is restricted to organisms resistant to the factor(s) used in the preservation process, e.g., low water activity, organic acids, and so on. (*See* **Freezing**: Structural and Flavor (Flavour) Changes; **Irradiation of Foods**: Basic Principles; **Sterilization of Foods**.)

Water Activity (a_w)

Water activity is, probably, the environmental factor which most strongly affects living organisms, given the narrow range of values allowing growth. Like other organisms, yeasts are also markedly affected by water availability, although, together with molds, they are the least sensitive. Thus, it is not surprising that molds and yeasts are the dominant flora of low-a_w foods. (*See* **Water Activity**: Effect on Food Stability.)

For identical a_w values, different solutes have different effects on yeast growth, salts (e.g., NaCl) being generally less well tolerated than sugars (e.g., sucrose). The most resistant yeasts to low a_w, in the presence of either sugar or salt, belong to the genus *Zygosaccharomyces, Z. rouxii* being the most resistant species (with an a_w of approximately 0.65 in the presence of sugar). Other species resistant to high sugar and salt levels are *Debaryomyces hansenii, Candida etchelsii, Candida parapsilosis, Torulaspora delbrueckii, Pichia membranifaciens*, and *Pichia anomala*.

pH

Yeasts and molds are generally more resistant than bacteria to low pH values and constitute the typical flora of acid food. Acetic acid bacteria, and particularly lactic acid bacteria, can compete with yeasts in acid foods, although they are more sensitive to low pH, low a_w, and some preservatives, such as sulfur dioxide. (*See* **Lactic Acid Bacteria; pH – Principles and Measurement**.)

Yeasts usually grow in the pH range 2.0–8.0, with an optimum at 4.0–4.5. The minimum pH for yeast growth is not easy to define, owing to the strong influence of the particular acid, other inhibitors, and environmental factors. The nature of acids present in foods significantly affects yeast activity, since their inhibitory effect is dependent on the concentration of undissociated form of the acid. Among other species resistant to low pH, *Zygosaccharomyces bailii* is considered the most resistant to organic acids. This feature, associated with resistance to low a_w, makes this species one of the most feared yeasts by food technologists, particularly in the production of fruit juices, fruit concentrates, marzipan, and acid-preserved foods like mayonnaises and salad dressings.

Temperature

The influence of temperature on yeast activity should be considered in two ways: as a lethal agent, during thermal processing, and as an environmental factor, during storage. Concerning the first, the thermal resistance of yeasts is considered to be low, as yeasts are destroyed at pasteurization temperatures. The higher resistance of some species is related to the formation of ascospores, which are slightly more heat-resistant than vegetative cells. Ascospores are not, however, thermally resistant forms in the same sense as bacterial endospores. (*See* **Pasteurization**: Principles.)

The yeasts more frequently referred to as contaminants of pasteurized foods belong to the species *Kluyveromyces marxianus, S. cerevisiae*, and *Z. bailli*. Thermal resistance varies with the nature of the media, the protective effect of high sugar concentrations being well known. In concentrated foods, therefore, the pasteurization conditions need to be more severe to obtain absolute safety. The following treatments are recommended: 20 s at 85 °C for concentrated orange juices of 50 °Brix, 30 s at 90 °C for chocolate syrups of 75 °Brix.

As an environmental factor, temperature does not favor spoilage yeasts in relation to other groups of microorganisms. Food yeasts are essentially mesophiles, capable of growing in the temperature range 0–40 °C, with an optimum temperature of about 25–27 °C. Some species capable of growing at low temperatures – psychrotrophic yeasts – are frequently isolated from refrigerated products, suggesting that, in this case, temperature plays an important selective role. These yeasts are nearly always pigmented, and consequently, colored spots may develop on foods. Storage temperature has a strong effect on spoilage yeast activity, often accelerating the food-alteration process. For this reason, some foods that are very susceptible to dangerous spoilage yeasts (e.g., *Z. bailii*), such as fruit concentrates, are generally stored under refrigeration.

Oxygen Availability

The presence of oxygen always enhances yeast activity, because it allows oxidative metabolism, which is energetically more efficient, as well as enabling the utilization of a wider range of energy-rich substrates (such as ethanol and organic acids). For this reason, in all foods susceptible to yeast activity, it is necessary to exclude oxygen so as to prevent film-yeast growth and reduce the yeast metabolism.

Nutrients

In general, the range of chemical compounds found in foods is adequate to supply the nutrient demands for the majority of spoilage yeasts. Essentially all food yeasts can utilize glucose and fructose as carbon and energy sources; less frequent is the utilization of organic acids (e.g., acetic and lactic acid) and alcohols (e.g., ethanol and glycerol); the utilization of starch and lipids is rare.

Organic nitrogen is not necessary for yeast metabolism, all yeasts being able to utilize ammonia as the sole nitrogen source. They can also utilize some amino acids owing to their ability to deaminate or transminate acids. Few yeasts have proteolytic activity. Consequently, foods with a low carbon-to-nitrogen ratio tend to be spoiled by bacteria, while those with a high carbon-to-nitrogen ratio are preferentially affected by yeasts. (*See* **Amino Acids**: Metabolism.)

Some yeasts grow very slowly, or do not grow at all, in certain foods as a result of difficulties in synthesizing one or more vitamins. *Z. bailii*, for example, requires group B vitamins, and *Brettanomyces/Dekkera* require biotin and thiamin (vitamin B_1). In addition, the inability of *Z. bailii* to utilize sucrose as an energy source is of some significance. Extreme care must be taken when sucrose syrups are substituted by fructose syrups.

Preservatives and Antimicrobials

Most preservatives used in the food industry are weak organic acids – sorbic, benzoic, acetic, sulfurous, and propionic acids. Their activity increases with reduced pH, ceasing to be effective at values much higher than their pK_a, i.e., for pH values where the undissociated form is insignificant. The acid resistance of yeasts is the major factor in their predominance over bacteria in the alteration of preserved food. Certain species, such as *Z. bailii*, may grow on foods with levels of sorbic acid (*c.* 800 mg/kg) much higher than those permitted by law. Other spoilage yeast species known for their high resistance to preservatives are *Saccharomycodes ludwigii, Schizosaccharomyces pombe, Issatchenkia orientalis, P. membranifaciens*, and *S. cerevisiae*. The contact of such yeasts with preservatives contributes to an adaptive process which can significantly increase their resistance and subsequent growth. (*See* **Preservation of Food**.)

The presence of antimicrobials in foods also strongly affects the contaminating flora. Among other compounds, ethanol exerts a strong selective effect, particularly on molds and most bacteria. Lactic and acetic bacteria are the most resistant to ethanol. The former may resist up to 20% (v/v) ethanol and the latter to about 14% (v/v). Thus, bacteria frequently compete with yeasts in the alteration process of alcoholic beverages. The yeasts' behavior in the presence of ethanol is quite variable. There are several very sensitive species such as *Hanseniaspora uvarum* and *Rhodotorula glutinis* and several quite resistant species, tolerating up to 18–20% (v/v) ethanol (e.g., some strains of *S. cerevisiae* and *Z. bailii*).

Prevention and Monitoring of Yeast Spoilage

When a food commodity is spoiled by yeasts, the yeasts are present as contaminants and environmental conditions make them stronger and quicker than other microorganisms. The prevention of spoilage, with fewer chemicals and milder preservation processes, requires a sound understanding of the problem, and so the food microbiologist should have available tools to evaluate the whole microbiological ecosystem. In a code of good manufacturing and distribution practices, several conditions should be met to avoid or to control the activity of yeast spoilers: (1) good-quality raw materials, i.e., with low yeast counts; (2) adequate and efficient hygiene;

(3) adequate and efficient processing operations; and (4) careful monitoring of spoilage yeasts.

Good-quality Raw Materials

The microbiological quality of raw materials is essential in the prevention and control of spoilage yeasts because higher initial contaminations increase the risk of failure of technological control processes. As a rule, natural raw materials (e.g., fruits and sugar cane) have an adventitious microbial flora which is not active in foods, after processing, being easily controlled through good manufacturing practices. However, when raw materials have already been processed (e.g., fruit concentrates, fruit juices, and sugar syrups), as in many foods of complex formulation (e.g., dessert yogurts, reconstituted fruit juices, and filled chocolates), the type of contaminant yeast is much more dangerous. This situation results from the enrichment of the contaminating flora in yeasts highly resistant to the environmental stress present during the processing of natural raw materials.

Processing Operations

One of the most efficient measures for controlling spoilage yeast activity is thermal processing of packaged foods and beverages. Unfortunately, there are few products where this is possible without any adverse effects on the quality of the food commodity. Among other measures that might be taken to prevent yeast spoilage, the following should be noted:

- preservatives should be added immediately before packaging so as to avoid contact with yeasts, which might lead to adaptation and increased preservative resistance;
- oxygen should be excluded through air evacuation or purging with inert gases before packaging to inhibit yeast metabolism;
- cross-contaminations should be avoided in plants processing more than one kind of product (e.g., jams and fruit juices);
- food products should be stored at low temperatures, particularly for foods made with ingredient mixtures with a high susceptibility to yeast activity.

Hygiene

It is generally accepted that the main source of contamination by yeasts is food residues remaining in processing equipment after inadequate cleaning and disinfection. It is essential, therefore, to ensure high standards of hygiene, for which several conditions should be met:

- suitable plant layout and easily accessible equipment;
- awareness of the most likely sites for spoilage yeasts (e.g., filler heads, diaphragm valves, pressure gauges, dead ends of sterilizing filters, pumps, stirrer bearings, and glands);
- cleaning and disinfection programs should include dismantling of pieces of equipment that are difficult to sterilize, and adequate contact time and concentrations of sterilants must be used. (*See* **Sanitization**.)

Monitoring of Spoilage Yeasts

Microbiological control Generally, food microbiological control does not provide satisfactory information for an effective prevention against spoilage yeasts. The main reasons for this are:

- there is a lack of specificity of culture media used for yeast identification, which does not allow a distinction between adventitious and spoilage species (often, the same media are used for yeast and mold counts);
- sampling procedures are usually statistically inadequate owing to time and cost restrictions;
- sampling size is often insufficient to detect low contamination levels;
- there is a lack of reference values needed for adequate interpretation of yeast counts.

Accordingly, it should be noted that for yeasts such as those from the genus *Zygosaccharomyces*, which are potentially dangerous even in very low numbers, the microbiological control information is often rather inadequate.

Microbiological control allows determination of the critical points of processing lines and estimation of their relative importance as origins of outbreak of spoilage yeasts. These critical points are dependent on the quality of the equipment. For example, in wine-bottling lines with poorly designed filling machines, the main critical points of yeast contamination are as shown in Figure 1.

Besides yeast detection and counting, the microbiological control may be further aimed to the typing or identification of contaminant yeasts. Classical identification is based on physiological, biochemical, or sexual characteristics and cannot be routinely utilized in the food industry. As a consequence, various miniaturized and simplified identification methods have been developed. However, they are based on the same approach of the classical method of yeast identification and are time-consuming, even when procedures are automated and computerized, and often lead to false or equivocal identifications. To overcome these difficulties, alternative faster typing methods have been developed, based, among others, on analysis of

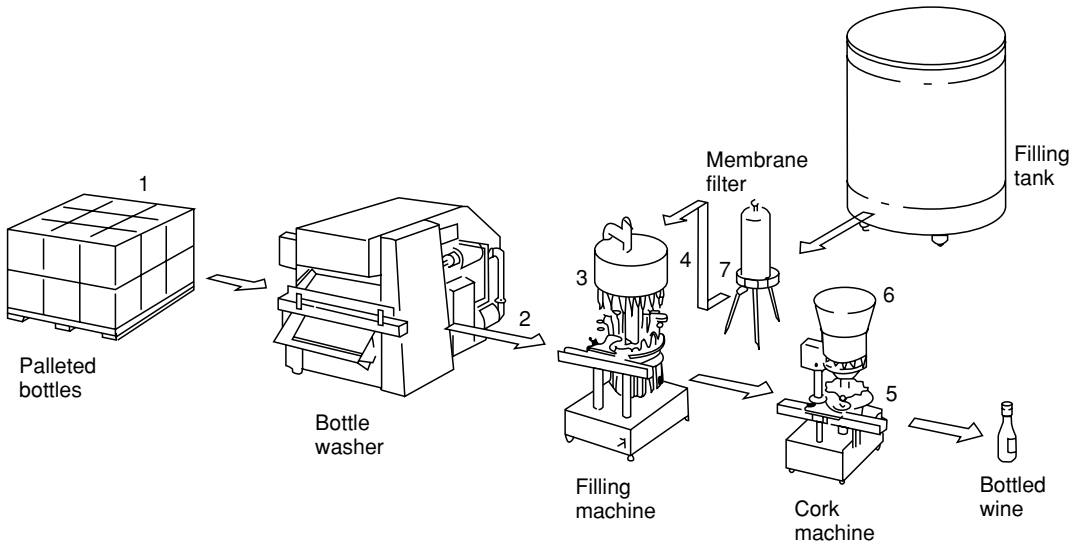

Figure 1 Main sampling points in spoilage-yeast monitoring of a cold-sterile wine bottling line. Empty bottles (1) are frequently infected by fungi, some bacteria (generally spore-forming), and adventitious yeasts; after washing/rinsing (2), an increase in the microbial load is frequently seen, and spoilage yeast infections may occur (about 5% of all outbreaks). The filling machine is usually the main cause of contamination (c. 50% of cases), particularly owing to deficient disinfection of the filling heads (3) and self-levelling system (4). The cork machine is responsible for about 30% of outbreaks, mainly owing to contamination of cork jaws (5) and also the corks (6); membrane filters occasionally (c. 10% of cases) may be a serious infection point when a membrane rupture occurs.

total proteins, total long-chain fatty acids, and isoenzymes. In addition, recent progress in molecular biology has led to the development of highly specific techniques (e.g., restriction-fragment length polymorphism of mitochondrial DNA, chromosomal DNA electrophoresis, restriction-enzyme analysis of polymerase chain reaction-amplified ribosomal DNA, and random amplified polymorphic DNA assay).

Zymological indicators The microbiological quality of foods is currently evaluated through microbiological indicators. When yeasts are the most dangerous microorganisms for the stability of foodstuffs, the microbiological indicator used is, generally, the 'yeast and molds,' resulting from the utilization of a general-purpose plating medium to enumerate microfungi. However, this indicator does not distinguish between dangerous and adventitious yeasts, and so other more meaningful indicators may be used. For instance, yeasts tolerant to environmental stress are detected/enumerated by general-purpose media modified according to the stress factor involved. Thus, 'acid-resistant yeasts' is a zymological (zymo = yeast) indicator used to characterize dangerous yeasts in acid food industries, 'xerotolerant (osmophilic) yeasts' is used for grouping yeast particularly dangerous in industries that process low-available-water foods. Occasionally, it may be of interest to detect the presence of yeasts with specific hydrolytic capacities, namely 'lipolytic yeasts,' 'pectinolytic yeasts,' and 'proteolytic yeasts,' using the appropriate culture media. These indicators may also be directed to detect individual spoilage yeast species provided the selective or differential media to quantify them in a rapid way. Examples of this approach include media for *Debaryomyces hansenii* (e.g., intermediate moisture foods and cheeses), *Dekkera/Brettanomyces* spp. (e.g., wines, beers, and ciders), *Kluyveromyces marxianus* and *K. lactis* (e.g., dairy industry), *Yarrowia lipolytica* (e.g., butter and cheeses) and *Z. bailii* and *Z. bisporus* (e.g., wines, beverages, and fruit concentrates).

An alternative approach to the zymological indicators, determined by microbiological methods, is to examine food samples for chemical (or sensorial) evidence of past microbial activity. The use of metabolites as indicators of spoilage is often more convenient and faster than using microbiological methods of examination. Examples are given by determination of ethanol and acetoin (e.g., fresh fruits), carbon dioxide (e.g., detection of fermentative yeasts in foods), 4-ethyl-phenol (chemical marker for *Dekkera/Brettanomyces* in wines) and 1,3-pentadiene (chemical marker for *Z. rouxii* and *D. hansenii* in marzipan based products preserved with sorbate). The two last chemical indicators may be regarded as 'spoilage predictors,' because at low concentrations, they may reflect future product deterioration.

Introduction

That familiarity breeds contempt is an oft-quoted maxim of political life, yet it might also be applied to many of our foodstuffs, which have acquired the epithet of common, basic, staple, or simple. The majority of these foods are, in a physicochemical sense, far from simple. Almost all are complex multiphase systems, in which gases, liquids, or solids are dispersed in a liquid continuous phase, typically aqueous, which itself contains a multitude of solutes. Examples of such natural foods are milk and eggs, whilst icecream and mayonnaise are representatives from manufactured foods.

Disperse systems are inherently instable, and this is true for many of these complex foods. Thus, full-fat milk spontaneously creams on standing, and acidified milk irreversibly curdles. This instability can be resolved into two principal processes:

1. Flocculation of fine or colloidally dispersed particles to aggregates which, if liquid or gaseous, may coalesce to form larger droplets or bubbles.
2. Displacement of particles under gravity as a result of density differences between the phases.

These processes can influence the appearance and rheology of the food and may detract from its perceived quality and acceptance. The precise effects, however, will depend on the volume fraction of the disperse phase, and will naturally be greater where this is higher. Particularly in such foods, it is important to control or inhibit flocculation and gravitationally induced phase separation. (*See* **Flocculation**.)

The word 'control' is included here by virtue of the fact that, in some foods, it may be advantageous to promote these processes. Thus, in fat-reduced mayonnaise, an aggregation of fat droplets may be required to give the product a structure and plasticity. Aggregation and structure formation may also be utilized to prevent phase separation. In fat-rich fresh cheese products, a casein network prevents the creaming of the fat, and a similar mechanism is operative in the stabilization of foams by fat crystals. Although contradictory in terms, a stabilizer may achieve stability by controlled and partial destabilization. (*See* **Casein and Caseinates**: Uses in the Food Industry.)

Control of flocculation and separation can be achieved by the judicious use of polysaccharide gums, proteins, organic salts (and emulsifiers), alone or more often in combination. In this role these substances have become known as stabilizers, a suitable definition for which would be as follows: food additives which prevent or control phase separation in foods consisting of two or more phases.

Because stabilizers influence the structure of a food, and because many of the additives used have, in their own right, a thickening or gelling function, the term stabilizer has become loosely used to describe any additive that influences the rheology of the products. This is a somewhat dangerous practice as, in many countries, food-labeling law has led to a legal definition of the term, and this usually restricts its use to multiphase systems. It should also be remembered that the term refers to a functionality; therefore one and the same additive may not always be properly described as a stabilizer. Thus, when carrageenans are used to prepare a clear jelly – a single-phase system – it should be declared not as a stabilizer but as a gelling agent. On the other hand, in chocolate milk, where the gel serves to hold the cocoa particles in suspension, the former declaration would be correct.

Flocculation

In order to illustrate how stabilizers influence flocculation, it is necessary to review the forces which are believed to be acting on dispersed particles. These were first set out in the theory of Derjaguin Landau Verwey Overbeck, which recognizes two types of interparticle interactions:

1. Van der Waals forces.
2. Electrostatic interaction.

Van der Waals forces are strong attractive forces which are principally attributable to fluctuating polarization of the electron distribution in the molecule. These forces decrease rapidly with distance, being inversely proportional to the sixth power of the separating distance.

Dispersed particles may also carry surface charges, with the resulting formation of an electrical double layer of counterions in the proximal continuous phase. When two similarly charged particles approach each other, these ion layers begin to overlap and interact, giving rise to repulsive forces. Typically, these forces are stronger than Van der Waals forces at larger separations, so resulting in a net repulsive force. As separating distance decreases these repulsive forces attain a maximum before Van der Waals attraction causes flocculation (Figure 1). The height of this barrier will naturally be dependent upon the magnitude of electric double layer but, in order to limit flocculation, it should be considerably larger than the thermal energy of the system. The absolute magnitude of these forces is generally related to the surface area of the particle. They are therefore important where the ratio of surface area to weight of the particles is large, and therefore increase in importance with diminishing particle size.

From these considerations it follows that a colloidal dispersion may be stabilized by increasing the surface charge and this, in turn, can be achieved by the adsorption of polyelectrolytes. This approach is particularly important in the stabilization of protein dispersions, which tend to flocculation when the pH of the continuous phase approaches their isoelectric point. Here sodium carboxymethylcellulose (CMC) has proved effective down to a pH of 4.2, below which the polymer itself becomes increasingly insoluble. CMC offers the additional advantages that: (1) its calcium salts are soluble, and there is therefore no restriction on its use in calcium-rich systems, in particular milk, and (2) it is in itself a good thickening agent, and when used in excess, it can retard gravitationally induced phase separation. (*See* **Colloids and Emulsions**.)

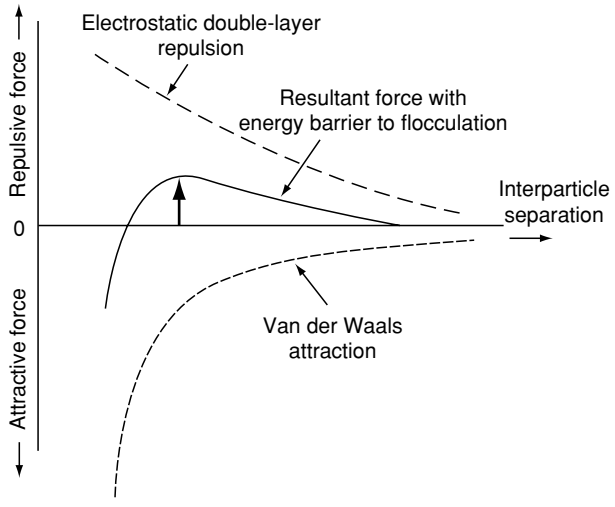

Figure 1 Schematic representation of particle interaction. Reproduced from Stabilizers/Types and Function, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Below pH 4.2, pectin and, to a lesser degree, alginate esters can be used. For stabilization, a high proportion of the carboxylic acid residues present in these molecules must be blocked, thus only high-methoxy pectin, with a degree of esterification (DE) above 70%, and propyleneglycol alginate (DE > 60%) are effective. Polymers with a higher proportion of free acid groups tend to facilitate flocculation, presumably by bridging the dispersed particles, and are calcium-sensitive. The esterification of the acid also promotes the cleavage of the glycosidic bond by β-elimination. These hydrocolloids are therefore susceptible to thermal degradation, particularly in neutral systems, and this can be a handicap for their use in pasteurized and sterilized products.

With these pectins and alginate derivates, a further mechanism of stabilization may be operative. The steric effects of the long molecules adsorbed on to the surface of the particles may prevent their mutual approach. In order to function in this way, the stabilizing polymer must have an appreciable portion of its length as a fully solvated chain in the proximal solvent (Figure 2). This requirement can rarely be met by homopolymers and usually requires block polymer species, such as high-methoxy pectin, containing both lyophilic and lyophobic segments. This stabilizing mechanism will be affected by the solvent quality with respect to the lyophilic portion; reducing the quality will decrease stability. The stabilization also requires that the surface be fully coated with polymer, which should therefore be used in excess. If added sparingly, lyophobic portions of the same molecule may cause bridging between particles and thereby induce flocculation.

Gravitationally Induced Phase Separation

Neglecting interparticle forces, the movement of particulate phase under gravity is governed ideally by Stokes law. This law relates the terminal velocity v of a spherical body to the viscosity of continuous

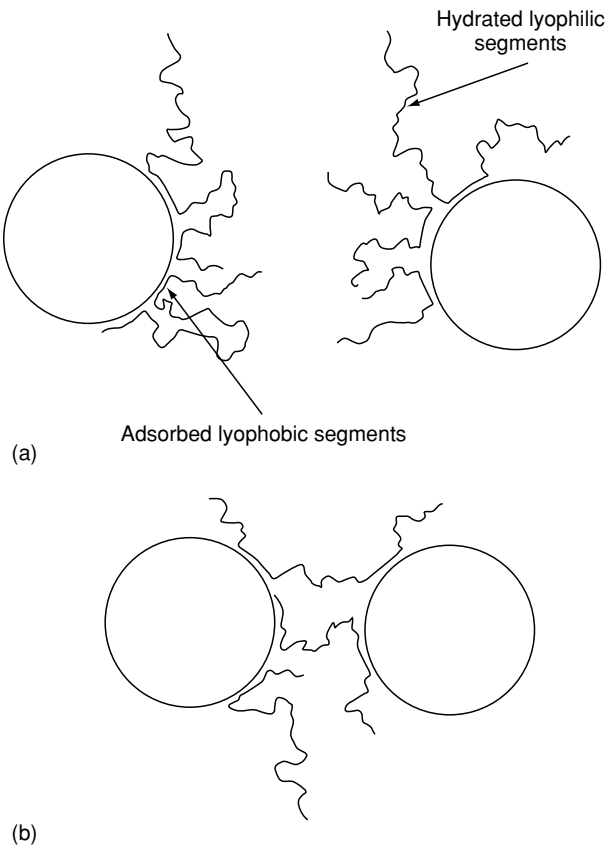

Figure 2 (a) Steric stabilization and (b) flocculation. Reproduced from Stabilizers/Types and Function, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

phase, η, the radius of the particle, r, and the force acting on the particle, f:

$$\nu = (6\pi f)/\eta r$$

$$f = (\rho_p - \rho_s)\tfrac{4}{3}\pi r^3$$

The density of the particle is ρ_p, and that of the continuous phase is ρ_s.

It follows from these equations that the speed of creaming or sedimentation increases with particle size and decreases with the viscosity of the continuous phase. This is, of course, the rationality behind the use of homogenization to delay creaming in milk, or the use of thickening agents to delay sedimentation.

In order to have appreciable influence on stability, the viscosity must be drastically increased and this can best be achieved by the use of polysaccharide gums. These substances are extremely efficient thickening agents, being effective at concentrations typically below 1.0%. (*See* **Gums**: Properties of Individual Gums.)

The effect on viscosity is believed to be the result of nonspecific entanglement of the randomly coiled polysaccharide chains. It follows from this model that the more extended the polysaccharide molecules are in solution, the more entanglement would be likely and the higher the viscosity obtained. The extension, and thereby the viscosity, is governed by size and topology of the molecule, its flexibility, and its interaction with the solvent. Given the same molecular weight, a linear molecule will be more extended and more prone to entanglement than a highly branched species. For linear molecules the extension should be directly related to the molecular weight. (*See* **Carbohydrates**: Classification and Properties.)

It is therefore not surprising to find that all commercially important gum thickeners are linear polymers, and that they are available in a wide range of viscosities which reflect their degree of polymerization.

The fact that these substances show a much larger effect on viscosity as compared with equally large synthetic polymers or proteins has been ascribed to the bulky monomer sugar which restricts chain flexibility. None of these polymers are rigid rods, however, so that the quality of the solvent will influence the degree of extension. In thermodynamically poor solvents, and in the presence of salts which shield electrostatic repulsive forces in polyelectrolytes, the molecules tend to assume more compact conformations and the efficiency of thickening will be reduced. It also follows from the model of molecular entanglement that the concentration must be such that physical contact is possible. This condition is usually satisfied when the concentration of hydrocolloid gums, c, is such that:

$$c.[\eta] \geq 4$$

In this equation, $[\eta]$ is the intrinsic viscosity of the polysaccharide; $c.[\eta]$ is known as the overlap factor. The intrinsic viscosity is a measure of the extension of the molecule in solution and can be related to its radius of gyration.

The flow properties of hydrocolloid-thickened solutions are markedly pseudoplastic (Figure 3). Under the influence of shear, the dynamic viscosity falls. This is thought to be the result of orientation of the extended molecules under the shear gradient, with a concomitant reduction in entanglement. This property can be used to great advantage in stabilizers. The shear stresses operative in gravitational sedimentation or creaming are in the order of 10^0–10^1 mPa. At these extremely low shear stresses, hydrocolloids exhibit extremely high dynamic viscosities. A 1% xanthan solution shows a viscosity of 10^5 mPa s^{-1} under a shear stress of 10 mPa. At shear rates of between 10 and 50 s^{-1}, believed to be present in the mouth during mastication, the viscosity of the same

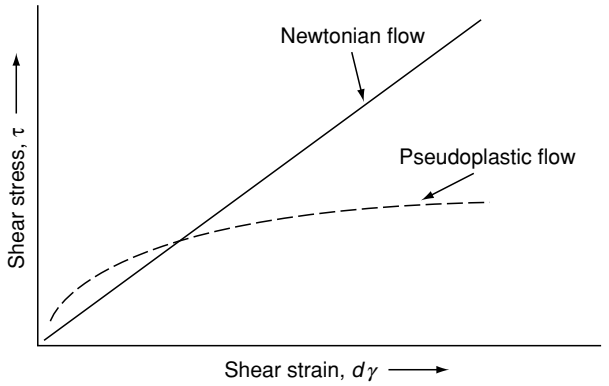

Figure 3 Schematic representation of pseudoplastic and Newtonian flow. $\eta = \tau/d\gamma$, where η is dynamic viscosity. Reproduced from Stabilizers/Type and Function, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

xanthan solution falls to $10^2-10^3\,\text{mPa}\,\text{s}^{-1}$. Thus, foods thickened in this manner exhibit a light, pleasant mouth feel.

The same stabilization effect cannot be obtained with a thickener showing Newtonic flow characteristics in which viscosity is independent of shear. If the high viscosities could be obtained at low shear then the product would be unacceptably thick on eating. This can be illustrated by honey, a Newtonic fluid thickened by mono- and disaccharides, which has a viscosity of only $10^4\,\text{mPa}\,\text{s}^{-1}$, independent of shear rate. Organoleptically, such Newtonically thickened solutions are perceived as long and slimy.

This approach to stabilization, and the use of non-absorbed polysaccharides in food in general, is limited by thermodynamic incompatibility with other colloidally dispersed polymers. This prevents the polysaccharide and its incompatible neighbor from occupying the same space, the so-called excluded volume, and can drive the excluded colloid to flocculate or lead to phase separation. Such thermodynamic incompatibility is known to exist between proteins and polysaccharides and the effect is therefore important in foods containing colloidally dispersed proteins such as milk or gelatin solutions. Thus, in milk, the addition of a low concentration of hydrocolloid with a large hydrodynamic volume (i.e., extended conformations) will cause curdling, while gelatin solution, in the presence of larger concentrations, will exhibit phase separation. Indeed this effect may be used to advantage in the gelatin encapsulation of fats or, possibly, in the stabilization of foams. (*See* **Carbohydrates**: Interactions with Other Food Components; **Protein**: Interactions and Reactions Involved in Food Processing.)

A further explanation for the flocculation of colloidal particles has been proposed; this relies on the driving force of the osmotic gradient, caused by the exclusion of bulky polymer molecules from the narrow gap between two approaching particles. This phenomenon, christened depletion flocculation, has yet to be definitively observed in food systems.

The seed gums, guar and locust bean gum (LBG), which are both galactomannans, together with the microbiological slime, xanthan, are the principal hydrocolloids used commercially for thickening foods. Of these, xanthan shows the most pronounced and desirable pseudoplastic flow and, in its purified form, is colorless and tasteless. Although in many respects an ideal stabilizer, xanthan is considerably more expensive than the seed gums and, presumably for this reason, its use has been somewhat restricted. Guar suffers from the problem of taste and, although it can be reduced by steam treatment, this erodes the price advantage. For LBG the critical quality characteristic is the presence of dark specks, which originate from the seed coat and which can prohibit its use in white products. (*See* **Gums**: Nutritional Role of Guar Gum.)

These hydrocolloid thickeners can be used individually, but it is well known that galactomannans interact with xanthan and other hydrocolloids. This so-called synergism results, in the case of guar and xanthan, in the mixture having a higher viscosity than predicted on the basis of the individual concentrations. In the case of LBG and xanthan, the mixture gels. These effects are believed to be the result of ordered associations forming cross-links between the chains. The naked mannan segments of the galactomannans are implicated in the formation of these junction zones with xanthan, although their exact form is at present unknown.

Generally speaking, viscosity increase should only be used to stabilize suspensions in which the particle size is small. With macroparticular suspension, such as herbs in oil-free dressings or chocolate particles in milk, greater resistance to movement is usually required and here the elastic properties of the continuous phase should be augmented, i.e., the gel character of the continuous phase increased.

The origin of gelling in polysaccharide solution is believed to lie in formation of intermolecular cross-links between the individual chains. With the onset of cross-linking, the solution becomes progressively more viscous until a distinct gel begins to form. With increasing cross-linking the gel loses its elasticity, becomes more brittle, and exhibits syneresis. Eventually, the hydrocolloids may precipitate out of solution. The cross-links, or junction zones, are

complex, involving at least two polysaccharide strands, and are believed to be crystalline in nature. The driving force in their formation is hydrogen bonding between hydroxyl groups and/or ionic bonding where polyelectrolytes are involved.

For the stabilization of liquid suspensions generally, a weak and, preferably, thixotropic gel should be used, and the breaking strength should be chosen so that the weakly gelled aqueous phase flows when subject to the high shear stresses on pouring. In principle, any gelling polysaccharide can be employed but, in practice, carrageenans enjoy the widest commercial use. At dosage levels of 0.5%, Jota carrageenans give a weak thixotropic gel suitable for water-based dressings. It is a requirement of their use, however, that the dressing is filled at a temperature of around 20 °C. This may be bacteriologically undesirable and, in such cases, a weakly gelling xanthan galactomannan mixture may be used, hot-filled. Where milk is the suspending medium, κ-carrageenans at dosage levels of 0.02% provide a satisfactory gel.

Ostwald Ripening

One further mechanism of destabilization is known.

In polydisperse systems it can be observed that larger particles grow at the expense of smaller ones. This disproportionation phenomenon, which was first described by Ostwald in crystallization processes, is only important in the context of food systems in the destabilization of foams. Gas trapped in a foam bubble is subject to a pressure, the Laplace pressure, due to the surface tension of the surrounding, typically aqueous, interface. The magnitude of this internal pressure is inversely proportional to the diameter of the bubble, i.e., the smaller the bubble, the higher the pressure. If the gas is soluble in the continuous phase then an equilibrium will be established between the pressure of the gas in the bubble and the concentration of dissolved gas in the continuous phase immediately surrounding the interface. This dissolved gas may diffuse away from the interface or the continuous phase itself may be transported in bulk through the foam. If this becomes adjacent to a larger bubble with a lower Laplace pressure then gas will be released from solution to reestablish the equilibrium.

The speed of Ostwald ripening in foams may be reduced by decreasing the surface tension of the aqueous interface or decreasing the solubility of the gas in the aqueous continuous phase. In practice, however, longer-term stability can be conferred on the foam by gelling the continuous phase so that bubble disproportionation cannot take place.

Applications

J E Fox, P Ingenpass and S Zachow, GC Hahn and Company, Lubeck, Germany

Neutral Milk Products

The inhabitants of Normandy and Ireland's west coast were historically the first to use hydrocolloids as food additives. With the help of calcium-sensitive, gelling polysaccharides which were extracted from red seaweeds, and which later became known as carrageenans, a gelled milk pudding or blancmange was prepared.

Carrageenans are still used in food in this capacity. κ-Carrageenan dosages between 0.2% and 0.3% produce a brittle-gelled pudding when hot-filled above the gel melting point of about 70 °C, but should the product be subject to shear whilst gelling and cold-filled, then a smooth, creamy, custard-type product results. The consistency and mouth feel of both the hot- and cold-filled products can be modified by the incorporation of other polysaccharides. Starch, for example, will improve the body and locust bean gum (LBG) the elasticity. (*See* **Gums**: Properties of Individual Gums.)

The classification of carrageenans as stabilizers is, in these products, a somewhat moot point. There are, however, two well-established applications of carrageenans in which their stabilizing functionality is undisputed.

Ultra-heat-treated (UHT) Whipping Cream

One aspect of the instability of milk, and particularly cream, arises from the flocculation and creaming of the milk fat. In short-life products, this can be adequately controlled by homogenizing the product to reduce the oil droplet size. However, this cannot be done with long-life UHT whipping cream because it would impair the whipping properties. The problem can be solved by the incorporation of stabilizers which form weak gels. (*See* **Cream**: Types of Cream.)

Carrageenans have proved efficient here when added at levels between 0.01% and 0.02%. The stabilizer should be dissolved at 70 °C in the skimmed milk used to standardize the fat content, before UHT treatment. In these systems, the casein micelles appear to play an active role in the gel structure. The carrageenan becomes attached to the micelle surface by a process other than that requiring the intermediacy of calcium ions, and probably involving the cationically charged section of the casein molecules. It is therefore not surprising to find that the strength of the gel is dependent on casein quality or, more precisely, on the thermal history of the cream. Where the heat treatment was prolonged or repeated, absorption or binding is poor and a higher dosage of carrageenan will be required to obtain the required stability. Carrageenans are also amongst the most thermal-instable hydrocolloids. Prolonged storage at elevated temperatures is therefore to be avoided.

Cocoa Drinks

A similar problem arises with chocolate milk. The cocoa particles tend to sediment to the bottom of the bottle, giving a deep brown, compact layer below a somewhat pale (milk) fluid. This can be corrected in the same way as the creaming in UHT cream by the formation of a weak gel using about 0.02% of carrageenans. Other hydrocolloids may also be included to improve the mouth feel of the drink. The dosage of carrageenan is critical. Too much carrageenan results in the formation of a gel which is too strong and shows syneresis on standing, leaving an almost clear serum at the top of the bottle. Too low a dosage results in a gel which is insufficiently strong to support the cocoa particles which sediment in the bottle. The quality of the cocoa can also affect the stability. Cocoa which has been treated with alkali to obtain a good color is difficult to stabilize. (*See* **Cocoa**: Production, Products, and Use.)

To obtain stabilization, the UHT or sterilized drink must also be bottled at a temperature below the gelling point of the system, and ideally 24 °C should not be exceeded.

Foamed Milk Products

Two groups of foamed milk products may be recognized: those containing fat in which the fat plays a functional role in stabilization, and those based on skimmed milk.

In fat-free systems, the milk proteins themselves are sufficient to lower surface tension and form a stabilizing layer around the air cells. This can be reinforced by the addition of other hydrolyzed proteins, and thickening agents can be added to reduce the speed of drainage of the aqueous phase from the lamellae between the air cells, which would otherwise lead to collapse of the foam. Thickening agents will not prevent Ostwald ripening, so that to insure complete stability the aqueous continuous phase must be gelled as in a mousse-type product.

An entirely different situation exists in fat-containing products. Here the fat displaces the protein from the air surface and prevents its stabilization of the foam. In such products, the foam is stabilized by an entirely different mechanism. An emulsifier, typically an acetic acid or lactic acid ester of a mono- or diglyceride, which is capable of displacing the protein from the oil-water interface, is included in the stabilizing system. On whipping or aeration, the emulsifiers promote coalescense of the fat globules, and the fat crystals, which must be present in the fat phase at the aeration temperature, form a supporting network around the air cell. Such a mechanism is operative in artificial cream, icecream, aerosol cream, cream toppings, milkshakes, and other products. (*See* **Emulsifiers**: Uses in Processed Foods.)

In addition to emulsifiers, a variety of gums are added to these stabilizer systems to modify the rheology of the aqueous phase. This is particularly important where the fat content is low or the crystallization poor. In cream toppings for desserts and cakes, 1.0–1.5% gelatin is added directly before aeration to stabilize the foam. In addition, carrageenans, guar, and starches may be added to influence the eating quality of the topping. In aerosol cream in spray cans, the cream must remain fluid in the can, and this system therefore cannot be used. Here the protein content of the cream is enhanced and a low dosage of gelling polysaccharide, carrageenan, or pectin added.

Surface-active polysaccharides, such as propylene glycol alginate or methylcellulose, may be used to enhance foaming and foam stability. Where the foam must be stable at elevated ambient temperature,

the gelatin may be totally or partially replaced by xanthan or gelling mixtures of xanthan and LBG.

Icecream

Hydrocolloids and gelatin are also widely used in icecream, and are customarily described and declared as stabilizers, although their funtionality here has little in common with stabilization in its strict sense. Depending upon the type of icecream to be produced and its fat content, typically between 0.5% and 0.8% of a stabilizer mixture is used. Of this, about 50–60% is a monoglyceride emulsifier to destabilize the fat globules; the remaining 0.2–0.4 % is hydrocolloid, of which about 80% is a thickening gum such as LBG, guar, or sodium carboxy-methylcellulose (CMC), and 20% a gelling agent, such as alginate or carrageenan (0.01–0.03%). The gums serve to improve mouth feel and limit ice crystal growth on freezing and storage. The gelling agents are added to prevent whey separation on thawing and give a slow meltdown. (*See* **Ice Cream**: Methods of Manufacture; Properties and Analysis.)

Sour Milk Products

Yogurt

On approaching the isoelectric point, the casein micelles in milk flocculate to give a delicate gel structure typified by natural yogurt. With the natural solid content of milk, the gel formed is extremely weak and fragile and unsuitable for commercial exploitation. The mouth feel is also poor and watery. The addition of 2–5% milk solids as milk powder to the base milk before incubation can remedy this situation. However, the problem remains that on aging or exposure to high ambient temperature the casein gel shows syneresis or wheying-off. To inhibit this, the milk powder may be totally or partially replaced by modified starches, gelatin, isolated milk protein, or combinations thereof. Although from an economic point of view the use of chemically modified starches is very attractive, too high a dosage gives the product a heavy, pasty and, for yogurt, very uncharacteristic mouth feel. Gelatin typically endows the product with a smooth, light texture. (*See* **Starch**: Modified Starches; **Yogurt**: The Product and its Manufacture.)

Polysaccharide hydrocolloids are not generally employed because of their flocculation of milk proteins at the isoelectric point, owing to the excluded volume effects when added at effective concentrations. The exception is the use of low-methoxy pectin, at low dosages of about 0.1%, to promote flocculation and thereby strengthen the gel.

Set yogurts, fermented in the tub, are inefficient to produce on an industrial scale. Much more suitable to the restraints of an industrial process are stirred yogurts, in which the fermentation can take place in larger vessels under carefully controlled conditions. Unfortunately, however, once the yogurt gel is broken by stirring, pumping, and filling, it will only partially reform in the tub. This situation can be remedied by the use of stabilizers which, if they are to be added to the milk before culture, are limited to those used in set yogurt, although they differ qualitatively from these.

With yogurt as a pumpable liquid, it becomes possible to pasteurize or even sterilize it in a plate heat exchanger. This removes one of the major hurdles to wide-scale distribution, i.e., the limited shelf-life. At a pH not far below the isoelectric point of the proteins, the stability of the dispersed protein is delicate and thermal energy can easily lead to flocculation. This flocculation is manifested as an unpleasant, sandy texture in thermized yogurt. This phenomenon can be delayed by the addition of high-methoxy pectin, typically at levels between 0.5% and 0.7%, before pasteurization. Pectin is believed to function by forming a protective layer on the surface of the casein micelles. A finer dispersion with a larger surface will therefore require a higher dosage. The dosage is also related to the thermal stress which the product must survive. Indeed, under ideal technology and recipe, a commercially satisfactory thermized product may be manufactured with almost no stabilizer. However, if the product is kept at elevated temperature over hours, no amount of protective colloid can prevent unacceptable sandiness. At extremely high dosage, pectin also causes flocculation owing to excluded volume effects. As an alternative to pectin, propylene glycol alginate can be, but seldom is, used commercially. CMC may be used above pH 4.2. (*See* **Pectin**: Food Use.)

Pasteurization also presents the opportunity to add new sterile ingredients to the sour product before thermization. Thus low concentrations of gums, typically guar and LBG at 0.1% dosage levels, can be added to improve the mouth feel of the product. (*See* **Pasteurization**: Principles.)

Quarg and Fresh Cheese Products

The problems associated with the production of fresh cheese products have their roots in the same phenomena as those that destabilize yogurt. (*See* **Cheeses**: Quarg and Fromage Frais.)

Collapse and contraction of the casein gel lead to syneresis or wheying-off, and heating of the casein enhances flocculation and causes sandiness in the product. Both these effects can be eliminated or

reduced by the use of stabilizers; the type and dosage depend greatly on the recipe, on the technology, and the type of product to be manufactured. A typical thermized quarg stabilizer contains 0.3% gelatin, 0.3% starch, and small amounts of gum, including CMC, guar, and LBG. Gelatin gives the quarg a pleasant, smooth, and light mouth feel and appears to function, at least partially, as a protective colloid for underefficient thermization processes – such as those occurring in a scraped-surface heat exchanger – and in the presence of moderate amounts of fat, no sandiness occurs.

When the product is subject to high thermal stress, such as prevails in a batch process with a long cooling time or when the product is fat-free, other protective colloids, such as CMC, may have to be included. Starches are usually included to give the product body. Gums confer viscosity on the product. This is of special importance in hot-whipped products, where the viscosity of the hot quarg would be insufficient to sustain a foam. In whipped products a higher dosage of gelatin is also used to stabilize the foam when cold.

Sour Milk Drinks

Compared to yogurt or quarg, sour milk drinks contain appreciably less protein, and the problem is not so much one of stabilizing a casein gel network as maintaining the individual casein flocculates in suspension. To this end, almost all sour milk drinks are homogenized under high pressure to break down the casein flocculates and give a stabilizable particle density. The resulting high surface area dictates that a higher than normal concentration of protective colloids must be employed. Typically, this is high-methoxy pectin for drinks below pH 4.2, and CMC for a pH above 4.2. Below pH 4.2, CMC becomes increasingly insoluble, and chain association leads to flocculation enhancement. Above this pH, however, CMC has the added advantage of increasing viscosity and thereby slowing sedimentation. With pectin, other gums may be added to increase viscosity.

Emulsified Foods

Two types of emulsified foods can be recognized: those such as mayonnaise and dressings, in which the oil is dispersed in a continuous aqueous phase (o/w), and those typified by such products as butter and margarine, which are water-in-oil (w/o) emulsions. Both these systems are inherently unstable owing to their high surface energy content and density differences between the phases.

Oil-in-water Emulsion

Traditional mayonnaise is an o/w emulsion containing 80% oil, in which egg yolk serves as an emulsifier. The short plastic structure of this product is attributable to three factors:

1. The fine oil droplet size, 1–10 μm, results in a relatively high Laplace pressure which resists droplet deformation.
2. The high volume of oil is somewhat in excess of the optimal packing condition, thus forcing the droplets to be in intimate contact.
3. Attractive forces between proteins on the aqueous face of the droplet surface cause adhesion and restrict movement. (*See* **Dressings and Mayonnaise**: The Products and Their Manufacture; Chemistry of the Products.)

With no room for gravitational separation and an adequate protein layer around the droplets, mayonnaise represents a perfectly stable system. The modern consumer, aware of the dangers of a high-lipid diet, has shied away from such products and demanded surrogate products showing identical rheological behavior, but with 50%, 30%, and even 15% oil contents. Although milk powder or caseinate, which promotes droplet adhesion, is used as the emulsifier, the volume of oil is too low either to form a continuous agglomerated network and to endow the product with stability against creaming, or to give the desired rheological properties. This problem may be solved by including a starch paste (10–12% solids) to replace the oil in a 1:1 ratio. This, especially in very-low-oil emulsions, gives the product a cheap and pasty mouth feel. A better and more acceptable salad or low-energy mayonnaise can be stabilized by replacing some of the starches by hydrocolloids. For example, for the cold preparation of a 30% emulsion, a blend of either LBG or guar gum and xanthan at a total dosage of 0.4–0.6% can be used in combination with starch. Guar gum or CMC can be used in addition where the fat content is very low in order to achieve a mayonnaise-like consistency. The stabilizers can be used with emulsifiers such as milk protein or egg yolk.

For the stabilization of hot-prepared dressings and mayonnaises, guar gum and xanthan in the ratio of 3:1 at an addition of about 0.50% can be employed. The viscosity can be adjusted by varying the combination and quality of raw material and stabilizer(s).

Mayonnaises are widely used for the preparation of salads. There are three special applications of hydrocolloid stabilized products. When marinated fish or fresh vegetables are included they tend to lose appreciable amounts of cell fluids which can

form unsightly pools in the mayonnaise. The incorporation of gums can help bind this water. For example, guar gum is used in combination with xanthan, LBG, and propylene glycol alginate. For dressings with high fat or cream contents, milk proteins, especially whey protein and caseinates, are widely used.

Fresh fruit and vegetables often contain amylases which attack and hydrolyze the starch in the mayonnaise with the concomitant loss of viscosity and stability. For such applications, special mayonnaises have been developed which are wholly stabilized by enzyme-resistant hydrocolloids. Typical are blends of guar gum and xanthan in the ratio of 3:1 at an addition rate of 0.50%. The water-binding ability and 'cling' of the dressing will be increased by adding CMC to this blend. Where the oil content of the mayonnaise has been reduced in the formulation of a calorie-reduced or 'light' product, the consequent reduction in opacity can be compensated by the addition of milk proteins.

In some salads, where the proportion of mayonnaise is low, it must be prevented from running-off the other components. This feature, known as cling, is important in such products as coleslaw and may be achieved by improving the pseudoplastic flow characteristics of the emulsion by the use of stabilizers. Good cling to salad ingredients, also to hot salads, will be obtained by using balanced combination of water-binding and gellifying hydrocolloids.

Water-in-Oil Emulsions

Those arguments which led to the introduction of low-oil mayonnaises have also promoted the development of fat-reduced spreads. In butter or traditional margarine, the distribution of the finely dispersed aqueous phase is stabilized by the crystal matrix in the fat. With half-fat products and spreads containing more than 60% aqueous phase, the crystal matrix is depleted and insufficient to insure stability. Hydrocolloid stabilizers are, of course, unable to influence the rheology of the fat phase. The usual approach is therefore to prevent coalescence of the droplets by increasing their viscosity or gelling. The viscosity can be raised by the addition of proteins or gums. The use of 2% caseinate in combination with other milk proteins at a total dosage of about 4% is necessary for the stability of the emulsion, possibly in combination with fatty acid emulsifiers. The quality of the product with regard to melting and spreadability can be improved when adding hydrocolloids such as carrageenan and xanthan. For gelling, gelating is customarily used by virtue of its low melting temperature. (*See* **Margarine**: Types and Properties; Methods of Manufacture.)

Deep-Frozen Foods

The crystallization of both oil and water phases in deep-frozen products presents a special stabilization problem. In addition to damaging and weakening cell structures, crystal growth also physically concentrates the dispersed phase and thereby promotes agglomeration. Icecream is typical of the foods in which this can occur. In an analogous manner, ice crystal growth within polysaccharide gels forces the chains together; these may then form macroscopic, solid-phase regions between the crystals which will not rehydrate on thawing. The effect is most pronounced in native starch gels where, after freezing, the gel resembles a sponge from which the water can be removed by simply squeezing. This situation can be remedied by the addition of low levels of a hydrocolloidal gum to the paste. Typically, 0.15% xanthan and CMC is used. Alternatively, chemically derivatized starches which show little or no retrogration, such as hydroxypropyl derivatives, can be used. The addition of emulsifiers and special starch-degradation products counteracts crystallization. (*See* **Freezing**: Principles.)

This behavior is not restricted to starch. Where the chemical nature of the gelling polysaccharide is conducive to ordered association, considerable syneresis results from a freeze–thaw cycle. Such gels are, by virtue of their propensity to cross-linking, naturally strong and brittle. As with starch, syneresis can be limited by the addition of small amounts of nongelling gums. With κ-carrageenan – a typical brittle, freeze–thaw-unstable gel – small additions of LBG may be used, but this will also influence gel rheology. As would be expected, weak, elastic, and preferably thixotropic gels may survive freeze–thaw cycles undamaged. Commercially, ι-carrageenans are widely used in this role.

Crystallization of the fat in an o/w emulsion usually results in a penetration of the protective layer around the oil droplet with subsequent coalescence on thawing. Provided that the oil content remains low, preferably $< 20\%$, emulsions which do not break can be prepared by using propylene glycol alginate as the emulsifier in combination with xanthan as the stabilizer at levels of 0.5–1.0%.

Miscellaneous Applications

More than 10 years ago, the first oil-free dressing appeared on the market in which the herbs were suspended in a clear aqueous phase. In these products the herbs are held in a suspension by a weak, preferably thixotropic gel, usually based on carrageenans. This technique may be applied to a wide range of

novelty drinks, including those that contain suspensions of fruit or fruit pieces.

Many fruits do not retain their physical integrity on cooking and turn into a nondescript mash. Where cooking stability is required, the raw fruit purée can be reformed into a fruit shape with an alginate gel. Such gels do not melt at normal cooking or baking temperatures. The technique is widely used, though for a different reason, to reform paprika in cocktail olives. Currently its use in reformed meat is being advocated.

Natural meats and fish show a considerable weight loss on cooking. To counteract this, mixtures of salts and hydrocolloids, typically carrageenans, are injected or pumped into the raw meat and the mixture gels after cooking. In meat pies and pastries, the escaping cell fluid can also disfigure the pastry surface. This may be obviated by incorporation of cellulose ethers, usually methylcellulose, into the filling. In contrast to almost all other polysaccharide food additives, colloidal solutions of methylcellulose form a gel when heated and thereby prevent the escape or boil-out of juices. The technique is also applicable to fruit-filled bakery products. Cellulose ethers have also been employed as film-building agents to reduce the penetration and uptake of fats in deep-fried foods.

STAPHYLOCOCCUS

Contents

Properties and Occurrence

A L Wong and M S Bergdoll[†], University of Wisconsin, Madison, WI, USA

Classification

In 1880, Ogston first demonstrated that a cluster-forming coccus caused many types of purulent infections in humans. He named the organism 'staphylococcus'. In 1884, Rosenbach isolated staphylococci from pus and determined that the organisms were identical to those described by Ogston. He proposed the genus *Staphylococcus* to contain these organisms. Rosenbach observed yellow and white colonies formed by the staphylococci and named the yellow colony-forming organism *Staphylococcus aureus*, and the white colony-forming organism *S. albus*. It was later determined that pigmentation was a variable characteristic and therefore not a valid criterion for classifying the staphylococci, and *S. albus* was reclassified as *S. aureus*. *Staphylococcus* was placed in the family Micrococcaceae in 1920.

In 1908, Winslow and Winslow proposed a second species, *S. epidermidis*. It was not until 1974 that a third species, *S. saprophyticus*, was added. By 1980, the number of species had increased to 13 and by 1984 to 20. Currently, at least 32 species have been described, based on DNA homology and immunochemical and biochemical characteristics.

[†]Deceased.

Staphylococci are Gram-positive, catalase-positive, nonmotile cocci that characteristically divide in more than one plane to form irregular clusters. The cell wall typically contains teichoic acid, and the peptide subunits of the peptidoglycan are cross-linked by pentapeptide bridges containing solely or primarily glycine. Staphylococci are facultative anaerobes but grow more rapidly and abundantly under aerobic conditions. A variety of carbohydrates and/or amino acids can be utilized as carbon and energy sources. The staphylococci can be differentiated from members of the strictly aerobic genus *Micrococcus* by their ability to grow and produce acid from glucose anaerobically. In addition, the two genera have different cell wall structures, cytochrome and fatty acid profiles, menaquinone content, and aliphatic hydrocarbons.

Some of the characteristics used to differentiate staphylococcal species are given in Table 1. *S. aureus* is the predominant species involved in staphylococcal food poisoning outbreaks. The illness is caused by the ingestion of preformed staphylococcal enterotoxins in foods. Thirteen enterotoxins have been identified: enterotoxins A (SEA), B (SEB), C1 (SEC1), C2 (SEC2), C3 (SEC3), D (SED), E (SEE), G (SEG), H (SEH), I (SEI), J (SEJ), K (SEK), and L (SEL). Two of the newer species, *S. intermedius* and *S. hyicus*, were formerly considered to be *S. aureus*. Although they differ in some of their characteristics, they can produce coagulase and thermonuclease (TNase), the two characteristics used most frequently to distinguish *S. aureus* from other staphylococci. All the other staphylococcal species are coagulase- and TNase-negative. The use of the name *S. aureus* herein includes both *S. intermedius* and *S. hyicus* because, essentially, all of the information presented was obtained before these two species were separated from *S. aureus*. Occasional strains of a few coagulase-negative species have been reported to produce enterotoxin. The degree of involvement of these organisms in food poisoning is unknown.

Ecology

Staphylococci are ubiquitous. Their main habitats are the noses, skin, and throats of humans and warm-blooded animals. Staphylococci can also be found in the air, soil, water, sewage, plant surfaces and products, meats, poultry, and dairy products.

Certain staphylococcal species show host preferences. The primary host for *S. aureus* is the human; however, the organism can be found also in a variety of animals and birds, and can cause many types of infections and diseases. *S. epidermidis* is the most prevalent on human skin, whereas *S. hyicus* commonly inhabits the nares and skin of chickens and pigs. Dogs are the preferred host for *S. intermedius*, which can also be found on pigeons.

About 30–50% of healthy individuals are carriers of *S. aureus*, with 40–50% of the isolates being enterotoxin producers. The incidence of enterotoxigenic strains among individuals with staphylococcal infections is higher than among healthy people. In general, the incidence of enterotoxin-producing staphylococci in healthy animals is relatively low. *S. aureus* causes many types of infections and diseases in animals. The incidence of enterotoxigenic staphylococci from mastitic animals depends on the animal species. A high percentage (60–80%) of staphylococcal isolates from mastitic sheep and goats are enterotoxigenic, whereas less than 15% of those isolated from mastitic cows produce enterotoxin.

Essentially all raw foods, especially raw meats and poultry, can be contaminated with *S. aureus*, by humans or animals, or both. Raw milk often contains staphylococci, and the organism may be isolated from 30–50% of poultry carcasses. Staphylococci isolated from goats and sheep usually produce SEC, and those

Table 1 Characteristics of *Staphylococcus* species

from cows produce either SEC or SED, whereas strains isolated from humans produce primarily SEA, the enterotoxin type most commonly involved in staphylococcal food poisoning. (*See* **Meat**: Preservation; **Milk**: Processing of Liquid Milk; **Poultry**: Ducks and Geese; Turkey.)

Growth and Enterotoxin Production

Growth and enterotoxin production by *S. aureus* are influenced by a variety of environmental and nutritional factors including temperature, pH, water activity (a_w), inoculum size, atmospheric composition, carbon and nitrogen sources, salt levels, and competing microflora. Generally, growth is necessary for enterotoxin production, although toxin production does not always accompany growth, especially in foods. Experimental nongrowing cell cultures have been observed to produce enterotoxin. Production of SEB and SEC is affected more by the culture conditions than is SEA production, which is more closely related to the growth of *S. aureus*.

Temperature

S. aureus can grow between 7 and 47.8 °C, with an optimum of 37 °C. Enterotoxin is produced at 10–46 °C, with an optimum temperature range of 37–45 °C. The temperature for supporting growth of staphylococci in a variety of foods ranges from 6.7 to 45.6 °C, with no growth occurring below 5.6 °C. Vanilla pudding inoculated with *S. aureus* supported enterotoxin production over a temperature range of 10–45 °C, whereas pasteurized milk supported growth and enterotoxin production at 20–35 °C, but not at 10 °C. Detectable levels of SEA were produced in 12 h when incubated at 35 °C. Longer incubation times were necessary at lower temperatures for enterotoxin production. SEB was produced in cured hams that were incubated for 2 weeks at 10 °C.

pH

The optimum pH for growth is between 6.0 and 7.0, but the organism can grow over a pH range of 4.0–9.8. The pH at which a strain will grow depends on other cultural parameters such as the atmosphere, a_w value, the type of medium and the salt concentration. Generally, the less optimal the other parameters, the narrower the pH range tolerated by *S. aureus*. For example, the lowest pH at which *S. aureus* grew and produced enterotoxin in aerobic cultures was 4.0, whereas the lowest pH values that supported growth and enterotoxin formation anaerobically were 4.6 and 5.3, respectively. (*See* **pH – Principles and Measurement**.)

Enterotoxin can be produced over a pH range of 4.0–9.0, the optimum being 6.5–7.5. As with staphylococcal growth, whether enterotoxin will be produced at a certain pH depends on other cultural parameters. The acid used for pH adjustment is also an influencing factor. When milk was acidified with hydrochloric acid, SEA was produced at pH levels of 4.5, 5.0, 6.0, and 6.4. However, when lactic acid was used, growth and enterotoxin production were observed at the higher pH levels, but not at pH 4.5. Foods having pH values below 5.0 or above 9.0 do not support enterotoxin production.

Water Activity

S. aureus can grow over a much wider a_w range than many other food-associated pathogens, with growth of some strains occurring at an a_w of 0.86; the optimum is > 0.99. The minimum a_w for anaerobic growth is 0.90. The minimum a_w for enterotoxin production is 0.86, and the optimum is > 0.99. (*See* **Water Activity**: Effect on Food Stability.)

The humectant used for a_w adjustment has a significant effect. For example, when sodium chloride was used, the minimum a_w for SEB production was 0.90–0.92. In a mixture of sodium chloride, potassium chloride and sodium sulfate, SEB production occurred at an $a_w < 0.90$. When glycerol was used, the minimum a_w was 0.98–0.99.

Temperature and pH also affect the a_w at which *S. aureus* will grow and produce enterotoxin. When these parameters deviate from their optimum levels, the minimum a_w tolerated by *S. aureus* is elevated.

Atmospheric Conditions

Staphylococci are facultative anaerobes, but the amount and rate of growth and enterotoxin production are considerably less under anaerobic conditions than under aerobic conditions. Excessive aeration or oxygen levels can decrease the amount of SEB produced. At a dissolved oxygen (DO) level of 100% growth of *S. aureus* at 37 °C was maximal, but no SEB was produced. The optimal DO level for SEB production was 10%. In contrast, SEA production was related more to growth and not affected by the level of DO.

Staphylococcal growth and enterotoxin production have been observed in Canadian bacon and ham, and sausage, turkey, and hamburger sandwiches stored anaerobically. As with culture media, enterotoxin yields were higher under aerobic conditions.

Nutritional Factors

Most species of staphylococci require an organic nitrogen source and one or more B vitamins for

aerobic growth. Media containing protein digests generally enhance growth and enterotoxin production. For anaerobic growth, a fermentable carbon source and uracil are required.

Addition of readily fermentable carbon sources such as glucose or pyruvate to aerobic cultures repressed enterotoxin synthesis by *S. aureus*. The repression is partially attributed to decreased pH due to acid production, and partly to catabolic repression.

Sodium Chloride

One characteristic of *S. aureus* is its ability to survive and grow in relatively high salt concentrations. The organism can grow in up to 20% sodium chloride, whereas enterotoxin production occurs with up to 10% sodium chloride. Growth and enterotoxin production are generally retarded at increased salt concentrations.

Competing Microorganisms

Staphylococci are not good competitors, especially when the inoculum is small compared with that of the other organisms present. Many common food bacteria have been shown to inhibit growth of *S. aureus* and/or its ability to produce enterotoxin. In raw foods, *S. aureus* will not grow appreciably because of the presence of other organisms. An exception would be in the case of raw milk from a cow with staphylococcal mastitis. The high numbers of staphylococci present would be able to overcome other microorganisms. In heat-processed foods, contaminating *S. aureus* would have a competitive edge, especially if the food contains salt and has a reduced a_w.

Survival in Foods

Staphylococcal food poisoning results from the ingestion of enterotoxin produced by *S. aureus* growing in the food. Raw foods such as meat and milk are frequently contaminated with staphylococci. However, they are seldom involved in food poisoning because other contaminating microorganisms inhibit their growth and enterotoxin production. In addition, not all staphylococcal isolates are enterotoxigenic.

Heat is the most effective way to inactivate *S. aureus* in food. Heating meat to an internal temperature of 73.9–76.7 °C will kill any staphylococci present. Temperatures normally used for cooking meats should be sufficient to inactivate *S. aureus*. The time–temperature treatments used to pasteurize milk are adequate to destroy the organisms. The *D* values of *S. aureus* in skim milk at 60.0 and 65.5 °C are 3.44 and 0.28 min, respectively. The enterotoxins, however, are very heat-resistant, and are not inactivated by pasteurization. An outbreak occurred in 1985 from chocolate milk served to schoolchildren. The milk had been held inadvertently for several hours at a warm temperature before pasteurization. *S. aureus* present in the milk was able to grow and produce SEA. No viable staphylococci were present in the pasteurized milk, but SEA was detectable. (*See* **Heat Treatment**: Chemical and Microbiological Changes.)

Temperatures used in commercial canning are sufficient to destroy staphylococci and the amount of enterotoxin usually present in foods involved in food poisoning outbreaks (1 ng to > 50 ng per gram of food). There have been outbreaks associated with the consumption of canned corned beef, but these were traced to recontamination of improperly sealed cans after processing. Two people were reported to become ill after eating lobster bisque that had been heated at 118 °C for 86 min, but this was due to inadequate processing of some of the cans. In general, the heat stability of the enterotoxins is greater in foods than in buffer. The degree of inactivation depends on a variety of factors, including the nature of the food, pH, and concentration and type of enterotoxin. (*See* **Canning**: Principles.)

S. aureus inoculated on to frankfurters was inactivated when they were heated to an internal temperature of 71.1 °C in the smoking procedure. *S. aureus* in the interior of ham that survived the curing process was slowly inactivated during heating in a smokehouse at 48.9 °C for 48 h. (*See* **Curing**.)

Freezing and thawing have no significant effects on the viability of *S. aureus*. However, prolonged storage at subfreezing temperatures reduces the number of *S. aureus* in meats. The population of *S. aureus* in raw minced beef was reduced by 91% after storage at −22 °C for 4 months.

S. aureus is relatively resistant to drying. Nonfat dry milk and foods containing nonfat dry milk have been implicated in several staphylococcal food poisoning outbreaks. Staphylococci present in the milk may survive spray drying, depending on the temperature, the moisture content of the product, and the strain of *S. aureus*.

Detection

M S Bergdoll[†] **and A L Wong**, University of Wisconsin, Madison, WI, USA

Introduction

The fact that staphylococcal food poisoning is caused by the ingestion of enterotoxins produced by staphylococci requires that methods be available for detection of both the organisms and the enterotoxins. Although it is essential that staphylococci are present and grow in the food to produce enterotoxin at some point in the preparation or processing of the food, their presence in the food is not proof that enterotoxin is present. Not all staphylococci are capable of producing enterotoxin. On the other hand, the absence of staphylococci in food does not prove that enterotoxins are absent because these organisms are easily destroyed by heat, whereas the enterotoxins are not. Detection of enterotoxins is most important because, if they are present at detectable levels in a food, ingestion of the food most likely will result in food poisoning.

Detection of Staphylococci in Foods

The isolation of coagulase-positive staphylococci from foods is of greatest concern because these are the types most often involved in food poisoning, although occasionally coagulase-negative staphylococci have been implicated. Coagulase-positive staphylococci include not only *Staphylococcus aureus* but also *S. intermedius* and *S. hyicus*; some strains from each of these species are known to produce enterotoxin. Hence, coagulase production by suspected food-poisoning isolates is one of the most important properties tested for. Thermonuclease (TNase) production is also commonly associated with food-poisoning staphylococci and is another important characteristic of these species.

Detection in Raw Foods

Normally, a 50-g sample of the food is used for detection of the presence of staphylococci. The sample should be as representative of the food from which it is taken as possible. Frozen samples should be thawed under refrigeration just before testing. All sampling should be done under sterile conditions and samples should remain under sterile conditions and kept refrigerated until tested.

The food samples are suspended in or mixed with a suitable diluent, plated on Baird–Parker agar and incubated. One or more colonies of each colony type are selected from a plate containing 20–200 colonies for coagulase determination. Any colonies testing negative for coagulase should be tested for TNase. Any colonies positive for either coagulase or TNase can be considered candidates for enterotoxin production.

Detection in Processed Foods

Collection of processed foods and preparation of the dilutions are the same as for the raw foods. The diluted samples are incubated in double-strength trypticase soya broth before single-strength trypticase soya broth containing 20% sodium chloride is added and the incubation continued. The cultures are plated on Baird–Parker agar and the same procedures as described above are used for testing colonies. This procedure can be used for raw or nonprocessed foods suspected of containing < 100 *S. aureus* organisms per gram in the presence of large numbers of competing organisms.

Detection in Cases of Food Poisoning

In most cases of food poisoning the food will have been contaminated after it was cooked or heated. In these cases the same procedures used for isolation of staphylococci from raw foods are employed. In those cases where the staphylococci have grown in the foods and produced enterotoxin before the food was processed and in those cases where the food history is not known, the procedure for processed foods is used. In some cases the staphylococci have either been killed or else they died during storage. Because TNase is heat-stable and survives in food for long periods of storage, testing for it can be undertaken to indicate whether sufficient staphylococcal growth had occurred to produce enterotoxin.

If staphylococci are isolated from the food they should be tested for enterotoxin production. If they

[†]Deceased.

produce enterotoxin, the food can be tested for the type of enterotoxin produced by them. In the case where staphylococci cannot be isolated but the TNase test is positive, the foods must be tested for enterotoxin because it is not known whether the staphylococci that grew in the food were capable of producing enterotoxin.

Phage typing of the staphylococci isolated from the food is done in order to aid in the identification of the source of contamination. Any staphylococci isolated from an individual who handled food that was implicated in a food-poisoning outbreak should be phage-typed. If the isolates from the food and the individual have the same phage pattern, it can be concluded that the individual was the source of the contamination. (*See* **Food Poisoning:** Tracing Origins and Testing.)

Detection of the Enterotoxins

All of the methods for the detection of the enterotoxins are based on the use of specific antibodies to the enterotoxins. Detection of the enterotoxins is complicated by the fact that seven enterotoxins have been identified – enterotoxins A (SEA), B (SEB), C_1 (SEC_1), C_2 (SEC_2), C_3 (SEC_3), D (SED), and E (SEE). Five specific antibodies are needed for their analysis; the SECs can be detected by one antibody. Unidentified enterotoxins do exist, but their involvement in food poisoning is minor. Antibodies prepared in animals such as rabbits are polyclonal and react with enterotoxins in gels to give precipitin reactions. Monoclonal antibodies cannot be used in gels because their reactions with the enterotoxins do not result in the formation of precipitates.

The detection of enterotoxin in foods requires methods that are much more sensitive than those required for determination of the enterotoxigenicity of strains. The quantity of enterotoxin present in foods involved in food-poisoning outbreaks may vary considerably, from less than 1 ng g^{-1} to greater than 50 ng g^{-1}. Usually, little difficulty is encountered in detecting the enterotoxin in foods involved in staphylococcal food-poisoning outbreaks. However, outbreaks do occur in which the amount of enterotoxin is less than 1 ng per gram of food. In such cases, the enterotoxin can only be detected by the most sensitive methods. Another situation in which it is essential to use a very sensitive method is in determining the safety of a food for consumption.

Gel Diffusion Methods

Many types of gel reactions have been used in the detection of the enterotoxins; the most common ones are some form of either the Ouchterlony gel plate or the microslide (Figure 1). These methods have been used widely in the determination of the enterotoxigenicity of staphylococcal strains. The modification of the Ouchterlony gel plate test that is used in the Food Research Institute, University of Wisconsin, and recommended to others is the optimum sensitivity plate (OSP) method (Figure 2). It is easy to use and, in conjunction with production of the enterotoxins by the membrane-over-agar method (Figure 3) or the sac culture method, is of adequate sensitivity to detect most enterotoxigenic staphylococci. In the sac culture method, the medium is inside a dialysis sac that is placed in an Erlenmeyer flask with the inoculum in buffer outside the bag; incubation is with shaking. The normal sensitivity of the OSP method is 0.5 μg ml^{-1}, but can be increased to 0.1 μg ml^{-1} by a fivefold concentration of the staphylococcal culture supernatant fluids. The microslide is used by some investigators, but care is needed in preparing the slides; even so, the results are often difficult to interpret. Experience is important in achieving its maximum sensitivity (50–100 ng ml^{-1}), but even with experience many individuals are unable to achieve this sensitivity.

The original methods for the detection of enterotoxin in foods employed the microslide as the test method for detection of the enterotoxins. These methods required the use of 100 g of food and extraction and concentration procedures to reduce the extract to 0.1–0.2 ml. These were cumbersome and time-consuming procedures which have been outdated by more sensitive methods for the detection of the enterotoxin in the extracts. The US Food and Drug Administration personnel still use the original method developed in 1965 and consider it the official method for the detection of enterotoxins in foods.

Sensitive Detection Methods

Development of sensitive methods for the detection of proteins at less than 1 ng per milliliter of fluid greatly simplified the detection of enterotoxins in foods. Thus, it was possible to use a simple procedure for extracting the enterotoxin from foods. The one used in the Food Research Institute, University of Wisconsin, is an example: (1) grind the food to a homogeneous slurry with 1–1.5 ml of fluid per gram of food; (2) adjust the pH to 4.5 and centrifuge; (3) adjust the supernatant fluid to pH 7.5 and centrifuge if necessary; (4) extract with chloroform if fat interferes, centrifuge, and filter. Use of simple extraction procedures not only greatly shortens the time required to prepare the sample for enterotoxin detection (from 2–3 days to 1–2 h), but also improves the recovery of the enterotoxin from the food. This is particularly important in cases where very low amounts of enterotoxin ($\leq$ 1 ng g^{-1}) are present. In these cases one can

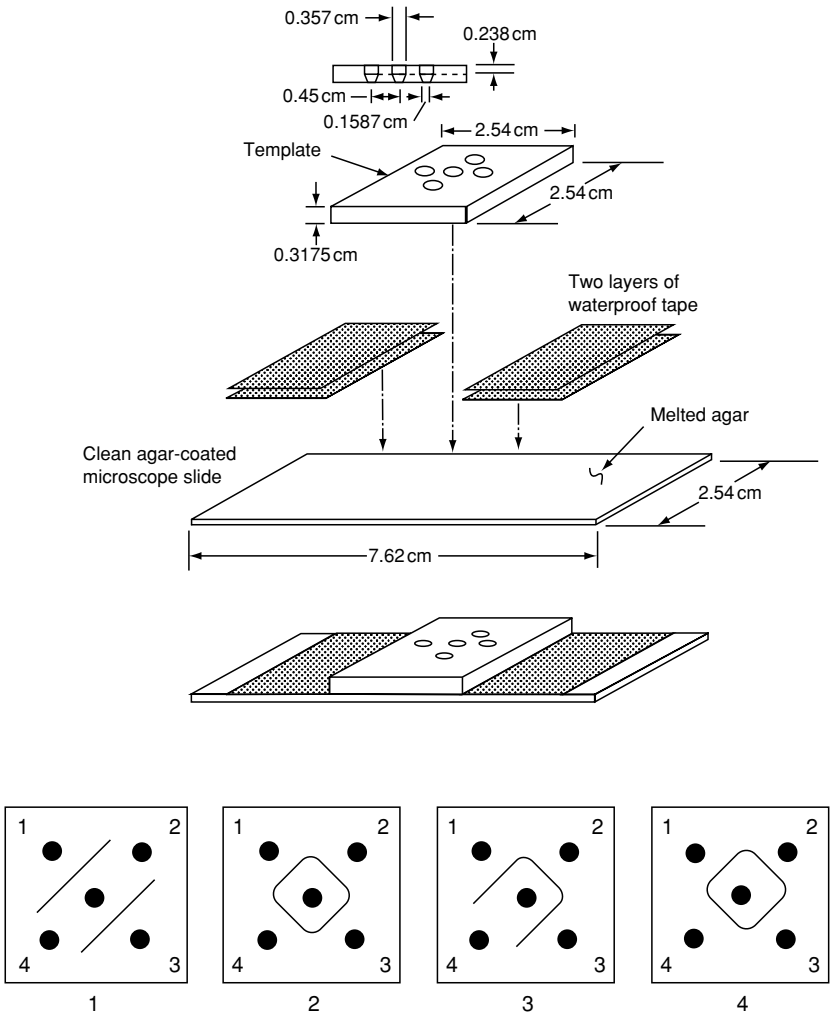

Figure 1 Microslide gel diffusion assembly showing typical results with the microslide test. The antibody is placed in the center well and the control enterotoxin is placed in wells 1 and 3. Slide 1, positive reactions with control toxin; slide 2, positive reactions with unknowns in wells 2 and 4; slide 3, positive reaction with unknown in well 2; reaction when unknown in well 4 contained a larger amount of toxin and unknown in well 2 contained less toxin than the unknown in slide 3. Reproduced from *Staphylococcus*: Detection, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

expect recovery of at least 50% of the enterotoxin but, in the long extraction and concentration procedures, less than 10% will be recovered.

Enzyme-Linked Immunosorbent Assay (ELISA)

The ELISA methods were applied to the detection of the enterotoxins in foods soon after they were originally developed for the detection of other proteins. Essentially, all of the ELISA methods used are of the sandwich type; in this type the enzyme is coupled to the antibody instead of the enterotoxin. The amount of enzyme and, thus, the color developed from the enzyme–substrate reaction, is directly proportional to the amount of enterotoxin present in the unknown sample. (*See* **Immunoassays:** Radioimmunoassay and Enzyme Immunoassay.)

Most users of ELISA methods employ microtiter plates to which the antibodies are attached. The large number of wells in a microtiter plate allow examination of several samples at one time, although there may not be uniformity in all of the wells, particularly those around the edge of the plate. A plate reader is necessary for recording the results, which adds to the expense of the method.

An alternative method is to use polystyrene balls to which the antibodies are attached. The ball method is more cumbersome because each ball must be handled separately. A relatively large volume of the unknown sample can be used, thus increasing the amount of enterotoxin adsorbed, and hence the sensitivity of the assay. The use of 1-ml volumes of substrate allows the color developed to be read in a simple colorimeter,

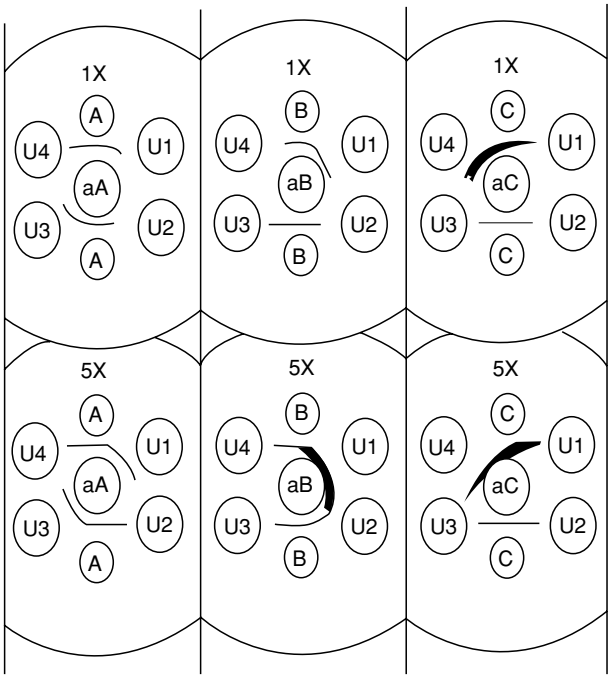

Figure 2 Optimum sensitivity plate (OSP) with typical results. The wells containing the control toxins are one-half the cross-sectional area of the antibody wells (middle) and the wells containing the unknowns (U1–U4). This results in a doubling of the sensitivity. Unknowns in wells U1 and U3 in the first place, U1 in plate 2, and U4 in plate 3 are enterotoxin-positive. The hook in U1 in plate 1 is confirmed by fivefold concentration of the unknown sample. The unknown in well 2 in plate 2 is not positive; the observed result is affected by the large amount of toxin in the unknown in well 1. Reproduced from *Staphylococcus*: Detection, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

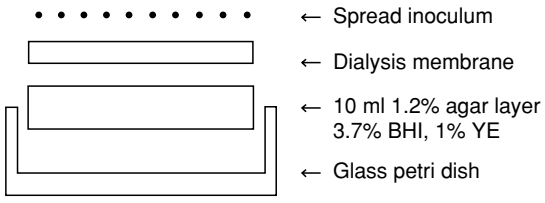

Figure 3 Membrane-over-agar enterotoxin production method. The organisms grow on the surface of the dialysis membrane as the nutrients in the medium (brain–heart infusion (BHI) plus yeast extract (YE)) in the agar can diffuse through the membrane, but the enterotoxin cannot pass through the membrane. The culture is removed from the membrane with buffer and centrifuged before analysis. Reproduced from *Staphylococcus*: Detection, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

an instrument that most laboratories would have available. The sensitivity of the ELISA methods is between 0.1 and 1.0 ng per gram of food (Table 1).

Table 1 Detection of staphylococcal enterotoxins (SEs) in foods by enzyme-linked immunosorbent assay

Food	*SE*	*Amount of SE added (ng g^{-1})*	*Amount of SE detected (ng g^{-1})*
Milk	A	0.63	0.63
Ham	A	0.63	0.34
		1.25	0.55
Genoa sausage	A	0.63	0.36
Cheese	A	0.63	0.59

Although polyclonal antibodies are used in most of the enterotoxin detection methods, the development of monoclonal antibodies to the enterotoxins has made possible their use in enterotoxin analysis. Two monoclonal antibodies are required for each enterotoxin in the sandwich ELISA as only one site exists on the molecule for each monoclonal antibody. Not all monoclonal antibodies are usable, particularly as the coating antibody, because the reacting site may be inactivated in the coating reaction.

In some instances it may not be necessary to determine the type of enterotoxin, only if enterotoxin is present; for example, in examining the marketability of suspect foods. The food would not be marketable if any enterotoxin were present. For this purpose, including all of the enterotoxins in one test saves time as only one test is needed. This would not save time in examining foods implicated in food-poisoning outbreaks, because identification of the type of enterotoxin is valuable in tracing the source of the contamination. However, if more than one enterotoxin was present, the amount of each could be below detectable levels for the individual enterotoxins. In this case it would not be possible to detect them by the methods used to identify individual enterotoxins.

Reversed Passive Latex Agglutination (RPLA)

In the RPLA method the specific antibodies are attached to latex particles. When these particles are added to a solution containing enterotoxin, the latex particles agglutinate. The sensitivity is less than 1 ng per gram of food. The method is adequately sensitive for the detection of enterotoxin in most foods implicated in food-poisoning outbreaks; however, it may be inadequate for detection of the small amounts

Table 2 Detection of staphylococcal enterotoxin (SE) in foods from outbreaks

Food	S. aureus *count* g^{-1}	*SE detected in food*			
		SE strain	*ELISA plate*	*ELISA kit*	*RPLA kit*
Ham	1.5×10^9	A	A	A	A

of enterotoxin that are sometimes present (Table 2). One problem with the RPLA method is that the food extract from an occasional food may give a nonspecific agglutination.

Use of Sensitive Methods for Strain Testing

More recently, a question has arisen regarding the sensitivity of the gel diffusion methods for determining the enterotoxigenicity of staphylococcal strains. It has been reported that enterotoxin production by strains was observed by the RPLA method that was not detectable by the OSP method. The amounts produced were approximately 10–20 ng ml^{-1}. This was confirmed by concentrating the culture supernatant fluid from five strains that tested positive for SEA by ELISA about 100-fold for testing by the OSP method. The importance of this low production may be questioned; however, we have found strains that were implicated in food-poisoning outbreaks to be negative by OSP but positive by ELISA. This resulted from examination of strains by ELISA that were negative by OSP but positive by the monkey feeding test. A number of these strains were positive for one or more of the identified enterotoxins by the ELISA method, particularly for SED (23 strains). Some of these strains had been isolated from food-poisoning outbreaks, which is significant because SED has been implicated as the second most important enterotoxin in food poisoning. It should be pointed out that, of all of the enterotoxins, SED is produced in the smallest amounts. Only three of the strains produced low amounts of SEA, the enterotoxin implicated in 75% of staphylococcal food-poisoning outbreaks. The production of 10–20 ng of enterotoxin per milliliter is probably of significance because only 100–200 ng of SEA has been shown to be necessary to produce food poisoning. The amount present in the vehicle, 2% chocolate milk, was 0.50–0.75 ng ml^{-1}. Admittedly, the amounts of enterotoxin produced by the membrane-over-agar or sac culture methods are 5–10 times those produced in shake flasks or even possibly in food, yet, if growth is sufficient, 10^7 colony-forming units (CFU) and 1–2 ng of enterotoxin per gram of food can be produced. This would be enough to result in food poisoning in sensitive individuals.

Kits Available for Enterotoxin Detection

Several commercial kits are available for enterotoxin detection:

1. An ELISA ball kit, available from Labor Dr W. Bommeli, Länggassstrasse 7, CH-3012 Bern, Switzerland. In this kit the specific antibodies to SEA, SEB, SEC, and SED are absorbed on to separate polystyrene beads and the enzyme alkaline phosphatase is coupled to the specific antibodies. The substrate, *p*-nitrophenyl phosphate, gives a yellow color with the enzyme. Although the test can be completed in 1 day, recommendations are that the antibody-coated balls are shaken with 20 ml of extract overnight to obtain the highest sensitivity (0.1–1.0 ng ml^{-1}). The color can be measured in a colorimeter because 1 ml of substrate is used. The method can be used for quantitative measurements.
2. An ELISA dipstick kit, available from Transia, 8 Rue Saint Jean de Dieu, 69007 Lyon, France. Monoclonal antibodies to SEA, SEB, SEC, SED, and SEE are coated on nitrocellulose paper in wells in the dipstick. The conjugate consists of different monoclonal antibodies coupled to horseradish peroxidase, which reacts with the substrate

to give a blue color. The method is sensitive to 0.5–1.0 ng per gram of food; the test can be completed in 6–7 h. The results are read visually; only one test is needed per sample.

3. An RPLA kit, available from Oxoid Ltd, Wade Road, Basingstoke, Hampshire RG24 0PW, UK. Latex particles are coated with specific antibodies to SEA, SEB, SEC, and SED. More than 24 h is required for completion of the test.
4. An ELISA tube screening kit, available from Transia. Monoclonal antibodies to SEA, SEB, SEC, SED, and SEE are coated on to the bottom of a small flanged tube. The conjugate is a mixture of monoclonal antibodies coupled to horseradish peroxidase. The enzyme reacts with the substrate to give a blue color. The sensitivity of the test is less than 0.2 ng ml^{-1}. The time required for an assay is 1 h.
5. An ELISA microtiter plate screening kit, available from Biotechnology Australia Pty Ltd, PO Box 20, Roseville, NSW 2069, Australia. A mixture of specific antibodies to SEA, SEB, SEC, SED, and SEE is adsorbed to the wells of microtiter plates. The enzyme used is horseradish peroxidase and the substrate is ABTS (a sulfonic acid), which gives a green color. The sensitivity of the method is less than 1 ng ml^{-1} and the time required is 4 h. An additional step of treating the food extracts with urea followed by concentrating 20-fold is included in the procedures in this kit for recovery of enterotoxin from heated foods. Supposedly, the purpose of the urea is to renature any denatured enterotoxin in the heated food, but it is doubtful that this is possible. In any case, the denatured enterotoxin would be digestible by pepsin in the stomach and would not cause food poisoning. However, the concentration procedure does increase the sensitivity of the method, but whether this additional sensitivity is necessary is questionable.

Food Poisoning

M S Bergdoll[†] **and A L Wong**, University of Wisconsin, Madison, WI, USA

Introduction

Staphylococcal food poisoning is one of the most common types of foodborne disease and probably occurs in every country of the world, although records of the milder foodborne diseases are not kept in most countries. Even when the illnesses are reported, inadequate investigation or laboratory examination frequently prevents proper diagnosis. The illness is due to the ingestion of enterotoxins present in the food as a result of enterotoxigenic staphylococci growing in the food. Recovery is rapid; hence, in most cases individuals do not consult a doctor, but conclude it was something they ate. It is not a reportable disease in the USA; however, enough identifiable outbreaks are reported to the Centers for Disease Control (CDC) to result in its listing as one of the leading foodborne diseases. During the period 1983–1987, 600 confirmed bacterial foodborne disease outbreaks were reported with *Staphylococcus aureus*, responsible for 47 (7.8%) of the outbreaks and 3181 (6.3%) of the cases, which probably represents only a small percentage of the actual number of staphylococcal outbreaks. Many cases of foodborne

[†]Deceased.

illness with symptoms similar to those of staphylococcal food poisoning are reported to the CDC, but are not classified because of inadequate information about the presence of staphylococci or enterotoxin in the foods involved. (*See* **Food Poisoning**: Tracing Origins and Testing.)

Staphylococcal foodborne outbreaks vary in size, and can involve one or two persons to as many as over 1000 people. One outbreak in the USA involved 1300 people attending a picnic in Indiana. Baked ham was the implicated food. An even larger outbreak occurred in Japan, involving 1500 people who became ill from eating contaminated rice balls contained in lunch boxes prepared at one location. (*See* **Food Poisoning**: Statistics.)

Symptoms of the Disease

The major symptoms of staphylococcal food poisoning, i.e., vomiting and diarrhea, occur within 1–6 h after ingestion of food containing enterotoxin. A representative set of symptoms observed in 122 cases of illness that occurred among high-school students after they had eaten cream puffs is given in Table 1.

Ninety-five (57%) of the 165 students who ate the cream puffs became ill, whereas none of those who did not eat them became ill. This is typical of outbreaks involving a large number of people. The average onset time in the outbreak was also normal for large outbreaks, with a few having earlier onset times, usually because of consumption of large amounts of toxin or increased sensitivity of some individuals, and a few that have delayed onset times of 7–8 h. Although vomiting is the symptom most frequently observed, some individuals may have other symptoms, such as diarrhea without vomiting. Diarrhea may not be observed in milder cases, whereas vomiting usually is. Changes in temperature and blood pressure are not common, particularly with milder cases, although it is known that in experimental cases a change in temperature can occur, either up or down; a drastic lowering of blood pressure may also occur.

Death is uncommon with this type of food poisoning, but deaths have occurred in children or older individuals, often with other complications. Two children, 3 and 4 years of age, died within 24 h after each drank 125 ml of milk from a goat with staphylococcal mastitis. The deaths of the children and the results of the autopsy indicated that the children received a relatively large amount of enterotoxin in the milk they drank.

Several deaths of older people who consumed food containing enterotoxin have been reported; the deaths usually occurred after severe vomiting and diarrhea. One elderly woman died of acute vascular collapse secondary to fulminating gastroenteritis in an outbreak of staphylococcal food poisoning after eating baked ham. Of 28 other people who were known to have become ill with symptoms characterized by vomiting, diarrhea, and severe prostration, six individuals required hospitalization.

A 57-year-old woman reportedly in excellent health died of shock within a few hours of the onset of illness after eating a cold plate lunch at a restaurant. Three other individuals developed severe gastroenteritis after eating plate lunches at the same restaurant.

Table 1 Symptoms of staphylococcal food poisoning from 122 cases[a]

Symptom	*Reaction*			
	Cases[b]	*None*	*Mild*	*Severe*
Vomiting	122	15	12	95
Pains in abdomen	122	6	40	76
Diarrhea	103	13	75	15
Headache	101	29	59	13
Muscular cramping	113	41	58	14

[a]Includes 94 students, eight lunchroom supervisors who took cream puffs home, and 20 cases resulting from the consumption of cream puffs sold at three cafés and from a bakery truck.
[b]Cases from which this information was available.

Requirements Necessary for Food Poisoning

Certain conditions are necessary for staphylococcal food poisoning to occur: (1) the food must be a good medium for the growth of staphylococci and the production of enterotoxin; (2) enterotoxigenic staphylococci must be present in the food; (3) the food must be held at a warm temperature for several hours for the staphylococci to grow to sufficient numbers to produce enterotoxin.

Foods Involved in Outbreaks

A variety of foods can support growth of enterotoxigenic staphylococci. Foods involved in outbreaks are usually rich in protein, and include meat and meat products, poultry, milk and dairy products, salads (tuna, chicken, ham, and potato), custards, pudding, and cream-filled bakery products. (*See* **Cream**: Types of Cream; **Milk**: Processing of Liquid Milk; **Poultry**: Chicken; Ducks and Geese; Turkey.)

Source of Contamination

Staphylococci can be found in most raw foods. However, the most frequent source of contamination of foods implicated in staphylococcal food-poisoning outbreaks is the food handler. Most foods involved in such incidents are cooked, and are recontaminated in the final preparation for serving. A food handler with any type of staphylococcal infection or one who is carrying the organism in his or her nose is a likely source of contamination.

An outbreak occurred in California in 1983 involving several hundred children in an Easter-egg hunt. The source of the contamination was an infected lesion on the hands of the person who prepared the eggs. Another outbreak involved packaged sliced ham that was contaminated with staphylococci from the nose of the person who packaged it. The ham was packaged on a Saturday morning and sold throughout the day without any of the consumers getting sick. The unsold ham was stored in a relatively deep pan and refrigerated overnight. Cooling might have been quite slow because of the size of the pan. On Sunday morning, the ham was warmed before being sold around 11:00 a.m. People who bought the ham on Sunday became ill with staphylococcal food poisoning. Enterotoxin A (SEA) was isolated from the leftover ham.

Animals carry staphylococci in their noses and certain animal diseases, such as mastitis, are caused by staphylococci. However, animals are less important sources of contamination because, even though raw meats and milk are usually contaminated with staphylococci, cooking and pasteurization temperatures will destroy the organisms. In addition, the presence of other competing microorganisms in the raw foods inhibits staphylococcal growth. An exception is when staphylococci are present in much higher numbers than other organisms, as in the case of milk from a mastitic animal, e.g., the two children who died after drinking milk from a goat with mastitis.

Equipment can sometimes be a source of contamination. An outbreak associated with baked ham resulted from contamination of the ham with the meat slicer. The same strain of enterotoxigenic *S. aureus* was isolated from both the ham and the slicer.

Conditions Necessary for Growth and Toxin Production

In order for food poisoning to occur, the food containing an enterotoxigenic staphylococcal strain must be held at a warm temperature, usually room temperature or above, for several hours (at least 4 h) for the staphylococci to grow to sufficient numbers to produce enterotoxin. Growth of staphylococci to a population of 1 million or more organisms per gram of food is assumed necessary to produce enough enterotoxin to cause illness.

Care needs to be taken in interpreting the significance of staphylococcal numbers in food when investigating an outbreak. Not all staphylococcal strains produce enterotoxin. A large number of staphylococci in a food may indicate poor hygienic practices but, to incriminate a food definitely as the cause of food poisoning, it is necessary to demonstrate that the staphylococcal isolate produces enterotoxin. Alternatively, the lack of staphylococci or the presence of low numbers does not indicate the absence of enterotoxin in the suspect food. This is especially important in the case of heat-processed foods. Absence of viable staphylococci does not necessarily indicate a safe product because preformed enterotoxin may not be inactivated.

Data from outbreaks indicate that less than 1 μg of SEA can result in illness. In a chocolate milk outbreak in 1985, it was found that 100–200 ng of SEA was sufficient to cause staphylococcal food poisoning in children. SEA is the most toxic enterotoxin and the one most commonly involved in staphylococcal food-poisoning outbreaks.

Site of Action

Emetic Action

The site of the emetic action of enterotoxin in the monkey is in the abdominal viscera, with the sensory stimulus for emesis reaching the vomiting center of the brain via the vagus and sympathetic nerves. This is supported by experiments in which transthoracic vagotomy partially protected the monkey from the emetic action of enterotoxin given intragastrically and, when coupled with abdominal sympathectomy, the monkey was completely resistant to the emetic action of enterotoxin. The monkeys with deafferentated abdominal viscera still vomited as normal animals when the emetic compound, Veriloid, was administered. Bilateral destruction of the area postrema on the floor of the fourth ventricle (chemoreceptor trigger zone) made the monkeys completely refractory to the emetic action of enterotoxin given intravenously or intragastrically.

Attempts to determine the site of action of enterotoxin in the intestinal tract have been unsuccessful. Specific binding of enterotoxin to cells closely related to intestinal epithelial cells that have been cited as potential target cells for direct cytopathic effects of the staphylococcal enterotoxins was not detectable. Binding of SEA in the rat intestinal tract was not

detectable, but rather the enterotoxin passed through the gastrointestinal mucous membrane within 15 min after administration and was detected in the kidney. Neuronal binding of SEA in the intestinal tract was not demonstrated; this binding might have been expected based on the finding that the sensory stimulus for vomiting reaches the vomiting center by way of the vagus and sympathetic nerves.

Diarrheal Action

Diarrhea is the second most common symptom seen in staphylococcal food poisoning. In outbreaks involving a large number of people, as many individuals develop diarrhea as have an emetic reaction. Stimulation of this reaction is not understood because the mechanism of action is apparently quite different from that of the so-called diarrheal diseases such as cholera and *Clostridium perfringens* and *Bacillus cereus* food poisoning. The toxins responsible for the diarrheal diseases elicit an ileal loop reaction in rabbits, whereas the staphylococcal enterotoxins do not. Enterotoxin B (SEB) had no effect on the absorptive mechanism of the rat small intestine, but the enterotoxin somehow triggered a secretory mechanism that resulted in a net secretion of fluids. The actual mechanism responsible for stimulating excretion has not been elucidated. (*See* ***Bacillus***: Food Poisoning; ***Clostridium***: Food Poisoning by *Clostridium perfringens*.)

Enteritis

Enteritis is another effect of enterotoxins taken orally, but it is not easily observed except by special examination. Pseudomembranous enterocolitis was observed to be associated with staphylococcal infections in patients who had been administered antibiotics to control infection during surgery. Many of these patients died before the cause of their illness was diagnosed. The staphylococci had become resistant to the antibiotics used and grew prolifically in the intestinal tracts of these patients because the normal flora had been eliminated by the antibiotics. These staphylococci were potent producers of enterotoxin, later identified as SEA and SEB. Experiments in animals with SEB revealed that enteritis can be produced in monkeys, dogs, and chinchillas, with the severity of enteritis depending on the amount of enterotoxin given intragastrically. Autopsy of dogs 24 h after ingesting SEB revealed acute enteritis with edema, hyperemia, and ulcerations of the mucosa, and destruction of the surface of the epithelium. Severe round cell infiltration of the mucosa and destruction of the surface of the epithelium were observed by microscopic examination. These observations in animals were similar to changes characteristic of acute exogenous gastritis in humans resulting from staphylococcal food poisoning. These findings, determined by gastroscopic examination, include patchy mucosal hyperemia, regional edema, muscular irritation, erosions, petechiae and purulent exudate. Examination 48 h later revealed the stomachs had returned to normal. Acute gastroenteritis was observed in monkeys 2 h after intragastric administration of SEB, with the most severe changes occurring at 4–8 h postinoculation. The mucosa was again normal after 72 h postinoculation.

Death

Death is uncommon in staphylococcal food poisoning, hence there is little opportunity to observe the pathological effects of enterotoxin. However, autopsy of the two children who died after drinking milk from a mastitic goat revealed a moderate amount of pulmonary edema marked with congestion of the alveolar vessels and, in a few areas, there appeared to be hemorrhages into the alveolae. There was a small amount of leukocytic infiltration in the periportal areas of the liver. These findings are similar to those observed in monkeys that received a lethal dose of enterotoxins by intravenous injection; in these animals there was a decrease in intravascular fluid volume with an increase in lung weight. The fluid was confined to the perivascular and peribronchial interstitial space; the lymphatics in these areas were gorged. The primary pathological change was degeneration and necrosis of capillary endothelial cells, with some but less frequent damage to the endothelium of venules. Also noted were interstitial hemorrhage and edema, a histolytic infiltrate, and a striking herniation of capillary endothelium into the vascular lumen. Apparently these changes were brought about by the enterotoxin binding to leukocytes with subsequent sequestering of toxin-bound leukocytes in the lungs.

Treatment and Course of Illness

The rapid development of the illness makes it impossible to prevent the symptoms from developing after the enterotoxin has been ingested; once the symptoms have occurred there is no treatment that will counteract them. In most cases recovery is within a few hours and no treatment is necessary; however, in severe cases where vomiting and diarrhea are excessive, treatment intravenously with fluids is beneficial, particularly to restore the salt balance.

A misunderstanding of the disease by the medical attendant can lead to unfortunate results. Such was the case when a young man afflicted with the illness was given antibiotics, with death as a result. If the disease was due to the ingestion of the organisms,

treatment with the proper antibiotic may be desirable but, because it is due to a toxin, antibiotic treatment is of no benefit. However, it could have an adverse effect, particularly if the staphylococci were resistant to the antibiotic. In this case the natural flora of the intestinal tract would be eliminated and this would allow the staphylococci to grow uninhibited and produce enterotoxin. Staphylococci are not good competitors and usually do not grow in the intestinal tract in the presence of the natural flora.

Prevention

Temperature Control

Most staphylococcal food-poisoning outbreaks could be prevented if proper temperature controls were observed during holding of the food after its preparation and before being served. One method is proper refrigeration of susceptible foods after they are prepared. The lower the temperature, the slower the growth of the staphylococci, with little or no growth at refrigeration temperatures. An excellent example of the effect of refrigeration is an outbreak from cream-filled coffee cake that occurred in Wisconsin in 1970. Approximately 50 people became ill after eating the cake, with differing severity of symptoms, depending on the length of time the cakes stood unrefrigerated before being eaten. The cakes were made by a bakery and delivered to several stores at 5:30 a.m. on a warm Saturday morning; the cakes were not refrigerated at the stores. Purchases were made all day Saturday and on Sunday morning. Many who bought the cakes on Saturday did not eat them until Sunday morning, but in most cases the cakes were refrigerated by the purchasers. Most of those who bought the cakes early Saturday morning and refrigerated them did not become ill. No one who ate cakes purchased at the bakery became ill because the cakes were refrigerated at the bakery. The source of the staphylococci was from the throat of the food handler who had placed the cream filling into the cakes with his hand. The organisms isolated from his throat and the cakes produced enterotoxin E; not many staphylococci produce this enterotoxin and its involvement in food poisoning is rare.

Some of the largest outbreaks of staphylococcal food poisoning have occurred at picnics, a number of these from baked ham sandwiches. Baked ham is an excellent medium for the growth of staphylococci, which is not always appreciated because it is a cooked food. However, if the ham is recontaminated after the baking, the results can be tragic. Providing refrigeration for such a large quantity of food is difficult at a large picnic and normally the food will be at the picnic for a number of hours before being consumed. In cases such as this, every effort should be made to provide refrigeration for the food at the picnic grounds or not to transport it to the grounds until shortly before it is to be served. (*See* **Pork**.)

One error that is frequently made is to place the food in large containers to conserve space before it is placed in the refrigerator. Under these conditions, cooling is very slow and allows sufficient time for the staphylococci to grow and produce enterotoxin. A staphylococcal food-poisoning outbreak, in which 104 of 231 inmates in a country jail in New York became ill, resulted from inadequate refrigeration of macaroni salad. It had been prepared the day before it was served and had been stored overnight in two large, deep containers in a walk-in cooler. Isolation of over 10^7 staphylococci per gram from the macaroni salad indicated inadequate cooling.

Food-Handling Practices

In the New York jail outbreak described in the previous section, it was ascertained that the food was prepared by inmates who were inadequately trained and not well supervised. Many food-poisoning outbreaks are a result of inadequate training and supervision of the individuals preparing the food. The major conclusion from both the First and Second National Conferences for Food Protection held in Denver, Colorado, in 1971 and in Washington, DC, in 1984 was the need to educate the food handler as well as the consumer on food safety. Unfortunately, very little has been done in this area.

Food-Handler's Infections

One method of preventing staphylococcal food-poisoning outbreaks is to prohibit food handlers with infections from handling foods. In some countries food handlers who are staphylococcal carriers are not allowed to handle foods as long as they are carriers. In the UK an assistant cook, who carried the same staphylococcal organism in her nose as the one isolated from lemon snow pudding involved in the illness of six adults and 101 children in a primary school, was excluded from work until the organisms were eradicated by treatment with gentamicin cream. The pudding contained large numbers of staphylococci ($1.5 \times 10^8\,g^{-1}$) that produced SEA and enterotoxin D, as did the staphylococci isolated from the nose of the assistant cook. Although it was feasible to exclude the cook in this case, usually it is difficult and impractical to bar workers who are carriers of staphylococci in their noses or throats from handling foods because approximately 50% of the population are carriers. On the other hand, food handlers with

any type of infection should not be permitted to handle foods, particularly if the food is for mass feeding. The only viable solutions to this problem are proper refrigeration of vulnerable foods between preparation and consumption, or maintaining the temperature above 45 °C.

Structure, Properties, and Determination

D S Jackson, University of Nebraska, Lincoln, NE, USA

Starch Structure

Amylose and Amylopectin Polymers

Starch is a mixture of two glucose polymers. These polymers are initially enclosed within a semicrystalline granule formed inside starch-synthesizing plant organelles. Amylopectin, the larger of the polymers, is an alpha-1, 4-linked, alpha-1,6-branched (4–6% branching) polymer with an average molecular weight near 10^8. Amylose, a smaller, mostly linear polymer, is also composed of alpha-1,4-linked glucose units; long chains are sometimes connected with alpha-1,6 branches, although branching probably accounts for < 1 % of the glucose unit connections. The molecular weight of amylose is approximately 10^5. The molecular weight of starch polymers varies depending upon its plant source. Amylopectins have been reported to vary from 50×10^6 to 500×10^6, and amyloses from 1600 to 1×10^6. The degree of branching also varies. Common starches typically have 25–35% amylose and 65–75% amylopectin.

Genetic Differences

Several genetically modified starches are available. The most common forms are the waxy starches and the high-amylose starches. Waxy starch, which contains 100% amylopectin, is found in grains (i.e.,maize, sorghum, and wheat) that have three recessive waxy genes. Combinations of recessive (*wx*) and dominant (*Wx*) waxy genes result in starches with varying percentages of amylopectin from 75 (*WxWxWx*) to nearly 100% (*wxwxwx*). High-amylose (*ae*) starches are available with approximately 53 or 70% amylose.

Microscopy of Granules

Starch granules have unique microscopic structures (**Figures 1** and **2**), and the source of starch can frequently be determined by a trained observer. The shape and size of starch granules differ according to the botanical source and the environmental condition under which a crop was grown. Typically, rice and maize starch have angular (polyhedral) granules; potato starch has oval-shaped granules. Wheat starch

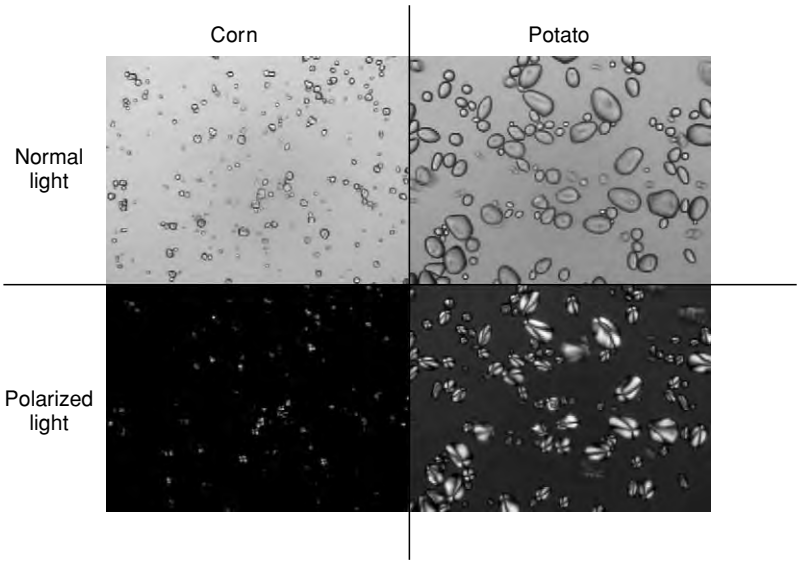

Figure 1 Light micrographs (× 100) of corn (left) and potato starch (right) shown using normal (top) and polarized (bottom) light microscopy.

consists of spherical and flat circular (lens)-shaped granules. Sizes also vary widely. Rice starch granules are very small (6 μm diameter), while potato starch granules can exceed 100 μm. The mean diameter of maize starch granules is 35 μm; wheat starch has a bimodal distribution of granular sizes – small (B) granules average 4 μm, while the large (A) granules average 14 μm. Granules can also have compound structures (i.e., oats, rice) which appear as separate starch grains in a single amyloplast enclosure.

Several microscopic techniques have found widespread use. When observed under polarized light, undamaged starch granules (as defined by the retention of crystalline structure) exhibit a phenomenon called birefringence (Figure 1). This birefringence is the result of polarized light being bent as it traverses a region of high molecular order. Scanning electron microscopy (Figure 2), as well as other higher-magnification techniques, have proven extremely useful in identifying the three-dimensional structure of starch granules, as well as showing the interrelationships of starch granules and other chemical components in cereal grains, tubers, and other food systems.

Changes during Hydration and Heating

Starch granules, when exposed to water, undergo swelling and upon heating undergo a process of irreversible swelling and crystalline melting called gelatinization. If the crystalline region is destroyed, granular birefringent properties disappear. The temperature at which birefringence is lost has been defined by some as the gelatinization point. Since loss of crystallinity causes loss of birefringence, additional thermal disruptions of the granule still occur after the gelatinization point as defined using microscopy techniques. When starch granules are exposed to liquid water below 40–50 °C, the amorphous gel-like portions of the starch granule absorb water, causing the granule to swell. When the temperature is > 40–50 °C, and water is in excess, granules begin to undergo reversible swelling and around 60–80 °C lose birefringence and undergo irreversible swelling. During the transition from reversible swelling to loss of birefringence, the amorphous regions have a rubber-like structure and the specific volume of the amorphous areas increases, as does the mobility of molecular segments which are thermally softened and plasticized by water. At the gelatinization temperature, the mobility of molecules increases rapidly. Granule components are in a more flowable state. The mobility of molecules in the amorphous regions and the mobility of molecular regions which traverse both crystalline and amorphous regions cooperatively contribute to intergranular stresses. The continued hydration of amorphous areas places additional stress on those molecular regions (including regions within the same molecule) which have remained crystalline. These molecular movements have a cooperative effect on granule swelling and the overall melting of starch crystallites.

Starch Sources: Grain and Tuber/Root Structure

The majority of starch in cereal grains is located in the endosperm. Many grains can be referred to as having 'soft or floury starch' or 'hard or vitreous starch.'

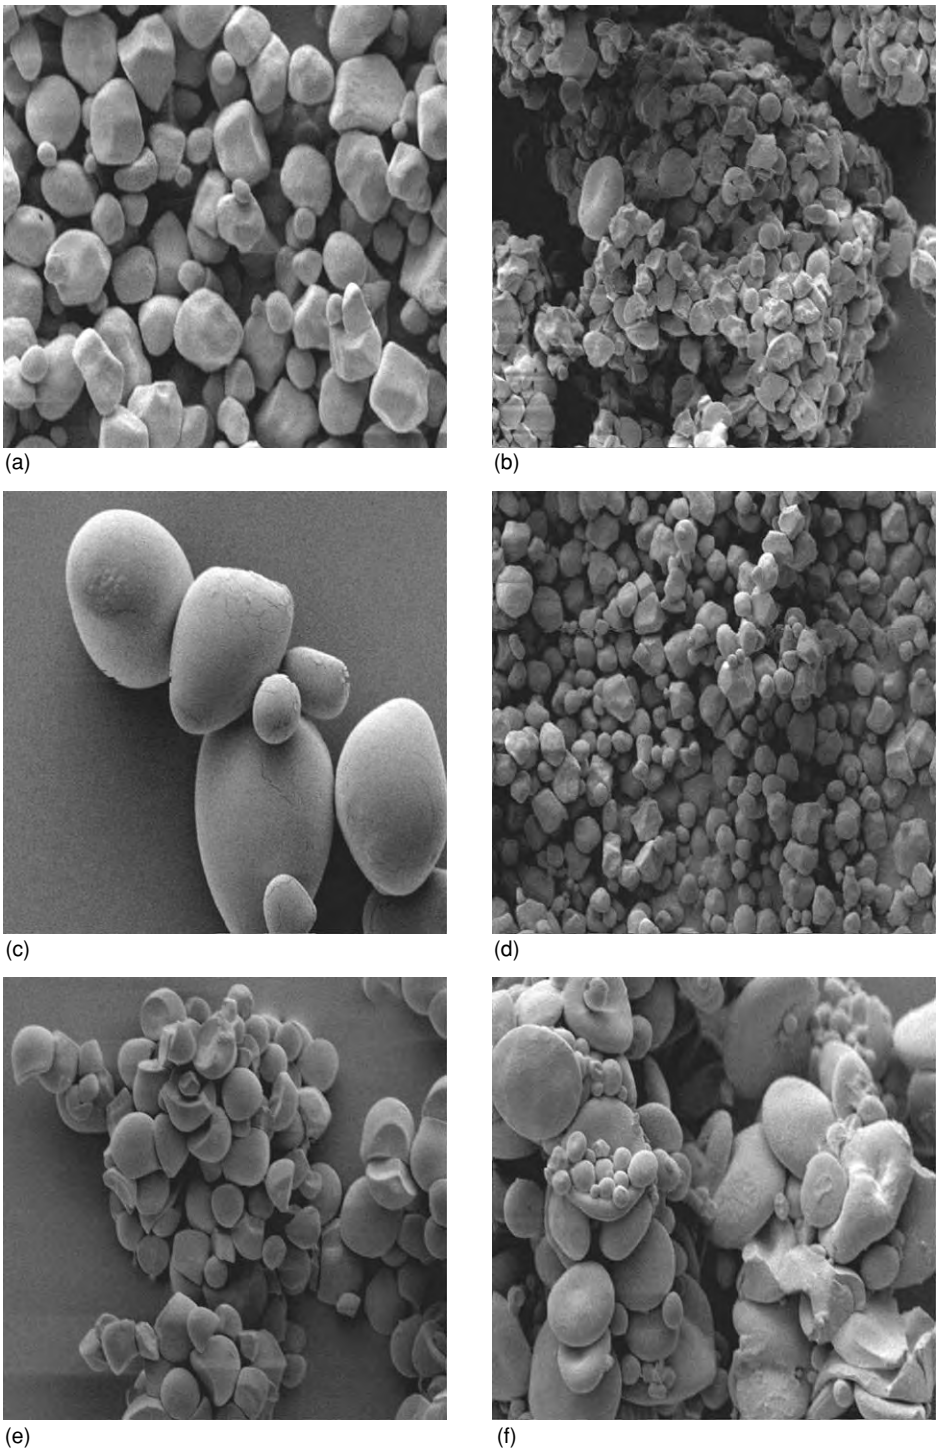

Figure 2 Scanning electron micrographs (× 1000) of (a) corn, (b) oat, (c) potato, (d) rice, (e) tapioca, and (f) wheat starches.

There is little evidence that the molecular components of their starches are any different. The packing of the starch granules within a kernel, however, is different. Floury maize kernels have less protein binding the starch granules together, and starch granules within more flinty maize kernels are encased more tightly within a protein matrix. Cereal starch is obtained via wet milling; after the endosperm is disrupted, the starch is collected by washing and centrifugation.

Cassava root, from which tapioca starch is produced, typically contains 25% starch. The roots have a hard or cork-like outer layer which is usually

removed before starch processing. Starch is collected by disrupting the cells, screening, and subsequent collection by washing and centrifugation.

Potatoes are also another important starch source; they typically contain about 22% starch. Raw potatoes are ground to disrupt cell walls; the pulp is washed, and screened. Starch is later collected via centrifugation. Starch can also be obtained, as a by-product, from commercial production of value-added potato products such as french fries, instant potatoes and potato chips (crisps).

Viscosity Measures

Amylograph/Rapid Viscoanalyzer

The viscosity of cooked starches is important to the food industry. One of the most important industrial measures of starch properties uses amylograph or Rapid Viscoanalyzer (RVA) instruments to measure a starch's thermal behavior. In the standard amylograph, a 3–5% starch dispersion is mixed in a cylindrical bowl. Paddles mix the starch dispersion, and the force these paddles encounter is recorded with a computer. The test begins with the gradual heating (1.5 °C min^{-1}) of the starch dispersion. The starch granules swell and the viscosity of the mixture increases as the temperature increases because the swollen granules occupy more area within the mixing vessel. When the temperature reaches 95 °C, the starch mixture continues to be stirred while the temperature is maintained for 60 min. When swollen unmodified granules are exposed to shear, the viscosity of the mixture decreases because the granules break apart into smaller pieces. After the holding cycle, the starch is subsequently cooled to 50 °C (also at 1–5 °C min^{-1}) and a highly viscous gel structure can form by hydrogen binding and water entrapment between starch polymers. The RVA is a similar device that uses smaller sample sizes and has programmable heating, cooling, and stir speeds (the manufacturers of the amylograph also make a instrument suitable for analyzing small amounts of starch). Typical RVA curves are shown in Figure 3.

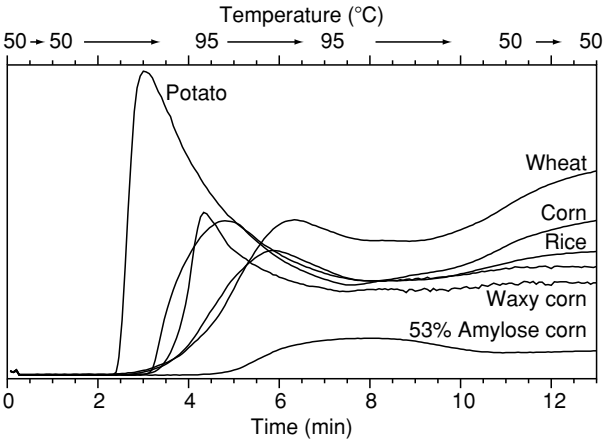

Figure 3 Representative Rapid Viscoanalyzer curves for potato, wheat, corn rice, waxy corn, and 53% amylose corn starches.

Chemical Methods

Determination of Total Starch

There are several chemical methods available to measure the total amount of starch in a sample. For samples high in starch content (cereal grains, tubers, and their products), starch's optical rotation in solution can be determined using a polarimeter. Samples are initially extracted with ethanol to remove optically active soluble materials and the remaining starch is suspended in a calcium chloride solution and placed in a boiling water bath. Proteins are removed in the procedure with stannic chloride-phosphotungstic acid. The resulting filtered solution's optical rotation is measured in the polarimeter and used to calculate percent starch; a similar optical procedure uses hydrochloric acid and a saturated lead solution. More recently developed methods of starch analysis, however, usually rely on the ability of the enzymes alpha-amylase and amyloglucosidase to degrade cooked (or chemically treated) starch to glucose. These methods often have the advantage of being applicable to a wider range of starch-containing products. For these procedures, it is usually essential to gelatinize fully (cook/disperse) the starch. For common materials without extensive resistant starch (fiber-like starch), the sample can be gelatinized in an autoclave. For more difficult-to-gelatinize samples, starch can be dispersed in methyl sulfoxide (also known as dimethyl sulfoxide or DMSO) prior to enzymatic digestion.

After the starch is digested with enzymes to glucose, most methods subsequently convert the glucose solution into a colored product that can be measured colorimetrically in a spectrophotometer. In fact, however, many of the glucose measurement techniques can be used at this stage. The percentage of starch is calculated by multiplying the measured amount of glucose evolved from the enzymatic treatment. Total glucose is multiplied by 0.9 to determine total starch; this calculation accounts for the difference in molecular weight between individual glucose units and glucose polymers. In addition to these chemical total starch methods, indirect procedures using near

infrared spectroscopy (NIR) technology (especially for grain/cereal crops) have proven to be very useful. While NIR methods must rely on these chemical procedures for method development and subsequent machine calibration, when used appropriately they are extremely rapid and can be performed by personnel not necessarily trained in complex chemical analyses.

Determination of Percentage Amylose

Since amylose and amylopectin have unique physical and chemical properties, and their relative proportions influence the overall properties of starches, the determination of the ratio of these polymers becomes important. Potentiometric titration is considered one of the better techniques for determining the percentage of linear components (i.e., amylose) in starch. It relies on the affinity between amylose and iodine. Potato and wheat starches have typical iodine affinities of approximately 19.9%, whereas maize starch has an iodine affinity of 19.0%.

Colorimetric tests for the percentage of amylose are also widely used. Solutions of amylose and iodine result in a deep blue-purple color. Amylopectin and iodine show only a slight affinity towards each other; their solutions have a reddish color. The blue value test relies on these properties; starch samples are dispersed in a sodium hydroxide solution and, after neutralization, the samples are allowed to react with an iodine solution. The absorbance (usually at 620–680 nm) of the solutions is measured to calculate blue value, and the apparent percentage amylose content can be determined by developing a blue value standard curve with 'purified' amylose. Unfortunately, commercially available amyloses are usually not exactingly pure, nor is such a pure amylose available for every kind of starch. Accurate chemical determinations of amylose content from different starch sources is made more difficult because not only do amyloses from different botanical sources have different iodine affinities, but different amylopectins will also bind a small amount of iodine and thus cannot be discounted in amylose determinations. A newer procedure for amylose determination relies upon the complexing action of concanavalin A (A) with amylopectin. The procedures precipitate amylopectin from starch solutions, leaving only amylose. The amylose is thus subsequently analyzed in much the same way as for total starch determinations.

Instrumental Methods

Differential Scanning Calorimetry

The differential scanning calorimeter (DSC) is widely used to determine the crystalline melting temperature of various starches (Figure 4). Small samples of starches are heated at a constant rate and the endothermic heat flow is recorded. Melting of crystalline sites (or some starch chemists postulate melting of crystalline sites and unfolding of double helices) results in a thermal event typically recorded as an endotherm. Usually, a broad crystalline melting range is recorded; sites of crystallinity melt at different temperatures depending upon their individual structure, the action of solvent (usually water), and the interaction of individual polymers which are contained and traverse crystalline sites. DSC can also be used to examine the recrystallization of gelatinized starches. Most notably, DSC is used to study the retrogradation process under various environmental conditions of time and temperature, and the interactions of starch with complexing agents and crystallization promoting or inhibiting ingredients.

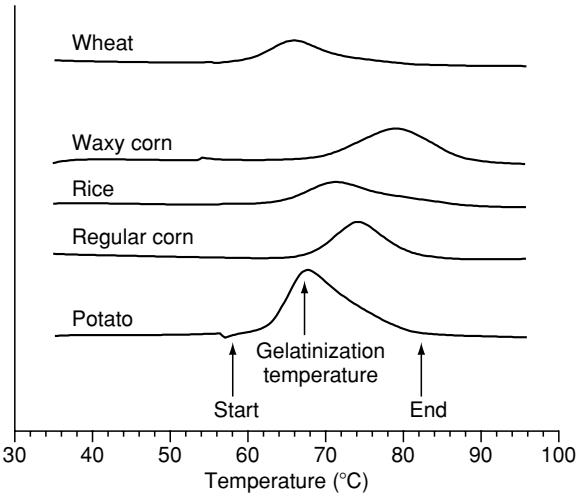

Figure 4 Differential scanning calorimetry (DSC) endotherms of wheat, waxy corn, rice, corn, and potato starches (scanned at 10 °C min^{-1}, > 60% water). The figure shows the start of crystalline melting, point of maximum endothermic energy (gelatinization temperature), and temperature at which all crystals have melted.

X-Ray Analysis

X-ray analysis of starch is useful in determining the extent of crystallinity and crystallite structure, the botanical origin of starches, the formation of starch complexes, and can be used in structural studies to determine spacing within starch helices. Unlike DSC, X-ray diffraction is less subject to scientific debate regarding the 'true' measurement of starch crystallinity. The diffraction patterns (groupings of spectral lines) of native starches have been broadly classified as A, B, C and V (Figure 5). Researchers have also proposed variants on these patterns. Cereal grain

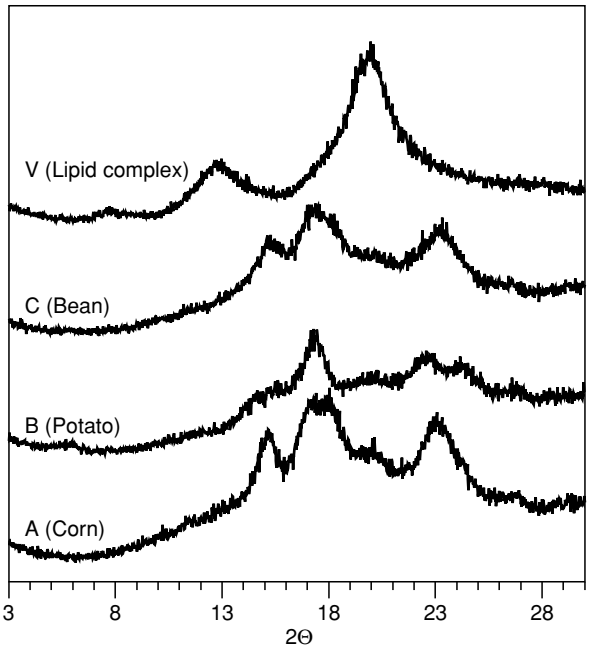

Figure 5 X-ray diffraction patterns (40 kV, 30 mA, Cu K-alpha radiation, 2-theta diffraction angle) of a lipid complexed corn (V-pattern), bean (C-pattern), potato (B-pattern), and corn (A-pattern) starches.

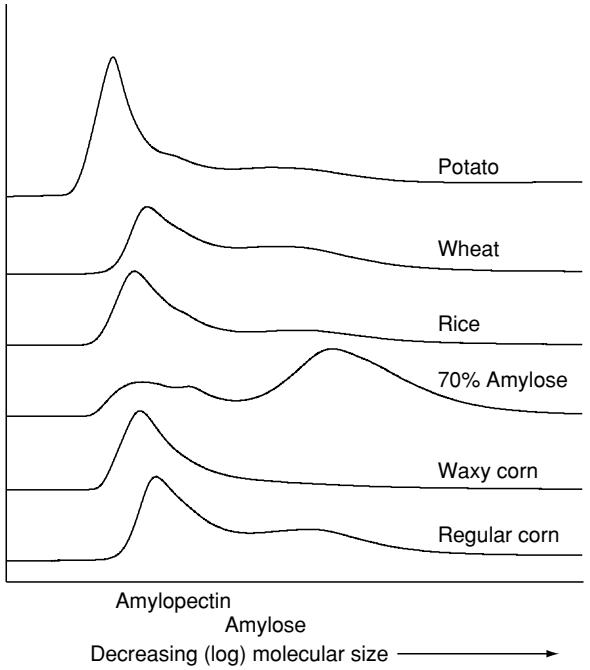

Figure 6 Typical high-performance size exclusion chromatograms (HPSEC) of potato, wheat, rice, 70% amylose, corn, waxy corn, and corn starches. The figure shows amylopectin and amylose peaks. Starch was dispersed in methyl sulfoxide (DMSO) before injection into the HPSEC system consisting of four columns linked in series. Carbohydrate was detected using a refractive index detector.

starches generally have the A pattern, although defatted high-amylose starches have a B pattern. Bean and cassava starches have a C pattern and potato starch has a B pattern. Complexes between fatty acids and amyloses, seen especially strongly in some high-amylose maize starches, exhibit a characteristic V pattern.

Chromatography

Size exclusion chromatography has been important in determining the fine structure of amylose and amylopectin molecules, as well as the relative proportion of those molecules in food materials. In addition, chromatographic techniques have proven useful in determining the relative solubility of starch polymers in solution and the percentage of amylose in starches. Chromatography can be conducted using conventional gel filtration techniques (soft gels), or more rapid high-performance liquid chromatography methods with rigid stationary-phase material (Figure 6). Starch samples are first dispersed (usually in methyl sulfoxide, also known as DMSO, NaOH, or water) and injected into a chromatographic system. The amylopectin usually elutes at or extremely close to the void volume of most modern column systems, and the smaller amylose elutes later. The molecular weight of these materials can be determined by coupling the chromatographic system to a laser light-scattering detector, or can be estimated by employing known-molecular-weight standards of pure carbohydrate polymers. The relative molecular weights or sizes of starch polymers can be compared, as well as the relative effect of various food-processing unit operations on starch structure. The extent of starch depolymerization caused by food or industrial processing is also easily measured using size exclusion liquid chromatography. Amylases can be used, coupled with chromatography and postchromatographic chemical analysis, to determine the extent and length of polymer branches, and other details about the fine structure of particular starches.

Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR) is a powerful tool that has been used to understand starch–water interactions and the molecular relationship between chemical groups in starch molecules. For example, wide-line ^{1}H NMR has been used to characterize the mobility of water associated with starch pre-, post-, and during gelatinization; these results have confirmed the notion that gelatinization is a melting phenomenon. In addition, both ^{1}H and ^{13}C NMR have been used to study the degree of branching

found in starches from different botanical sources. ^{1}H NMR can distinguish between anomeric protons involved in alpha-1,4 and alpha-1,6 branching, and small peaks found in ^{13}C NMR scans have been associated with nonreducing ends. NMR has also proven useful in understanding interactions between starch and other chemicals such as sugars, proteins, and fatty acids.

Sources and Processing

W S Ratnayake and D S Jackson, University of Nebraska, Lincoln, NE, USA

Background

Starch is found in almost all tissues (leaves, roots, tubers, seeds, stems, flowers, etc.) in green plants. Only a small number of plants, however, are commercially grown for starch; they include cereal (such as wheat, corn, sorghum, and rice), tuber (mainly potato), root (tapioca and arrowroot), stem (sago), and legume (mainly pea) crops. All starches occur as minute granules in nature, but the size, shape, and nature of molecular arrangement inside the granule depends on the species and sometimes on crop cultivar or variety. The processing methods employed for starch extraction mainly depend on the nature and composition of raw material, i.e., source of starch.

Cereal Starches

Corn and Sorghum

Corn (maize, *Zea mays* L.) has been grown for 5000–7000 years and was probably first grown in Central Mexico. That first corn was very different from today's varieties, which were evolved through mutation, hybridization, and random and conscious selection. Among the types of corn available today are popcorn, sweet corn, dent corn, flint corn, and flour corn. The availability of dent corn at low prices, its storability, and its high starch content have led to its increasing use for starch production.

Grain sorghum (*Sorghum bicolor*), also known as milo, was probably initially cultivated 5000–7000 years ago in eastern Africa. Although sorghum is a major cereal crop and resembles corn in general composition, it is sometimes considered inferior to corn for food, feed, and industrial uses. Compared with corn, it can be grown effectively in more arid regions and can be milled in a similar way. Sorghum starch has properties similar to those of corn starch, and the extraction procedure (wet milling) is similar to that applied in corn starch extraction.

The corn kernel is a caryopsis (a berry), borne on an inflorescence called 'an ear.' The caryopsis matures approximately 60 days after pollination, and corn is harvested in late summer or early autumn. In sorghum, the seeds are borne in a terminal, bisexual rachis (head). Waxy sorghum or corn starches are produced by the varieties containing three recessive *wx* genes.

The corn (and sorghum) wet milling process consists of: (1) cleaning the grain, (2) steeping, (3) milling and fraction separation, (4) starch processing, and (5) product drying. Grain is initially cleaned by screening to remove foreign material and broken kernels. The grain is then steeped to soften the kernel. Sorghum typically needs longer steeping times than yellow dent corn. Steeping involves maintaining the correct balance of steeping water with regard to flow, temperature, sulfur dioxide concentration, and pH. Normal steeping conditions are 30–40 h at 48–52 °C. Sulfur dioxide (*c*. 0.1%) was initially used in steep water to prevent the growth of spoilage organisms but was later recognized as an indispensable reagent to maximize starch yield. The effect of sulfur dioxide on the protein matrix is apparently such that it disperses the protein matrix by breaking disulfide bonds, thus

releasing more starch. The use of unusually high temperatures and/or sulfites during steeping reduces the starch yield. Proper steep temperature is also important, as steeping between 45 and 55 °C promotes the growth of indigenous lactic acid bacteria. Growth of these bacteria lowers the pH of the steep, making the antimicrobial action of SO_2 more effective, and is helpful in softening the kernel structure. Lactic acid also increases the absorption rate of sulfur dioxide into the kernel. Steep-water pH is normally maintained at about 4.0 and is highly buffered.

After steeping, the grain is milled to obtain as complete a separation of components as possible. Milling is usually done in an attrition mill (Bauer-type) in preparation for germ separation. Once the grain integrity is disrupted, it is a fairly simple process to separate the lighter germ, an oil-rich fraction, from the heavier starch and protein fractions by use of a centrifugal hydroclone. Separated germ is cleaned by washing and dewatered by mechanical squeezers in preparation for oil recovery by hexane extraction. In milling grain sorghum, starch and protein are more difficult to separate, because the sorghum pericarp is more fragile than that of corn. Separation is enhanced if the kernels are dehulled prior to milling. This gives a sharper separation of starch and gluten with starch of whiter color and lower protein content. Sorghum dehulling prior to milling also improves germ separation.

Free starch and protein from the first pass through the mill are separated from unmilled endosperm and fiber by screening. The unmilled endosperm–fiber fraction is re-milled in a grinding mill to maximize starch separation. Screening after this process separates the starch–protein fraction from the remaining fiber fraction. The fiber fraction is dewatered and further processed and often incorporated with other wet milling end products (evaporated steepwater, spent germ cake and protein) to produce feed fractions.

The starch–protein mixture (mill starch) is separated by centrifugation. Protein (sometimes called 'gluten' in the corn processing industry) is less dense ($1.1\,g\,cm^{-3}$) than starch ($1.5\,g\,cm^{-3}$), so that these fractions may be easily separated. Starch obtained has 1–2% protein, which is mainly removed by further washing in a second centrifugal separator or set of hydroclones to obtain a final protein content of less than 0.38% (dry-weight basis). The pigments of sorghum sometimes discolor (light pink or gray color) starch. Bleaching with $NaClO_2$ or rinsing with NaOH or methanol is done to reduce this discoloration in isolated starch.

The final starch slurry may be dried and sold as unmodified starch, or the starch may be modified and dried, gelatinized and dried, or hydrolyzed to a syrup, which may be used directly or fermented to produce ethanol or other chemicals.

Starch is usually dried by flash drying. The starch slurry is dewatered by centrifugation or filtration, and the moist starch is introduced into the bottom of a stream of rapidly moving air (93–127 °C). Drying is rapid, and the product is collected in cyclones. Drying conditions can be altered to control bulk density and particle size. Wet milling is water- and energy-intensive; the wet-milling industry is the second most energy-intensive food industry in the USA.

Wheat

Wheat has been grown by man for 8000–9000 years, its cultivation probably beginning in the Middle East. The first commercial manufacture of wheat starch was in England in the 1500s. Wheat is mainly harvested by mechanical means, and starch is separated by one of several processing methods, such as the Martin process, the Batter process, the Fesca process, the ammonia process, the acid process, wet wheat milling, whole wheat fractionation, the Rasio process, or the hydroclone process. The first two processes are the most commonly used. Wheat has 60–70% starch (on a whole-seed basis).

At present, low-grade flour (rather than wheat) is used as the starting material for most wheat starch production. There are two, somewhat similar processes commonly used, i.e., Martin process and batter process.

The Martin (dough ball) process was first used in 1835 and employs wheat flour as its raw material. It consists of making a flour dough, washing out the starch, drying the gluten protein, purifying the starch, and drying the starch. Wheat flour and water (2:1) are blended to form a stiff dough, and the dough is then allowed to rest, hydrate, and strengthen the gluten. The dough is then washed with water while being kneaded or rolled, to remove the starch. Separated gluten is dewatered by roller compression and dried in a flash-drier. Starch slurry overflow from the dough washer is sieved to remove gluten particles and then fine-screened to remove bran particles. Purification and dewatering of the starch slurry are performed by centrifugation to produce a high-solids starch cake, which is then flash-dried. The final product is dried to 10–12% moisture and contains approximately 0.3% protein.

The Batter process is a derivative of the Martin process and differs in both the way the dough is formed and the way it is treated. Wheat flour and water (approximately 1:1) are mixed and the resultant dough allowed to rest for 30 min. This dough is then vigorously mixed with additional water equal to twice the weight of the original flour. Protein is

separated from this mixture by screening, and the starch further purified from bran by additional screenings. Centrifugal separation of the filtrate separates the large, lenticular starch granules (prime or type A starch) from the type B starch (a mixture of small granules, damaged granules, and pentosan complexes – also called tailings or squeegee starch), that is about 20% of the total starch. Type A starch is essentially pure and is subsequently dewatered and flash-dried. Type B starch is likewise processed but is of low purity. Sulfur dioxide is not used in wheat starch processing, as (1) it is not required to soften the wheat flour particles because water alone can soften the particles to an extent that protein is effectively separated from starch, and (2) it would destroy the desirable characteristics of the gluten.

Most wheat starch manufactured is sold unmodified and is mainly used in paper adhesives, laundry sizing, and cotton finishing, rather than in food. In foods, the thickening power of wheat starch is inferior to corn starch, but paste texture and strength, as well as paste clarity, are about equal to corn starch. Wheat starch may be preferred for use in certain baked goods owing to the lack of chemicals used in its production. Some modified wheat starches show emulsification properties in selected foods.

Rice

Rice (*Oryza sativa*) cultivation probably originated in Asia, and rice is still a staple food. In the USA, more than 90% of the rice crop is produced in four states: Arkansas, Louisiana, Texas, and California. The rice grain consists of a hull and an edible berry (caryopsis). The outer fibrous layers cover the starchy endosperm and the germ. The endosperm contains mainly starch granules and protein bodies, with little matrix protein in evidence.

To isolate rice starch, broken rice is treated with dilute (0.3–0.5%) sodium hydroxide for about 12 h to soften the grain and aid protein removal. It is wet hammer-milled, the cell walls are removed by screening, and the protein is extracted. The rice starch slurry is purified by further centrifugal washing and then dried.

Rice starch is little used, because of its high cost of production relative to other commercial starches but may be used as a custard or pudding thickener in foods, as a dusting powder in cosmetics, and as a stiffening agent in the cold-starching of fabrics. Rice starch is used in Europe in baby foods, and in the laundry and paper industries.

Potato

Potato starch is extracted from the tubers of *Solanum tuberosum*, which was first cultivated around AD 200 in Peru. Potato starch is mainly produced in Europe. Starch is typically isolated from cull potatoes, surplus potatoes, and waste streams from potato processing. However, there are special cultivars developed for starch manufacture. The tubers generally contain 65–80% starch (w/w).

Culled or surplus potatoes are washed with water in a flume, to remove dirt and foreign matter. They may be washed again on arrival at the processing plant. They are then disintegrated by a saw blade rasp or hammer mill, and the mashed product is screened to remove skins and fiber. During the disintegration process, sulfur dioxide is usually added to preserve the color and inhibit oxidation. Water-soluble impurities are separated by washing, and other impurities are separated by gravity separation.

Screening, by using a screening battery, separates the starch from the potato pulp, which can be reground, and a second starch extraction made to obtain a total yield of 12% starch based on raw potatoes. Starch isolated from the screens or sieves is reslurried in water to remove soluble material, and then dewatered in a continuous centrifuge. Addition of water, and concentration in a hydroclone is followed by further batch centrifuge or tabling operations for final purification of the potato starch. Starch slurry isolated from these operations is dewatered by vacuum filtration and flash-dried ($< 175\,^{\circ}C$ inlet temperature). Potato starch, dried to 17–18% or less moisture, is then screened and packaged. Unmodified potato starch has a relatively low temperature of gelatinization, and exhibits high viscosity on gelatinization, but breaks down on further heating and stirring. It can form useful films and has a high binding power.

Potato starch is used unmodified, or it may be pregelatinized, converted to a cationic form, dextrinized, or derivatized by hydroxyethylation, hydroxypropylation, or carboxymethylation. Large amounts of potato starch are used in thickening commercial soups, and pregelatinized potato starch is useful in instant puddings. Other uses of potato starch include pie fillings, sweets, chewing gums, and extrusion cooking, and as a filtering medium in breweries, where it is employed as a filter precoat when filtering yeast from the wort.

Tapioca

Tapioca starch is obtained from the large, tuberous roots of the cassava plant (*Manihot utilissima*, *Manihot esculenta*), which grows in many equatorial regions. Cassava roots may be either 'sweet' (containing less than 50 mg of potential hydrogen cyanide per kilogram of fresh root) or 'bitter' (containing 250 mg

or more of hydrogen cyanide per kilogram of fresh root). Sweet root varieties are grown for food purposes and bitter varieties for other industrial uses. In either case, the hydrogen cyanide is lowered to acceptable levels during processing.

Harvesting of roots is often manual, and the yield is usually 13–50 t ha^{-1}. Typically, roots contain 70% water, 24% starch, 2% fiber, 1% protein, and 3% fats, minerals, and sugars. Tubers should be processed within 24 h of harvest, since deterioration sets in from the time of root extraction and proceeds throughout the process.

The roots are initially washed to remove dirt and other field debris, and then the outer skin is removed. Breakage of root cell walls is accomplished by chopping the root into small pieces and passing them through a rasp disintegrator. During this process, hydrogen cyanide is released and washed away. Obtained pulp is washed on screens through which starch passes, but fiber is held back. Fiber is generally used in fertilizer or cattle feed. The starch slurry (also called starch milk), after screening, is put through a continuous centrifuge to separate the starch from fine fiber and soluble material. This can also be achieved by sedimentation. Starch thus collected may be reslurried and put through a centrifugal purification process as desired. Typically, sulfur dioxide (0.05%) is added to water used in the centrifugation purification processes to prevent microbial growth.

Starch slurry from the purification process is dewatered by centrifugation or vacuum filtration and then dried by drum, belt, tunnel, or flash methods. Flash-drying is most common. The final moisture content of the dried starch is in the range of 12–14%. Dried starch aggregates are pulverized to obtain a free-flowing powder. Tapioca starch is sold unmodified or is modified by derivatization, pregelatinization, or cross-linking. The viscosity of tapioca starch depends on plant variety, geography, harvest time, age of roots, soil fertility, rainfall, and manufacturing practices during production of the starch.

In some Asian countries, there is a commercial product called 'sago' made from tapioca starch. This 'sago' has no relation to actual sago starch. It contains starch pearls ($\sim$0.5–1.0 mm diameter) made from the extracted tapioca starch cake. During the production, the starch cake is mechanically globulated (or 'pearled') and then roasted to obtain a final moisture content of 9–11% moisture.

Arrowroot

Arrowroot starch is obtained from the root of the tropical perennial, *Maranta arundinacea*. Roots are harvestable after 6–12 months of growing and may contain more than 20% starch, most of which is extractable in the same manner, as previously described for tapioca starch. The difference in processing between the two roots is that arrowroot requires more washing than cassava. In addition, the outer skin of arrowroot root must be completely removed to prevent the starch from having an off-color and off-flavor. Arrowroot starch is principally produced in China, Brazil, and St. Vincent in the West Indies.

Sago

Sago starch is derived from the stem of palms (principally *Metroxylon* spp., *Arenga* spp., and *Maurilia* spp.) that are eight or more years old. The main production areas are Sarawak and Papua New Guinea; *Metroxylon sagu* is the popular species in these areas. Starch production is primarily done at the household level by hand. Cut palm trunks are split, and the pith (which contains about 40% starch) is scooped out. Kneading of the pith with water releases the starch, which is sieved to remove fiber, isolated by filtration, and dried. In commercial production, starch extraction is conducted in a manner similar to that of the household method. The pith of the trunk is rasped out, and the kneading is done mechanically. The crude, extracted starch is further purified in factories by water washing and sieving, and then dried using hot air. One palm trunk can yield 90–180 kg of sago starch, the granules of which are large (20–60 μm in diameter). Sago starch is used in foodstuffs or in textile sizings and adhesives.

Pea

Pea starch is extracted from the species *Pisum sativum*. It is also identified by many other names and produced throughout the world (field pea, garden pea, green pea, yellow pea, smooth pea, and wrinkled pea, etc.). The largest producer ($\sim$25% of the total) and the largest exporter (40% of the total) of peas in the world is Canada. France produces about 17% of the total.

Pea starch is mainly available as a byproduct of protein extraction. Therefore, it is considered to be a relatively cheap source of starch compared with corn, wheat, and potato starches. Pea starch is primarily used in industrial applications; its use in foods is limited, owing to its poor functional properties.

The isolation of starches from peas is difficult, owing to the presence of insoluble flocculent proteins and fine fiber, which decreases sedimentation and cosettles with the starch to give a brownish deposit. Pea starches are isolated using aqueous techniques as well as dry methods (pin milling and air classification). Air classification is the most commonly used

Table 1 Comparative properties of some commercial starches

Source of starch	*Amylose (%, w/w)*	*Amylopectin (%, w/w)*	*Granule diameter (μm)*	*Granule shape*	*GTR[a] (°C)*
Normal corn	28	72	3–26	Round, polyhedral	62–72
Waxy corn	0	100	3–26	Round, polyhedral	63–72
High amylose corn (amylomaize)	50–70	30–50	3–24	Round, deformed	67–92
Sorghum	28	72	15	Round (compound granules)	71–80
Wheat	30	70	2–38	Lenticular, round	58–64
Rice	17	83	3–8[b]	Polygonal, angular	68–78
Oat	16–29[c]	71–84[c]	3–10[b]	Polyhedral	53–59
Potato	20	80	5–100	Oval, spherical	50–68
Tapioca	16	84	4–35	Oval, truncated	49–65
Arrowroot	21	79	15–70	Oval, truncated	62–70
Sago	26	74	5–65	Oval, truncated	60–77
Peas (normal)[d]	33–49	51–77	5–40	Round, oval, spherical	55–61

[c]Depends on the variety.
[d]Wrinkled peas and genetically modified varieties have different properties.

commercial method for pea starch isolation. The process requires a very high degree of particle size reduction (achieved by pin milling) in order to separate the starch granules from the protein matrix. The major fraction from the air classification process is the low-protein-containing starch fraction, which is separated from the fine protein fraction during the process. The crude starch concentrate contains about 65% starch. The residual protein associated with air-classified field pea starch granules is derived from protein bodies, agglomerates, chloroplast membrane remnants (which enclose the starch granule), and a water-soluble fraction that is presumably derived from the dehydrated starch. Remilling and reclassifying the starch fraction remove most of the protein bodies and agglomerates, and water washing removes most of the remaining attached protein. Purified, air-classified starch contains 0.25% protein.

The purity of pea starch obtained by wet milling is higher than that obtained by air classification. Repeated filtration through polypropylene screens (20 and 70 μm) combined with alkaline treatment (0.02% NaOH) causes substantial reduction in the protein content of wet process extracted pea starch. However, wet processing is not used to any great extent at commercial levels.

There is a slightly different procedure used for wrinkled pea extraction. Wrinkled pea seeds are steeped in warm water, followed by dehulling using rubber rollers (to separate hulls from cotyledons), and then the cotyledons are disintegrated by applying high pressure. The slurry is suspended in water, and the starch fraction is screened out. This process enables up to 89% of the starch present in the wrinkled peas to be extracted with a residual protein content of around 1%.

Comparative Properties and Applications

Some comparative properties of various commercial starches are given in Table 1. The general uses and applications of major commercial starches are discussed under the specific sections above.

In general, the physicochemical properties of a given starch vary depending on the source of starch and often on the starch extraction method. Commercially, wet milling techniques result in higher-quality and purer starches compared with dry techniques, as: (1) there is high starch granular damage in dry techniques, and (2) most impurities are easily removed by water washing in wet processing. Ultimately, however, the process chosen for starch extraction is usually determined by consumer/industrial demand, availability of utilities, yield/quality considerations, and various other economic factors.

Functional Properties

D S Jackson, University of Nebraska, Lincoln, NE, USA

Introduction

Starches are used in a wide range of food products. They are sold to consumers as ingredients for thickening, and are used by food companies as thickeners, binding agents, stabilizers, texturizers, fat replacers/enhancers, encapsulation agents, gelling agents, film formers, moisture barriers, and crispness enhancers.

Solution Properties

Starches can be found in many physical forms. In water they can be found as raw (uncooked) granules, swollen (solvated) granules, granule pieces, entangled polymer masses of amylose and/or amylopectin, or as individual molecules of amylose and amylopectin. The presence and proportion of the components contribute to the unique functional properties of starch in specific food systems. Undamaged (partially crystalline) starch granules are insoluble in cold water and cannot be permanently dispersed in cold water without the addition of solvents such as methyl sulfoxide (DMSO) or alkali. If granules are suspended in water at 50–60 °C, however, they swell considerably and are partially dispersed. Upon prolonged gentle stirring of swollen starch granules at temperatures just below gelatinization, amylose is leached from the granules. After 4 h of aqueous leaching at 85 °C, approximately 29% of the total amylose in normal dent corn can be solubilized. This fraction of the amylose, however, is generally that which is exclusively within the amorphous regions of the starch granule. Specifically, without crystalline melting or gelatinization, amylose that traverses crystalline regions or whose movement is restricted within the granule by crystalline regions would be unable to leach from the granule. Upon vigorous agitation or some other induction of shear, more amylose and a small amount of amylopectin can also be solubilized at this temperature.

At temperature above the point of complete crystalline melting, starches can be thoroughly dispersed in water. Such a dispersion typically consists of soluble amylose and amylopectin, entangled polymer masses, and granule pieces consisting of mostly amylopectin. Complete dispersion of most normal starches (solubilized individual amylose and amylopectin molecules, and entangled polymers) occurs at autoclave temperatures without exposure to shear. Solubilization of 80–90% of individual molecules of amylose and amylopectin (no granule pieces or entangled polymers masses) can be achieved when corn starches (with amylose contents ranging from < 1 to 70%) are autoclaved (120 °C) and subsequently exposed to shear.

The degree of water solubility and dispersibility of starch depend largely on the temperature at which crystalline melting takes place. In the presence of excess water, the melting of crystalline areas takes place at relatively low temperatures (60–110 °C) because water helps to plasticize these regions. In water-limiting systems (including many foods), the temperature of melting (and hence gelatinization) is increased. Typical crystalline melting data, as determined by differential scanning calorimetry (DSC), are shown in **Table 1**.

Individual crystalline regions within starch molecules melt within a specific narrow temperature range, and the melting of some crystalline regions probably facilitates the melting of adjacent regions as amylopectin molecules that traverse the crystalline regions become more mobile. The temperature at which the first crystalline regions melt is referred to as the endotherm peak start and the temperature at which a tangent drawn along the steepest point of the endotherm curve intersects the baseline is the onset

Table 1 Typical differential scanning colorimetry starch crystalline melting (gelatinization) data when starch is exposed to excess water

Starch	*Endotherm peak start (°C)*	*Endotherm peak*[a] *(°C)*	*Endotherm peak end (°C)*
Waxy corn (< 1% amylose)	61.8	72.7	82.4
Normal dent corn (25% amylose)	61.8	71.4	80.1
53% Amylose corn	62.6	74.8	104.6
70% Amylose corn	62.3	92.2	108.4
Waxy sorghum (< 1% amylose)	70.8	76.1	82.7
Normal sorghum (24% amylose)	69.0	74.5	83.6
Waxy rice (< 1% amylose)	63.6	72.0	79.0
28% Amylose rice	68.6	77.5	86.2
Potato starch (16% amylose)	56.0	61.5	68.2

[a]Endotherms peaks, depending upon convention, are displayed as either going upward from a baseline or as dropping below the baseline.

temperature. The temperature at which the largest quantity of crystalline regions is melting is at the endotherm peak (often referred to as the gelatinization point or gelatinization temperature), and the temperature at which all crystalline regions have melted is the endotherm peak end. Since complete molecular solubility cannot be achieved without complete crystalline melting, it is apparent that high-amylose corn starches, whose endotherm peaks are wider and end at higher temperatures than other starches, are more difficult to solubilize completely. Even after the temperature of crystalline melting is exceeded, however, polymer entanglements must be dislodged by either increased temperatures and/or introduction of shear.

When concentrated suspensions of starch granules (i.e., 5%) are heated in water, complete solubilization of individual molecules of amylose and amylopectin is unlikely. When the granules swell, complete disruption of their original molecular structure may not take place, even if all of the crystalline areas are melted. The concentrated, dispersed polymers do not have complete freedom of movement. They are easily entangled with polymers and polymer segments within their originating starch granule, from other starch granules, and with molecules that leached from granules during the initial stages of swelling and gelatinization.

Gel Systems

Upon cooling, hydrated cooked starches form complex gel systems. The degree of association and the final rigidity of the gel system are largely dependent on the amylose/amylopectin ratio and the molecular characteristics (chain lengths and degree of branching) of both polymers. The initial gel formation, however, is largely dependent upon amylose properties; not only is linear amylose the primary component solubilized but it is that component which forms associations with other starch polymers most easily. Amylose is usually the component that forms the initial gel matrix which 'entraps' amylopectin and incompletely solubilized granule pieces. Waxy starch gels are far less rigid than normal starches or high-amylose starch. The final rigidity of an unmodified starch gel is largely dependent upon how closely solubilized starch polymers can associate and hydrogen-bond with each other. Solubilized amylopectin molecules, because of their highly branched nature, cannot associate as closely as linear amylose molecules. Therefore, the polymers in high-amylopectin-containing starches are prevented from establishing long, close associations of parallel hydrogen-bonded chains. The hydrogen-bonding that does take place between amylopectin molecules and amylopectin–amylose molecules results in water entrapment between the polymer chains. Linear amylose polymers, however, can form rigid and closely hydrogen-bonded associations (researchers often use a zipper analogy). Nevertheless, in the initial stages of cooling (when hydrogen bonds are being formed between amylose molecules), water is also entrapped between the polymers.

After prolonged cooling, the amylose–amylose, amylose–amylopectin, and amylopectin–amylopectin hydrogen bonding results in the squeezing out of water between associated polymers. This weeping process is referred to as syneresis. The process frequently manifests itself as a layer of water on a food product when unmodified starches are used to prepare fruit pie fillings or starch puddings and these gel systems are allowed to cool for several days (or shorter times depending upon the amylose–amylopectin ratio of the starches).

Because of differences in the closeness of association and the amount of water entrapment, the appearance of starch gels differs depending upon the amount of amylose and amylopectin. High-amylose starches are more white and opaque, while

high-amylopectin gels are more clear and have a slightly gray-white appearance. Potato starch, because its amylose component has a significantly higher molecular weight than that of other starches (corn amylose 100 000–200 000; potato amylose 400 000), has gels whose physical/chemical characteristics are closer to waxy starches than to cereal grain starches with equivalent amylose contents. Some amylose within potato starch associates by folding back on itself. Because of intramolecular hindrance, the association is not as tight as two separate amylose polymers lined up parallel to each other.

Starch Gel Characteristics

In addition to differences in starch gelatinization properties discussed elsewhere, native starches have widely differing gel-forming properties. These properties are summarized in Table 2.

The characteristics that starch imparts during gelatinization can be substantially influenced by chemical or physical modification of the starches. Much of the starch used in commercial food processing has been modified in some manner to impart desirable swelling, thickening, gelatinization, and retrogradation properties. Chemical modification of native starches can result in decreased swelling, changes in gelatinization temperature, and increased or decreased gel and retrograded starch-forming capacity. Most modifications, however, take advantage of the inherent properties of the native starch that is being modified.

Starch Inclusion Complexes

Starches form inclusion complexes with several chemical constituents, including fatty acids and mono- and diglycerides, emulsifiers, and many small flavor compounds. In general, starch complexes are formed when molecules bind within the alpha-helical structures found in amylose and portions of amylopectin polymers. Starch inclusion compounds, however, also encompass those instances when a nonstarch chemical constituent is entrapped within the three-dimensional network of starch polymers.

Starch–Iodine Binding

One of the simplest tests for identifying the presence of starches is by the application of iodine solutions to the sample in question. Since iodine can readily penetrate raw starch granules, gelatinization is not a prerequisite for staining. Starch will typically stain a vivid purple-blue color; waxy starches stain red. A central core is formed by amylose's alpha-helical structure; polyiodide ions are typically found within this core. Similar binding also takes place with outer chains of amylopectin, as well as smaller carbohydrates. The affinity of starch for iodine decreases as the starch chain-length is decreased. Since linear portions of starches are the primary binder of iodine, isoamylase- or pullalanase (breaks alpha-1,6 branch points)-treated starches show a far smaller decrease in iodine affinity versus starches treated with acid or alpha-amylases. Iodine complexing is also temperature-sensitive. Binding is reduced as temperatures increase above 40 °C; this corresponds to the change in starch structure from helical to coil-shaped. If allowed to cool, the iodine–starch complex reforms.

Starch–Lipid Complexes

Inclusion complexes similar to those involving iodine also form between starch and lipid components. This effect was first noticed when it was discovered that

Table 2 Starch properties during cooking in water (5% starch concentration)

Starch property during cooking	*Corn*	*Waxy corn and sorghum*	*High-amylose corn*[a]	*Potato*	*Tapioca*	*Rice*	*Wheat*
Rate of granular swelling (onset of thickening)	Slower	Slower	Very slow	Fast	Fast	Fast	Slower
Extent of granule swelling and solubility (viscosity during cooking)	Moderate	High	Low to moderate	Very high	Moderate	Moderate	Low
Swollen granule fragility (cooked starch susceptibility to shear)	Moderate	High	Moderate	High	Moderate	Moderate	Very low
Retrogradation of linear polymers (gel viscosity)	Very high	Very low	Extremely high	Low	Low	Low	Moderate

[a]High-amylose starches require more extensive cooking (to gelatinize) than regular starches (see Table 1). **Table 2** data assume extensive cooking. When not fully cooked, high-amylose corn starch paste viscosities are substantially lower than for cooked regular starches.
Certain data adapted, in part, from Zobel HF (1984) Gelatinization of starch and mechanical properties of starch pastes. *Starch Chemistry and Technology*, 2nd edn. Orlando: Academic Press.

lipids interfere with amylose–iodine complex formation. The carbon-chain segment of a lipid is located in the alpha-helical structure of amylose molecules and in long, linear segments of amylopectin (or amylopectin-like 'intermediate material') molecules. Hence, the binding of lipid is somewhat dependent on the molecular availability or solubility of starch polymers, especially amylose. If starch is fully gelatinized (amylose-solubilized), as the chain-length of saturated fatty acids increases, the amount of starch-lipid binding also increases. Also, there is less binding of lipids (given equivalent lipid solubility) to previously gelatinized starch as the temperature of starch–lipid mixtures increases. This is in contrast to an increase in binding that occurs between starches and lipids during the gelatinization process. Since starch–lipid binding is not a surface effect, amylose molecules are not readily available for binding with lipid if they are not gelatinized. Therefore, as the starch granule swells during gelatinization, more amylose is molecularly available for binding with lipid.

Monoglycerides generally bind less to starch than their corresponding fatty acid. A combination of lower lipid solubility and a slightly increased three-dimensional incompatibility between the monoglyceride and central binding core found within helical amylose probably account for this difference. Incompatible molecular shape also accounts for the decrease in lipid binding of unsaturated lipids as compared to their saturated counterparts; double bonds found in unsaturated lipids decrease subtle molecular movements in solution and form a molecular shape that may partially interfere with lipid inclusion within the amylose core.

The binding between starch and lipids has practical implications in the formulation of several starch-containing food products. For example, various surfactants (mono- and diglycerides) and fats are widely used to reduce bread staling. During the breadmaking process, starch granules become swollen in the presence of amylose-complexing lipid components. Since, during baking, starch–lipid interactions take place while the granule is swelling (50–60 °C), but before gelatinization, lipids can complex with amylose prior to its becoming soluble. As a result, starch granule swelling and gelatinization are reduced. Thus, less free amylose is subsequently available to hydrogen-bond (retrograde) with other amylose molecules. In addition, because of the reduced swelling, the moisture distribution between the wheat gluten and starch is altered, contributing to a softer crumb structure. Interestingly, the softening of crumb structure by amylose–surfactant complexing does not significantly affect the mechanism by which bread firms, i.e., the retrogradation of amylopectin. Surfactants have only a low affinity for complexing with amylopectin, although they may act via other mechanisms to retard staling.

Other Starch Inclusion Compounds

Flavor compounds and similar low-molecular-weight organics also readily complex with starch. The primary binding mechanism, as with iodine and lipids, is the formation of an inclusion complex within the helical structure of amylose. In addition, some flavor molecules may become physically entrapped by the long polymer chains of starches, although these molecules would be less likely to be retained during storage. The commercial application of flavor inclusion complexes is the preparation of dry flavor compounds using starch and liquid flavor ingredients. Inclusion compounds are most likely to form when starch is molecularly dispersed in the presence of flavor molecules. When hot water is used as a dispersant, the reformation of helical segments (from a coil) in amylose forms inclusion complexes in the presence of flavor compounds. Commercial application of this property includes the encapsulation of pollen flavor for Honey Bee food, and the encapsulation of thousands of flavoring substances for dry flavoring mixes for direct consumer use and as an aid in commercial food processing. The inherent property of starches to form inclusion complexes can be enhanced or reduced by chemical modification.

Modified Starches

J N BeMiller, Purdue University, West Lafayette, IN, USA

Background

Food processors generally require starches with better behavioral characteristics than provided by native starches. Cereal starches produce particularly weak-bodied, cohesive, rubbery pastes and undesirable gels when cooked. However, via modification, the functional properties of starches can be improved. Modification is done to introduce specific functionalities and to make resultant cooked products better able to withstand the conditions of heat, shear, and pH (acid) associated with processing conditions. The final products, modified food starches, are abundant, functional, and useful food ingredients, generally macroingredients. (*See* **Starch**: Functional Properties.)

Modifications can be chemical or physical. Chemical modifications are oxidation, cross-linking, stabilization, and depolymerization. Physical modifications make pregelatinized and cold-water-swelling products. Chemical modifications have the greatest effects on functionalities. Modifications can be single modifications, but modified starches are often prepared by combinations of two, three, and sometimes four processes. Chemical derivatives found in modified food starches (in the USA) are the following:

1. Stabilized starches
   a. Hydroxypropyl starches (starch ether)
   b. Starch acetates (starch ester)
   c. Starch octenylsuccinates (monostarch ester)
   d. Monostarch phosphate (ester)
2. Cross-linked starches
   a. Distarch phosphate
   b. Distarch adipate
3. Cross-linked and stabilized starches
   a. Hydroxypropylated distarch phosphate
   b. Phosphorylated distarch phosphate
   c. Acetylated distarch phosphate
   d. Acetylated distarch adipate

Property improvements that can be obtained by chemical modifications include the following:

1. Hypochlorite-oxidized starches
   a. Whiter
   b. Lower gelatinization and pasting temperature
   c. Decreased maximum paste viscosity
   d. Softer, clearer gels
2. Stabilized (hydroxypropylated or acetylated) starches
   a. Lower gelatinization and pasting temperatures
   b. Improved freeze–thaw stability of pastes and gels
   c. Decreased setback of pastes and gels (improved paste stability)
   d. Easier redispersibility when pregelatinized
   e. Greater clarity of pastes and gels
3. Cross-linked (phosphorylated) starches
   a. Increased gelatinization and pasting temperatures
   b. Increased shear resistance
   c. Increased acid stability
   d. Decreased setback of pastes and gels (improved paste stability)
   e. Increased viscosity of pastes
4. Cross-linked and stabilized starches
   a. Lower gelatinization and pasting temperatures, but increased paste viscosity
   b. Other attributes of stabilized and cross-linked products
5. Thinned (depolymerized) starches
   a. Decreased viscosity of pastes
   b. Lower gelatinization and pasting temperatures
   c. Increased solubility

Any starch (corn, potato, tapioca/cassava, wheat, rice, etc.) can be modified, but modification is practiced significantly only on corn (both common corn and waxy maize) and potato starches and, to a much lesser extent, on tapioca and wheat starches. This article is written primarily from the point of view of corn and waxy maize starches. (*See* **Starch**: Sources and Processing.)

Methods of Production and Applications

Cross-linked and/or stabilized starch products are prepared by chemical derivatization of a starch, most often in an aqueous slurry in a batch process. In such a process, a slurry of 30–45% solids (starch) as obtained from the mill is introduced into a stirred reaction tank. Sodium chloride or sodium sulfate is added to inhibit granule swelling. The pH is adjusted with sodium hydroxide (up to values of ≈ 11.5, depending on the reaction). Chemical reagents are added. Temperature is controlled. Reactions may be done at temperatures up to 50 °C, but gelatinization must be avoided to allow recovery of the modified starch in granule form by filtration or centrifugation. Because the gelatinization temperature may be lowered by the modification, there may be, and often is, a limit to the degree of substitution that can be made in this manner. (The degree of substitution is the average number of hydroxyl groups per α-D-glucopyranosyl unit (the monomeric unit of starch)

that have been derivatized, the maximum being 3.) In some reactions, the pH needs to be controlled by the metered addition of dilute sodium hydroxide solutions. Following modification to the desired level, the starch is recovered by centrifugation or filtration, washed, and dried.

Chemical reactions currently both allowed and used to prepare modified food starches in the USA are as follows:

- Esterification with acetic anhydride, succinic anhydride, the mixed anhydride of acetic and adipic acids, 1-octenylsuccinic anhydride, phosphoryl chloride, sodium trimetaphosphate, sodium tripolyphosphate, or monosodium orthophosphate
- Etherification with propylene oxide
- Acid modification with hydrochloric or sulfuric acids
- Bleaching with hydrogen peroxide, peracetic acid, potassium permanganate, or sodium hypochlorite
- Oxidation with sodium hypochlorite
- Various combinations of these reactions

Other reagents may be used in other countries.

Waxy maize starch modifications are especially popular in the US food industry because the inherent properties of waxy maize starch make them preferred over modifications to common corn starch.

Cross-Linking

Cross-linking is the most important modification of a food starch. Cross-linking occurs when starch granules are reacted with difunctional reagents to connect hydroxyl groups on two different molecules within the granule. Cross-links reinforce the granule and reduce both the rate and the degree of granule swelling and subsequent disintegration, i.e., reduce sensitivity to processing conditions (high temperature; extended cooking times; low pH; high shear during mixing, milling, homogenization, and/or pumping). Cooked pastes of cross-linked starches are more viscous, heavier-bodied, shorter-textured, and less likely to break down with extended cooking times, greater acidity, or severe agitation than are pastes of the native starches from which they are prepared. Only a small amount of cross-linking is required to produce a noticeable effect; for example, one cross-link for every approximately 1200 α-D glucopyranosyl units greatly reduces both the rate and the degree of granule swelling, greatly increases paste stability, and changes dramatically both the viscosity profile as the starch is cooked and the textural characteristics of its paste. Three times that much crosslinking, for example, produces a product in which granule swelling is restricted to the point that a peak viscosity is never reached in a slurry heated to 95 °C and held at that temperature with moderate stirring. As the number of cross-links increases, the granules become more and more tolerant to physical conditions and acidity, and swell and disintegrate (solubilize) upon cooking less and less. Energy requirements to reach maximum swelling and viscosity are also increased.

By far the most common cross-links are distarch phosphate esters. These distarch phosphates are prepared with either phosphoryl chloride or sodium trimetaphosphate. Phosphoryl chloride is very reactive and undoubtedly reacts near granule surfaces. To prepare cross-linked starches with phosphoryl chloride, the reagent is added to an aqueous starch suspension of pH 8–12. To cross-link a starch with sodium trimetaphosphate, it is slurried in a solution of the reagent at pH 5.0–8.5; the suspension is filtered, and the starch is dried. In this case, the cross-links are undoubtedly more evenly distributed throughout the granule.

A relatively small amount of cross-linked starch is made by reaction of corn starch with the mixed anhydride of adipic and acetic acids in aqueous alkaline suspension.

Stabilization

Derivatization of a starch with monofunctional reagents reduces the intermolecular associations which result in gelation of its paste and/or precipitation of the starch polymers (combined processes termed retrogradation or setback). Pastes of unmodified starches generally will gel, and the gels will usually be cohesive, rubbery, long-textured, and prone to syneresis. (Waxy maize starch pastes gel to a very limited extent at room temperature, but will become cloudy and chunky and exhibit syneresis when stored under refrigerator or freezing conditions.)

The most common derivatives employed for starch stabilization are the hydroxypropyl ether and acetate and monostarch phosphate esters. Acetylation is accomplished by treating a starch slurry with acetic anhydride at pH 7–11, the optimum pH depending on the reaction temperature. Acetylation of starch lowers the gelatinization temperature, an indication of a weakening of granules. Upon cooking, a higher peak viscosity is obtained due to greater granule swelling. Upon cooling of the resulting paste, the viscosity becomes lower than that obtained from the unmodified starch, an indication of improved stability, i.e., less retrogradation. Acetylated starches with an acetyl content of up to 2.5% (degree of substitution, DS, 0.09) can be used in food products (USA). (A DS of 0.09 indicates an average of nine acetyl groups per 100 α-D-glucopyranosyl units.)

Sodium phosphate monoesters are prepared by impregnating the starch with a solution of sodium

tripolyphosphate. After adjustment of the pH to 5.0–8.5, the slurry is mixed, then filtered, and the filter cake is dried and heated. Sodium tripolyphosphate is used to make products of up to 0.002 DS (one phosphate group per 500 α-D-glucopyranosyl units), the maximum allowed in the USA. Monosodium orthophosphate in the pH range 5.0–6.5 is also used to produce monostarch phosphates in the same way.

Monostarch phosphates produce stable pastes that are clear and have a long, cohesive texture. Paste viscosity can be controlled by varying the concentrations of phosphate salt, time of reaction, temperature, and pH. Increasing substitution lowers the gelatinization temperature; products become cold-water-swelling at DS 0.07. Corn starch phosphates of DS 0.01–0.03 produce pastes with hot viscosity, clarity, stability, and texture more like those of potato starch. Starch phosphates are good emulsion stabilizers and produce pastes with improved freeze–thaw stability.

Hydroxypropyl ether derivatives of starches are prepared by reacting an alkaline slurry with propylene oxide. To a starch slurry is added sodium sulfate and sodium hydroxide. The reactor is charged with propylene oxide and sealed. Reaction is continued for about 24 h at about 49 °C. The maximum allowable moles of substitution in the USA is 0.2 (7.0% of hydroxypropyl groups). (Moles of substitution, MS, is essentially the same as DS but is used in place of DS because each hydroxypropyl group contains a hydroxyl group that can itself be etherified, so that the maximum number of substituent groups per glucosyl unit can be more than 3.)

Low-MS hydroxylpropylstarches behave much like low-DS starch acetates and are used because of similar improvements in texture and appearance. The hydroxypropyl ether linkage is, however, much more stable than an ester linkage.

Starch succinate half-esters are prepared by reacting starch with succinic anhydride.

Starches with Hydrophobic Groups

Reaction of starch with 1-octenylsuccinic anhydride introduces hydrophobic substituent groups. Such derivatives can be used as emulsifiers and emulsion stabilizers in products based on oil-in-water emulsions, such as pourable dressings and flavored beverages. Flavor oil emulsions containing a thin-boiling starch or dextrin (see below) derivatized with 1-octenylsuccinate ester groups may be spray-dried. The flavor oil in the resulting powder is protected against oxidation, and the emulsion will reform when the powder is stirred into an aqueous medium. Gum arabic is, however, usually the material of choice for this application. Higher-DS products are nonwetting and are used as release agents for dusting on dough sheets and as processing aids. The maximum DS level allowed in the USA is 0.02.

Acid Modification

Thin-boiling starches are prepared by treating a suspension of a native or derivatized starch with dilute mineral acid at a temperature below the gelatinization temperature. When a product that gives the desired paste viscosity is produced, the acid is neutralized, and the product is recovered by centrifugation or filtration, washed, and dried. Even though only a few glycosidic bonds are hydrolyzed, granules disintegrate more easily and after only a small degree of swelling. Acid-modified starches form gels with improved clarity and increased strength, even though their pastes are less viscous. Thin-boiling starches are used as film formers and adhesives in products such as pan-coated nuts and candies, whenever a strong gel is desired, e.g., in gum candies such as jelly beans, jujubes, orange slices, and spearmint leaves, and in processed cheese loaves. To prepare especially strong and fast-setting gels, a high-amylose corn starch is used. More extensive modification with acid produces dextrins. (*See* **Dextrins**.)

Oxidation

Depolymerization, viscosity reduction, and decreased pasting temperature can also be achieved by oxidation with sodium hypochlorite (chlorine in an alkaline solution). Oxidation also reduces association of amylose molecules, i.e., results in some stabilization via introduction of small amounts of carboxylate and carbonyl groups. Oxidized starches produce intermediate-viscosity and soft gels and are used when these properties are needed. They are also used to improve adhesion of starch batters to fish and meat and in breadings. Mild treatment with sodium hypochlorite, hydrogen peroxide, or potassium permanganate simply bleaches the starch and reduces the count of viable microbes.

Pregelatinization

Pregelatinized starches are precooked starches that can be dispersed (dissolved) in water at temperatures below the gelatinization temperatures of the parent starches; thus, these 'instant' starches need no cooking. To prepare a pregelatinized starch, a slurry is simultaneously cooked and dried on hot drums. Because pregelatinized starch products are powders prepared from dried pastes, generally no granules are present, although granule fragments may be. Both chemically modified and unmodified starches can be used. The resulting products contain no intact starch

granules. If chemically modified starches are used, the properties introduced by the modification(s) are found in the pregelatinized products; thus, paste properties such as freeze–thaw stability can be characteristics of pregelatinized starches. Several physical forms of pregelatinized starches are produced. For example, some will produce smooth solutions; others will produce pulpy or grainy dispersions and find use in fruit drinks and tomato products. Pregelatinized starches are often used in dry mixes, as are maltodextrins, because they disperse readily, even when mixed with other ingredients. Starches that are not pregelatinized are known as cook-up starches.

Cold-Water-Swelling Starches

Starch products that are gelatinized starches, i.e., starches that have lost their crystallinity, but which retain their granular form, in contrast to standard pregelatinized starches, are called cold-water-swelling starches. There are several ways that such products can be prepared; one way is to heat a starch in an aqueous alcohol solution with sufficient water to allow gelatinization and sufficient alcohol that granule integrity is maintained. Cold-water-swelling products swell rapidly and thicken unheated aqueous systems. (A granular, cook-up starch requires heating a slurry to the pasting temperature before thickening occurs.)

Multiple Modifications

Modified food starches are tailor-made for specific applications. Most modified food starches are made by cross-linking, introduction of monosubstituent groups (stabilization), or a combination of these two approaches. Many products, in fact, have received two or more modifications. For example, a modified food starch may be a cross-linked and stabilized waxy maize starch; another may be a stabilized, acid-thinned, and pregelatinized common corn starch. Characteristics that can be controlled/improved by multiple modifications include, but are not limited to, one or more of the following:

- Adhesion
- Clarity of solutions/pastes
- Color
- Emulsion stabilization
- Film formation
- Flavor release
- Hydration rate
- Moisture retention and control in product
- Mouth feel of product
- Oil migration control in product
- Paste texture/consistency
- Product form (liquid, semisolid, solid)
- Sheen of product
- Shelf-stability of product
- Stability to acids
- Stability to heat
- Stability to shear
- Tackiness
- Temperature required to cook
- Viscosity (hot paste and cold paste)

Digestion and Metabolism

Various regulations concerning reagents that may be used and the maximum allowable modification of a starch for food use, alone or in combination with another modification, are in effect around the world. Generally, the level of substitution in a derivatized food starch is below DS 0.1 and in the range DS 0.002–0.2. Because of this low level of modification, the digestion, metabolism, and caloric values of modified food starches are reduced only to a minor, usually unmeasurable, extent as compared to native starches. Because only monosaccharides (D-glucose in this case) are absorbed, fragments containing esterified, etherified, or oxidized α-D-glucopyranosyl units should not be absorbed from the small intestine. (*See* **Carbohydrates:** Digestion, Absorption, and Metabolism.)

Resistant Starch

R M Faulks, Institute of Food Research, Norwich, UK

Introduction

The term 'resistant starch' was first coined by Englyst, Wiggins, and Cummings in 1982 to describe a small

fraction of starch that was resistant to hydrolysis by exhaustive α-amylase and pullulanase treatment *in vitro*. This starch fraction was found during the destarching of food samples for dietary fiber analysis and consists of retrograded amylose, B-type starch granules, starch encapsulated within plant or tissue structures, and some modified starch structures.

Recognition that this small fraction of starch could be a significant contaminant of the dietary fiber led to calls to have it included in the definition of dietary fiber. More fundamentally, it also led to a reappraisal of the way starches behave *in vivo* and, in particular, whether or not resistant starches possessed any of the properties usually associated with dietary fiber, e.g., fecal bulking, laxation, shorter transit times. However, because starch reaching the large intestine may be more or less fermented by the gut microflora, some workers prefer to consider resistant starch as that portion of dietary starch which escapes digestion in the small intestine. This is an important distinction because resistant starch measured as a dietary fiber contaminant can only account for a fraction of the starch lost from the terminal ileum. (*See* **Dietary Fiber**: Physiological Effects.)

Because of the possible nutritional significance of unavailable dietary starch, it is now widely accepted that resistant starch is best defined as that fraction of dietary starch which escapes digestion in the small intestine. Resistant starch is therefore a variable fraction of starch, defined by physical, chemical, and physiological factors, but not necessarily resistant to hydrolysis by starch-degrading enzymes *in vitro*. This definition permits the fractionation of resistant starch into different categories according to the reason for its nondigestion (e.g., enclosed in food matrix, slowly digested, enzymatically resistant), and allows the determination of any functional or physiological role in the small intestine. Furthermore, this classification may permit a clearer understanding of how much starch is lost from the small intestine, and of its function and fate in the large intestine.

Formation

The formation of resistant starch, or, more accurately, the change in the degree of resistance of starch to hydrolysis by α-amylase and glucoamylases, is a function of the structure and composition of the starch, its processing environment, and subsequent storage conditions.

The well-known granular structure of starches is lost if starches are heated above about 70 °C in an aqueous environment, although some starches, particularly those from some legumes or high in amylose, may not gel unless heated to a much higher temperature, e.g., 120 °C. In conditions of limited or no moisture, heating may not result in significant changes in starch granules, which may retain their native crystalline form. Formation of resistance normally occurs most extensively in high-amylose starches that have been thoroughly dispersed by cooking (100–120 °C) in water and subsequently allowed to cool to produce a set gel containing 10–30% starch. Prolonged storage of gels under cool conditions, freezing and thawing, and reheating and cooling may also increase the degree of resistance.

As the dispersed gel cools, sections of the linear amylose molecules rapidly associate by hydrogen bonding to produce retrograded crystalline structures. Starch gels can therefore be considered as gelatinized granules embedded in an amylose matrix. If the amylopectin in the gelatinized granules is not too highly branched, parts of its structure may also crystallize. This retrogradation of amylopectin is a much slower process. The result is therefore the production of a gel system containing two phases: a highly structured phase, containing predominantly retrograded amylose, and a less structured amorphous phase, containing some retrograded amylopectin.

Examination of retrograded starch gels by differential scanning calorimetry clearly shows two endotherm peaks relating to the melting of retrograded amylopectin (*c.* 70 °C) and retrograded amylose (*c.* 160 °C).

It is the formation of physically ordered structures within the gel which is believed to confer resistance to amylolysis. The degree of association (retrogradation) of cooked starches may be influenced by a range of factors, including amylose-to-amylopectin ratio, starch concentration, pH, ions, temperature, age, and the presence of lipids.

Physical and Chemical Properties

Resistant starch is not a chemically defined entity. Its properties *in vivo* or *in vitro* can therefore be described only in general terms.

Resistant Starch Granules

Raw starch granules embedded in the cellular structure of food fragments may escape digestion because they are inaccessible to α-amylase and glucoamylases *in vivo*. This occurs mainly with the consumption of 'whole-foods', in which the particle size is large, or in tissues that have thick cell walls, or in some processed foods, in which the food structure restricts access by amylolytic enzymes. In these cases, both the chemical and physical properties of the starch are normal for the type of starch.

Although most native starches undergo quite rapid hydrolysis *in vivo*, in that they are found only in trace amounts in the terminal ileum, some native starches are very resistant to digestion. The main dietary starches to show marked resistance to amylolysis *in vivo* are raw banana and potato. It has been suggested that resistance to digestion is caused by the B form of crystallinity of the granule, unlike the A forms (wheat, maize) and C forms (sweet potato, tapioca) more commonly found. Retrograded starches are also known to develop the B-form structure. (*See* **Bananas and Plantains**; **Potatoes and Related Crops**: Processing Potato Tubers.)

Resistant Cooked Starch

The amorphous phase of retrograded starch gels is rapidly hydrolyzed (in minutes) by α-amylase, leaving the structured phase which is only slowly attacked (days). The hydrolysis curve of cooked retrograded starch gels takes the general form shown in Figure 1. The initial rate and extent of hydrolysis are dependent on the botanical origin of the starch and factors influencing the degree of retrogradation and the α-amylase activity. Prolonged treatment with α-amylase may lead to almost 100% hydrolysis of the starch, except in the case of pure amylose, when the degree of hydrolysis is much lower. *In vivo*, therefore, resistant starch from cooked foods is probably composed of a variable proportion of highly α-amylase-resistant starch (depending on the efficiency of digestion) and any residual starch that is truly α-amylase-resistant (retrograded amylose).

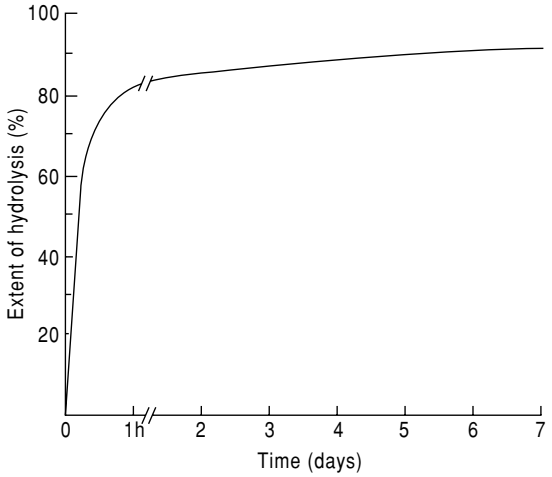

Figure 1 Typical hydrolysis curve of retrograded starch gel treated with α-amylase *in vitro*. Reproduced from Starch, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Enzymatic treatment of starch gels may be used to isolate the more resistant fractions for further study.

Isolated starch with a high degree of resistance to α-amylase is a water-insoluble white solid which has none of the functional characteristics normally associated with water-soluble polysaccharides (e.g., viscosity) or with the heterogeneous mixture of polysaccharides that make up the cell wall of plants.

Retrograded amylose isolated by α-amylase treatment has been found to consist mainly of linear glucose polymers with a degree of polymerization of 60. Careful acid hydrolysis of retrograded amylopectin yields the associated regions which have been shown to contain branched fragments in which the individual chains have a degree of polymerization of 15.

Resistance to α-amylase can be effectively abolished by melting the retrograded structures (*c.* 70 °C for amylopectin and *c.* 160 °C for amylose).

Disruption of the H bonds that hold the crystalline structures together may be achieved chemically by treatment with cold dilute alkali (potassium hydroxide, 2 mol l^{-1}) or with hot (100 °C) anhydrous dimethyl sulfoxide (DMSO).

Some of the resistant structures from high-amylose starch gels (retrograded amylose) may also show considerable resistance to hydrolysis in dilute mineral acid (sulfuric acid, 1 mol l^{-1}) and may need a Seaman-type hydrolysis (cold sulfuric acid, 12 mol l^{-1}, followed by 1 mol l^{-1} at 100 °C) to achieve 100% yield of glucose.

Physiological Effects

When resistant starch residues were first described in 'destarched' dietary fiber residues, it was considered appropriate to allocate them to the dietary fiber complex, despite the fact that they are predominantly α-1,4-linked glucans and potentially digestible in the small intestine. It was later realized that the amount of resistant starch could be manipulated by processing and would therefore be variable as well as chemically distinct from the nonstarch polysaccharides (NSP). More recently, it has been demonstrated that highly α-amylase-resistant starch fractions that have been isolated from different sources differ with respect to the extent of digestion in the small intestine and fermentation in the large intestine. Resistant starch is therefore a variable fraction of the starch, and the fact that it escapes digestion either *in vivo* or *in vitro* is insufficient reason to allocate it as dietary fiber. All the current main methods for the measurement of dietary fiber (Englyst, Uppsala, Association of Official Analytical Chemists) have modifications that allow the inclusion or exclusion of residual starch from the dietary fiber value. (*See* **Dietary**

Fiber: Properties and Sources; **Dietary Fiber**: Determination.)

There is little experimental evidence for the functional properties or physiological effects of resistant starch *in vivo*. This is because (1) it is difficult to define resistant starch other than in physiological terms; (2) there are inadequate *in vitro* methods for resistant starch measurement; and (3) feeding trials have tended to use foods in which there are overlying effects of the food matrix and a great excess of readily digestible starch.

It is known that when isolated, highly α-amylase-resistant starch is fed to rats, there is some (20–60%) digestion of the carbohydrate in the small intestine, the remainder being lost to the cecum. This starch is digested and absorbed more distally in the ileum than rapidly digestible starch. More distal absorption of glucose might be expected to have some effects on gut physiology and gut hormones. However, no differences were found in glucagon, enteroglucagon, and cholesterol between rats fed isolated resistant starch from high-amylose maize starch as the only complex carbohydrate, and those fed corn starch. However, in the resistant-starch-fed rats, the crypt cell production rate in the ileum was significantly greater.

The presence of resistant starch in the diets of unadapted rats appears to cause a slowing in both the rate and velocity of ileal digesta transport. It may be that this constitutes some evidence for an 'ileal brake' mechanism which slows digesta movement as a result of presence of absorbable carbohydrate in the distal ileum. This effect is lost during adaptation.

Starch that is not digested in the small intestine is lost to the cecum or large intestine, where it may undergo fermentation by the microflora. Evidence from rat-feeding experiments has shown that the amount of fermentation is dependent on the source of the resistant starch and the extent of adaptation of the animal.

The ceca of rats fed resistant starch are generally much enlarged, and the pH of the cecal contents is lower than normal, indicating fermentative production of fatty acids. By analogy with fermentable NSP, the main fatty acids produced from the fermentation of resistant starch are believed to be acetate, propionate, and butyrate.

Initially, a large proportion of resistant starch is voided in the feces but this falls quite quickly as the cecal microflora adapts. The rate of adaptation also depends on the origin of the resistant starch. Rats fed resistant starch from normal maize adapted quickly (5 days), losing only a few percent of the ingested resistant starch whereas those fed resistant starch from wrinkled peas or high-amylose maize adapted more slowly (28 days) and were still losing a high percentage of the ingested resistant starch. Resistant starch may therefore contribute significantly to fecal bulk but this is variable depending on the state of adaptation of the animal. (*See* **Microflora of the Intestine**: Role and Effects.)

Significance

At this stage it is difficult to estimate the significance of resistant starch. It is not well defined, and proposed methods of analysis may determine fractions that possess different structures and functions or that may be physiologically irrelevant.

What can be said relates mainly to the properties of resistant starch by analogy to dietary fiber and, by extension, its deliberate production, either within a food or as a food additive. Where resistant starch is present in a food it will help to flatten the glycemic response curve by reducing the amount of rapidly digestible starch and by moderating the rate of digestion. The resistant starch that reaches the more distal part of the small intestine may exert an influence on the rate of transport along the ileum, and help the more uniform absorption of carbohydrate. This type of 'slow-release' carbohydrate may find application in improving the carbohydrate tolerance of diabetics, and it has implications for the utilization of energy. (*See* **Glucose**: Glucose Tolerance and the Glycemic(-Glycaemic) Index.)

Any starch that is lost from the small to the large intestine represents a loss of dietary energy since, even if it is fully fermented, the energy salvaged is only about 50% of that in the original carbohydrate. Some additional losses from the small intestine of other energy sources may occur as a result of any 'carry-over' effect.

The energy value of resistant starch is therefore somewhat less than $16.8\,\mathrm{kJ\,g^{-1}}$; its actual value depends upon how much can be salvaged by fermentation in the large intestine, the pattern of short-chain fatty acids produced, and any energy lost to hydrogen or methane.

The fermentation of dietary fiber in the large intestine is believed to be a protective factor against large-bowel cancer because the short-chain fatty acids produced lower the pH and inhibit 7α-dehydroxylase. This prevents the formation of secondary bile acids that are suspected of a promotional role in colonic carcinogenesis. In addition, butyrate, produced by fermentation, is known to be a major energy source for the colonic tissue and is believed to be a protective factor in the development of colon cancer.

Carbohydrate fermentation in the large intestine may therefore be a major protective factor against the development of colon cancer. Because resistant

starch is at least partially fermentable, it may play a crucial role in these mechanisms. (*See* **Colon**: Cancer of the Colon.)

Resistant starch has also been demonstrated to have fecal-bulking properties and this could also play a role in the dilution of fecal carcinogens by reducing the time and level of exposure of the colonic mucosa.

From the energy point of view, there may be some health benefits from consuming foods high in resistant starch. Foods in which resistant starch may be created *in situ* would have a lower energy density but otherwise maintain their nutrient density. Starches high in resistant starch or isolated resistant starch fractions may be created with suitable functional characteristics to find application in the food industry as an ingredient or simply as a lower-energy bulking agent.

STARTER CULTURES

L Durso and R Hutkins, University of Nebraska, Lincoln, NE, USA

Introduction and History

Starter cultures are an essential component of nearly all commercially produced fermented foods. Simply defined, starter cultures consist of microorganisms that are inoculated directly into food materials in order to bring about desired and predictable changes in the finished product. These changes may include enhanced preservation, improved nutritional value, modified sensory qualities, and increased economic value. Although many fermented foods can be made without a starter culture, the addition of concentrated microorganisms, in the form of a starter culture, provides a basis for insuring that products are manufactured on a consistent schedule, with consistent product qualities.

Fermented foods and beverages have long been manufactured without the use of commercial starter cultures. Traditional methods of production include backslopping, or using a small amount of the finished specifically preserved product to inoculate a new batch, the use of microorganisms found naturally on the product, and the use of special containers that allow for the survival of the starter culture microorganisms within cracks and pores. These traditional

methods allow for the development of individual varieties of fermented foods and beverages, and they are still practiced today for small- to mid-scale production facilities, as well as in less developed countries and in homemade-type products. Traditional methods, however, are prone to slow or failed fermentations, contamination, and inconsistent quality. In contrast, modern large-scale industrial production of fermented foods and beverages demands consistent product quality and predictable production schedules, as well as stringent quality control to insure food safety.

Given that pure culture techniques in microbiology were not developed until Pasteur in the 1860s and that lactic acid bacteria (LAB), in particular, were identified by Lister in the 1870s, it is noteworthy that an industry devoted to producing pure cultures had its beginnings only a short time later. In the late 1880s, Storch in Denmark, Weigman in Germany, and Conn in the USA showed that pure cultures could be used to ripen cream, and soon the role of flavor-producing bacteria (i.e., citrate-fermenting diacetyl-producers) was established. By 1878 Christian Hansen began a culture business that continues even today to be a major supplier of starter cultures for the dairy, meat, brewing, baking, and wine industries.

Initially, starter strains were prepared by the manufacturer by growing pure strains in heat-sterilized milk. Calcium carbonate was often added as a buffer in order to maintain a neutral pH. These liquid cultures remained popular until relatively recently, even though they had a relatively short shelf-life due to the loss of cell viability and fermentative activity. Eventually, rather crude dry culture preparations were produced which required several transfers in milk to revive the culture to an active state. Freeze-dried cultures also became available, but the early product also required growth in intermediate or mother cultures. Frozen cultures, now the most common form for dairy cultures, were not introduced until the 1960s. Significant improvements in freezing and freeze-drying technologies have led these types of cultures to dominate the starter culture market.

The modern starter culture industry provides cultures for nearly every type of fermented food and beverage. Most culture houses also produce and sell the media used to propagate starter cultures, the enzymes used to coagulate milk for cheese production, and other ancillary products. In addition, the starter culture companies maintain a staff of highly trained microbiologists who provide expert technical service and support when issues or problems related to culture performance arise. And although there are many small culture manufacturers throughout the world, specializing in cultures for specific products or applications, the industry is dominated by a small number of large companies.

This article will review the types of microorganisms used as starter cultures, how starter cultures are produced and preserved, criteria used by manufacturers to assess culture performance, and ultimately how these cultures are used by the fermented foods industry. Issues facing the starter culture industry and the new technologies being developed to address these issues will also be examined. Throughout this chapter, dairy starter cultures will be emphasized, since the cheese and cultured dairy products industry represents the largest user of commercial starter cultures.

Starter Culture Microorganisms

Given that fermented foods have historically been made using various species of bacteria, yeasts, and molds, it follows that modern starter cultures also contain these organisms. In general, bacteria are used in the production of cheese, cultured dairy products, fermented sausages, and fermented vegetables. Yeasts are used in the manufacture of bread and alcoholic beverages, and molds are used for cheeses and sausages as well as for soy-derived products, such as soy sauce and tempeh. In most cases, the organisms contained within a starter culture preparation are well-defined, often to the species or even strain level, and are carefully selected based on criteria relevant for a particular product. Some starter culture organisms, however, are not well defined, but instead are selected based on a history of successful use.

Bacterial Starter Cultures

LAB are clearly the most important group of bacteria used as starter organisms (*See* **Lactic Acid Bacteria**). The LAB consist of a cluster of low G + C Gram-positive cocci and rods from at least 11 genera; however, only a few of these are used as starter cultures (Table 1). *Lactococcus lactis* subsp. *lactis* has long been considered the most important LAB, due to its widespread use in cheese manufacture, but other species, such as *Streptococcus thermophilus*, which has gained in importance due to its use in yogurt and Mozzarella cheese, are also widely used (Figure 1).

In general, the LAB are catalase-negative heterotrophs having complex nutritional requirements. They have a fermentative metabolism, deriving energy, in the form of adenosine triphosphate (ATP), via substrate-level phosphorylation. Sugar metabolism is either homofermentative or heterofermentative. In homofermentation, nearly all (> 90%) of the

sugar substrate is converted directly to lactic acid, whereas in heterofermentation, lactic acid, acetic acid, CO_2, and ethanol are produced. Although most genera are either one or the other, some species of *Lactobacillus* have the biochemical capacity for both pathways. Both hetero- and homofermentative LAB are used as starter cultures. Their optimum temperature for growth varies; however, most LAB used as dairy starter cultures are either mesophilic (*Lactococcus lactis*) or are moderate thermophiles (*S. thermophilus* and *Lactobacillus* spp.).

Table 1 Lactic acid bacteria used as starter cultures

Organism	*Application*
Lactococcus lactis subsp. *lactis*	Cheese, cultured dairy products
Lactococcus lactis subsp. *cremoris*	Cheese, cultured dairy products
Lactococcus lactis subsp. *lactis* biovar. *diacetylous*	Cheese, cultured dairy products
Lactobacillus helveticus	Cheese, cultured dairy products
Lactobacillus delbrueckii subsp. *bulgaricus*	Cheese, yogurt
Lactobacillus sanfranciscensis	Sourdough bread
Lactobacillus casei	Cheese, cultured dairy products
Lactobacillus sakei	Sausage
Lactobacillus plantarum	Sausage, fermented vegetables
Lactobacillus curvatus	Sausage
Lactobacillus sanfrancisco	Sourdough bread
Streptococcus thermophilus	Cheese, yogurt
Pediococcus acidilactici	Sausage, fermented vegetables
Pediococcus pentosaceus	Sausage
Pediococcus halophilus	Soy sauce
Oenococcus oeni	Wine
Leuconsotoc lactis	Cheese, cultured dairy products
Leuconsotoc mesenteroided subsp. *cremoris*	Cheese, cultured dairy products, fermented vegetables

Since the primary function of starter culture bacteria is to ferment sugars and to produce acids, the ability of LAB to metabolize carbohydrates is of critical importance. Indeed, the specific substrate range and rate at which metabolism occurs may be used as criteria for strain selection. In dairy fermentations, for example, rapid lactose fermentation is required, whereas in sourdough fermentation, maltose and glucose metabolism are relevant and in sausage fermentation glucose or sucrose metabolism is most important. In addition, these bacteria are often selected based on their ability to perform other metabolic functions. In cheese, degradation of proteins via proteolytic and peptidolytic enzymes is essential to develop proper aged cheese flavor and texture. In sour cream and cultured buttermilk manufacture, the ability of the starter culture bacteria to utilize citrate and to form the aroma compound diacetyl is required. Production of exopolysaccharides by strains of *S. thermophilus* is desirable in yogurt in order to impart greater viscosity. In wine-making, the conversion of malic acid to lactic acid by starter malolactic

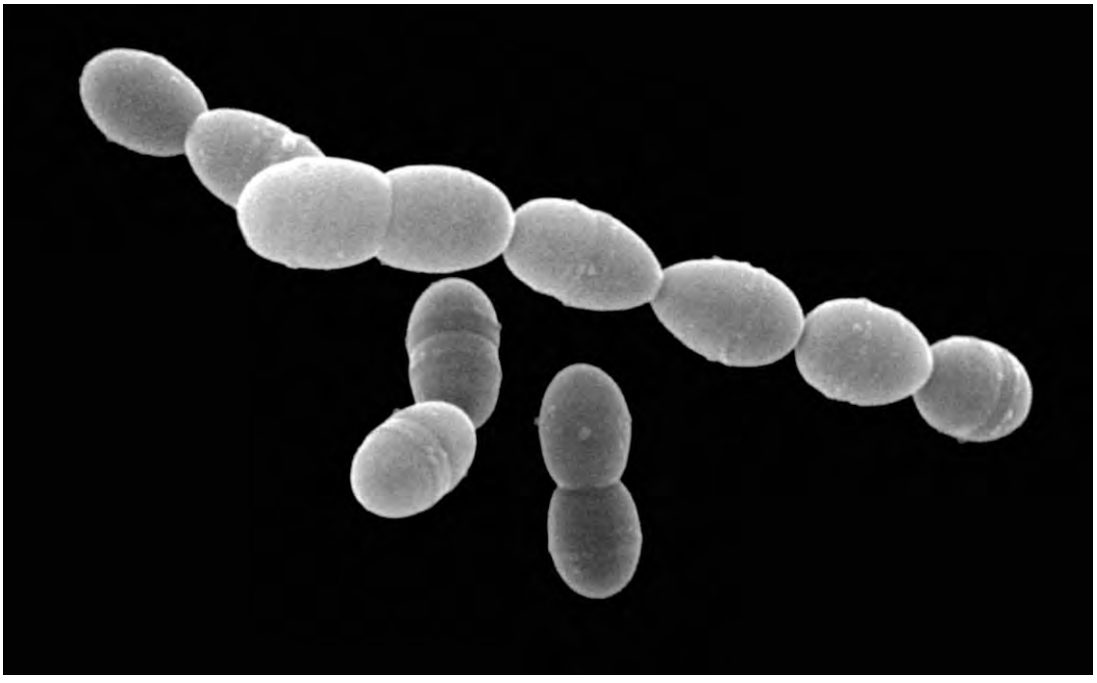

Figure 1 Electron micrograph of *Streptococcus thermophilus*.

bacteria is necessary to reduce the acidity of certain grapes.

Although LAB are clearly the most widely used and most important group of bacteria used as starter cultures in fermented foods, other bacteria are also used (Table 2). In the cheese industry, *Propionibacterium shermanni* and *Brevibacterium linens* are used in the Manufacture of Swiss (and related varieties) and Limburger, Muenster, and Brick cheeses, respectively (*See* **Cheeses**: Types of Cheese; Starter Cultures Employed in Cheese-making; Chemistry of Gel Formation; Chemistry and Microbiology of Maturation; Manufacture of Extra-hard Cheeses; Manufacture of Hard and Semi-hard Varieties of Cheese; Cheeses with 'Eyes'; Soft and Special Varieties; White Brined Varieties; Quarg and Fromage Frais; Processed Cheese; Dietary Importance; Mold-ripened Cheeses: Stilton and Related Varieties; Surface Mold-ripened Cheese Varieties). Some fermented sausage manufacturers add *Micrococcus* spp. to meat batters in order to develop flavor and color attributes (*See* **Fermented Foods**: Fermented Meat Products). The manufacture of vinegar requires *Acetobacter aceti*, which oxidizes the ethanol generated from alcohol fermentations. (*See* **Vinegar.**)

Yeast Starter Cultures

Nearly all alcoholic beverages are made using one or more strains of yeast (Table 2). Although many of the wines produced around the world are made via natural fermentations, relying on yeasts ordinarily present on the processing equipment or on the grape surface, the trend for most wine manufacturers has been to use starter culture yeasts, mainly strains of *Saccharomyces cerevisiae* (*See* **Wines**: Types of Table Wine; Production of Table Wines; Production of Sparkling Wines; Dietary Importance; Wine Tasting). Like LAB, strain selection is based primarily on the desired attributes of the final product. In addition, traits such as the ability to flocculate (and, hence, be easily separated from the wine), to grow at high sugar concentrations, and to produce adequate ethanol levels, are all considered. Yeast starter cultures are also used by the brewing industry, and although many large breweries maintain their own proprietary cultures, commercial ale (*S. cerevisiae*) and lager (*S. carlsbergensis*) cultures are widely used (*See* **Beers**: History and Types; Wort Production; Raw Materials; Chemistry of Brewing; Biochemistry of Fermentation; Microbreweries). Again, strain selection is based on characteristics relevant to the needs of the particular brewer, and these include flocculation, flavor development, and ethanol production rates. Bread manufacturers represent the other large user of yeast starter cultures (*See* **Bread**: Dough Mixing and Testing Operations; Breadmaking Processes; Chemistry of Baking; Sourdough Bread; Dietary Importance; Dough Fermentation). Yeast starter cultures used for bread-making are optimized for the production of CO_2 from sugar or starch, whereas brewing strains used in the production of alcohol are generally optimized for the production of ethanol.

Table 2 Other organisms used as starter cultures

Organism	*Application*
Bacteria	
Brevibacterium linens	Cheese: pigment, surface
Propionibacterium freudenreichii subsp. *shermanii*	Cheese: eyes in Swiss
Staphylococcus carnosus subsp. *carnosus*	Meat: acid, flavor, color
Mold	
Penicillium camemberti	Cheese: surface ripens white
Penicillium roqueforti	Cheese: blue veins, protease, lipase
Penicillium chrysogenum	Sausage
Aspergillus oryzae	Soy sauce, miso
Rhizopus microsporus subsp. *oligosporus*	Tempeh
Yeast	
Saccharomyces cerevisiae	Bread: carbon dioxide production
Saccharomyces cerevisiae	Ale beers
Saccharomyces carlsbergensis	Lager beers
Saccharomyces cerevisiae	Wine

Mold Starter Cultures

Mold cultures are used for several types of cheeses, including all varieties of blue cheese, as well as the white surface mold-ripened cheeses typified by Brie and Camembert (Table 2). Blue mold cheeses are made using spore suspensions of *Penicillium roqueforti* and white mold cheeses are made using *P. camemberti*. Mold cultures are also used in the production of so-called Asian or soy-derived fermented foods. Examples include tempeh, made using *Rhizopus microsporus* subsp. *oligosporus*, and miso and soy sauce, made using *Aspergillus oryzae*. Fungal starter cultures are also occasionally used for the production of European-style sausages and hams.

Types of Starter Cultures

One of the first requirements of a starter culture is that it rapidly initiates a fermentation. Thus, the initial inoculum must contain large numbers of microorganisms. As the volume of the food (or liquid) increases, then either larger starter culture volumes or greater

starter culture cell concentrations are required. Assuming that 1% inocula is ordinarily used, 10 kg (or 10 l) of starter culture would be sufficient to inoculate 1000 kg (or 1000 l) of substrate. Such an inoculum could easily be produced from a colony or culture slant, simply by successive transfers through intermediate cultures (i.e., 1 ml into 100 ml, and 100 ml into 10 l). Indeed, when pure cultures, rather than backslopping techniques, were introduced nearly a century ago in the cheese industry, the propagation of a 'mother' culture and intermediate cultures was the normal practice. However, as the size of the cheese industry increased, such that starter culture volumes of over 10 000 kg could be required for a single day's production, it no longer became feasible for cheese manufacturers to prepare cultures in this manner.

Currently, there are two general types of cultures that are manufactured and sold to the fermented food and beverage industries. The first type, often referred to as 'bulk cultures,' is used to inoculate a bulk tank, which is then used to inoculate the production vat (Figure 2). The bulk culture essentially represents the intermediate cultures that have traditionally been required. After a suitable incubation period in the appropriate culture medium, the fully grown bulk culture is used to inoculate the raw material. Provided that the starter culture organisms are protected against acid damage, oxygen, hydrogen peroxide, or other inhibitory end products, bulk cultures will remain viable for many hours. Thus, in the cheese industry, bulk cultures can be used to inoculate multiple cheese vats throughout a manufacturing day. Maintenance of culture viability is an important issue, however, and methods to insure that cultures remain active will be discussed below.

The second type of starter is designed to be inoculated directly into the food material, thus eliminating the need to grow bulk cultures. In the cheese industry, these are often referred to as 'direct-to-vat set' or DVS cultures. Of course, such cultures are also widely used in the sausage, baking, and other industries, where product volumes are usually small, compared to cheese manufacture. These cultures have the obvious advantage of eliminating the labor, hardware, and accessory problems that accompany the preparation and maintenance of bulk starter cultures. In order to provide a sufficient inoculum into large volumes of raw material, however, DVS cultures must be highly concentrated, especially those used for cheese manufacture. The added concentration steps may reduce culture viability, causing slow-starting fermentations. Direct-to-vat cultures are also more expensive to purchase than bulk cultures, and may not be economical for large-scale operations.

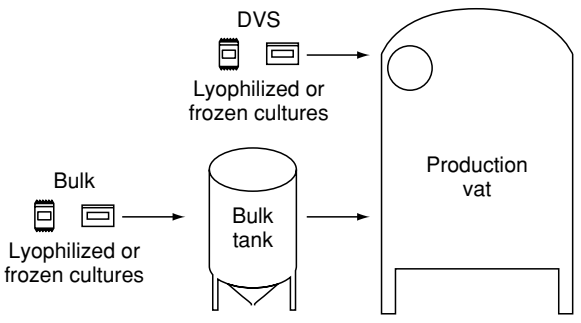

Figure 2 Bulk versus direct-to-vat set (DVS) culture preparation.

Mixed versus Defined Cultures

Mixed cultures contain historically tested blends of starter culture organisms. They can include several genera, species, or even strains of organisms. Often the actual identities of the organisms present in a mixed culture are not known, and the individual species may not have been characterized microbiologically or biochemically. Moreover, the proportion of different organisms in a mixed culture may not be constant from one product lot to another. Yet, mixed cultures containing undefined strains are still used as starter cultures for many applications because they have a proven history of successful use. When used in the manufacture of cheese, strains that are sensitive to a specific bacteriophage may quickly die out. However, other strains present in the mixed culture may be resistant to that particular phage and can then complete the fermentation. Frequent exposure to different bacteriophages, therefore, provides an effective mechanism for insuring that phage-resistant strains will be present in repeatedly propagated mixed cultures. These so-called P starter cultures are commonly used in the Netherlands for the manufacture of Gouda, Edam, and related cheese varieties.

The main disadvantage of mixed cultures is that they may yield finished products of inconsistent quality. In addition, fermentation rates may vary from day to day, affecting production schedules. For applications where time is flexible, and product quality variations are more tolerable, such as in small-scale cheese factories, mixed cultures are still widely used. However, in large production facilities where precise schedules are critical and consistent product quality is expected, mixed cultures have become less common. Instead, defined starter cultures have become prevalent.

Defined cultures simply refer to cultures that contain microbiologically characterized strains, which

are used individually or as blends. Most defined strains have been isolated from wild or mixed cultures, and characterized for metabolic properties, phage-resistance, and other desirable traits. When assembling a culture blend (containing multiple defined strains), all strains must be compatible. That is, one strain must not dominate over the others or produce inhibitory agents that would affect the growth of other organisms. Blends are often preferred over single or paired strains for their predictability and consistency. They are formulated to contain a broad spectrum of strains having resistance to different phage types, so that if one strain is affected, the other strains can complete the fermentation.

Manufacture of Starter Cultures

Bacterial starter cultures, including those produced for the dairy industry, are mass-produced in modern fermenters, under aseptic conditions, not unlike those used in the pharmaceutical industry for the production of biomedical products. Although the size of the fermentors may vary from as little as 10 l to over 300 l, the basic operational parameters and control features are consistent. For production of dairy starter cultures, milk- or whey-based media are most often used; however, molasses or corn syrup can also be used as the basal medium. Nutrients are usually added to the medium. Vitamins, especially water-soluble B-vitamins, are required for optimum growth of lactococci and lactobacilli, and some species of *Streptococcus, Leuconostoc*, and *Lactobacillus* also require specific amino acids. In addition, stability of some lactobacilli species during frozen storage may be enhanced when the growth medium contains Tween 80, a surfactant thought to stabilize cell membranes. Acids produced during culture growth can reduce final cell densities and decrease cell viability; thus the pH is controlled by the addition of alkali, usually gaseous NH_3, NH_4OH, Na_2CO_3, or KOH. Catalase is often added to degrade hydrogen peroxide that is generated by growth of some LAB, and oxygen incorporation is minimized. Cells are typically grown to achieve cell densities of 10^9 to 10^{10} cells per ml, and then packaged in a liquid form, concentrated or lyophilized (freeze-dried). LAB are ideally harvested either at late log phase or early stationary phase; however, the optimum harvest time depends on the specific organism. Liquid cultures are packaged in cans having volumes ranging from 100 to 500 ml, then rapidly frozen in liquid nitrogen ($< -196\,^{\circ}C$). It is important that the cultures remain frozen ($< -40\,^{\circ}C$) throughout storage, as well as during transportation, since freezing and thawing lead to the formation of ice crystals, which can puncture and kill cells. Thawing can occur even when the cells are held below $0\,^{\circ}C$, and so it is important to put frozen cultures promptly into a $-40\,^{\circ}C$ or $-70\,^{\circ}C$ freezer as soon as they arrive at the plant.

To produce frozen direct-to-vat cultures, cells are prepared via high-cell-density fermentations (as above), and then must be concentrated prior to freezing. Either continuous centrifugation or cross-flow membrane filtration is used. A washing step may be included to remove the spent medium. Cell densities of concentrated cultures can be as high as 10^{11} to 10^{12} cells per gram. Typically, a single can (usually 360 ml) can be used to inoculate 2000 kg of milk.

For lyophilization, cells are grown and harvested, as above, then freeze-dried under vacuum. Freeze drying is simply a process whereby water is removed from the frozen material by sublimation (*See* **Freeze-drying**: The Basic Process; Structural and Flavor (Flavour) Changes). It provides a means not only for concentrating cultures, but also preserves them due to the low water activity that is achieved. Freeze drying is a far gentler process compared to other drying technologies, such as spray drying. Freeze-dried cultures can contain from 10^9 to 10^{12} cells per gram. The cells are usually packaged in foil pouches or other oxygen-impermeable material. Lyophilized cells are best maintained at $-20\,^{\circ}C$, but are somewhat stable even at room temperature. Although lyophilized cultures have become popular as DVS starter cultures for cheese, yogurt, and cultured milk products, cells may be sluggish after inoculation, with a longer lag phase. To maintain cell viability for both frozen and lyophilized cells, cryoprotectant agents are usually added. Common cryoprotectant agents include glycerol, lactose, sucrose, trehalose, ascorbate, and glutamate. It is important to note that freezing and lyophilization parameters vary for different lactic acid starter bacteria. For example, *L. lactis* subsp. *lactis* is far more tolerant to freezing and lyophilization than *L. lactis* subsp. *cremoris*.

Criteria for Evaluating Culture Performance

In general, the job of most starter cultures is to carry out the desired fermentation, promptly and consistently, and to produce products having the appropriate level of fermentation end products and desired flavor and texture. The particular requirements for a given strain, however, depend entirely on the application for that culture (Table 3). For example, LAB used as dairy starter cultures are selected based not only on lactic acid production rates, but also on flavor- and texture-producing properties, salt-sensitivity, phage resistance, and durability during production and

Table 3 Desirable properties of starter cultures

Culture	*Property*
Dairy cultures	Lactic acid production rates
	Lag phase times
	Phage resistance
	Ease of manufacture
	Stability and consistency
	Produce desired flavor and texture
	Preservation tolerance
	Produce
	Lack of off-flavors
Meat cultures	Fast acidification
	Produce desired flavor
	Antimicrobial activity
Beer cultures	Rapid fermentation
	Produce desired flavor
	Preservation tolerance and stability
	Flocculation
	Lack of off-flavors
	Proper attentuation
	Growth at wide temperature range
	Tolerant to osmotic, temperature, and handling stresses
Wine cultures	Osmotolerant
	Ethanol-tolerant
	Flocculation, sedimentation
	Growth at low temperature
	Produce consistent flavor
	Malolactic fermentation
Bread cultures	Freeze-tolerant
	Produce desired flavor
	Produce adequate leavening

storage. The strains of *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* used as yogurt starter cultures, for example, are selected based, in part, on acid development rates, acetaldehyde production, exopolysaccharide synthesis, and lack of postfermentation acidity. However, different strains of these bacteria may be used for Mozzarella and Swiss cheese manufacture, since the latter products have their own requirements.

To assess functional properties of dairy cultures, several tests are routinely performed. Acid-production rates are easily determined by inoculating heat-treated milk with a suitable (and standardized) inoculum (e.g., 0.1–3.0%), incubating the milk at a given temperature, and then either measuring the decrease in pH as a function of time or simply by determining the pH or titratable acidity after a specific incubation period. Lag times can also be estimated and are useful in determining the effects of frozen or lyophilized storage on culture activity. Another critical test is determination of bacteriophage resistance, especially under conditions that simulate cheese making. In the Heap–Lawrence challenge test, cells are inoculated into culture tubes of milk, representative or factory phage mixtures are added, and the tubes are incubated according to a cheese production time–temperature profile. After incubation, the entire process is repeated up to six times. An increase in pH (less acid produced) in successive cycles indicates that the culture has become sensitive to bacteriophage and should be removed from the rotation.

Yeast cultures used for wine, beer, and bread should ferment rapidly and have good sensory properties and good storage stability. In addition, wine yeasts and beer yeasts should sediment or flocculate to enhance their separation and to reduce autolysis. Flocculation is a heritable trait, requiring several genes that encode for proteins involved in cell aggregation. Flocculated cells sediment much faster relative to the free cells. Other performance characteristics will depend on the specific product. Many wine yeasts, for example, are selected based on growth at low temperatures (10–14 °C), resistance to sulfiting agents, and high ethanol tolerance. Beer yeasts should also be able to grow at low temperature, produce flavorful end products, and deplete fermentable carbohydrates (good attenuation). Bread yeasts should withstand freezing (so that frozen bread doughs will rise after thawing).

Using Starter Cultures

As described above, many starter culture preparations, whether in a frozen or lyophilized form, are simply added directly into the food material. Frozen canned cultures are routinely thawed in cold chlorinated water immediately prior to use. Lyophilized cultures may require additional stirring or mixing in the vat to facilitate hydration. For bulk cultures, additional steps are required to insure that the organisms have reached sufficient levels and viability. In the dairy industry, specialized culture media are almost always used for bulk starter preparation, not only to provide optimum growth conditions, but also to protect the cells from acid damage and from infection by lytic bacteriophage. The bulk culture media is not much different from the media used by the culture supplier to mass-produce starter culture cells. A basal medium containing a fermentable carbohydrate (lactose, glucose, or sucrose) is supplemented with additional sources of nitrogen, vitamins, minerals, and other nutrients. Commercially available yeast extract is an excellent source of many of these materials. Phosphate salts are frequently added to provide buffering as well as chelating properties.

Controlling pH during bulk culture preparation is especially important since most LAB grow best above pH 6.0, and can lose viability if held at pH values below 5.0. The use of acid-injured starter cultures in cheese manufacture will result in a long lag phase and

prolonged fermentation times. Several notable approaches have been developed to minimize or prevent acid damage to lactic starter cultures. The first approach, known in the industry as 'external pH control,' relies on the addition of alkaline solutions, such as ammonium hydroxide, or ammonia gas, into the bulk culture tank during fermentative growth. The tank is fitted with a pH electrode, and a pH-monitoring device that sends a signal to a pump when the pH has decreased below a critical threshold. Alkali is then added until an upper pH limit is reached. Although the range at which the pH is controlled depends on the specific organisms, most external control systems maintain a pH between 5.8 and 6.2. Thus, as cells grow and produce acid, the pH never falls below the set threshold. Such systems yield starter cultures having high cell densities (as much as 10 times more cells) with enhanced viability. Lactate salts that accumulate as a byproduct result in higher media osmolality and ionic strength, but these effects do not appear to have any significant negative effects on cell viability. Due to the hardware expenses (pH electrodes, pumps, pH-monitoring devices) inherent in external pH control systems, however, a less expensive alternative is simply to manually neutralize the bulk culture tank. This is done by a one- or two-time addition of neutralizing agent (sodium or potassium hydroxide) that raises the pH from around 5.0 to near 7.0.

Although most culture media ordinarily contain phosphate or citrate salts that provide some buffering, it is not possible to add enough of these salts to maintain a near-neutral pH during growth by LAB. This is because high phosphate concentrations are inhibitory to some LAB used as starter cultures. Media can, however, still be formulated to contain buffer agents provided that the buffers are either in an insoluble or encapsulated form. These so-called internal pH control systems typically contain carbonate or phosphate salts (e.g., sodium carbonate or trimagnesium phosphate) that are released into the medium as a function of low pH, such that the pH of the culture medium is maintained above 5.0. Internal pH control systems have the added advantage of not requiring the expensive external pH control apparatus. Agitation is required, however, to prevent the buffer agents from settling out during bulk culture growth.

Although equipment and labor costs for external pH control systems and for internal pH control media are higher than those for conventional culture preparation systems, several advantages are realized. Since higher cell densities are achieved, and cell viability is enhanced, less culture is needed. In addition, because the cells are maintained in a viable state, they can be used for a longer period of time.

Bacteriophage

Bacteriophage are viruses that can infect and eventually lyse bacteria (**Figure 3**). They can multiply rapidly and decimate the starter culture. Bacteriophage problems during bulk culture production are relatively rare because culture media are heated to a high temperature and aseptic conditions (i.e., closed, sterilizable vats) are usually employed. However, milk used for cheese manufacture receives only a modest heat treatment, and cheesemaking, in general, is an 'open' process, providing ready access by air- or whey-borne phage. Thus, in most modern cheese production factories, where vats are filled and refilled during the production day, phage may have ample opportunity to propagate and to reach high levels, resulting in slow or arrested fermentations and poor-quality product. Until recently, lactococcal bacteriophage were the main concern; however, increased production of Mozzarella cheese, yogurt, and other products that rely on thermophilic starter cultures has led to the proliferation of phages against *S. thermophilus* and *L. bulgaricus*.

For nearly 50 years, problems caused by bacteriophage have been the driving force for much of the

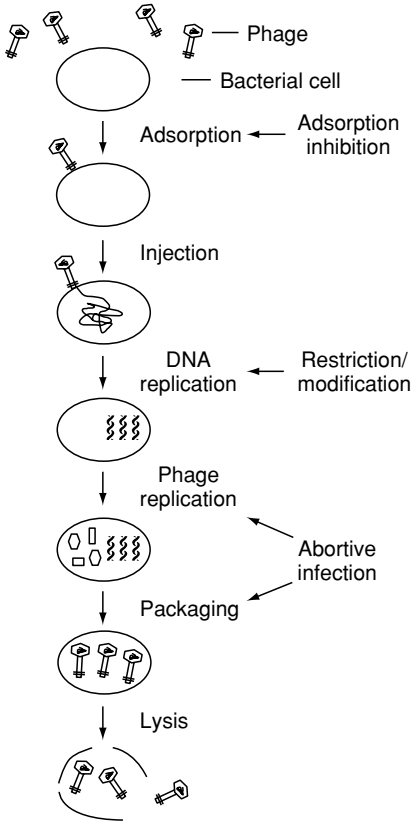

Figure 3 Lytic cycle of lactic bacteriophage and steps at which lactococcal phage resistance mechanisms operate.

research on starter cultures. The dairy starter culture industry and the cheese industry have adopted several strategies to prevent or reduce the impact of bacteriophage problems. Strict sanitation and attention to plant design are the first lines of defense against phage. Ideally, rooms used to 'step up' starter cultures to the concentrations needed for production are isolated from the rest of the processing facility. Since phage are commonly transmitted via air, these contained areas should be held under positive pressure, and filtered air should be used both for the intake into the starter room, as well as into the starter tanks. The production rooms should be designed such that 'downstream' product and waste flow do not contaminate the starter preparation room.

Phage-inhibitory media have been embraced as another means of phage control. Phage require calcium ions to attach to, and subsequently invade, their bacterial hosts. In 1956, the US Department of Agriculture introduced the idea of using phosphates in culture media to bind calcium, thus making the calcium ions unavailable for the phage. In addition to their role in binding calcium, the phosphate salts in phage-inhibitory media provide buffering capacity. Citrate salts provide similar protection. Phage-control strategies are summarized in Table 4.

Most starter culture strains are only sensitive to a specific bacteriophage, and some strains are naturally resistant, due to one or more of several types of phage-resistant mechanisms (Figure 3). In addition, sensitive strains can become resistant by frequent exposure to lytic phage (bacteriophage-insensitive mutants or BIM) or by genetic manipulation. If the phage-resistant variants still have good cheese-making properties (which must be tested), then these strains can be introduced as a starter culture, usually as one of several other defined phage-resistant strains. As described above, multiple defined strain starters contain as many as five different strains, selected largely on the basis of being phage-unrelated. These cultures can be used on a continuous basis providing consistent product quality. It is important, however, to monitor phage levels in the cheese whey on a regular daily basis, so that strains that become phage-sensitive can be removed from the mixture and replaced by a resistant strain.

Additional protection against phage can be achieved by rotating cultures, meaning that a single culture (containing as many as five or six different strains) is used on a given day and then followed by successive cultures containing strains whose phage-sensitivity pattern is different from the preceding culture. Thus, since phage proliferation requires susceptible host strains, removing those strains from the cheese production environment will reduce the background level and accumulation of phages such that normal fermentation rates can be achieved. However, this practice is constrained by the limited availability of phage-unrelated strains, as well as by less consistent product quality. Many of the defined, phage-resistant cultures now contain only two or three strains.

New Developments in Starter Culture Technology

The pioneering work of McKay and coworkers led to the discovery that most of the phenotypic traits necessary for lactic starter cultures, including lactose fermentation, casein hydrolysis, and diacetyl formation, were encoded by plasmid DNA. The Klaenhammer group subsequently demonstrated that phage-resistant determinants were also plasmid-encoded. These discoveries, and the development of gene-exchange and gene-transfer techniques, made it possible to manipulate the genetic properties of lactic starter cultures (*See* **Biotechnology in Food Production**). However, because of regulatory and consumer concerns regarding genetic modification of foods, the applications of these technologies have generally been restricted to noninvasive approaches. (*See* **Genetically Modified Foods.**)

Engineering Phage Resistance

Of particular importance has been the construction of genetically modified, phage-resistant lactococcal strains. In the early 1980s, the Klaenhammer group identified a 46-kb plasmid in *Lactococcus lactis* subsp. *lactis* that encoded for a heat-sensitive abortive infection mechanism and that conferred resistance to specific bacteriophage. This self-transmissible

Table 4 Phage-control strategies

Method	*Purpose*
Sanitation	Kill and remove phage in plant environment
Plant design	Keep phage out of production area, prevent cross-contamination
Phage-inhibitory media	Prevent phage from attaching to and infecting culture cells
Phage-resistant cultures	Design starter cultures cells that will grow and perform well even in presence of phage
Culture rotation	Prevent proliferation of phage by limiting access to suitable host

plasmid, named p TR2030, was later found to contain other regions, including genes coding for a restriction and modification system, that also conferred bacteriophage resistance. Transfer of the plasmid into a phage-sensitive, cheesemaking strain via conjugal mating resulted in fast lactose-fermenting transconjugants having resistance to a broad range of lytic industrial phages. Although this approach was successful for a time, phages eventually appeared that could overcome the host resistance. In fact, due to the dynamic nature of phage–host interactions and the nonsterile manner in which cheese manufacturing occurs, the propensity of lytic phages to adapt to and ultimately appear against formerly resistant strains is nearly inevitable.

Several recent strategies have since been described to provide more long-term phage protection. One approach is simply to introduce or 'stack' two plasmids, each carrying phage resistance mechanisms against different phage types, into a single strain. In contrast, different phage-resistant genes can be introduced individually into a single strain generating several isogenic phage-resistant derivatives that can then be used in a rotation scheme. Since each strain harbors genes effective against different phage types, the same parental strain can be used on a continuous basis. Another system, called Per, relies on the integration of a phage DNA fragment (containing the origin of replication region or *ori* site) into the genome of the host strain. Ordinarily, when a bacterium is infected by bacteriophage, phage DNA replication begins at the *ori* site. However, in the Per strains, phage development is stalled, since the chromosomal copy of the *ori* site acts as a decoy for the phage replication machinery. Antisense RNA strategies function in a similar manner, in that the modified cell is directed to transcribe an antisense messenger RNA that is complementary and capable of hybridizing to the normally transcribed RNA. Recently, a triggered-suicide system was described that, when activated by the presence of a lytic phage, causes the infected cells to lyse and die before phage replication has occurred.

Strain Identification

Advances in nucleic acid-based bacterial fingerprinting methods have led to new identification tools and renewed interest in bacterial taxonomy. The ability to distinguish between strains of the same species is important not only for identification purposes, but also because it provides a basis for understanding the phylogenetic and evolutionary relationships between LAB. Although morphological, biochemical, and other phenotypic characteristics remain useful for genus and species identification, molecular approaches that rely on nucleotide sequences have proven to be more reliable, more reproducible, and more robust. Several techniques, in particular, are widely used, including pulsed-field gel electrophoresis (PFGE), restriction fragment length polymorphism (RFLP), ribotyping, 16S ribosomal RNA sequence analysis, and various polymerase chain reaction-based protocols. More precise methods of strain identification have also become important as proprietary organisms are developed with unique characteristics and production capabilities.

Encapsulated and Immobilized Cells

Another manner in which starter cultures can be produced and used is to encapsulate or surround cells in inert materials, such as alginate beads. Alternatively, starter culture cells can be adsorbed to a carrier surface or covalently attached to inert support materials. In theory, encapsulated cells may be less sensitive to phage infections, be more stable during storage, and be recovered after fermentation for reuse in subsequent fermentations. However, immobilization procedures can be costly and may alter starter culture metabolism. For these reasons, immobilized culture technology has not yet been adopted in the dairy industry.

It is worth noting that a natural form of encapsulated starter culture has long existed in the form of kefir grains. Kefir, a fluid-fermented product widely consumed in Russia and Eastern Europe, is traditionally made by inoculating milk with kefir grains. Kefir grains are irregularly shaped, polysaccharide-containing particles up to 15 mm in diameter that harbor a complex microflora, including homo- and heterofermentative LAB and yeasts. Kefir grains can be removed from the completed fermentation by filtration or sieving, washed, and reused in subsequent fermentations. Pure cultures, usually containing strains of *Lactobacillus* spp. and *Lactococcus* spp., are now available commercially, and are commonly used in the USA for kefir manufacture.

Probiotics and Antimicrobials

Although starter cultures usually consist of those organisms required to perform a specific fermentation, the same technology, for the most part, is used to produce bifidobacteria and other probiotic cultures, even though they are used differently (*See* ***Bifidobacteria* in Foods; Probiotics**). Additionally, it has long been known that some strains of LAB produce compounds that inhibit other microorganisms. One particular class of inhibitory compounds are the

bacteriocins, proteinaceous materials produced by an organism that inhibits other closely related organisms. Nisin, a bacteriocin produced by strains of *Lactococcus lactis*, is approved for use in processed cheese and other foods as a direct food additive (*See* **Nisin**). LAB that produce nisin and other bacteriocins can be used as part of a lactic acid-producing starter culture or as an adjunct in dairy, meat, and other foods to inhibit pathogens as well as spoilage organisms. In some cases, the organism produces bacteriocin in the food, but does not produce acids or other fermentation end products that would alter the sensory characteristics of the product. Alternatively, the organism can be grown in a dairy- or nondairy-based medium, and the fermented medium containing organic acids and bacteriocin is subsequently pasteurized and concentrated. Viable cells are absent, but the material, when added to foods, would still contribute antimicrobial activity. These 'bioprotective' products have been marketed as shelf-life extenders, although pathogens may also be inhibited. Most of these products are effective only against Gram-positive bacteria; however, some products also inhibit Gram-negative spoilage bacteria, including psychrotrophs.

STERILIZATION OF FOODS

M N Ramesh, Central Food Technological Research Institute, Mysore, India

Background

Sterilization is the complete destruction or elimination of all viable organisms in/on an object being sterilized. Sterilization destroys yeasts, molds, vegetative bacteria, and spore formers, and allows the food processor to store and distribute the products at ambient temperatures, thus extending the shelf-life. Sterilization procedures involve the use of heat, radiation, or chemicals, or physical removal of cells. The sterilization process involves four distinct stages. First, the product must be heated at 110–125 °C to ensure sterilization. After this, the product requires a few minutes to equilibrate, since the surface will be hotter, and the central portion of the container will still be cool. The equilibration stage allows a reduction in the temperature gradient. Next, the product must be held

at this temperature for a certain period of time to ensure a predetermined sterilization value designated by the F_0 value. Finally, the product has to be cooled down mainly to arrest further heat treatment and to avoid bursting of the container at hot conditions.

The basic principles of sterilization technology as applied to food processing are as follows:

- The processed product must be free from microorganisms capable of producing food poisoning toxins and those microorganisms that cause food spoilage during the product's shelf-life, until it is consumed.
- *Clostridium botulinum* spores are capable of growing in low acid (pH > 4.6) products during storage and hence must be heat-treated to the equivalent of at least 121.1 °C for 3 min (an F_0 value of 3) to achieve a 12-decimal reduction in the numbers of the microorganism.
- The processing conditions should be applied to the slowest-heating point, referred to as the 'cold point.' This facilitates the assumption that, when the slowest heating part is sterilized, by exposing it to the required time–temperature profile, the rest of the product will be sterilized.

Practically, complete sterilization leads to a deterioration in product quality and nutrient retention (Figure 1). Hence, in practice, commercial sterility is defined as a product that has been processed so that, under normal conditions, the product will neither spoil nor endanger the health of the consumer. The pH of the product is an important factor in determining the severity of the sterilization process.

Theory of Sterilization

Thermal treatment of food products to render them free of pathogenic microorganisms has been practiced for several years. However, a method to quantify the microbial destruction that takes place during thermal treatment has only been understood for the last 75 years. In order to determine the amount of microbial destruction that a thermal treatment delivers to a process, an understanding of the amount of heat delivered to every portion of the food product and the destruction kinetics of the microorganisms of interest is required. The amount of heat delivered by a food process is dependent on the way in which the product is heated and its physical nature. Process-dependent factors can include: processing equipment design, type of heating media, container, food size and shape, product composition, and viscosity (conduction- or convection-heated). The thermal destruction kinetics of microorganisms or their ability to be killed within the food matrix is dependent on a number of factors, including: pH of the product, levels and types of preservatives, water activity, the previous growth conditions of the microorganisms of concern, product composition, and competitive microorganisms.

The two types of bacteria of concern in food preservation are organisms of public health significance and spoilage-causing bacteria. In low-acid foods with a pH greater than 4.6, the organism of public health significance is *Clostridium botulinum*. Canned foods are processed, based on the survival probability for *C. botulinum* of 10^{-12}, or one survivor in 10^{12} cans. The organism most frequently used to characterize low-acid food spoilage by mesophilic spore-formers is PA 3679, a strain of *C. sporogenes*. Most food companies accept thermal inactivation of 10^{-5} for mesophilic spore-formers and 10^{-2} for thermophilic spore-formers. The processing time depends on the bioburden of the most resistant bacteria in a particular food, the spoilage risk involved, and whether food can support the growth of potential contaminating bacteria. Although a large amount of research work has been carried out on the influence of different factors on the processing time and the corresponding sterilization value, a number of uncertainties still exist on the application of these factors to arrive scientifically at the exact processing conditions. In order to avoid any risk resulting from these uncertainties, a safety factor is added to increase the processing time to sterilize the food product completely, which invariably reduces the nutrient content and the increase in energy cost.

Decimal Reduction Time or *D* value

The decimal reduction time, or D value, is the time at any temperature to destroy 90% of the spores or vegetative cells of a given organism. It is equal to the number of minutes for the survivor curve to traverse

one log cycle and can be calculated from the reciprocal of the slope of the survivors, assuming a logarithmic death rate:

$$N = N_0 e^{-kt},$$

where N is the final number of survivors after heat treatment, N_0 is the initial number of organisms, e is the exponential function, k is the thermal death rate coefficient (traditionally measured in s^{-1}), and t is the processing time. Rearranging gives

$$\log\ N = \log\ N_0 - (60kt/2.3).$$

Plotting log N against t in minutes gives the slope $-60k/2.3\,\text{min}^{-1}$. The inverse of the slope is

$$D = 2.3/60k\ \text{min}.$$

Thermal Death Time Constant or *z* Value

The D value may be calculated from the inverse of the slope of the survivor curve by regression analysis of the data points. If a presence/absence (growth/no growth) method is used to estimate the number of survivors, N_u can be calculated using the equation

$$N_u = 2.303 \log(n/r),$$

where n is the number of units heated, r is the number of sterile units, and N_u is the most probable number of survivors. The graphical representation of the D-value concept is indicated in Figure 2.

The change in D value with temperature can be obtained by plotting log D against temperature. The z value is the number of degrees for the thermal resistance curve to transverse one log cycle and is equal to the reciprocal of the slope of the curve. The equation applied to the thermal resistance curve is given by

$$\log\ D_{\text{Ref}} = \log\ D_T = 1/[z(T - T_{\text{Ref}})],$$

where D_{Ref} is the D value at the reference temperature (T_{Ref} of 121.1 °C), D_T is the D value at any other temperature, T, and z is the thermal death time constant.

A graphical representation of the D-value concept is shown in Figure 3.

Heat Resistance of Microorganisms

The most important bacterial spore former with respect to heat processing is *Clostridium botulinum*, because of the potent neurotoxin that it produces. The organism occurs in seven distinct stereotypes A–G, which are further subdivided into proteolytic and nonproteolytic strains. The most heat-resistant spores are those produced by type A and the proteolytic B strains. The D value at 121.1 °C of the most resistant strains is generally considered to be 0.21 min. *Clostridium sporogenes*, which is closely related to the proteolytic strains, produces spores that are more heat-resistant. The D value of the spores at 121.1 C° can be up to 1.5 min. *C. sporogenes* has been reported to be the most common mesophilic putrefactive anaerobe in the spoilage of low-acid (pH $\geq$ 4.6) canned foods.

The butyric anaerobes (*C. butyricum*, *C. beijerinckii*, and *C. pasteurianum*) are usually associated with spoilage of products with pH values between 3.9 and 4.6 (e.g., tomatoes and pears), producing blown cans and a butyric odor. Another organism that causes spoilage of products down to pH 4.2, *Bacillus coagulans*, has been reported to have a D value at 98.9 °C of 3.1 min and a z value of 16.1C°. Other mesophilic *Bacillus* species that produce heat-resistant spores and have been implicated in food poisoning outbreaks are *B. subtilis* and *B. licheniformis*. Spores of

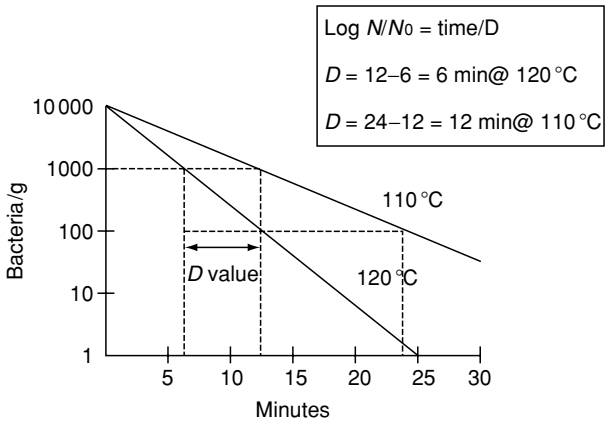

Figure 2 *D*-value of a microorganism. From http://courses.che.umn.edu/00fscn1102-1s/pdf_files/topic_11_Past_and_-Ster.pdf with permission.

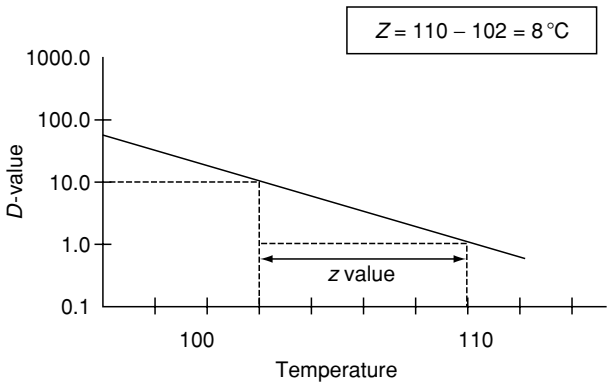

Figure 3 *z*-value of a microorganism. From http://courses.che.umn.edu/00fscn1102-1s/pdf_files/topic_11_Past_and_-Ster.pdf with permission.

the thermophilic organisms that have an optimum growth temperature of ≈55 °C are usually much more resistant to wet heat than mesophilic organisms.

The most resistant thermophile is *Clostridium thermosaccharolyticum*, which produces blown cans and a butyric or 'cheesy' odor, with D values as high as 68–195 min at 121.1 °C. The spores of *Bacillus stearothermophilus* have often been used in process evaluation studies because of their high heat resistance. The organism can cause spoilage of products with pH values > 5.3. Another unusual bacterial spore former is *Sporolactobacillus inulinus*. This organism has been isolated from a number of food and environmental sources and has been reported to have a D value at 90 °C of 5.1 min and a z value of 13 C°. Quality-control personnel should be aware, therefore, that not all isolates of Gram–positive spore-forming rods belong to the genera *Bacillus* or *Clostridium*. Typical D and z values for some of the spore formers are listed in Table 1.

Lethal Rate

Using the z value, the lethal rate, L, can be calculated from

$$L = \log^{-1}[((T - T_{\text{Ref}})/z)].$$

The lethal rate is a measure of the lethality of any temperature, T, relative to the reference temperature T_{Ref}. For example, for a reference temperature of 121.1 °C and a z of 10C °, the lethal rate at 111.1 °C will be

$$\log^{-1}[(111.1 - 121.1)/10)] = 0.1.$$

Thus, 1 min at 111.1 °C is worth 0.1 min at 121.1 °C in terms of lethality. Note that z is written C ° and not °C, since z represents a change of 10 Centigrade degrees in the above example and not a temperature of 10 degrees Centigrade.

F Value

The symbol F designates the equivalent in minutes at 121.1 °C of the combined lethalities of all time–temperature relationships at the point of slowest heating for a product during heat processing. Thus, the F value is a measure of the killing power of a heat process. The term F_c denotes the F value at the center of a pack, F_0 denotes the equivalent F value in minutes at 121.1 °C, and F_s denotes the integrated lethality of heat received by all points in a container. F_s can be related to the D value by the equation

$$F_s = D_{\text{Ref}}(\log\ N_0 - \log\ N),$$

where D_{Ref} is the D value at 121.1 °C, log N_0 is log of the initial number of organisms, and log N is the log of the final number of surviving organisms. In the above equation, F_s can be considered as equivalent to F_0 or F_c in rapid heating systems such as the thermoresistometer. The F_0 value of a process can be obtained in practice by summing the lethal rates at 1-min intervals from the heating and cooling curve of a product during a heat process. This is a simplified view, and process calculations in the industry involve rather more complicated mathematics and usually do not include the cooling curve contribution to the process. The process time can be calculated using the equation

Table 1 Typical heat resistances of selected spore formers

Organism	*Medium*	*Temperature (°C)*	D *value (min)*	z *(C °)*
Clostriduim sporogenes (PA 3679)	Several substrates including pea purée	104.4–143.3	0.75–2.03	9.0–14.7
	Phosphate buffer pH 7	112.8–148.9	1.06	9.3

From Brown KL (1991) Principles of heat preservation. In: Rees JAG and Bettison J (eds) *Processing and Packaging of Heat Preserved Foods*, pp. 15–49. New York: Van Nostrand Reinhold.

$$B = f_h(\log\ J_{ih}I_h - \log\ g_c),$$

where B is the thermal process time corrected for the time to bring the retort to the process temperature, f_h is the time in minutes for the semilog heating curve to traverse one log cycle, J_{ih} is the heating lag factor, I_h is difference in temperature between the retort and the food at the start of process and g_c is the difference between the retort temperature and the maximum temperature reached by the food at the center. In the processing of low-acid foods with a pH value of 4.6 or above, a process equivalent in lethality to at least F_0 of 3 min must be applied to minimize the risk of spores of *C. botulinum*. An F value determined on the basis of one z value to an F value determined on the basis of a second z value can be converted using the appropriate formula.

Cook Value or *C* Value

Mansfield introduced the concept of a lethality-like value for sensory degradation, termed the cook value or C value. This has a reference temperature of 100 °C and a z value typically in the range 20–40C°.

$$C_{100} = 10^{(T-100)/z}\text{c min.}$$

The processing conditions mainly depend on the pH value of the product.

Acid Products (pH < 4.6)

At a pH below 4.6, the risk of growth and toxin production by *C. botulinum* is extremely low, and for products with pH values between 4.0 and 4.6, processes are aimed at controlling the survival and growth of spore forming organisms such as *Bacillus coagulans, Bacillus polymyxa, Bacillus macerans*, and the butyric anaerobes such as *C. butyricum* and *C. pasteurianum*. A heat process of $F^{10}_{121} = 0.7$ is regarded as adequate for this purpose, and a process equivalent to 10 min at 93.3 °C ($F^{8.3}_{93.3} = 5$) when the pH is between 4.0 and 4.3. However, more severe processes may be required to control excessive contamination. In a previous study of nine cases of botulism from products with pH below 4.6, including canned pears, apricots, tomato ketchup, tomato–onion chili sauce, and green tomatoes, it was suggested that growth of spoilage organisms raised the pH to a level at which dormant spores of *C. botulinum* could germinate and grow. Below pH 3.7, the processor is concerned with the control of nonsporing bacteria, yeasts, and molds. These may be generally controlled by heat processes at temperatures below 100 °C.

Methods of Sterilization

The food sterilization methods are divided into two categories: sterilization by heating (thermal processing) and sterilization without heating (nonthermal processing). Thermal processing is widely practiced these days, in spite of some problems such as that the process of heating might reduce nutrition or deteriorate the quality of foods, and that it is ineffective against certain types of bacteria. Nonthermal processing is considered an effective method that does not cause any deterioration of quality, in contrast with thermal processing. However, no reports have shown the effect of sterilization without heating. Research on the evaluation of the technology of nonthermal sterilization without heating is widely being pursued internationally.

Thermal processing is divided further into two categories: in-container sterilization (processing). The principles involved in thermal sterilization of foods remain the same whether attempting to sterilize products in containers or sterilize products prior to filling in the final container (aseptic processing). Thus, it is necessary to know the thermal destruction rate for the microorganisms of consequence in the food being processed. The procedures necessary for acquisition of such data are available. It is important to use this information properly so that the appropriate time and temperature for destruction of the organisms can be achieved. Sterilization procedures for products in containers usually require longer times, since the heat transfer to the product is relatively slow. Sterilization prior to filling in the container, as accomplished in aseptic processing, requires relatively short heating periods. This sterilization process is usually accomplished by heating the product rapidly to 130–145 °C, holding for an appropriate time, then rapidly cooling the product. The specific product will determine the actual combination of temperature and time required for sterilization.

Product heating is accomplished by either indirect or direct heat exchange. In liquid homogeneous products, indirect heating occurs when the product to be heated and the heating medium are separated by the heating surface. This type of heating is accomplished using a scraped surface, tubular, or plate heat exchanger. Direct heat exchange is achieved by placing the heating medium directly into the product or vice versa. In either case, the added water from the steam must be either removed or accounted for in the formulation. The specific type of heating used is usually dictated by the nature of the product and the economics of operation. Following heating to the sterilization temperature, the product must be held at this temperature for a specific length of time to

accomplish sterilization. The sterilization time in continuous-flow aseptic systems is obtained by conveying the product through a nonheating pipe attached to the heating system. This pipe is called the holding tube and is of a specified uniform diameter and length. Its capacity is such that the fastest particle is held at the maximum time required to sterilize the product. The length of time for which the product remains in the tube is dependent not only on the holding capacity of the tube and the rate at which the product is pumped through the tube, but also on the manner in which the product flows through the tube.

Thermal Processing

During sterilization, the type of heat, time of application, and temperature to ensure destruction of all microorganisms are very important. Endospores of bacteria are considered the most thermoduric of all cells, so their destruction guarantees sterility. The lethal temperature varies for microorganisms. The time required to kill the microorganisms depends on the number of organisms, species, nature of the product being heated, pH, and temperature. Whenever heat is used to control microbial growth, inevitably both time and temperature are considered.

Sterilization (boiling, autoclaving, hot air oven) kills all microorganisms with heat and is commonly employed in canning, bottling, and other sterile packaging procedures. Heat sterilization is the unit operation in which foods are heated at a sufficiently high temperature and for a sufficiently long time to destroy microbial and enzyme activity.

Sterilized foods have a longer shelf-life but undergo substantial changes in quality. Developments in processing technology therefore aim to reduce the overall processing time. The effects of microbial heat resistance on the design of heat-sterilization procedures and equipment are an important aspect of sterilization in both in-container heat sterilization and aseptic processing.

In order to determine the process time for a given food, it is necessary to obtain information on both the heat resistance of microorganisms and the rate of heat penetration into the food. A process that reduces cell numbers by eight decimal reductions (an 8D process), applied to a raw material containing 10^5 spores per container would reduce microbial numbers to 10^{-3} per container, or one microorganism in every thousand containers. Commercial sterility, therefore, means that the vast majority of containers are sterile, but there is a probability that nonpathogenic cells survive the heat treatment in a predetermined number of containers. A 12D process is used when *C. botulinum* is likely to be present but in foods that contain less heat-resistant spoilage microorganisms. In addition to information on heat resistance, it is necessary to collect data describing the rate of heat penetration into the food in order to calculate the processing time needed for commercial sterility.

Retorting (Heat Processing)

The most widely used system for sterilization uses overpressure retorts or agitating sterilizers. Generally, the overpressure retorts are of the batch type with steam or pressurized hot water as the heating media. The pressure in the retort is maintained during the entire processing cycle, with steam during the heating cycle and with compressed air during the cooling cycle. Agitating sterilizers gently move the product within the container, which facilitates more uniform heating and cooling owing to better heat transfer. This reduces the come-up time, delivering an improved product.

Heating by Saturated Steam

Latent heat is transferred to food when saturated steam condenses on the outside of the container. If air is trapped inside the retort, it forms an insulating boundary film around the cans, which prevents the steam from condensing and causes under processing of the food. It also produces a lower temperature than that obtained with saturated steam. It is therefore important that all air be removed. Sterilization requires a temperature of 121.1 °C. This creates pressure inside the container, and if the pressure on the outside of the container is less than that inside, the container will expand and subsequently break. This is more critical in glass jars and flexible containers like pouches and plastic cans. To avoid this situation, an overhead pressure of 230–250 kPa is applied to equalize the internal pressure.

Aseptic Processing

Conventional retorting of A2 cans of vegetable soup requires 70 min at 121 °C to achieve an F_0 value of 7 min, followed by cooling for 50 min. Aseptic processing in a scraped-surface heat exchanger at 140 °C for 5 s gives an F_0 value of 9 min. Increasing the can size to A10 increases the processing time to 218 min, whereas with aseptic processing, the sterilization time is the same. In aseptic processing, containers are not required to withstand sterilization conditions. Cartons are presterilized with hydrogen peroxide, and filling machines are enclosed and maintained in a sterile condition by ultraviolet light and filtered air.

A positive air pressure is maintained in the filling machine to prevent entry of contaminants. The process is successfully applied to liquid and small-particulate foods, but problems remain with larger pieces of solid food.

Nonthermal Processing

Nonthermal methods for the preservation of foods are under intense research to evaluate their potential as an alternative or complementary process to traditional methods of food preservation. Traditionally, most preserved foods are thermally processed by subjecting the food to a temperature of 60–100 °C for a few seconds to minutes. During this period, a large amount of energy is transferred to the food. This energy may trigger unwanted reactions in the food, leading to undesirable changes or formation of byproducts. For example, thermally processed milk may have a cooked flavor accompanied by a loss of vitamins, essential nutrients, and flavors. The fact that the shelf-life and the quality of food are important to consumers gave birth to the concept of preserving foods using nonthermal methods. Nonthermal methods of food preservation are currently being developed to eliminate, or at least minimize, the quality degradation of foods that results from thermal processing.

During nonthermal processing, the temperature of the food is held below the temperature normally used in thermal processing. Therefore, the quality degradation expected from high temperatures is minimal in nonthermal processing. The vitamins, essential nutrients, and flavors are expected to undergo minimal, or no, changes during nonthermal processing. In addition, nonthermal processes use less energy than thermal processes. Foods can be processed nonthermally using high hydrostatic pressure, oscillating magnetic fields, high-intensity pulsed electric fields, intense light pulses, irradiation, chemical, biochemical, and hurdle technology. Although these technologies have been used for a long time to inactivate microorganisms and/or preserve food, they have gained recognition as nonthermal methods of food preservation only in the recent past. Nonthermal processes are expected to induce only minimal degradation of food.

High-pressure Processing

High-pressure processing (HPP), also described as high hydrostatic pressure (HHP) or ultrahigh pressure (UHP) processing, subjects liquid and solid foods, with or without packaging, to pressures between 100 and 900 MPa. A high hydrostatic pressure is used for the inactivation of microorganisms and certain enzymes and for shelf-life extension of foods. Spores can be inactivated by combining high pressure with temperature. The germination of spores is an important step in spore inactivation. The process temperature during pressure treatment can be specified from less than 0 °C to more than 100 °C. Commercial exposure times can range from a millisecond pulse to more than 20 min. HPP acts instantaneously and uniformly throughout a mass of food, independent of the size, shape, and food composition. Compression uniformly increases the temperature of foods by approximately 3 °C per 100 MPa. Compression of foods may shift the pH of the food as a function of imposed pressure and must be determined for each food treatment process. Water activity and pH are critical process factors in the inactivation of microbes by HPP. An increase in food temperature above room temperature and, to a lesser extent, a decrease below room temperature increase the inactivation rate of microorganisms during HPP treatment. Temperatures in the range of 45–50 °C appear to increase the rate of inactivation of food pathogens and spoilage microbes. Temperatures from 90–110 °C in conjunction with pressures include batch and semicontinuous systems, but no commercial continuous HPP systems are operating.

The critical process factors in HPP include pressure, time at pressure, time to achieve treatment pressure, decompression time, treatment temperature (including adiabatic heating), initial product temperature, vessel temperature distribution at pressure, product pH, product composition, product water activity, packaging material integrity, and concurrent processing aids. Chemical changes in the food generally will be a function of the process and treatment time. Because some types of spores of *C. botulinum* are capable of surviving even the extreme pressures and temperatures of HPP, there is no absolute microbial indicator for sterility by HPP. For vegetative bacteria, nonpathogenic *Listeria innocua* is a useful surrogate for the foodborne pathogen, *Listeria monocytogenes* a nonpathogenic strain of *Bacillus* may be useful as a surrogate for HPP-resistant *E. coli* 0157:H7 isolates.

Subjecting foods to pressures of 100–800 MPa inactivates vegetative bacteria, yeasts, molds, and parasites in products such as jams, orange juice, and meat products. Factors that affect the rate of microbial inactivation include pressure and magnitude, microbial type and growth stage, temperature, pH, water activity, and food composition. Application of a pressure of 680 MPa on grape juice for 10 min would arrest the growth of the microbes and thereby stops further fermentation of the grape juice. Peaches and pears subjected to a pressure of 410 MPa for 30 min exhibit a shelf-life of 5 years. One of the important

challenges in using HPP is the fabrication of pressure vessels and seals that can withstand the high pressures during the cycles of pressurization and depressurization.

Pulsed Electric Fields

High-intensity pulsed electric field (PEF) processing involves the application of pulses of high voltages (typically 20–80 kV cm^{-1}) of exponentially decaying, square wave, bipolar, or oscillatory pulses and at ambient, subambient, or slightly above ambient temperatures for less than 1 s to foods. High-intensity electric fields applied to a food in the form of short-duration pulses can inactivate the microorganisms and certain enzymes. Energy loss due to heating of foods is minimized, reducing the detrimental changes of the sensory and physical properties of foods. Some important aspects in pulsed electric field technology are the generation of high electric-field intensities, the design of chambers that impart uniform treatment to foods with minimal increase in temperature, and the design of electrodes that minimize the effect of electrolysis.

Although different laboratory- and pilot-scale treatment chambers have been designed and used for PEF treatment of foods, only two industrial scale PEF systems are available. The systems including treatment chambers and power supply equipments need to be scaled up to commercial levels. To date, PEF has been applied mainly to improve the quality of foods. Application of PEF is restricted to food products that can withstand high electric fields, have a low electrical conductivity, and do not contain or form bubbles. The particle size of the liquid food in both static and flow treatment modes is a limitation. Several theories have been proposed to explain microbial inactivation by PEF. The most-studied theories are electrical breakdown and electroporation. Factors that affect the microbial inactivation with PEF are process factors (electric field intensity, pulse width, treatment time and temperature, and pulse wave shapes), microbial entity factors (type, concentration, and growth stage of microorganism) and media factors (pH, antimicrobes and ionic compounds, conductivity, and medium ionic strength). Microbial inactivation increases with increasing electric field intensity, exposure time, and temperature of the food. However, it is desirable to maintain the temperature below 30–40 °C by providing a cooling system. Different bacteria have different sensitivities to electric field treatment. In general, Gram-positive bacteria and yeasts are more resistant to electric fields than Gram-negative bacteria. The optimum conditions for maximum inactivation of a specific microorganism can be determined after preliminary research. Although PEF has potential as a technology for food preservation, existing PEF systems and experimental conditions are diverse. The effects of critical process factors on pathogens of concern and kinetics of inactivation need to be studied further. An electric pulse process for the treatment of fresh citrus juices capable of reducing target pathogens without alteration of the juice was granted an FDA letter of no objection for its use in April 1999.

High-voltage Arc Discharge

Arc discharge is an early application of electricity to pasteurize fluids by applying rapid discharge voltages through an electrode gap below the surface of aqueous suspensions of microorganisms. A multitude of physical effects (intense wave) and chemical compounds (electrolysis) are generated, inactivating the microorganisms. The use of arc discharge for liquid foods may be unsuitable, largely because of electrolysis and discharge, but more recent designs have shown some promise for use in food preservation.

Pulsed Light Technology

Pulsed light is a method of food preservation that involves the use of intense and short-duration pulses of broad spectrum 'white light' (ultraviolet to the near-infrared region). The use of pulsed high-intensity light to inactivate microorganisms is a relatively new technology. For most applications, a few flashes applied in a fraction of a second provide a high level of microbial inactivation. This technology is applicable mainly in sterilizing or reducing the microbial population on packaging or food surfaces. Extensive independent research on the inactivation kinetics under a full spectrum of representative variables of food systems and surfaces is needed. Application of light pulses involves exposure of foods to short duration pulses (1 μs to 0.1 s) of intense incoherent light. Light with an energy density of about 0.01–50 J cm^{-2} and a wavelength in the range of 170–2600 nm is used. Such incoherent intense pulses of light may be generated using gas–filled flash lamps or spark gap discharge apparatus. Full – or filtered – spectrum light may be used, depending on the degree of sterilization expected. The filtered–spectrum light is devoid of wavelengths known to cause undesirable reactions in foods. Glass or liquid filters are used to obtain the filtered spectrum. In general, filtered light is more effective for microbial inactivation than full–spectrum light.

Ultraviolet Light

There is particular interest in using ultraviolet (UV) light to treat fruit juices, especially apple juice and

cider. Other applications include disinfection of water supplies and food contact surfaces. Ultraviolet processing involves the use of radiation from the ultraviolet region of the electromagnetic spectrum. The germicidal properties of UV irradiation (200–280 nm) are a result of DNA absorption of the UV light. This mechanism of inactivation results in a sigmoidal curve of microbial population reduction. To achieve microbial inactivation, the UV radiant exposure must be at least 400 J m^{-2} in all parts of the product. Critical factors include the transmissivity of the product, the geometric configuration of the reactor, the power, wavelength and physical arrangement of the UV source(s), the product flow profile and the radiation path length. UV may be used in combination with other alternative process technologies, including various powerful oxidizing agents such as ozone and hydrogen peroxide, among others.

Oscillating Magnetic Fields

Static (SMFs) and oscillating magnetic fields (OMFs) have been explored for their potential to inactivate microorganisms. For SMFs, the magnetic field intensity is constant with time, while an oscillating magnetic field is applied in the form of constant amplitude or decaying amplitude sinusoidal waves. An OMF applied in the form of pulses reverses the charge for each pulse. The intensity of each pulse decreases with time to about 10% of the intensity. Preservation of foods with OMFs involves sealing food in a plastic bag and subjecting it to one to 100 pulses in an OMF with a frequency of 50–500 kHz at a temperature of 0–50 °C for a total exposure time ranging from 25–100 ms. The effects of magnetic fields on microbial populations have produced controversial results. Consistent results concerning the efficacy of this method are needed before considering this technology for food-preservation purposes.

Oscillating magnetic fields with a magnetic flux of 5–50 T and a frequency of 5–500 kHz have been reported to inactivate microorganisms. Foods with an electrical resistivity of 10–25 $\Omega \cdot$ cm may be sealed in a plastic bag and subjected to OMFs. One of the attractive features of using magnetic fields for food preservation is that the food can be packaged prior to processing, reducing the possibility of cross-contamination during packaging. Studies on the effects of static and pulsed magnetic fields as an alternative to conventional thermal treatments on the inactivation of *Saccharomyces cerevisiae* have been reported. The potential advantages of food preservation by magnetic fields, the proposed interaction mechanisms, and some of the results that have been obtained by exposing living systems to low- and high-frequency, high-intensity magnetic fields were discussed in the IFT Annual Meeting in 2000.

Pulsed X-rays

A number of studies have compared the effects of electron beam, gamma rays, and X-rays, but comparison between these technologies is inconclusive owing to differences in the doses applied. Electrons have a limited penetration depth of about 5 cm in food, whereas X rays have significantly greater penetration depths (60–400 cm) depending on the energy used. The use of pulsed X-rays is a new alternative technology that utilizes a solid-state opening switch to generate an electron beam 30 ns down to a few nanoseconds; repetition rates of up to 1000 pulses per second. The practical application of food irradiation by X-rays in conjunction with existing food-processing equipment is further facilitated by:

- the possibility of controlling the direction of the electrically produced radiation;
- the possibility of shaping the geometry of radiation field to accommodate different package sizes;
- its high reproducibility and versatility.

Potentially, the negative effects of irradiation on the food quality can be reduced. Irradiation of foods was one of the earliest nonthermal food preservation technologies. Irradiation is the exposure of food to radiation with an energy of 5–10 kGy and wavelengths of 2000 Å or less. Ultraviolet, beta, gamma, and X-, and microwaves are included in this range. One of the attractions of irradiation is its ability to pasteurize foods in the frozen state. The World Health Organization (WHO) approved a radiation dosage of up to 10 kGy as being 'unconditionally safe for human consumption.' Irradiation has the potential to replace the use of many hazardous chemical pesticides and preservatives.

Ultrasound

Ultrasound is the energy generated by sound waves of 20 000 or more vibrations per second. Although ultrasound technology has a wide range of current and future applications in the food industry, including inactivation of microorganisms and enzymes, presently, most developments for food applications are nonmicrobial. Data on inactivation of food microorganisms by ultrasound in the food industry are scarce, and most applications use combinations with other preservation methods. The bactericidal effect of ultrasound is attributed to intracellular cavitations, a phenomenon in which mechanical high-frequency vibrations cause alternate compressions of millions of microscopic bubbles containing gas and vapor. The

bubbles expand then implode violently, releasing large amounts of energy and generating very high temperatures and pressures within the bubbles. The molecules of the vaporized reaction mixture are fractured, forming highly reactive free radicals. Cavitations occur as a result of micromechanical shocks that disrupt cellular structural and functional components up to the point of cell lysis.

The heterogeneous and protective nature of food with the inclusion of particulates and other interfering substances severely curtails the singular use of ultrasound as a preservation method. Although, at present, these limitations make commercial development unlikely, the combination of ultrasound with other preservation process (e.g., heat and mild pressure) appears to have the greatest potential for industrial applications. Critical processing factors are assumed to be the amplitude of the ultrasound waves, the exposure/contact time with the microorganisms, the type of microorganisms, the volume of food to be processed, the composition of the food, and the temperature of treatment.

Microwave and Radio-frequency Processing

Microwave and radio-frequency heating refers to the use of electromagnetic waves of certain frequencies to generate heat in a material by two mechanisms – dielectric and ionic. Microwave and radio-frequency heating for pasteurization and sterilization is preferred to conventional heating, because they require less time to come up to the desired process temperature, particularly for solid and semisolid foods. Industrial microwave pasteurization and sterilization systems have been reported for over 30 years, but commercial radio-frequency heating systems for the purpose of food pasteurization or sterilization are not known to be in use. For a microwave sterilization process, unlike conventional heating, the design of the equipment can dramatically influence the critical process parameters – the location and temperature of the coldest point. This uncertainty makes it more difficult to make general conclusions about processes, process deviations, and how to handle deviations.

Many techniques have attempted to improve the uniformity of heating. The critical process factor when combining conventional heating and microwave or any other novel processes would most likely remain the temperature of the food at the cold point, primarily due to the complexity of the energy absorption and heat-transfer processes. Since the thermal effect is presumably the sole lethal mechanism, the time–temperature history at the coldest location will determine the safety of the process and is a function of the composition, shape, and size of the food, the microwave frequency, and the applicator (oven) design. Time is also a factor in the sense that, as the food heats up, its microwave absorption properties can change significantly, and the location of cold points can shift.

Ohmic and Inductive Heating

Ohmic heating (sometimes also referred to as Joule heating, electrical resistance heating, direct electrical resistance heating, electroheating, and electroconductive heating) is defined as the process of passing electric currents through foods or other materials to heat them. Ohmic heating is distinguished from other electrical heating methods by the presence of electrodes in contact with the food, frequency, and waveform. The principal advantage claimed for ohmic heating is its ability to heat materials rapidly and uniformly, including products containing particulates. The principal mechanisms of microbial inactivation in ohmic heating are thermal. While some evidence exists for nonthermal effects of ohmic processes, which rely on heat, it may be unnecessary for processors to claim this effect in their process fillings.

Inductive heating is a process wherein electric currents are induced within the food owing to oscillating electromagnetic fields generated by electric coils. No data on microbial death kinetics under inductive heating have been published.

Hurdle Technology

Hurdle technology combines nonthermal food processing with traditional or other emerging technologies. The most promising combinations include nonthermal methods, such as high hydrostatic pressure, ultrasound, and pulsed electric fields. In the inactivation of spores, it is necessary to use a combined methods approach using 'hurdles.' Hurdles are physical or chemical parameters that can be adjusted to ensure the microbial stability and safety of foods. The physical parameters include the processing and storage temperatures, water activity, pH, and redox potential at levels that inhibit or inactivate the microorganisms and thus render the food safe. Hurdle technology is used in the preservation of meat and seasonal or regional fruits and vegetables.

Besides preserving food quality, new nonthermal technologies have to achieve an equivalent or, preferably, a better enhanced safety level than that for procedures that they replace. Most nonthermal preservation techniques are highly effective in inactivating vegetative forms of bacteria, yeast, and molds, but bacterial spores and most enzymes remain difficult to inactivate.

STORAGE STABILITY

Contents

Mechanisms of Degradation

M Hole, University of Lincolnshire and Humberside, Lincoln, Grimsby, UK

Background

The storage of a food is limited by changes to the food, which render it unacceptable to the consumer for reasons of safety and of quality, whether organoleptic or nutritional.

The cause of these undesirable changes can be related to physical, microbiological, enzymatic, and chemical reasons. (*See* **Spoilage:** Chemical and Enzymatic Spoilage; Bacterial Spoilage; Fungi in Food – An Overview; Molds in Spoilage; Yeasts in Spoilage.) Which mechanism of degradation operates depends on the type of food and the storage conditions (see Figure 2).

Postharvest storage of fresh commodities (whether of plant or animal origin) is mainly limited by microbial action and the natural metabolic (i.e., enzymatic) processes occurring after harvest or death. The modern food industry is primarily concerned with minimizing the degradation reactions occuring during storage. (*See* **Preservation of Food.**) Thus, storage at a reduced temperature is a successful strategy (*See* **Chilled Storage:** Principles; Attainment of Chilled Conditions; Quality and Economic Considerations; Microbiological Considerations; **Freezing:** Storage of Frozen Foods) as is modified atmosphere packaging (MAP) (*See* **Packaging:** Packaging of Solids) for the control of microbial growth in foods. High-temperature processing aims to eliminate the microbial mechanism of degradation, and also to inactivate enzymes. This would leave chemical mechanisms as the main possible degradation pathway, and examples of such changes during the extended ambient storage periods of canned foods are given below. More generally, the relatively high reactivity of oxygen with food components, especially lipids, is a major chemical degradation route and is discussed further below. (*See* **Oxidation of Food Components.**)

Physical changes in foods result in undesirable textural changes, especially for fresh commodities where the texture relates to the cellular nature of the food and the way in which water is held within these cells. This 'cellular water' can be adversely affected by frozen storage/thawing cycles.

The classification of foods as cellular (i.e., plants, animal commodities) or dispersive (i.e., colloidal) is relevant to physical mechanisms of degradation. For dispersive foods, which are usually fabricated (e.g., margarine, icecream, salad cream, gelled products), the inherent physical instability of colloidal dispersions must be considered in relation to their mode of storage. (*See* **Colloids and Emulsions.**) Water in foods (*See* **Water Activity:** Effect on Food Stability) is a major factor for the possible mechanisms of degradation. It is essential for microbial growth and

reactions involving enzymes (hence the success of traditional drying methods for food preservation). The presence of water, as indicated above, is important for food texture, but the absence of water can be desirable for the crispness of snack foods. Storage that allows snack foods to absorb water, and hence lose their crispness, is clearly undesirable – as is the opposite effect of drying out for foods (e.g., cakes, cheese). (*See* **Intermediate-moisture Foods**.) From a chemical point of view, water can react with food components in a hydrolysis reaction, and examples are discussed below.

Physical Degradation Mechanisms

Water binding is especially important in relation to the texture of fresh foods, whether of plant or animal origin. For fresh leafy vegetables, e.g., lettuce, the desirable firmness is dependent upon the turgor pressure of the cellular water – excessive transpiration owing to storage in a warm or dry environment will cause a reduction in turgor pressure with a resultant undesirable loss of firmness, and reduced consumer appeal for the 'limp' result. Chilling can be beneficial, but if frozen, undesirable texture changes can occur resulting from the loss of cellular water. The mechanism involves differential freezing of water in the intercellular space, with a resultant, irreversible, osmotically induced flow of water from inside the cell into the intercellular space. On thawing, this water is expelled, leading to the unattractive 'drip loss' and leaving a less desirable texture. This is a general problem for fresh meat and fish, and is especially severe for fruits such as strawberries.

The instability of water in disperse foods (i.e., colloidal systems) is illustrated by the separation of water from oil in emulsions (e.g., low fat spreads) or by water being lost from gels (i.e., syneresis), especially during low-temperature storage. Syneresis of gelled dairy products, e.g., set yogurts, can be a problem, as can gels or thickened foods based on starch. The linear amylose polymers in starch tend to associate (a process referred to as 'starch retrogradation'), to cause gels to undergo syneresis or pastes to go lumpy, especially on long-term frozen/chilled storage. This has led to specialized modified starches being developed for food products designed to be stored frozen. The starch in wheat flour is responsible for the staling of bread, but this is due to the highly branched amylopectin component undergoing retrogradation (i.e., a form of crystallization). Staling refers to the interior of the bread becoming firmer, in contrast to crust firming if the crust dries out. Such staling can be slowed down by storing bread at 30 °C; in fact, stale bread can be 'freshened' by heating it and so reversing, to some extent, the crystallization of the amylopectin.

Pectin-based gels, e.g., in traditional jams, can also show syneresis, and the increasing tendency to store jams in the refrigerator will hasten such an effect – the suggestion is made in order to slow down microbial spoilage, which is discussed in the next section.

Microbiological Degradation Mechanisms

Microorganisms are the major cause of deterioration in foods, not least because foods generally have a high water activity, which microorganisms require in order to grow. (*See* **Microbiology**: Detection of Foodborne Pathogens and their Toxins.) In particular, storage of plant and animal products that are unprocessed is limited by microbial action. Fabricated foods can have water activities that are too low for microbial growth (e.g., margarine, high-sugar-content preserves), and frozen storage (e.g., − 21 °C) can effectively prevent microorganisms growing.

The use of foods as a source of organic compounds by microorganisms is a natural decay process, and the initial stages can give rise to undesirable organoleptic effects, ranging from visual discolorations to off-odors and slime formation. When the process produces toxic effects without the accompanying spoilage indicators, consumers are unable to recognize that the food is unsafe to eat, as in cases of salmonellosis and botulism, and this is a most dangerous situation. (*See* **Food Poisoning**: Classification.)

The food degradation involving microorganisms depends upon the type of microorganism present. Food spoilage arises from the presence of bacteria or fungi, fungi being subdivided into molds and yeasts (*See* **Microbiology**: Classification of Microorganisms.) With a water activity above 0.90, the faster growing bacteria tend to dominate, but with a water activity of about 0.90–0.80, molds and yeasts can be dominant, especially if the pH is below about 5. In fact, yeasts and molds can grow at a pH of around 2. An important difference between yeasts and molds is that molds require oxygen (i.e., are aerobic), whereas yeasts can grow in air (oxygen) or in the absence of air; thus, molds are found on the surface of solid foods (e.g., bread mold), whereas yeasts can be found in liquids (e.g., in acetic acid (vinegar) preserves).

For the large number of different bacteria that can be found in foods, some require air (oxygen) for growth (i.e., aerobic), whereas others can grow in the absence of oxygen (i.e., anaerobic). Thus, if a food is stored in a vacuum, or in a modified atmosphere with no oxygen, the bacteria that flourish will be different from those present in the food when

stored in air. This change to an anaerobic bacterial population may result in a danger to health on consumption of the food, since many anaerobic bacteria are pathogenic, e.g., *Clostridium botulinum*, which has been the cause of deaths from botulism from its occurence in canned meats (e.g., corned beef). (*See* **Canning**: Quality Changes During Canning; **Emerging Foodborne Enteric Pathogens**; **Meat**: Preservation.)

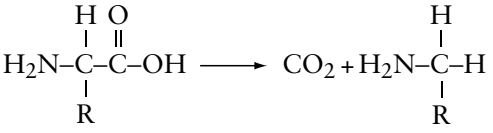
Foods that are especially subject to deterioration resulting from surface mold growth include fruit, cheese, sausage, bread, and cereals. With fruit, the molds produce enzymes (see below) that catalyze reactions leading to the breakdown of pectins and cellulose, with resultant rotting of the fruit. Molds that produce toxins, e.g., aflatoxin, ochratoxin, and patuline, can be particularly dangerous to health – a particular problem can exist with stored grain and nuts, especially peanuts when used as animal feed. (*See* **Aflatoxins**; **Mycotoxins**: Toxicology.)

Yeasts are very useful in producing foods such as bread and alcoholic drinks, but they can also cause food spoilage, especially where food is less severely processed in order to maximize organoleptic properties, or fruit pieces are added to dairy products, or in low-calorie (and hence low-sugar) formulations. The undesirable results of yeast activity include, especially, off-flavor formation and gas production in foods ranging from jams and mayonnaise to yogurts (*See* **Yeasts**.) Gas production as a problem, e.g., in jams, is a result of alcoholic fermentation (i.e.,the desirable process in ethanol production), producing carbon dioxide, i.e.:

$$\underset{C_6H_{12}O_6}{\text{Sugar}} \longrightarrow \underset{2C_2H_5OH + 2CO_2}{\text{Ethanol} + \text{Carbon dioxide}}$$

Bacteria constitute the major microbial mechanism of food degradation, especially for raw foods with a high amount of protein such as raw meats and fish, and also for pasteurized milk and dairy products.

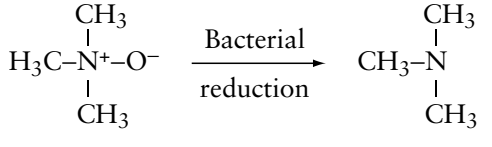
Lactic acid bacteria are able to grow in mildly acidic foods, e.g., milk, and the lactic acid formed is the cause of the 'souring' observed. This is an example of a sugar being used by a bacterium – with resultant formation of a possibly organoleptically undesirable compound. (*See* **Lactic Acid Bacteria**.) Some bacteria, e.g., *Clostridium butyricum* convert sugars to butyric acid, which is particularly foul-smelling with an odor of rancid butter. It can occur in fermented cabbage (sauerkraut). Bacterial decomposition of organic nitrogen compounds in foods, i.e., proteins and amino acids, leads to very offensive odors and potentially dangerous toxins – a process referred to as putrefaction. The major initial change in this process is the decarboxylation of the α-amino acids, i.e.:



In histamine poisoning, especially relevant for scombroids such as mackerel and tuna, the amino acid histidine is decarboxylated to histamine in this particular type of mild but alarming enteric poisoning. The enteric bacteria responsible do not grow above 10 °C, and hence carefully controlled chilled storage can be used. Histamine is referred to as a biogenic amine; others with very undesirable odors include cadaverine and putrescine. More complex decomposition of the protein, especially using the sulfur groups present, gives rise to the foul-smelling hydrogen sulfide (rotten egg smell) and the thiols, e.g., methanethiol, H_3CSH.

Putrefaction is caused by several bacteria, both aerobic and anaerobic types, and salmonellosis and botulism, as indicated above, represent the dangerous initial stages before putrefaction is organoleptically detectable. With canned foods that are weakly acidic and high in protein, improper sterilization can lead to sulfide spoilage resulting from the growth of the anaerobic bacterium *Clostridium nigrificans*. This results in the production of hydrogen sulfide and blackening of the can interior. Foods that are high in lipid content and consequently low in water activity do not favor bacterial growth. However, bacteria such as the *Pseudomonas* species can cause hydrolysis of lipids, e.g., triacylglycerols, to fatty acids and glycerols (see below also) – and further oxidation to methylketones. This type of rancidity can occur with 'fatty fish' such as herrings and salmon.

The range of bacterial effects on food is enormous – not least because of the wide range of organic compounds that bacteria use for energy, and the possibility of producing a vast array of new compounds of questionable safety or organoleptic quality. Raw fish are particularly prone to bacterial degradation – being examples of high-protein foods as illustrated above. The characteristic fishy smell is due to the production of trimethylamine (TMA), resulting from the bacterial reduction of the naturally occuring trimethylamine oxide (in marine but not fresh water fish), i.e.:



The level of TMA produced can be used as an 'index of freshness,' as the fish decays during storage on ice. This illustrates how a volatile compound can be classed as desirable, or as an off-odor, dependent on its concentration.

Enzymatic and Chemical Degradation Mechanisms

The metabolic processes in plants and animals, which are critical in relation to their storage stability after harvesting or after slaughter, involve a complex series of enzyme-catalyzed chemical reactions (i.e., biochemical reactions). These lead to deterioration of food quality, and the process is normally referred to as autolysis (i.e., self-destruction). The endogenous enzymes causing autolysis are an integral part of the plant or animal food – and any treatment to affect the enzyme activity cannot be done without the possibility of affecting the food itself.

Enzymatic and chemical reactions overlap in the sense that the enzyme speeds up the chemical reaction, but to such an extent that the reaction rate is not significant in the absence of the enzyme. A 'chemical catalyst,' e.g., a transition metal ion such as copper, iron, or nickel, can cause a large increase in the rate, but the reaction will normally proceed at a measurably rate in the absence of the 'chemical catalyst.' Thus, the oxidation in air of fish oils is catalyzed by copper ions, but the oxidation still proceeds measurably in the absence of copper ions. In contrast, the hydrolysis of fish oil occurs readily at room temperature when catalyzed by the enzyme lipase, but in the absence of lipase, the hydrolysis does not occur significantly, not even at 100 °C (at pH 7).

Enzymes are complex proteins, and their catalytic action is related to the shapes taken up by the protein chains. This shape is held together mainly by numerous weak hydrogen bonds, and these can be weakened and changed by processes such as heating, freezing, or changing the pH. The result is a loss of catalytic activity by the enzyme; however, for endogenous enzymes, the effect of such treatments on the organoleptic qualities of the food must be considered. More specific methods of inhibiting enzyme activity include the use of specific enzyme inhibitors such as sulfur dioxide and bisulfites, the use of competitive substrates, or chelation of metals necessary for the activity of the enzyme.

The undesirable effects of enzyme-catalyzed reactions (i.e., autolysis) can be prevented in principle, but often, the effect on the food's organoleptic quality may not be acceptable.

The major chemical components of foods, i.e., lipids, proteins, and carbohydrates, can undergo chemical changes, whether enzyme-catalyzed or not, which can influence the safety, organoleptic quality, or nutritional quality of the food. The major reactions involved are oxidation and hydrolysis, at least initially, but more complex chemical changes may occur subsequently. These can result in the production of rancidity and browning (i.e., discoloration) which are often undesirable (see Figure 1).

In general terms, the chemical changes can:

- produce new compounds – possibly with undesirable toxic or organoleptic properties
- destroy food components of relevance to its nutritional quality (e.g., vitamins) or organoleptic quality (e.g., loss of color).

Some examples of enzymatic and chemical degradation mechanisms are discussed below, but reference to Figure 1 will emphasize how these mechanisms are interconnected, especially in cellular foods.

Enzymatic Degradation Mechanisms

As previously stated, fresh meat and fish deteriorate in quality mainly for microbiological reasons when stored at ambient or chill temperatures. Frozen storage (e.g.,– 30 °C) will prevent microbiological growth, but enzyme activity may still proceed slowly.

Coldwater fish often show rapid autolysis when stored chilled or on ice, and in this case, enzymatic degradation mechanisms are as important as microbiological degradation mechanisms. This arises because coldwater fish live at temperatures near zero, and their enzymes work efficiently in this temperature range – hence, storage in ice, or at refrigeration temperature, affords little reduction in temperature. This contrasts with tropical fish where ice storage is effective in slowing down autolysis. (*See* **Fish**: Spoilage of Seafood.)

Thus, for coldwater fish (e.g., cod, haddock), enzyme activity proceeds noticeably during chilled storage, especially protease activity leading to protein hydrolysis and resultant excessive softening of fish tissue. This tissue breakdown encourages microbial growth, especially involving the breakdown of sulfur containing amino acids to volatile, foul smelling thiols, and disulfides. The fish gut is the source of very active proteases, and gutting of the fish is effective in slowing down this autolysis and so extending the chill storage life. (*See* **Fish**: Processing.) Frozen storage also slows down the enzyme activity, but for gadoid fish, such as cod, haddock, and hake, enzyme activity can convert trimethylamine oxide to dimethylamine and formaldehyde, i.e.:

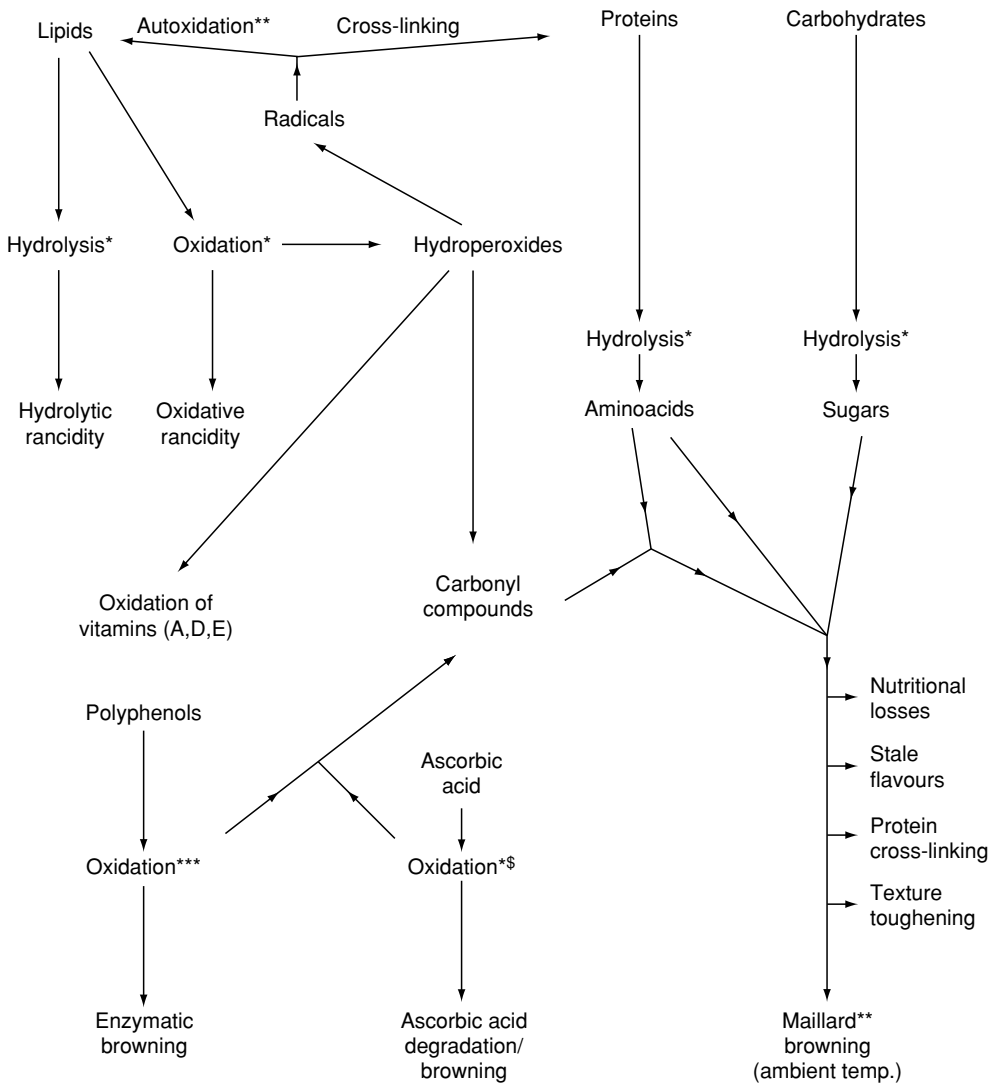


Figure 1 Enzymatic and chemical degradation mechanisms – rancidity and browning. *Enzymatic or chemical mechanism; **chemical mechanism; ***enzymatic mechanism; *$anaerobic also, involving hydrolysis.

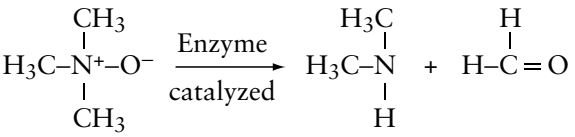


Trimethylamine oxide — Dimethylamine — Formaldehyde

The formation of formaldehyde has been related to the toughening of such fish in frozen storage by its ability to cross-link proteins.

Meat and fish may be high in lipid content, and for fish, the lipid is highly unsaturated and susceptible to oxidation (see Figure 1). Lipoxygenases catalyze oxidation in air of lipids with at least two double bonds (*See* **Oxidation of Food Components**), and specific lipoxygenases have been identified in the gill tissue of fish. The initially formed hydroperoxides are decomposed to volatile carbonyl compounds (aldehydes) with undesirable odors (see Figure 1).

Even though plant foods have a low lipid content, they have various hydrolytic and oxidative enzymes that catalyze hydrolysis and oxidation of the lipids to produce rancidity. The initial action of lipases in producing fatty acids from the hydrolysis of triacylglycerols may not produce the necessary volatile fatty acids for rancidity, but the lipoxygenase enzymes effectively catalyze the oxidation of the unsaturated fatty acids to give the carbonyl compounds, which have the rancid odor, i.e.:

$$\text{Triacylglycerols (unsaturated)} + H_2O \xrightarrow{\text{Lipases}} \text{Fatty acids (unsaturated)}$$

$$\xrightarrow[O_2]{\text{Lipoxygenases}} \text{Carbonyl compounds}$$

This process occurs more readily if the plant food is crushed or ground, allowing the substrates and enzymes to mix. Thus, raw peanuts only go rancid rapidly if they are ground, but if they are dry-roasted, the enzymes are inactivated, and no oxidation occurs.

The blanching process used for unprocessed plant foods (e.g., peas, beans) prior to freezing is necessary to prevent flavor deterioration resulting from enzyme-catalyzed oxidation, especially lipoxygenase. (*See* **Freezing**: Operations.) Additionally, for plant foods, the oxidation (in air) of phenolic substrates catalyzed by a group of enzymes referred to as the polyphenol oxidases (PPO) is important if they are to be processed and stored under ambient or chilled conditions. This is referred to as enzymatic browning (see Figure 1) and is typified by the surface browning of peeled fruit and vegetables (e.g., apples and potatoes). Processing involving chopping, slicing, and peeling allows the substrate, air, and enzymes to mix and promotes enzymatic oxidation of the phenolic substrate to quinones. These undergo further complex nonenzymatic reactions to form melanin pigments, which may be pink, brown, or black.

$$\text{Polyphenol substrate} + O_2 \xrightarrow{\text{PPO enzymes}}$$

$$\text{Quinone} \longrightarrow \longrightarrow \longrightarrow \text{Melanins}$$

The process may be controlled by inactivating the polyphenol oxidase enzyme system – but care must be taken not to cause undesirable changes in texture (e.g., by blanching) or flavor (if the enzyme inhibitor sulfur dioxide is used). Addition of a competitive substrate (e.g., 4-hexylresorcinol) for the enzyme may be more acceptable, or simply the addition of ascorbic acid, which is able to reduce the quinone back to the phenolic compound, hence preventing the conversion of the quinone to the melanins. (*See* **Browning**: Enzymatic – Biochemical Aspects; Enzymatic – Technical Aspects and Assays.)

Plants after harvesting are still respiring, and some plants, fruits in particular, show a large increase in respiration during storage. This is linked to the rapid ripening of some fruits, e.g., bananas and pears, which can limit their desired shelf-life. The enzyme systems involved in the ripening process can be slowed by chilling the fruit (though for bananas, the temperature must not be below 10 °C) and also by decreasing the oxygen concentration and increasing the carbon dioxide concentration (i.e., the reverse of the respiration process). However, the oxygen concentration must not drop below about 3–5% in order to prevent anaerobic respiration, where alternative enzyme systems operate to convert sugar to ethanol (i.e., fermentation) rather than to carbon dioxide and water. (*See* **Ripening of Fruit**.)

During the ripening process of plant foods, the taste and texture develop to give an acceptable sweetness and softness. In relation to the taste, the process involved is the starch – sugar conversion, and this can be temperature-dependent in a complex manner.

The overall starch – sugar (sucrose, glucose, fructose) conversion is as follows:

$$\text{Starch} \xrightarrow[H_3PO_4]{\text{Phosphorylase}} \text{Glucose-1-phosphate}$$

$$\downarrow \text{Several steps involving glycolytic enzymes}$$

$$\text{Sucrose phosphate}$$

$$\downarrow H_3PO_4$$

$$\text{Glucose} + \text{Fructose} \xleftarrow[H_2O]{\text{Invertase}} \text{Sucrose}$$

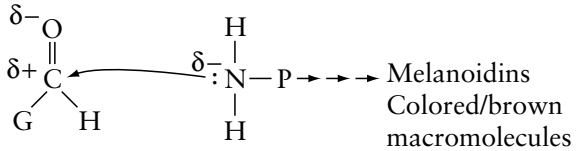
The starch may be converted mainly to sucrose (a nonreducing sugar), or the sucrose may undergo hydrolysis catalyzed by the enzyme invertase (sucrase) to the reducing sugars glucose and fructose. The mixture of glucose and fructose (so-called 'invert sugar') is sweeter than sucrose – hence, the actual sweetness achieved can vary in relation to the sucrose – 'invert sugar' ratio. An important commercial aspect of the starch–sugar conversion is the storage of potatoes to be used for making crisps (i.e., fried potato slices, called 'chips' in the USA). If the potato has too much of the reducing sugar, the crisp may become too dark as a result of the Maillard browning reaction (see Figure 1). Storage of the potatoes at 4 °C (to reduce respiration) results in 'cold-induced' sweetening, i.e., the reducing sugar level increases, and the crisps produced are too dark. Storage at about 10 °C results in less starch–sugar conversion, and the crisps produced are of an acceptable light brown color. The higher storage temperature (10 °C) appears to inactivate the glycolytic enzymes, hence inhibiting the sugar production. (*See* **Potatoes and Related Crops**: Processing Potato Tubers.)

Chemical Degradation Mechanisms

Storage conditions under which microorganisms and enzymes are inactive (e.g., after heat processing) can

still enable chemical degradation mechanisms to operate, especially where radicals are involved in oxidation reactions (see below). In general terms, however, the conditions, especially temperature, required for rapid chemical reactions are more extreme than used for food storage, where ambient and subambient temperatures are used. However, the long storage times required for processed foods (often in terms of months) can allow time for products from a slow chemical reaction to become noticeable. One example is the Maillard reaction, an example of nonenzymatic browning (see Figure 1) but better considered as a 'carbonyl-amino' reaction. (*See* **Browning**: Nonenzymatic; Toxicology of Nonenzymatic Browning.) The Maillard reaction occurs quickly on heating foods containing amino compounds (e.g., proteins, amino acids) and reducing sugars (e.g., glucose, lactose) and is responsible for the desirable colors and flavors of baked, fried, and toasted foods. The Maillard reaction is slow at normal storage temperatures but, over extended storage periods, can produce undesirable darkening and a stale flavor (e.g., in dried fruits and milk powder) and toughening of texture (through protein cross-linking) in frozen fish.

The Maillard reaction involves a reaction between a polar carbonyl compound (aldehyde or ketone) and a polar amino compound, as outlined below:



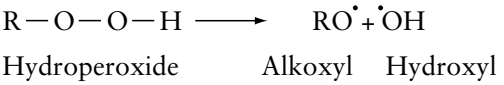
Polar carbonyl compound (e.g., glucose) — Polar amino compound (e.g., protein)

The opposite charges initiate a linking (as indicated by the arrow) between the glucose and the protein, which ultimately produces the brown melanoidins.

The degradation aspects arise from the fact that nutritionally important proteins and essential amino acids react and so become unavailable for digestion and assimilation. Additionally, the complex series of reactions leading to the undesirable brown melanoidins involve side-reactions leading to volatile off-odors (stale odors) for the stored foods.

The broader description of the Maillard reaction as a carbonyl-amino reaction indicates how the carbonyls produced from the oxidation of lipids, polyphenols, and ascorbic acid can also give the Maillard reaction with proteins/amino acids in the absence of reducing sugars (see Figure 1). Ascorbic acid is oxidized readily in air, and the dehydroascorbic acid produced is a diketone, which can give the carbonyl-amino reaction – this explains why some foods brown quickly, even though their reducing sugar content is low. The Maillard reaction (carbonyl-amino reaction) is very slow at pH 3–3.5, but ascorbic acid can oxidize at this pH and still produce darkening as a result of its own specific degradation. Such ascorbic acid degradation is the form of nonenzymatic browning occuring in stored citrus fruit concentrates and spray-dried powders, especially noticeable for lemon and grapefruit. Obviously, the nutritional value as a source of vitamin C is reduced. (*See* **Citrus Fruits**: Lemons; Grapefruits.)

The oxidation of unsaturated lipids giving rise to oxidative rancidity is perhaps the most important chemical degradation mechanism for stored foods, and especially so for refined edible oils and derived products such as margarine and salad creams. *See* **Oxidation of Food Components**. On exposure to air, and especially in the presence of sunlight and transition metals (e.g., copper, iron), unsaturated lipids are oxidized to hydroperoxides by a radical chain reaction normally referred to as autoxidation (self-oxidation). This process is important since the autoxidation, once started, is self-perpetuating, and the hydroperoxides produced not only decompose to rancid odors but are good oxidizing agents, which can cause the destruction of fat-soluble vitamins (A, D, E) and the oxidation of sulfur side groups in proteins leading to their cross-linking, with consequent loss of nutritional quality and toughening of texture. The autoxidation of lipids requires a radical to be formed to initiate the radical chain reaction, this may take a long time, and this induction period may be followed by a surprisingly rapid oxidation, making prediction of storage life difficult (*See* **Storage Stability**: Shelf-life Testing). The initial radical may be derived from enzyme (lipoxygenase)-catalyzed lipid oxidation (during the extraction/processing procedures) producing a trace of hydroperoxide. The subsequent breakdown of this hydroperoxide to radicals gives the autoxidation mechanism its required initial radical (i.e., an unpaired electron system):



Hydroperoxide — Alkoxyl radical — Hydroxyl radical

For other possible sources of this first radical, (*See* **Oxidation of Food Components**.)

Once a radical has been produced (e.g., OH), the following chain reaction can occur with the lipid (L — H):

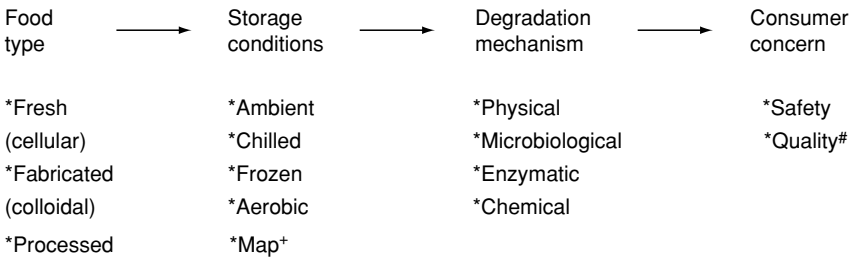


Figure 2 Factors of relevance to mechanisms of degradation of foods. +Modified atmosphere packaging/vacuum packaging; #Both organoleptic and nutritional.

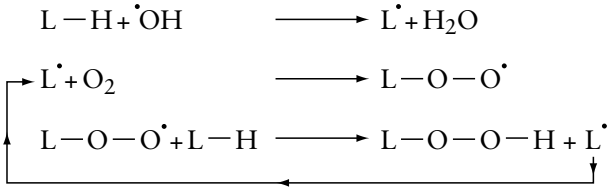

The last two steps provide the repeating chain reaction, and as long as air (oxygen) is present, the conversion of the lipid to hydroperoxide will continue. In addition to the points made above concerning the reactions and decomposition of the lipid hydroperoxide, it has been observed that one particular dialdehyde (malondialdehyde) is produced, which, with protein, gives the Maillard reaction in such a way that protein cross-linking occurs.

The role of transition metals in catalyzing chemical reactions has been referred to above, e.g., the decomposition of the lipid hydroperoxide is catalyzed by transition metals and especially by the heme iron pigments in meat. Other reactions of metals are examples of chemical degradation mechanisms when undesirable precipitates or colors are produced. The heme pigments in meat react in the presence of oxygen to produce either the desirable bright red oxymyoglobin or the undesirable metmyoglobin. (*See* **Meat:** Preservation.) Anthocyanins (phenolic compounds) in fruits can form colored salts with metals, one example being the formation of a pink tin complex on the surface of pears when they are canned. The blue–black discoloration that can occur with some canned peaches is of a similar origin An example of undesirable precipitate formation is the formation of magnesium ammonium phosphate (struvite) in canned crutaceans (e.g., crab). (*See* **Shellfish:** Contamination and Spoilage of Molluscs and Crustaceans.) The crystals formed resemble glass and hence lead to consumer rejection. However, this can be prevented by adding calcium disodium ethylenediaminetetraacetic acid, which preferentially binds with the magnesium. For acidic foods, the reaction of metals with acids to produce hydrogen and dissolve the metal can be a problem during storage of canned foods. (*See* **Acids:** Properties and Determination; and **Canning:** Quality Changes During Canning.) The tin plate used in steel cans can be dissolved by acidic foods, and the dissolved tin concentration could be a health problem – the use of protective lacquers to prevent this is well established. However, the recent recall (November, 2000) of a batch of canned tomato soup because of its high dissolved tin concentration shows that this chemical reaction can still be a problem!

The complex nature of foods makes it difficult to be sure of the degradation mechanisms operating, as reference to Figure 2 will confirm. In some cases, all the mechanisms proposed could be operating, as is found for milk. Milk is highly susceptible to degradation by mechanisms that are:

- physical (e.g., cream (fat) separation);
- microbiological (e.g., both spoilage and pathogenic bacterial growth);
- enzymic (e.g., lipase-catalyzed lipolysis to fatty acids);
- chemical (e.g., 'light-induced flavor' from lipid oxidation and methional formation catalyzed by riboflavin in the presence of light)

(*See* **Milk:** Physical and Chemical Properties.)

The above list of food degradation mechanisms provides a framework that can be used as a starting point for appreciating the degradation mechanisms operating in specific food systems.

Parameters Affecting Storage Stability

M Hole, University of Lincolnshire and Humberside, Lincoln, Grimsby, UK,

Introduction

In developed countries modern attitudes to food retailing include the demand for even longer shelf-lives at the point of sale and within the home. Together with the increasing demand for convenience foods and complete meals (which can readily be reheated if required, even from the frozen state) the parameters influencing the necessary storage stability must be increasingly better understood. This is especially so considering the trend towards short-shelf-life, chilled foods, which have the desired 'fresh' qualities.

The nature of the changes which influence have been characterized in part (*See* **Storage Stability: Mechanisms of Degradation**) as physical, chemical, enzymatic, and microbial.

The relevance of such changes in influencing storage stability will depend on the treatment of the food prior to storage. It is useful to consider foods as either fresh or processed. Processed foods (e.g., heated, frozen, dried, salted, smoked) generally will have no active microbial population and minimal enzymatic activity prior to storage. In contrast, fresh foods (i.e., not processed and stored at ambient or chill (typically 0–5 °C) temperatures) will have active microbial populations, and some residual enzymatic activity. There is also an increasing demand, both by the catering sector and the individual consumer, for minimally processed fruit and vegetables (e.g., sliced, peeled). Additional problems exist for this form of fresh food in relation to its storage, due to increased enzymatic reactions, e.g., discolorations, and increased susceptibility to microbial growth.

The parameters of major importance for storage stability are temperature, moisture content, packaging and food additives (i.e., added chemicals). Each of these parameters will be considered in turn but it should be appreciated at the outset that the combined use of the above parameters is usually beneficial in practice.

The methods used to extend the storage life of foods are increasingly subject to critical examination by consumers, and this can influence their implementation by the major supermarket chains. Thus the use of irradiation as a means of extending shelf-life is not presently used in the UK, except for some spices. A recent (1999) statement by the Institute of Food Science and Technology (UK) commends irradiation as a safe and effective method for food preservation. Applications identified include:

- certain fruits and vegetables: to reduce spoilage by microorganisms, e.g. molds in strawberries
- poultry: to reduce levels of *Salmonella* and other food-poisoning organisms
- red meats: to reduce levels of *Escherichia coli* 0157:H7 and other food-poisoning organisms
- imported sea foods, e.g., warm-water prawns: to improve their safety during storage
- dried herbs and spices: to reduce food-poisoning bacteria

The use of irradiation allows for extended storage if foods are suitably packed to prevent contamination, although frozen storage may also be beneficial.

The use of irradiation in this way is gaining acceptance in the USA but not in the UK. In trials in the USA irradiated fruit (e.g., strawberries) outsold the non-irradiated form – not least because of their extended mold-free storage period. (*See* **Irradiation of Foods: Basic Principles.**) The major parameters for storage stability described reflect those widely used in present

commercial practice. Consumer opinion is very important when supermarkets consider new methods of storage stability and this is especially the case with genetically modified (GM) foods. Genetic modification of foods can allow extended storage, and a genetically modified tomato with a reduced ripening rate (and hence longer storage period) was used to produce a tomato paste which was successfully sold in UK supermarkets until quite recently, when the supermarkets made a decision not to stock GM foods in general. (*See* **Biotechnology in Food Production; Gene Expression and Nutrition.**)

Temperature

The temperature at which food is stored is the most important parameter which influences storage stability – especially for fresh foods. Biological processes, such as the respiration of fruit and vegetables, enzymatic activity, and microbial growth, such as the mold on cheese or bread, can all be greatly reduced in rate by the use of chill or refrigerated conditions (0–5 °C): whilst in the frozen state (−20 °C typically) they effectively cease. Chemical reactions are typically reduced by 50% of their ambient (20–25 °C) rate by a drop of 10 °C but some reactions can still proceed even during frozen storage if this exceeds a few months. Physical effects resulting in textural changes are one potential disadvantage of frozen storage, especially for intact tissue systems, such as vegetables, fruit, meat, and fish. This has led to the increased use of chilled storage where the 'fresh' image is maintained for such tissue systems. The use of chilled storage combined with modified-atmosphere packaging can extend the storage period significantly. However some fruits and vegetables suffer chilling injury, notably bananas below 12 °C, tomatoes below 7 °C, apples below 2 °C, and cucumbers below 7 °C. (*See* **Chilled Storage**: Use of Modified-atmosphere Packaging; **Chill Foods**: Effect of Modified-atmosphere Packaging on Food Quality.)

Reference to Table 1 shows the much greater storage periods possible with frozen storage but possible texture changes must be considered. An extreme example concerns the strawberry which loses all its firmness on thawing with excessive loss of water ('drip loss'). Frozen storage of eggs leads to the yolk gelling and fish texture can toughen appreciably after frozen storage. Frozen stored milk acquires a gel-like consistency and frozen cream has large aggregates of demulsified fat after thawing. Icecream can acquire a 'sandiness' due to lactose crystallization. The use of cryoprotectants to reduce such detrimental effects is described below. (*See* **Freezing**: Principles.)

Table 1 Temperature effects on shelf-life stability

Commodity	*Storage temperature and shelf-life days (D), months (M) at (°C)*		
	Ambient	*Chill*	*Frozen[a] (−20 °C)*
Fish (lean)	< 1D	5–7D (0)	10–12M
Fish (oily)	< 1D	3–5D (0)	6–8M
Meat (red)	< 1D	4D (2)	6–12M
Pork	< 1D	4D (2)	3–6M
Milk (pasteurized)	0.5D	4D (5)	NS
Bread	2–4D	NS	3M
Peas	1–2D	4–8D (5)	12M
Lettuce (iceberg)	< 1D	10D (5)	NS
Strawberries	1–2D	3D (5)	NS
Cakes (nondairy)	7D	NS	3M

[a]Wrapped to prevent dehydration: see text.
NS, not suitable: see text.

When water freezes to form ice there is a 9% increase in volume and since ice is 'pure H_2O,' the remaining water will have a higher concentration of solutes (so-called 'freeze concentration'). These two aspects can cause undesirable changes, especially textural, during frozen storage. In addition temperature fluctuations during frozen storage will allow small ice crystals to melt and reform as larger ice crystals which can result in cellular damage. Sublimation of ice crystals from the surface of the food due to the low humidity at frozen storage temperatures (−10 °C to −30 °C) can result in 'freeze-drying' of the surface, with the resultant discoloration. (*See* **Freeze-drying**: The Basic Process.)

Despite the above limitations, frozen storage is perhaps the most widely accepted method (in developed countries) of long-term storage of tissue foods, such as vegetables (with prior blanching to inactivate enzymes), meat, and fish. For processed foods such as bakery products and increasingly for complete meals, frozen storage is used and can be combined with microwave treatment for rapid regeneration.

Bread is an example of a processed food where there is no cellular structure but where texture is important – rejection due to 'staling' is an important contribution to waste. Chill storage accelerates such staling but frozen storage below −20 °C will prevent staling for up to 3 months.

More generally, processed foods containing starch can suffer textural changes due to the starch polymer chains associating. Thus starch gels will be lumpy on thawing after frozen storage. An array of structurally modified starches has been produced which can prevent these undesirable changes occurring during frozen storage of such processed convenience foods. (*See* **Starch**: Modified Starches.)

In general the minimal changes in organoleptic properties of appropriate frozen foods, along with

low nutritional changes (e.g., vitamin losses) and the inherent safety from microbial growth at such low temperatures (−20 °C or below) suggest the continued popularity of frozen storage where extended storage times (months) are required. With chill storage the knowledge that some pathogens can grow at 0 °C, e.g., *Listeria monocytogenes*, restricts storage times and necessitates strict time–temperature regimes. However the increasing demands for 'fresh-like' produce has led to improved storage periods at chill conditions by utilizing specific packaging (see below). (*See* ***Listeria***: Properties and Occurrence; **Spoilage**: Bacterial Spoilage.)

Moisture

The moisture (water) content of fresh tissue foods can be very high (above 70%) and this allows microbial spoilage to limit storage stability, if the temperature is not controlled. (*See* **Water Activity**: Effect on Food Stability.)

Foods can be made stable towards microbial changes, and also enzymatic and chemical changes, by reducing the water content. Figure 1 indicates how water activity, a_w (which is related to moisture content but attempts to measure how available the water is), is related to possible changes during storage. Fresh tissue foods have a_w above 0.95, jams (30% moisture) have a_w 0.80–0.75, dried fruits (20% moisture) have a_w 0.65–0.60, pasta (12% moisture) has a_w 0.50, whilst dry foods such as biscuits and cornflakes with 5% moisture or below have a_w below 0.30. Figure 1 would suggest that storage stability is assured if a_w is kept below about 0.3. For processed foods of such low a_w which are consumed directly (rather than rehydrated), their texture can be of critical importance. Thus the crispness of breakfast cereals, biscuits, and potato crisps (chips in the USA) is perhaps the major consumer expectation. Such products are hygroscopic due to their high carbohydrate content and can absorb water with resultant loss of the desirable crisp or brittle texture. Figure 1 also shows that dry foods, if lipid containing, can readily undergo oxidative rancidity – hence a potato crisp with oil content of 35% and a moisture content of 2–3% would be prone to both off-flavor production and loss of crispness during storage. (*See* **Drying**: Theory of Air-drying.)

Dehydrated foods intended for rehydration prior to consumption, e.g., dried potato mash, will absorb moisture with resultant clumping, which adversely affects the texture on rehydration.

In contrast to dried foods, intermediate-moisture foods (a_w 0.6–0.9) represent processed foods storable without refrigeration but which can lose moisture and acquire a dry rather than the desired moist texture – cakes and pastry products are typical examples. (*See* **Intermediate-moisture Foods**.)

The undesirable ingress or loss of moisture depends on the humidity of the surrounding atmosphere and can be controlled by packaging. Where intermediate-moisture foods and fresh (tissue) foods are concerned,

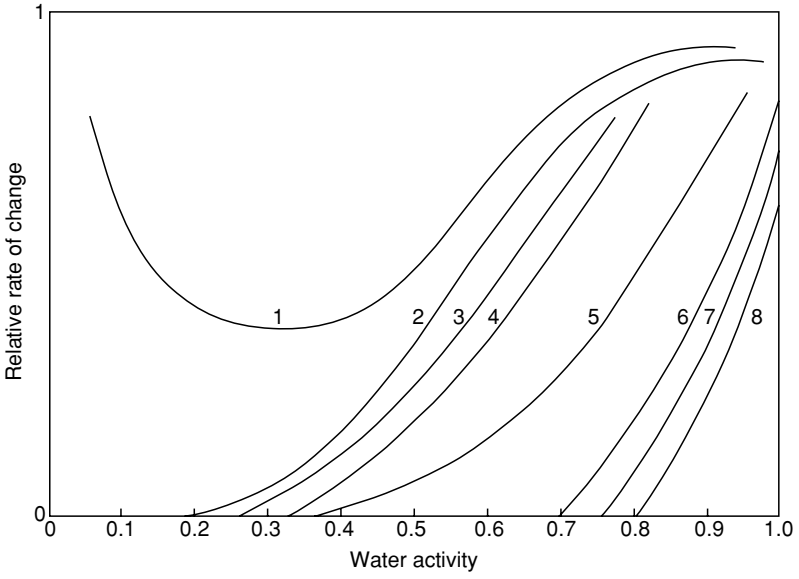

Figure 1 Stability of food as a function of water activity (a_w) at ambient temperature. $a_w = p/p_0$, where p and p_0 are the equilibrium partial vapor pressure of water in the food and of pure water respectively. Key: 1 Lipid oxidation; 2 nonenzymic browning; 3 hydrolytic reactions; 4 loss of ascorbic acid; 5 enzymatic activity; 6 mold growth; 7 yeast growth; 8 bacterial growth.

the high a_w could allow microbial – especially mold – growth. The composition of intermediate-moisture foods is controlled by use of humectants (e.g., sugar), pH, and preservatives in order to prevent migration of moisture and microbial growth. (*See* **Preservation of Food**; **Spoilage**: Molds in Spoilage.)

For fresh fruit and vegetables, where respiration continues, water is produced and will encourage mold growth if not removed, e.g. by storage in a dry atmosphere. However, such water loss must be minimized if undesirable texture changes are not to occur (e.g., loss of firmness of green vegetables and potatoes) – hence a reduction in temperature in order to slow respiration is often used. Bread has a relatively high moisture content (35–40%) and to maintain the desirable firm crust (which has a moisture content of 3–5%) the moisture which migrates from the interior towards the crust must be allowed to escape.

Packaging

Along with the general function of containing the food and preventing contamination, packaging can be an effective barrier against transfer of microorganisms, oxygen and, as already considered, moisture.

Additionally, exclusion of light and increasingly the control of the gaseous contents of the pack are important.

For sterilized foods prevention of ingress of microorganisms is the major requirement and metal containers (cans) have been so used for over 100 years. Flexible pouches and rigid plastic containers – the latter allowing direct reheating by microwave – are increasingly used. With oxygen removal (or reduction) such sterilized foods are storable for up to 12 months at ambient temperature. Detrimental oxidation of lipids, color, and flavors is accelerated by light and hence opaque packaging, e.g., metallized films, is beneficial. Discoloration in (metal) cans, e.g., with high-pH protein-rich foods (meat, fish), is avoided by the use of special lacquers on the inside surface of the can. (*See* **Canning**: Quality Changes During Canning; **Sterilization of Foods**.)

Where lipid oxidation is the major limitation to storage stability, vacuum or inert gas (nitrogen) packaging is beneficial. Vacuum packaging of cured meats and nitrogen flushing of dry roasted nuts and muesli are examples.

Carbon dioxide (CO_2) at -1 to $+2\,^{\circ}C$ has an inhibitory effect on microbial growth and this allows modified-atmosphere packaging (MAP), coupled with chill storage, to give 'fresh' food an extended storage life, which is commercially important for foods such as fresh meat, fish, fruit, and vegetables, and for fresh baked products but not for dairy products (Table 2). For fresh red meat, storage with high levels of oxygen (70–85%) is needed to maintain the desirable red color (otherwise the brown color typical of frozen stored meat is formed). Other examples are shown in Table 2, where the avoidance of oxygen for fatty fish should be noted, along with the high nitrogen concentrations to prevent pack collapse due to the high solubility of carbon dioxide in fish flesh. This latter aspect gives rise to increased 'drip loss' which is absorbed into a pad placed beneath the fish.

For fresh fruit and vegetables, their continuous respiration results in changes in the oxygen and carbon dioxide concentrations in the pack and the permeability of the packaging film to these gases must be considered.

The continuing and rapid respiration after harvesting of fruits, especially climacteric fruits such as bananas and apples, presents particular problems in extending their storage lives. The use of relatively low oxygen concentrations (2–3%) and high carbon dioxide concentrations (approximately 5%), allied with chill temperatures (0–5 °C), can reduce the rate of respiration and give a useful extension of the storage period. The required gas mixture can be achieved

Table 2 Examples of shelf-life extension using modified-atmosphere packaging

Commodity	*Gas mixture (%)*			*Shelf-life days (°C)*
	Oxygen	*Carbon dioxide*	*Nitrogen*	
Fish (lean)	30	40	30	10 (0) 5(+2)
Fish (oily)		60	40	10 (0) 5(+2)
Meat (red)	75–85	25–15		21 (0) 7(+2)
	70	20	10	21 (0) 7(+2)
Poultry		90	10	11 (+2)
Meat (cooked)			100	10 (+2)
Baked products (nondairy)		20–70	30–80	3 months (ambient)
Pasta (fresh)		50	50	3–4 weeks (0 to 5)
Strawberries	1–3	4–6	95–91	7 (+5)
Lettuce (iceberg)	2–3	5–6	93–91	21 (+5)

rapidly by gas flushing, and with permeable plastic packaging it can be maintained if the permeability to oxygen (from outside) and to carbon dioxide (generated inside the pack) is correctly allowed for. It is possible to achieve the required carbon dioxide and oxygen concentrations by simply packaging in air but equilibration then occurs more slowly. Recognition of the role of ethene (ethylene) in initiating the ripening process has suggested the use of 'active packaging' where ethene is removed by oxidation with potassium permanganate, normally included in a sachet within the pack. Such an approach has been used in Japan with kiwi fruit but is not presently (2002) used in the UK.

Genetic modification to prevent ethene formation, and hence ripening, is an alternative possibility and has been demonstrated with tomatoes. Ripening can then be initiated as required by the introduction of exogenous ethene. Such an approach would reduce dependence on MAP and refrigeration, resulting in a simpler and cheaper storage system. However, the present adverse consumer opinion concerning GM foods would be a major problem in applying this approach.

Some novel gas mixtures for use in MAP have recently been shown to have additional beneficial effects for fruit and vegetables. These include the use of very high oxygen levels (70–100%) and the gases argon and nitrous oxide. High-oxygen MAP can inhibit enzymatic discolorations, prevent anaerobic fermentations, and inhibit microbial growth, including aerobic microbial growth. The inhibition of enzymatic discolorations is particularly useful for minimally processed fruit and vegetables (e.g., peeled, sliced), such as apples and potatoes, susceptible to enzymatic browning, and offers an alternative to the use of sulfites.

The use of argon and nitrous oxide MAP is effective in reducing fungal growth, reducing ethene formation, and generally maintaining a higher-quality product, especially by comparison to the use of nitrogen.

The application of edible semipermeable coatings (e.g., semper-fresh) to fruits, especially exotics, has doubled shelf-lives at ambient temperatures. The coating, which can be applied to the ripe fruit at harvest, is edible, invisible, tasteless, and odorless and seals the fruit in its own modified atmosphere, which, while inhibiting oxygen inflow (and hence respiration) allows carbon dioxide to escape and hence prevents anaerobic effects which lead to unpleasant tastes. This approach could usefully be applied to minimally processed fresh produce, e.g., peeled and sliced fruit.

Food Additives

The technical functions of such chemicals, as distinct from any cosmetic, nutritive, or processing-aid functions, can be categorized as:

1. control of microbial changes, e.g., preservatives, a_w control
2. control of enzymatic changes, e.g., pH control, sulfites (SO_2)
3. control of chemical changes, e.g., antioxidants, sulfites
4. control of physical changes, e.g., emulsifiers, stabilizers, cryoprotectants

Traditional ingredients such as salt, sugar, and vinegar also serve as preservatives but are not legally defined as food additives. Hence the traditional use of salt was to reduce a_w and so restrict microbial growth. However the food additive preservatives are effective at very low concentrations, as shown in Table 3. Although high-acid foods (pH below 4) will restrict microbial growth, the preservatives in Table 3 allow control of microbial growth at up to pH 6.5. The majority are weak acids for which the presence of the undissociated acid is necessary for antimicrobial activity. Such preservatives allow storage at ambient temperatures for extended periods, e.g., benzoic acid in fruit squashes and nitrite in cured (canned) meat. Nisin is unusual in being a polypeptide and an

Table 3 Examples of chemical food preservatives

Preservative	*Typical food application*	*Maximum level (mg kg^{-1})*	*Organism affected*
Benzoic acid and benzoates (E210–213)	Low-sugar jams, marmalades	800	Yeasts and molds
Sorbic acid and sorbates (E200–203)	Cheese	1000	Yeasts and molds
	Low-fat spreads	2000	
Propionic acid and propionates (E280–283)	Bread	3000 (mg kg^{-1} flour)	Molds
Sulfur dioxide, sulfites, hydrogen sulfites	Fruit juice	350	
and metabisulfites[a] (E220–228)	Jams	100	Microorganisms
	Dried fruit	2000	
Nitrites and nitrates (E249–252)	Cured meats	150 (nitrite < 50)	Bacteria
Nisin (E234)	Cheese (processed)	12.5	Bacteria

[a]Enzymes are inhibited also.

antibiotic. It occurs in milk and is effective against some bacteria, but not yeasts or molds, and is used in processed cheese. (*See* **Curing; Nisin.**)

The development of low-sugar preserves necessitates the addition of a preservative (often sorbic acid) to prevent mold growth and a similar situation exists for low-fat spreads where the usual 80% fat of margarine can be reduced to below 30%, with corresponding increase in a_w and susceptibility to mold growth.

Table 3 indicates that propionic acid, usually in the form of calcium propionate, is used to control mold growth in bread. However some bakers have chosen to replace this preservative by vinegar, a solution of acetic acid in water. This change was due to adverse consumer perceptions of food additives or 'chemicals' (which could be identified by their E-numbers) in contrast to vinegar which is classed as an ingredient and does not carry an E-number. However the preservative action of vinegar is due to the acetic acid present – a weak acid like propionic acid.

Enzymatic activity varies widely with pH and is reduced by lowering the pH to below 4 but this acidic environment (e.g., use of vinegar) must be acceptable in terms of flavor – otherwise blanching may be preferred. Treatment with sulfur dioxide or sulfites is also effective – a particular application is prevention of darkening of potato slices/chips during chill or frozen storage. Such use for prevention of enzymatic browning of apple slices is restricted due to flavor taints but acid dipping (e.g., citric acid, lemon juice) is effective. Peroxidases in general cause oxidative changes to color and flavor and their control by heat treatment, pH control, or sulfites must be adopted to the particular food system. (*See* **Enzymes**: Functions and Characteristics.)

Chemical changes limiting storage stability are principally lipid oxidation and nonenzymatic (Maillard) browning. The latter is particularly relevant for dried milk, dried egg white, and dried fruits. Oxidative rancidity of lipids is a radical oxidation process and phenolic antioxidants (e.g., tocopherols, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT)) are effective at concentrations below 200 p.p.m. In practice combinations of a phenolic antioxidant and ascorbic acid are often used since they have a synergistic effect. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants; **Browning**: Nonenzymatic; **Oxidation of Food Components**.)

The maintenance of the correct physical state of a food can include maintaining the free-flow properties of a powder (e.g., table salt or icing sugar) and the stabilization of oil–water emulsions (e.g., salad cream), whilst humectants (sugar, glycerol) help to prevent moisture loss and hence dry textures. The texture of a food often depends on it being a colloidal system (emulsion, gel, foam) and additives are necessary to stabilize such systems, especially if long storage times at low temperatures are involved. (*See* **Stabilizers**: Types and Function; Applications.)

Emulsifiers, like the naturally occurring lecithin in egg yolk, help to form stable mixtures (emulsions) of oil and water which are found in salad creams, mayonnaise, margarine, icecream – the last has air incorporated whilst freezing to form a solid foam. To aid emulsion stabilization, e.g., in salad creams, thickening agents (referred to as stabilizers) are used to increase viscosity and so hinder oil and water separation. Such stabilizers are natural polysaccharides like starch, seaweed extracts such as alginates and carrageenans, plant extracts such as gum arabic, carob gum (locust bean gum) and pectins, and microbially produced xanthan gum. Blends of these so-called hydrocolloids are widely used to create and to maintain texture in chilled and frozen processed foods, especially dairy products ranging from icecream to gelled milk products and yogurt. (*See* **Emulsifiers**: Organic Emulsifiers; Phosphates as Meat Emulsion Stabilizers; Uses in Processed Foods.)

Less obvious applications are the use of the emulsifiers to retard bread staling, the use of a suspending agent, often carboxymethyl cellulose, to maintain the water-insoluble carotene pigment as a fine dispersion in orange squashes (and so prevent the 'orange scum' at the top of the bottle!), and the use of glyceryl monostearate in dried potato mash to insure rehydration without stickiness developing.

Additives can usefully be incorporated into products to minimize textural changes during their frozen storage. The use of hydrocolloids in this connection has been referred to above, and they are often referred to as cryoprotectants in this connection. Thus the addition of cryoprotective alginates to icecream helps to prevent ice-crystal formation (and hence 'grittiness') during storage. The manufacture of surimi (frozen, stabilized washed fish mince) depends on the incorporation of a cryoprotectant mixture consisting of 4% sucrose, 4% sorbitol, and 0.3% polyphosphate. This prevents protein denaturation during frozen storage, and so maintains the heat gelation properties of the fish proteins required for the production of products such as shellfish analogs (crab sticks), fish sausage, noodles, and burgers. Recently so-called 'antifreeze proteins' have been isolated from cold-water (e.g., Antarctic) fish and shown strongly to inhibit ice-crystal formation in icecream products and to reduce ice-crystal formation in frozen meat, with resultant reduced drip loss on thawing. Presently the high cost of these cryoprotectants precludes their commercial application.

Shelf-Life Extension

It is clear from the examples mentioned that methods adopted to insure shelf-life extension must consider the state of the food at the point of storage and select the best combinations of the relevant parameters.

Organoleptic reasons and concepts of naturalness are increasingly important factors in determining the methods used to insure the required storage stability. Thus the increased use of MAP allied with the use of chill rather than frozen storage is related to its 'fresh' appeal, in contrast to frozen food which has a 'processed' image. Heat sterilization and sealing under reduced air content, as typified by traditional canning, or frozen storage at −20 °C or below allows safe storage for many months but flavor/texture changes may arise.

The sous-vide or nouvelle carte processes have been promoted as maximizing flavor, texture, and nutrient content, as well as being bacteria-free. These processes involve vacuum packing in heat-resistant packaging, cooking the vacuum-packed product under vacuum in a moist steam oven or pressure cooker at less than 110 °C, rapidly cooling, and storing at 1–4 °C for up to 3 weeks. This represents the combination of chill storage, relevant packaging, and exclusion of oxygen to extend shelf-life. Where low-acid foods are concerned, the additional use of preservatives is suggested and overall a maximum storage time of 2 weeks is recommended.

When chill storage is used, the shelf-life is measured in days and there is less of a margin for storage abuse than with frozen storage. For foods which are chill-stored and which are not reheated (above 70 °C) before consumption, the recommended chill storage temperature and time must be carefully observed. This places more emphasis on accurate sell- and use-by dates by the processor, careful stock control by the retailer, and increased awareness by the consumer.

Shelf-life Testing

M Hole, University of Lincolnshire and Humberside, Lincoln, Grimsby, UK

Introduction

The shelf-life of a food is perhaps the most important detail a consumer needs to know in relation to their purchase and home storage of foods. This information is embodied in the 'best before' and 'use by' dates indicated for the food, and which are required by law to be clearly shown on the food packaging. The 'use by' date is particularly critical in relation to the safe consumption of a purchased food. Such foods have relatively short shelf-lives, often in terms of days, and include fresh and chilled meats and dairy products. In contrast, 'best before' dates are used for foods where quality, rather than safety, is the practical concern – thus, a potato crisp, which has absorbed moisture so that it has lost its crispness, is of undesirable quality but does not pose a food safety issue.

If the manufacturer should propose an unrealistic shelf-life, leading to a 'use by' date that is too long, then the likely consumer complaints due to adverse health and/or quality aspects, possibly requiring product recalls, would do great damage to the manufacturer's reputation. The subsequent commercial consequences for the food manufacturer would be serious, and it is obvious that the correct determination of the shelf-life is most important – for both the manufacturer and the consumer. The consumer can obtain very useful information on the purpose of 'use by' dates from the Foodsense leaflets provided by the Ministry of Agriculture, Fisheries and Food.

In unprocessed and unpreserved foods, the factors that limit the shelf-life are mostly related to the growth of spoilage microorganisms, whilst, in non-perishables, chemical and physical factors become more important, e.g., development of off-odors and off-flavors due to rancidity in fried snack foods, moisture migration in biscuits, and staling of bread and cakes. The factors that limit the shelf-life of a selection of foods are indicated in Table 1.

In order to give an indication of the shelf-life of a product, some type of test must be available to the manufacturer. Storage studies would normally be performed as new products are developed, with regular testing for the shelf-life limiting factors. However, with some long-term preservation methods, it may be more convenient to have accelerated shelf-life studies. This would enable production to commence quite rapidly after the initial development of the product.

Table 1 Factors that limit the shelf-life of foods

Type of food	*Acceptability criteria*
Bread	Mold growth
	Loss of moisture, staling
Breakfast cereals	Rancidity development
	Moisture gain/loss of crispness
	Vitamin loss
Dried pasta	Moisture gain (or loss)
	Color loss
	Adsorption of undesirable flavors
Fried snack foods	Oxidative and hydrolytic rancidity
Fresh poultry	Pathogen growth/microbial decay
	Bruising
Frozen poultry	Sensory quality changes
	Color changes/rancidity
	Syneresis, moisture loss
Fresh meat	Bacterial growth
	Loss of color
Fresh fish	Bacterial decomposition
Frozen fish	Lipid oxidation
	Protein denaturation (toughening)
Frozen vegetables	Color
Dairy products and milk	Bacterial growth
	Lipid hydrolysis/flavor changes
Ice cream	Textural changes
	Oxidation of lipid
Evaporated milk	Loss of vitamins
Salad dressing	Breakdown of emulsion
	Color/flavor changes
Canned foods	Taste/flavor changes
Chilled foods	Bacterial growth
	Flavor changes

Experimental Design

With any experimental procedure, results will only be valid if the initial sampling and testing stages are carefully planned and controlled. If any statistical analysis of the result is required, then the testing procedure should be designed to be appropriate to the statistical method being applied. The samples taken should be representative of the whole batch and, in careful shelf-life studies, samples should include any extremes of product storage conditions. It is also important to test at regular intervals during production, especially after any change in ingredients or methods of production. The design of any procedure for testing shelf-life should include consideration of the following factors:

- elucidation of the major types of quality loss for the product (see Table 1 for examples);
- knowledge of the factors that control the initial quality during manufacture, e.g., use of food additives;
- the environmental conditions of storage, e.g., temperature, equilibrium relative humidity (ERH), and light;
- the type and properties of the packaging to be used, e.g., permeability to oxygen, light and moisture;
- the kinetics of the reaction or reactions leading to loss of quality in the actual food (stored in the usual way).

Acceptability Criteria

The acceptance of a food product depends to some extent on the individual preferences of the consumer; however, all consumers have a right to expect wholesome foods that will not cause disease, are of attractive appearance, and are of a good (unchanged) nutritional value. The major attributes of acceptability can be described as: absence of pathogenic microorganisms; low levels of spoilage organisms; absence of off-flavors; no deterioration in color or overall appearance; no loss of desired texture; and high (unchanged) nutritional value. It is the function of the manufacturer to decide upon suitable acceptability limits for each type of product, and this should form part of the specification of that product.

Methods of Testing

It is vital that the tests carried out need to relate specifically to the safety aspect concerned or, in quality terms, relate to the limiting quality criteria.

The main methods of testing the shelf-life of a food include chemical/physical tests, microbiological enumerations and sensory evaluations. Due to the complex nature of most composite foods, many chemical tests, e.g., to establish nutrient levels, are very lengthy, often involving complex extraction procedures and use of sophisticated and expensive equipment. Microbiological and sensory tests are generally regarded as easier to perform and are more adaptable for use in nonspecialized laboratories.

Although the ultimate test of a product's acceptability or attractiveness lies with the consumer, the consumer cannot necessarily judge whether foods are safe.

Microorganisms

The first criterion of any testing is to insure that the product is safe – both from food-poisoning microorganisms and from any toxins. Food-poisoning organisms, e.g., *Salmonella typhimurium*, may be detected by growth of the organism on selected media, but growth is usually relatively slow, and a result would not be obtained until 3–4 days after the test had been initiated. Rapid methods of measuring microbial concentrations are now available, and a range of automated instrumental methods can be used, e.g., the 'Bactometer'. (*See* **Food Poisoning**: Tracing Origins and Testing; **Microbiology**: Detection of Foodborne Pathogens and their Toxins.)

Chemical Toxins

A variety of tests can be utilized to test for the range of toxins found in foods. For example, the presence of toxic metals, e.g., mercury or lead, may be determined by the use of atomic absorption spectrometry, and the highly toxic aflatoxins, produced as secondary metabolites from the growth of the mold *Aspergillus flavus* on cereals, may be detected by using the fluorescent properties of the compounds, e.g., use of high-performance liquid chromatography with fluorescence detection. (*See* **Heavy Metal Toxicology**; **Mycotoxins**: Occurrence and Determination.)

Flavor Changes

From Table 1, it is apparent that the shelf-life of 'microbiologically safe' foods is often limited by either changes in flavor or development of off-odors and off-flavors, e.g., production of volatile carbonyl compounds from lipid oxidation leading to rancid flavors. These changes in flavor may be monitored by sensory means or from utilization of analytical techniques such as headspace gas chromatography. With this technique, the volatiles arising from a foodstuff are swept into a chromatography column contained in a thermostatically controlled oven. A carrier gas moves the flavor compounds through the column where selective separation occurs, depending on the polarity of the packing material (stationary phase) of the column and the molecular structure of the volatiles. Eventually, the separated compounds are detected and are registered as a peak on a trace. The identity of the peaks may be established by comparison of their retention times with standards or from coupling the gas chromatography with a mass spectrometer. The contribution of a specific volatile to any off- or undesirable odor may be found by smelling the individual components as they emerge from the column. Increasing use is made of 'electronic noses' (e.g., 'Aromascan') for the instrumental characterization of aroma. In contrast to gas chromatography, these electronic noses detect the overall aroma, giving rise to an aroma fingerprint that can be used to indicate the shelf life limit. (*See* **Sensory Evaluation**: Aroma.)

It is well established that a wide range of analytical tools are available to the food analyst for determination of the (molecular) components of foods that may be responsible for any shelf-life deterioration, e.g., nutrients (essential amino acids and vitamins). In some foods, determination of the factors that actually limit shelf-life may involve very complex analyses; thus an associated factor, which changes at the same rate but does not affect shelf life directly, may be used. The reader is referred to the bibliography for a more thorough review of methods used in the chemical analysis of foods.

Color

Changes in the color of foods are often major factors limiting shelf-life. Instrumental testing of surface color, or of the color of a well-homogenized sample, may be achieved with a colorimeter, which gives results in terms of the Hunter L, a and b values. That is, a measure of the degree of 'whiteness,' 'redness,' and 'blueness' of a sample. Otherwise, comparisons of the food color with acceptable colors are useful, but this is essentially a sensory method of analysis. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; Properties and Determinants of Synthetic Pigments; **Sensory Evaluation**: Appearance.)

Texture

Sensory methods are also used to provide information on the texture of foods. Attributes such as firmness, crispness, juiciness, and chewiness are fairly typical of those used. In addition, the texture of certain foods, e.g., biscuits and apples may be measured using physical (instrumental) tests and equipment such as the Instron. This particular piece of equipment may be modified to undertake a variety of penetration, extensibility, or shearing tests. (*See* **Sensory Evaluation**: Texture.)

Sensory Methods

A wide variety of sensory evaluation tests are available for use in testing the acceptability of foods. The tests may be classified into those that are affective (i.e., ask for an opinion or preference) and those that are nonaffective (i.e., require a score to be assigned for a particular attribute). However, for shelf-life studies, it is usually more appropriate to use scoring tests. For the results to be meaningful, it is important to have a suitably designed taste panel/sensory test giving results that can be statistically validated. This also requires the establishment of a null hypothesis, e.g., no difference between the samples presented, in order to establish the significance of the results. It is usually recommended that at least 10 persons are required to act as panellists if the results obtained are to be valid, the actual number depending on their level of training (if untrained, then more panellists will be required). Sensory panels are sometimes regarded as time-consuming and expensive to set up, but they do have an advantage over instrumental methods in that several attributes of the food can be measured in one session. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods; Food Acceptability and Sensory Evaluation; Practical Considerations; Descriptive Analysis.)

Accelerated Shelf-life Testing

Ideally, a food would be tested under the conditions of intended storage in order to measure the length of time over which it is acceptable, whether from a safety or quality aspect. For a food with a shelf-life of a few days or weeks (e.g., chilled meat), this is no problem, but for foods with shelf-lives of months, or years, the manufacturer would like a quicker method, i.e., one that gives a result in a shorter time than the shelf-life under the intended storage conditions.

Since storage temperature is usually the main factor influencing the shelf-life, most accelerated methods simply use a higher temperature than the intended storage temperature and hope to relate the shorter shelf-life at the higher temperature to the shelf-life at the intended storage temperature. The theoretical basis is related to the Arrhenius relationship, one form of which is:

$$\ln k = cst. \frac{-Ea}{RT},$$

where *cst.*, *Ea* (the activation energy), and *R* (universal gas constant) can be taken as constants. Hence:

$$\ln k \propto \frac{1}{T},$$

where T is the temperature (degrees Kelvin), and k is the rate constant, which, in this context, can be related to the shelf-life time, i.e.:

$$\ln(\text{shelf-life}) \propto \frac{1}{T}.$$

A graph of ln(shelf-life) against $1/T$ will give a straight line (see Figure 1). Thus, if the shelf-life is measured

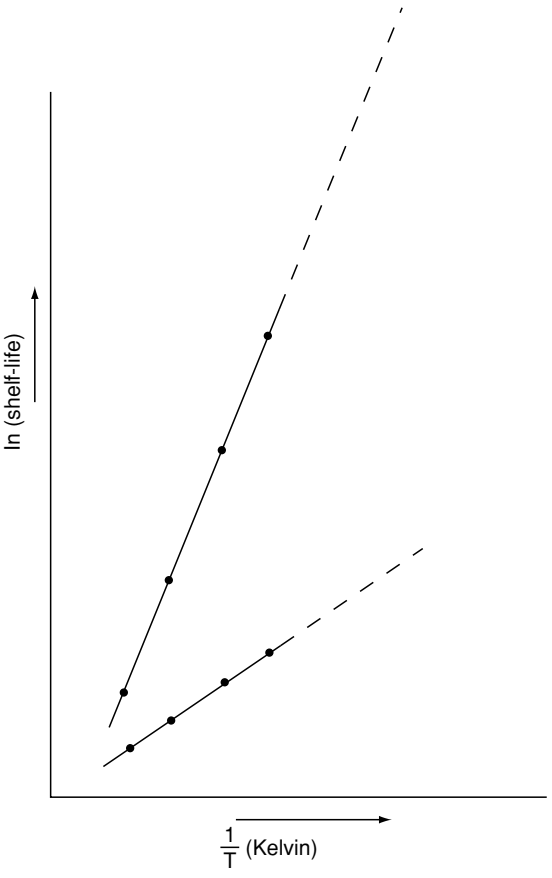

Figure 1 Arrhenius plot showing extrapolated shelf-lives for two foods with different rates of quality deterioration.

for a series of temperatures higher than the intended storage temperature, extrapolation will give the shelf-life at the lower temperature. The method has limitations and can be costly, but this approach is often used. Some examples are given below; other examples will be found in the bibliography. Frozen foods often have shelf-lives of many months, or years, and accelerated shelf-life testing can be usefully applied. However, the elevated temperature in this case must be realistic – a temperature at which the food was not frozen would not be realistic. Thus, the shelf-life at an intended storage temperature of $-30\,^{\circ}C$ might be usefully indicated from shelf-life measurements made at up to $-5\,^{\circ}C$. This would ensure that the food matrix was similar (i.e., frozen) at the elevated temperatures. This illustrates an important point; the nearer the elevated temperatures are to the intended storage temperature, the more realistic the extrapolated shelf-life will be.

Where foods are being reformulated and the effect of different formulations on shelf-life is needed, accelerated methods are very useful in indicating relative shelf-lives. This allows a new shelf-life to be proposed from a knowledge of the original shelf-life. It has been stressed that the shelf-life determinations are only relevant if based on measurements of the actual limiting factor, for example, odor. This aspect can become critical when accelerated shelf-life testing is carried out, if the limiting factor changes at the higher temperature. An example (discussed by Labuza – see Further Reading) is provided by the storage of dehydrated mashed potato. At ambient temperatures, the limiting factor is off-odors from lipid oxidation, but above about $40\,^{\circ}C$, the limiting factor for organoleptic acceptance is discoloration due to Maillard browning (*See* **Browning**: Nonenzymatic). Hence, if accelerated shelf-life testing is carried out above $40\,^{\circ}C$, sensory analysis will give results that extrapolate to an incorrect shelf-life for ambient temperature storage. More specifically, results obtained above $40\,^{\circ}C$ extrapolate to a shelf-life above 1000 days at $20\,^{\circ}C$, whilst measurements made at $20\,^{\circ}C$ (where odor is the limiting factor) indicate a shelf-life of about 500 days.

Thus, the food system must be carefully studied to insure that the accelerated shelf-life testing is done as realistically as possible. The sensitivity of a food to temperature changes is indicated by the slope of the 'Arrhenius graph' (*See* Figure 1) – the more sensitive food having the larger gradient. An alternative approach is the use of the Q_{10} value, where

$$Q_{10} = \frac{\text{rate at } (T+10)^{\circ}C}{\text{rate at } T\,^{\circ}C}$$

or

$$Q_{10} = \frac{\text{shelf-life at } T\,^{\circ}C}{\text{shelf-life at } (T+10)^{\circ}C}.$$

The more sensitive the food is to temperature change, the higher the Q_{10} value, as illustrated in Table 2. For an initial shelf-life of 100 days at $T\,^{\circ}C$, a food with $Q_{10}=2$ would have a half-life of 50 days at $(T+10)\,^{\circ}C$, whilst if $Q_{10}=4$, the half-life would be 25 days at $(T+10)^{\circ}$.

Table 2 Q_{10} values for selected foods

Type of food	*Q_{10} value*	*Criteria for end of shelf-life*
Fresh cod	4.4	Bacterial growth
Sterilized milk	1.71	Flavor change
Pasteurized milk	2.64	$>10^6$ CFU[a] ml^{-1}
Pasteurized egg	5.37	Flavor change
Spray-dried egg	1.21	60% loss of vitamin A
Margarine	1.91	25% loss of vitamin A
Canned kidney beans	1.7	20% loss of thiamin

[a]CFU, colony-forming units.

Prediction of Shelf-life

The use of accelerated shelf-life testing avoids the need for prolonged storage studies – and in reality is a predictive method based on measurements made at higher temperatures than the actual storage temperature. The possible problems with accelerated shelf-life testing can be minimized if predictive methods using data from the actual storage conditions can be used. Thus, if the rate of deterioration (i.e., the kinetics) is known (at the actual storage temperature), initial values of the loss of quality, for example, can be used to indicate the quality loss, and hence shelf-life, for extended storage times.

The loss of quality for most foods can be represented by:

$$-\frac{dA}{dt} = kA^n,$$

where A is the quality factor measured, e.g., extent of nonenzymatic browning, t is the time, k is a constant that depends on the temperature and water activity, n is a power factor giving the order of the reaction and dA/dt is the rate of change of A with time (negative, loss of A; positive, production of undesirable end products). In practice, zero-order ($n=0$) or first-order ($n=1$) kinetics are relevant for quality changes in foods.

Zero-order Kinetics

The order of the reaction, n, defines whether the rate is dependent on the value of A. Many food systems

are assumed to behave as zero-order reactions ($n = 0$). Thus, the rate of loss is constant under constant storage conditions. Thus:

$$-\frac{dA}{dt} = k,$$

which may be integrated to give

$$A = A_o - kt \quad \text{or} \quad A_e = A_o - kt_s,$$

where A_o is the initial quality value at time t, A_e is the value of A at the end of the shelf-life and t_s is the shelf-life in days, months, or years.

A may be defined analytically or by taste-panel evaluation. If A_o is assumed to be 100% quality and A_e just acceptable quality, then:

$$k = \frac{A_o - A_e}{t_s} = \frac{100\%}{t_s},$$

Thus, based on this knowledge, it is possible to predict the shelf-life of a food at a single given temperature, if the value of the quality change at any given time is known.

For example, if it is known that a certain food has lost 25% of its quality in 50 days when held under constant conditions, then the rate of loss:

$$k = \frac{A_o - A}{t} = \frac{100 - 75}{50} = 0.5\% \text{ per day}.$$

The amount of shelf-life left as a function of time may also be represented by a graphical plot (Figure 2).

Reaction types in foods that are thought to give zero-order kinetics include enzymatic degradation, nonenzymatic browning, and lipid oxidation (rancidity). Loss of quality of frozen foods in general follows zero-order kinetics.

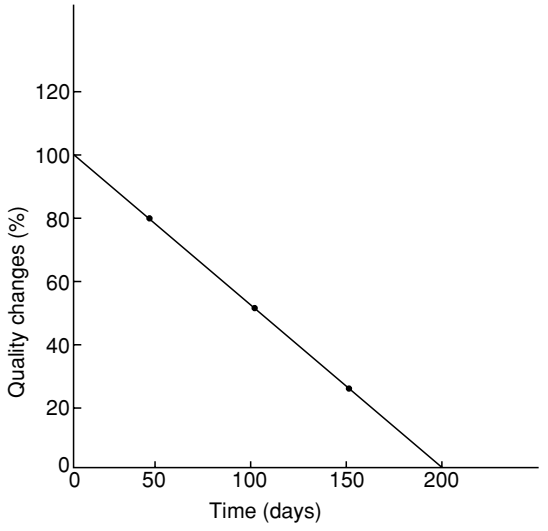

Figure 2 Zero-order reaction plot showing residual shelf-life against time ($k = 0.5\%$ per day).

First-order Kinetics

Many foods deteriorate by first-order kinetics ($n = 1$), which results in an exponential decrease in the rate of change as the quality decreases. Thus, the rate of quality loss is directly dependent on the amount left:

$$-\frac{dA}{dt} = kA.$$

Integration gives:

$$\ln (A_c/A_o) = -kt_s.$$

A semi-logarithmic plot of A_c/A_o against time (t) gives a straight line with slope k.

The types of deterioration that follow first-order kinetics include microbial growth (fresh meat and fish), microbial production of off-flavors, vitamin losses (canned and dried foods), and loss of protein quality (dried foods). (*See* **Canning**: Quality Changes During Canning; **Fish**: Spoilage of Seafood; **Meat**: Preservation.)

A knowledge of the kinetics of food deterioration has been incorporated into computer packages, which can be applied to rapidly predict shelf-lives for more complex situations.

Such computer-based predictive models were developed initially to predict the growth of pathogens in foods in order to predict shelf-lives where the food would be safe to eat. The 'Food Micromodel', developed by the Ministry of Agriculture, Fisheries and Food in the early 1990s is such a model and can be applied to predict the growth of a wide range of microorganisms, both pathogenic and spoilage organisms, under a wide range of storage conditions. The approach is particularly relevant for chilled foods, and the 'Forecast' service provided by Campden and Chorleywood Food Research Association (CCFRA) allows the prediction of the growth of common spoilage bacteria for a range of storage conditions (pH, temperature, salt content, etc.). Another example of a computer-based predictive model (also from CCFRA) is the prediction of mold-free shelf-life using the ERH CALC™ package. This model allows rapid calculation of the ERH (or water activity) and hence the growth of molds from a knowledge of the ingredients and storage conditions of bakery products.

Time–Temperature Indicators (TTIs)

Since temperature is such an important factor in determining shelf-life, it would be useful to know the full thermal history of a food after processing. Any thermal abuse during distribution and storage would alter the shelf-life, and hence the 'use by' date of the food.

Time–temperature indicators are available that give a full thermal history of the food, and such sensors attached directly to the packaged food would be most useful in this connection. If they were linked to the computer-based models for shelf-life prediction, any temperature abuse would result in a new shelf-life prediction.

Home Storage

There is an obvious need for the manufacturer's storage instructions to be followed in order that the 'use by' date is valid. The food industry can arrange the correct storage conditions up to the point of sale, but thereafter, it is necessary for the consumer to insure correct home storage, especially for chilled foods. The possible lack of correct temperature control during home storage indicates the need for some margin of error to be incorporated, especially into the 'use by' date.

STRAWBERRIES

R B Smith and L J Skog, University of Guelph, Vineland Station, Ontario, Canada
A Dale, University of Guelph, Simcoe, Ontario, Canada

Background

The strawberry belongs to the genus *Fragaria*, and is a member of the rose family, Rosaceae. The cultivated strawberry, *F.* × *ananassa* L. Duchesne, is a hybrid between *F. chiloensis* Duch and *F. virginiana* Duch. The *ananassa* designation is due to the resemblance to the pineapple in flavor, odor, and shape. *F. chiloensis* was introduced into Europe from Chile and *F. virginiana* from eastern North America. The fruit of the strawberry is grown and enjoyed worldwide. This article discusses the global distribution, varieties, commercial importance, morphology, nutritional composition, handling, storage, and industrial uses of this crop.

Global Distribution

The strawberry plant is highly adapted to a wide range of climatic and soil conditions. Commercial plantings of strawberries are found on every continent (except Antarctica) and from the subarctic (Finland) to the tropics (Ecuador). However, most of the world's production is in the northern hemisphere (Table 1). Strawberries are planted on soil types ranging from desert sands requiring extensive irrigation to heavy clay soils requiring underdrainage and the addition of organic matter. In subarctic areas, the plants may be exposed to temperatures as low as $-50\,^{\circ}C$ in winter and as high as $40\,^{\circ}C$ in summer. In desert areas, temperatures may be above $50\,^{\circ}C$ in the day and near $0\,^{\circ}C$ at night. Where harsh winter conditions prevail, plants may be protected from extreme temperatures by covering with straw or other organic mulch. Mist irrigation is sometimes used to cool the fruit and leaves under conditions of high summer heat.

The geographical areas with the highest total production and the highest production per hectare are located where there is a Mediterranean-type climate. These areas include California, Spain, southern Italy, and southern France. In these areas strawberries can be produced virtually all year and day-neutral varieties, i.e., those in which fruit bud initiation is independent of day length, are grown more extensively. The June-bearing varieties, which predominate in most other growing areas, have a requirement for a short day (some as little as 8 h).

Varieties

The commercial strawberry is a heterozygous octoploid with characteristics inherited mainly from two genetically variable wild species. The first crosses between *F. chiloensis* and *F. virginiana* were made in Europe in the early 1760s. Breeding work with other species has not been successful, primarily owing to genetic incompatibility.

Variability in the wild species has been used by breeders who use parents with desired traits when crosses are made. When seeds from a cross are planted, the resultant plant is a clone. Thus, breeders select individual plants with desired characteristics rather than selecting a population of plants.

The general objectives of strawberry-breeding programs are as follows: (1) to enhance yields; (2) to improve fruit quality, which includes factors such as flavor, firmness, keeping quality or other characteristics; (3) to produce plants adapted to specific environmental or cultural conditions; (4) to develop varieties resistant to diseases and insects; and (5) to develop varieties with specific requirements, such as suitability for mechanical harvesting and processing, or extra firmness for long-distance shipping. New strawberry varieties are continuously being introduced, thus worldwide they number in the hundreds. Some of the more important varieties are listed in Table 2.

Commercial Importance

The Food and Agriculture Organization (FAO) lists strawberry production statistics for 64 countries. Seven countries – Spain, Japan, Korea, Turkey, Poland, Mexico, and the USA – account for more than 66% of the world's 2.7×10^9 kg annual production (Table 1). This worldwide production would have a farm-gate value of over $\$5.4 \times 10^9$ (US) based on their value in North America. This return would represent $\$2\ kg^{-1}$, averaged for fresh-market berries.

In countries such as Poland and Mexico, a large portion of the crop is processed and sold for foreign currency. In the European Community (EC), strawberries are an important cash crop as this trading block produces over 7.0×10^8 kg annually. Much of the fresh crop produced in the USA and the EC is shipped to northern areas for fresh-market consumption. Growers harvesting for fresh-market consumption receive a higher price per unit of fruit than those harvesting for processing, but fresh market harvesting costs are higher.

Yields in the state of California are over 40 000 kg ha^{-1} – a level of production two to six times that of other areas in the USA or in other countries. California produces 80% of the US crop, and 65% of the

North and Central American crop, making it an important cash crop in that state.

In some countries, particularly around large cities, consumers are invited by growers to pick their own fruit. This has become a very important means of harvesting and marketing the strawberry crop. Pick-your-own farm operators do not have problems finding labor to harvest their berries. However, there are other problems, such as in-field consumption, crowd control, incomplete harvesting, and grower–public interaction.

Morphology

The strawberry is an accessory fruit with an aggregate of achenes (the true fruits which contain the seed), attached in an orderly fashion to the epidermis of the receptacle (the floral axis to which the various flower parts are attached). The large, fleshy receptacle (consisting of pith, cortex, and a vascular system) is the succulent, edible portion of the fruit. It expands in response to hormones produced by the ovules after fertilization has occurred.

The fruit of the commercial strawberry has a red-colored exterior and an interior color ranging from white to dark red. Fruit shape depends on such factors as variety, environmental conditions under which it was grown, and planting location. Fruit size, which varies considerably even within cultivars, depends on environmental factors and position of the fruit within a cluster. The primary berry is the largest and has the most achenes. Secondary and tertiary berries become progressively smaller and have fewer achenes. The fruit ranges between 2 and 5 cm in length depending on variety and other factors. Descriptors used to identify the shapes of strawberries include globose, globose conic, conic, long conic, oblate, necked (a long neck), long wedge, and short wedge.

Table 3 Nutrient composition (per 100 g fresh weight) of strawberries compared to that of apples and oranges

Nutrients and units	*Strawberry*	*Apple*	*Orange*
Water (g)	91.57	83.93	86.75

Vitamin A (μg)	8.1	1.5	6.3

Data from USDA (1982) *Composition of Foods: Fruits and Fruit Juices, Raw, Processed, Prepared*. US Department of Agriculture, Human Nutrition Information Services, Agriculture Hand-book, pp. 8–9. Washington, DC: US Government Printing Office.

Chemical and Nutritional Composition

A list of some of the nutrients in strawberries is presented in Table 3, with those for apples and oranges included for comparison. The strawberry contains the

highest percentage of water and the lowest level of food energy of these fruits. An intake of 100 g of strawberries would provide the US Department of Agriculture adult daily requirement for ascorbic acid (vitamin C). The ascorbic acid content of strawberries is slightly higher than that of oranges, and much higher than that of apples. Although not a rich source of potassium, a 100-g portion would provide about 10% of the suggested minimum estimated safe daily intake. This is more than apples, less than oranges, and about 42% of that provided by bananas.

Strawberries contain several vitamins and minerals (Table 3) in concentrations that would provide less than 5% of the minimum daily requirement. There are also 18 amino acids in strawberries, but all occur in extremely low concentrations. (Refer to individual nutrients.)

Handling and Storage

Strawberries are sold by volume or by weight. The volume containers hold approximately 0.25, 0.5 or 1 l. A small container would hold approximately 225 g; some of the larger containers may hold up to 3 kg. Fruit for the fresh market is generally harvested directly into the retail container. These are placed in fiberboard or corrugated trays, or masters, each holding a convenient multiple of the smaller harvesting containers.

Fresh-market strawberries must be harvested in a manner which eliminates, or keeps to a minimum, bruising, skin disruptions, and the bleeding of fruit juices. Berries should be harvested by pinching off the stem at the cap, as clasping the fruit between the fingers and then pulling causes excessive bruising. Good commercial practice is to hold harvested fruit out of the sun and protected from warm winds and blowing dirt. Growers following recommended practices move their fruit to cold storage within 1 or 2 h of harvest. Warm fruit bruises easily and must be transported gently.

Field heat must be removed rapidly to reduce losses from rot, caused by fungi such as *Botrytis cinerea* (grey mold), *Phytophthora cactorum* (leather rot), and *Rhizopus nigricans* (black whisker rot). These fungi either grow very slowly, or not at all, at fruit temperatures of 0–2 °C. Changes in the fruit associated with senescence, e.g., skin darkening, softening of the flesh, and loss of flavor, occur more slowly at lower temperatures. (*See* **Ripening of Fruit**.)

Forced-air cooling is the preferred method of removing field heat in many strawberry-producing areas. In these coolers, the fruit can be cooled from 25–35 °C to 2–4 °C within 1–2 h. In these coolers, trays of fruit are placed so as to form the side walls of a plenum, open to a wall with an exhaust fan. With the open top and end covered with fabric, chilled air is drawn from the cold room through the trays of fruit. To retain the best quality, the chilled fruit is held at 0–2 °C and 90–95% relative humidity. Fruit treated in this manner can be stored for 5–7 days and retains its quality during 3–5 days of marketing after storage. (*See* **Controlled-atmosphere Storage: Applications for Bulk Storage of Foodstuffs.**) In some growing areas, fruit is forced-air-cooled on pallets and then covered with an airtight plastic bag. Carbon dioxide is added to an approximate level of 15% to help maintain quality during shipping to market. Some varieties of strawberries become 25–40% firmer when they are exposed to 10–20% carbon dioxide; with others, the carbon dioxide serves only to maintain firmness. There are fewer losses from decay among these berries, and their respiration rates are reduced.

Although the vast majority of strawberries are harvested by hand for the fresh market, a small number are mechanically harvested (predominantly in Europe). Mechanically harvested berries are not suitable for the fresh-market trade because of extensive bruising during the harvesting process. However, mechanically harvested fruit is suitable for processing. The berries from the harvester are collected in large totes, or bulk bins, for transporting to the processing facility. This fruit is processed within a few hours of harvest and thus may not be cooled before processing. Recovery of finished product is generally higher when the fruit is cooled before processing. The quality of mechanically harvested berries does not deteriorate excessively for 2–3 days, possibly longer when they are cooled to 0–2 °C immediately after harvesting. Mechanically harvested fruit does contain a moderate quantity of green berries. Some of this green fruit is incorporated into the end product without affecting quality.

Industrial Uses

Although most strawberries are destined for the fresh market, there are certain production areas that concentrate on processed fruit. Inferior fruit from the fresh market, and a small quantity of mechanically harvested fruit with green berries included, are used for making purée, juice, and concentrate. The purée and the juice are preserved by freezing or by adding sulfur dioxide. Hand-harvested fruit is processed as frozen whole pack with or without sugar, individually quick-frozen (IQF), brined in sulfur dioxide, or heat-processed in lacquered cans. Since fruit is needed throughout the year, products for further processing are usually stored in bulk containers. During

processing, calcium salts are often added to the fruit to minimize structural changes. (*See* **Freezing**: Operations.)

Brined fruit, used in the manufacture of some strawberry jams, can be preserved in more than 2000 p.p.m. sulfur dioxide. Much of the sulfur dioxide dissipates during the cooking process. Fast freezing of strawberries is essential for retention of firmness and quality. Fast freezing is either accomplished in an air-blast freezer where jets of cold air blow up through berries on a mesh belt, or the berries are frozen in liquid nitrogen; both methods provide IQF fruit. Berries can also be fast-frozen in small packages in a blast freezer or more slowly in larger containers on pallets in a freezing room. When berries are frozen in a sugar pack, the ratio of sugar to fruit, by weight, can range from 1:3 to 1:27, depending on the secondary manufacturer's specifications. (*See* **Freezing**: Blast and Plate Freezing.)

Strawberries or strawberry-based products are present as the main fruit ingredients or as a mixture with other fruit in many consumer products. Large volumes are used in the production of jams, jellies, icecream and fruit yogurts. Strawberries in moderate quantities are used in spreads, preserves, icecream toppings, strawberry syrups, juices, juice blends, nectars, drinks, milkshakes, and various bakery products, such as pies, pastries, turnovers, doughnuts, and cheesecakes. Lesser quantities of fruit are used in the production of fruit beverage mixes, alcoholic beverages, flakes, glazes, powders, and freeze-dried whole fruit used in cereals and other products.

STRESS AND NUTRITION

A C Brown and C I Waslien, University of Hawaii at Manoa, Honolulu, HI, USA

Introduction

Hans Selye first described the stress phenomenon as the body's response to a wide range of stressors. Others have defined stress as anything interfering with a person's optimal mental and physical health. Sources of stress can be exogenous (external) or endogenous (internal) and include anything that is 'perceived,' psychologically or physiologically, to be a threat to the organism. Examples of physical stressors include trauma, injury, or violence, illness (heart attack, cancer, infection, hemorrhage), surgery, climate (cold, heat), muscular exercise, fasting, weather changes, chemical exposure, drugs, and biochemical changes (postnatal depression, schizophrenia). Some psychological stressors include driving to work, phone calls, having lunch with a client, giving a speech, unstable relationships, work conflicts, purpose-in-life conflicts, and significant life events, as shown in **Table 1**.

Some people are more susceptible to stress by their exaggerated perception of the stressor, lack of necessary skills to handle minimum daily life stressors, and/or lack of an ability to adapt or cope in such a way to restore homeostasis. A person's reaction to stress, whether psychological or physical, orchestrates a neuroendocrine response that can in turn cause

Table 1 Part of the Holmes–Rahe Social Adjustment Scale that assigns values to various stressful events (good or bad) (the higher the score, the greater the risk of a stress-related health condition)

Events	*Value*

more stress by resulting in illness or diminished psychological or physical health (Table 2). The question arises, however, as to why the response to stress becomes so severe and prolonged in some individuals that it develops into an incapacitating clinical disorder. This individual susceptibility may be attributable to factors in the person's genetic background, personality, and environment. (*See* **Atherosclerosis; Colon:** Diseases and Disorders; **Coronary Heart Disease:** Intervention Studies; **Inflammatory Bowel Disease; Migraine and Diet.**)

Stress Reaction

The stress reaction is defined by Hans Selye in his general adaptation syndrome model (Figure 1). Each of the stages in this model – alarm, resistance, and exhaustion – involves the body's neuroendocrine system, which is influenced by psychological and physical stimuli.

Alarm, fight or flight, is the immediate response of the body to 'perceived' stress. Physiologically, this starts at the brain's hypothalamus, which acts as the central computer chip of the body regulating such functions as heart rate, blood pressure, respiration, body temperature, digestion, hunger, thirst, and libido. Surrounding the hypothalamus is the limbic system, one of the oldest parts of the brain, which houses the emotions. Powerful feelings such as fear and rage trigger the hypothalamus, which sends messages to the autonomic nervous system by the hypothalamic–pituitary–adrenal (HPA) axis and separately through the autonomic nervous system. The nerves of the autonomic nervous system are split into either parasympathetic or sympathetic branches, the latter of which causes an immediate stress reaction by releasing catecholamines (adrenaline-like chemicals). These chemicals released from the adrenal gland increase heart rate, respiration, and blood pressure.

The activated hypothalamus also secretes its own hormones and stimulates the pituitary gland to secrete hormones, which produce some of the same effects as those of the catecholamines but which last some 10 times longer and have a far wider reach. One of these hormones, corticotropin-releasing hormone (CRH), is sent to the pituitary to trigger the release of adrenocorticotropin hormone (ACTH). ACTH travels through the bloodstream to the adrenal glands, on top of the kidneys, to produce glucocorticoids (such as cortisol), which start a cascade of events, including increased blood glucose concentrations, elevated blood pressure, and slowed digestion (Figure 2). Specifically, insulin's ability to facilitate glucose uptake by the cells is reduced, while gluconeogenesis, the synthesis of new glucose (from glycerol and amino acids) is increased. Blood pressure rises as the kidneys are signaled to retain more sodium, which raises water volume in the blood vessels. Also, digestion slows as hormonal changes cause muscles to become engorged with oxygen and glucose-rich blood that is shunted away from the digestive tract. The body in this conditional response

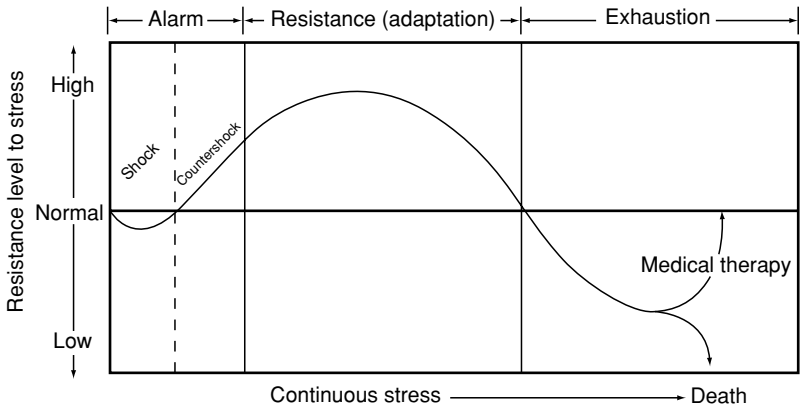

Figure 1 General adaption syndrome, consisting of three stages: (1) alarm, (2) resistance, and (3) exhaustion.

to stressors is ready for fight or flight. (*See* **Hormones**: Pituitary Hormones.)

Resistance (adaptation), the second stage of the stress response, is to achieve optimal adaptation in resisting the stressor. Everyday stressors (eustressors) are beneficial in maintaining the psychophysiological balance that results when the stressor is successfully removed, adapted, or coped with by the person. Stress is actually a necessary component in life because it contributes to survival and, ultimately, growth. Optimal stress fuels maximum performance, but excess stress results when the demands on a person exceed or fall far below their capabilities. Hans Selye said the only time an individual is free from stress is death – the ultimate flight. However, too much stress, and failure to adapt and reach a healthy homeostasis, can also result in illness or death.

Exhaustion, the last stage of the stress response, a continued, chronic response to stress, can be a risk factor for many multifactorial disorders. These in turn may lead to a downward spiral of more stress, exhaustion, and possibly extinction. Eustress becomes distress if not adequately handled by the body and mind (Table 3). Physical and psychological well-being become 'ill,' decreasing the quality of life, if not its very presence.

While the changes produced by stress-initiated hormones are beneficial in the short term, they can be detrimental when prolonged. It is now generally believed that most signs and symptoms of stress-related disease are the result of stress hormones marshaled by the hypothalamus in response to an alarm for which their particular actions are no longer appropriate.

Stress and Nutritional Needs

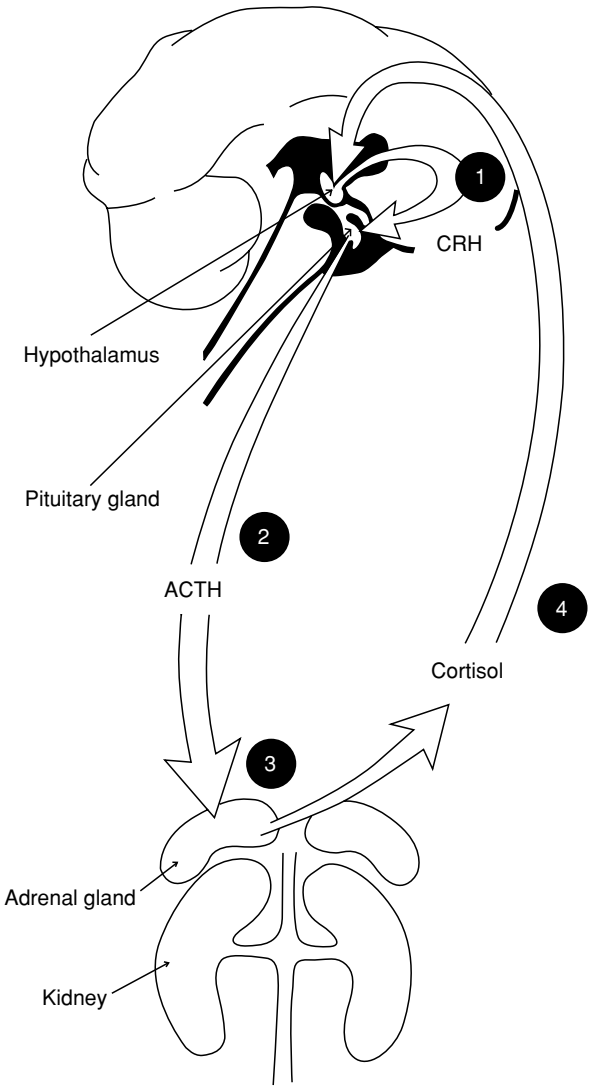
The hormonal concert of changes occurring in the stress response creates a cascade of biochemical and physiological events that require energy and nutrients. The main physical stressors to the body requiring an increase in energy and nutrients are injuries, surgeries, burns, illnesses, and infections. These conditions inflict greater requirements than emotional stressors whose exact nutrient needs have not yet been clearly documented. However, it is well established that physical stressors do increase requirements for energy and protein. Less information is available for the vitamins, minerals, and electrolytes. The degree to which these physical stressors foster a need for more nutrients is based on the severity/duration of the condition, the person's age and nutritional status, and individual ability to overcome stressors in life. If not corrected, malnutrition during these states can result in an increased recovery time, length of hospitalization time, and/or morbidity and mortality.

Energy

With acute stress, such as surgery, energy requirements rise only about 10%; severe infections raise requirements by 20–40%, bone fractures by 10–30%, and burns by 40–125%. The extra energy requirements caused by psychological stresses such as fear, anger, or rage are difficult to determine but presumably fall within the range error and are not given a special allocation. Acute stress of short duration is usually self-corrected by an increase in appetite after the stress has abated, but special enteral or parental formulae may be needed for treating severe stress. (*See* **Burns Patients – Nutritional Management**.)

Protein

Additional energy intake not only supplies necessary energy, but spares the body's protein reserves – primarily the muscle. If glycogen reserves from the liver



1. Stress triggers cells in the brain (hypothalamus) to release corticotropin-releasing hormone (CRH).
2. CRH signals the brain's pituitary gland to release adrenocorticotropin hormone (ACTH).
3. ACTH travels through the bloodstream to the adrenal glands – just above the kidneys – where they produce glucocorticoids such as cortisol.
4. Excess cortisol levels are prevented by feedback to the hypothalamus that occurs when elevated cortisol levels signal the brain to stop releasing CRH.

Figure 2 Hypothalamic–pituitary–adrenal (HPA) axis that sets in motion a myriad of stress-related psychophysiological events.

and muscles are depleted and additional energy is not provided during the catabolic state of acute stress, the body turns toward its fat and protein resources. Although the loss of fat is usually not a problem initially, it is detrimental to the skeletal muscles if they are broken down to serve as a source of amino acids

Table 3 Factors and feelings associated with eustress and distress

Eustress	*Distress*
Increased mental acuity	Forgetfulness
	Diminished attention to detail
	Poor work performance
Pleasure/happiness	Sadness
	Emotional outbursts
Euphoria	Lethargy, apathy

Modified from Clancy J and McVicar A (1993) *British Journal of Nursing* 2(8): 410–417.

to make glucose (gluconeogenesis). Physical stressors also stimulate glucocorticoid secretion, which induces protein breakdown. If prolonged, this leads to massive tissue wasting. Adequate protein of a high biological value is necessary to avoid a negative nitrogen balance and to prevent the following: diminution in immunocompetence, hypoalbuminemia, decreased wound healing, decreased synthesis of enzymes and plasma proteins, infection, and pressure sores associated with poor protein status.

Moderate stress requires 1.0–1.5 g of protein per kilogram or bodyweight, whereas severe stress requires 1.5–2.0 g protein per kilogram. This is only slightly higher than the 0.8 g of protein per kilogram required in most healthy adults. During severe stress, the body may be unable to convert essential amino acids to nonessential amino acids, so they must be obtained from the diet. Research shows promising results for the use of branched-chain amino acids, glutamine, and arginine during periods of hypermetabolic states. Blood levels of branched-chain amino acids (BCAA), leucine, isoleucine, and valine, are low during stress. Mixed results have been reported with BCAA formulas for improving morbidity or mortality, reducing the length of hospital stay, or maintaining tissue protein reserves of hospital patients. As a precaution, a 35–50% BCAA formula is recommended for highly stressed patients who cannot achieve nitrogen balance within a reasonable amount of time after receiving a standard formula. A similar recommendation exists for glutamine, the principal free amino acid in muscle. Catabolic patients receiving a glutamine-peptide-supplemented solution were in a more positive nitrogen balance than control patients given isonitrogenous, isoenergetic, or conventional total parenteral nutrition amino acid mixtures. Another amino acid, arginine, is beneficial during critical illness. Supplementation during this time with arginine may increase nitrogen retention, accelerate wound healing, and enhance the immune system by increasing lymphocyte response. (*See* **Glucose**: Function and Metabolism; **Glycogen**; **Protein**: Requirements.)

Fatty Acids

ω-3 fatty acids appear to improve survival rates of burn patients, and reduce infections and wound complications of postoperative patients. Perhaps this is related to the fact that certain polyunsaturated fatty acids are used in the biosynthesis of eicosanoid mediators influencing the systemic inflammatory response. ω-3 fatty acids lessen inflammation, whereas ω-6 fatty acids increase the inflammatory response. Sources of ω-3 fatty acids include canola oil, fish oils, and green vegetables, whereas ω-6 fatty acids are derived from corn, safflower, soybean, and sunflower oils. It has been postulated that patients with inflammatory conditions (systemic lupus erythematosus, rheumatoid arthritis, and multiple sclerosis) on hospital tube feedings (enteral and parenteral formulas, intravenous emulsions) would fare better if the lipid source were ω-3 instead of ω-6 fatty acids.

Vitamins, Minerals, and Electrolytes

The adrenal glands have the highest concentrations of vitamin C of any organ in the body, and because this vitamin is needed for the synthesis of catecholamines, massive doses of the vitamin have been advocated to help cope with modern-day stress. However, clinical evidence at this time does not support this supposition. Other nutrients that are lost in the urine with stress, such as zinc, copper, magnesium, and calcium, do not present problems for people with good dietary intakes. Potassium, which is lost along with protein catabolism of muscle and organ tissue, may be an exception but can be replaced with increased consumption of fruits and vegetables.

In severe stress, the requirements for vitamins A, B_1, B_2, B_6, C, D, E, K, nicotinic acid, folate, and pantothenic acid, as well as for the minerals iron, zinc, copper, selenium, and magnesium are probably increased, although actual requirements are unknown. Vitamin C is known to be required for wound healing and collagen formation, and urinary losses are increased during stress; thus, supplements may be prescribed to promote extensive tissue regeneration. Studies have shown that 1000 mg of vitamin C per day appears to speed the healing of bone fractures. Tissue regeneration is also dependent on vitamin A; low levels of plasma retinol have been observed in fracture patients after surgery. Pyridoxine, potassium, magnesium, phosphate requirements, and, to a lesser extent, calcium requirements seem to parallel the level of protein consumption; hence, supplements of these nutrients may be needed when protein and carbohydrate intakes are greatly increased. (Refer to individual nutrients.)

Actually, the immediate major concern following a physical stress is correcting fluid and electrolyte losses. Intravenous infusions may be needed, but even hydration may be restricted if stress leads to renal shutdown. A diet high in protein and energy can be initiated within approximately 5 days. Excess delay in realimentation is also not warranted as it is critical to prevent weight loss that may approach 20–30% of body weight if nutritional support is not promptly implemented. A weight loss of 40–50% is generally fatal.

Stress and Appetite

Stress, depending on the individual, can either increase or decrease appetite. Some people under pressure eat less, whereas others overeat in an effort to relieve stress. According to one study, snacking behavior in 212 college students exposed to stress increased by 73%. However, the total daily food intake decreased in 42% of the students, whereas 38% reported an increase. This study, along with other research, revealed that dieters are much more likely to overeat during stress than nondieters. The increased food consumption in dieters is especially pronounced when the stress source is a threat to the ego or self-image. Results from a study revealed that psychosocial stress induces a large cortisol response in glucose-treated subjects, compared with fasting subjects subjected to the same stressor but without the resulting cortisol peak. The researchers concluded that low glucose levels appear to inhibit the HPA axis response resulting in the secretion of cortisol and its influence on appetite. Another appetite theory is that stress-prone subjects are prone to serotonin deficiency, which may be related to 'carbohydrate craving' and subsequent binging and/or obesity. It is interesting to note that the weight gains of genetically obese rats are abolished by adrenalectomy, while cortisol (corticosterone) treatment restores their diminished food intake to normal levels.

Stress-inducing Foods

Refined Carbohydrates

Refined cereals and sugars have been made scapegoats, responsible for the stress of Western diets. Claims are made that these foods, low in B vitamins, rob the body of vitamins. Some authors go on to advocate up to 100 times the recommended intake of vitamins as compensation. Certainly, when chronic stress increases nutrient requirements, 'empty calories' are inappropriate, but there is no rationale for labeling moderate amounts of refined cereals and

sugars as 'stress producing.' Sugar has come under particular fire because of its supposed role in hypoglycemia. Although it is true that hypoglycemia can affect behavior in a number or ways, e.g., alternating 'highs' and 'lows,' there are two major misunderstandings. Contrary to popular opinion, diagnosable hypoglycemia is quite rare; the Mayo Clinic finds a rate of approximately one case per 2500 persons. Although a person with hypoglycemia should avoid sugar in any form, sugar does not cause the disease. Both the low blood sugar reaction and the hormonal response described as the alarm reaction are symptoms of hypoglycemia. (*See* **Glucose**: Maintenance of Blood Glucose Level.)

Fasting

Researchers report that a good portion of the psychological syndrome of anorexia nervosa is in response to starvation. Emotional instability is a classic sign of the ketosis that accompanies fasting. One does not have to endure long-term starvation to feel less than able to cope with stress. Just skipping a meal or two can have this effect. Steady eating of moderate, balanced meals is likely to be more beneficial to stress-prone individuals than a lifetime supply of various supplements. (*See* **Anorexia Nervosa**.)

Caffeine

Certain commercial advertisements insist that stress can be reduced by drinking decaffeinated coffee or caffeine-free soft drinks. While some research reports indicate that caffeine induces stress, others show that caffeine reduces it. A recent study clarified the situation by demonstrating that persons habituated to the use of caffeine had increased anxiety when deprived of it but were calmed by a dose of caffeine. In contrast, low-caffeine users showed a slight increase in tension when given caffeine. Apparently, the kind of response depends on previous use and individual differences.

Sodium

For many people, excessive fluid retention, and other premenstrual changes in women, may be related to emotional stability and resistance to stress. Stress itself induces sodium retention and water accumulation. Any dietary factors that further contribute to fluid retention, in particular excessive intake of sodium, may therefore increase the stress effect. (*See* **Premenstrual Syndrome : Nutritional Aspects**.)

Stress-relieving Foods

Can specific foods be used to reduce stress? When under stress, most people instinctively turn to certain foods – foods that create a feeling of security. The most common security food is milk, perhaps as a symbol of the more protected days of childhood and a desire to return to them. In fact, it has been speculated that the use of milk to treat ulcers may be successful partly because it stimulates this 'return to the womb' association. Our choice of security foods seems to be based on our childhood experiences, and those that trigger comfort in one person may trigger anxiety in another.

Among women, chocolate is the most craved food. Researchers believe that this may be due to a combination of chocolate's sensory characteristics, nutrient composition, and psychoactive ingredients. It has been suggested that chocolate may be used by some women as a form of self-medication to balance low levels of neurotransmitters involved in mood regulation. The desire for chocolate by women fluctuates with hormonal changes and is higher just before and during their menses. This hormonal link in turn might be related to endogenous opiates (endorphins) that influence appetite. Women tend to eat when they feel emotionally low, and the affinity to chocolate may be due to its 'drug-like' constituents that remain elusive.

Dietary Supplements

Alternative/complementary treatments are used by 20–30% of the general North American population. Among these are plants that have been used medicinally throughout history for thousands of years. About 25% of pharmaceutical drugs used today are derived from botanical sources. Among psychotropic herbs, two of the earliest were the opium poppy and the coca plant, producing two of the most notorious street drugs, heroin and cocaine. Drugs are often taken to treat the symptoms rather than the cause, and many people opt to select dietary supplements rather than prescriptions to reduce the side-effects of stress such as anxiety, depression, and insomnia. A few of the more popular, but not necessarily proven effective, psychotropic herbs are discussed below.

California Poppy (*Eschscholtzia californica*)

This flowering plant has a long history of treating insomnia. It does not contain the narcotic morphine found in its cousin, the opium poppy.

Chamomile (*Matricaria recutita*)

This flower, usually in the form of a tea, has been used medicinally for thousands of years. Its primary use is for anxiety and mild insomnia as well as an antispasmodic and antiinflammatory agent, especially for ulcers. The active ingredient is attributed to chrysin, a flavonoid component. Potential rare side-effects include allergies and contact dermatitis.

Kava (*Piper methysticum*)

The roots of this plant have long been used by people in the South Pacific, where it is grown, for ceremonial purposes in much the same way that some cultures use wine. Kava differs from wine in that it is nonaddictive. Its sedative-like quality may be due to kavalactones (kavapyrones), which appear to act as monoamine oxidase inhibitors. Side-effects include dizziness, a drunk-like state, and gastrointestinal upset. Excessive use is associated with Kava dermopathy (scaly, shiny skin), seizures, impaired vision and hearing, yellow discoloration of skin/nails, and liver dysfunction. Reports linking Kava to hepatitis have resulted in some European countries banning this supplement. Kava has also been known to potentiate the effects of alcohol, barbiturates, and Xanax.

Hops (*Humulus lupulus L.*)

Although hops are traditionally used by the brewing industry, the flowers of this plant have long been utilized as a mild sedative. Side-effects include allergy and disrupted menstrual cycles.

Passion Flower (*Passiflora incarnata L.*)

Native to the Americas, its vine leaves are used as a sedative, which is supported by some animal studies.

Skullcap (*Scutellaria laterifolia*)

Rooted in traditional Chinese medicine, this herb has a long history of being used as a sedative and anticonvulsant. Scutellarin is the plant flavonoid glycoside thought to be responsible for the sedative effects of skullcap. Reported adverse reactions include giddiness, confusion, sedation, and seizures. The most serious possible side-effect is hepatitis, which was reported in a some people taking herbal stress remedies that contained skullcap and valerian. It is important to read the label of such products to determine whether skullcap is an ingredient.

St. John's Wort (*Hypericum perforatum*)

Long-term stress is occasionally a risk-factor for mild depression, which has been reported in some cases to respond to St. John's Wort. An analysis of 23 controlled studies concluded that it is significantly more effective than a placebo in treating mild to moderate depression. The effective dose in clinical trials is 300 mg three times a day from an extract standardized at 0.3% hypericin. This active ingredient in St. John's Wort appears to act as a weak monoamine oxidase inhibitor. The main side-effect associated with this herbal antidepressant is photosensitivity to the sun, resulting in rashes. Other less commonly reported side-effects include gastrointestinal upset, dizziness, dry mouth, sedation, and constipation.

Valerian (*Valeriana officialis*)

The root of the valerian plant has been used as a calming and sleep-promoter for centuries. German health officials have approved it as a mild sedative and sleep-aid. Two double-blind, placebo-controlled cross-over studies (400–450 mg before bedtime) resulted in significantly improved sleep quality. There was also no reported residual sedation in the morning or addiction associated with valerian use. Valerian appears to work by inhibiting the enzyme-induced breakdown of γ-aminobutyric acid (GABA) in the brain. Symptoms are rare, but may include headaches, palpitations, insomnia, and possibly hepatitis.

Amino Acids

High intakes of tryptophan – the amino acid precursor of the neurotransmitter serotonin – have been popularized as a treatment for stress. Although taken off the market because of a contaminant that elicited neurological side-effects, tryptophan still has many proponents. A high-carbohydrate meal can have some of the same benefits by causing insulin secretion and favoring the uptake of amino acids other than tryptophan into muscle. This increases the concentration of tryptophan present in the blood and increases its uptake by the brain and its subsequent conversion to serotonin. Supplementation with tyrosine, the precursor for the catecholamine neurotransmitters, has also been shown to reduce psychological and physiological effects of stress. Tyrosine has also been recently demonstrated to ameliorate stress-induced increases in ventricular vulnerability to arrhythmias in conscious animals.

Limited research suggests that subclinical deficiencies of other nutrients involved in the synthesis of neurotransmitters (e.g., nicotinic acid, riboflavin, folic acid, vitamin C, and copper) may contribute to the ability to withstand stress, and that others (e.g., ω-3 fatty acids) may alter the stress response, making it less hazardous for the arteries. In most cases, the alteration in the level of these nutrients needed to make a detectable difference in stress response is of such a magnitude as to preclude normal diets. However, differences in an individual's stress-related illness may in part reflect lifelong differences in intakes of some of these nutrients.

Melatonin

This hormone secreted by the pineal gland is used by some people as a sleep-aid taken 30 min to 2 h before bedtime. Melatonin acts as a mild sedative, but its affect on insomnia remains controversial. It is known that melatonin released nightly by the pineal gland to signal the body to sleep does subside as people age.

However, supplements often contain 10 times the amount secreted by the body (3 mg or more), and it is recommended that less than one-third of that be taken. Melatonin is also not appropriate in children younger than 12. Side-effects include fatigue, headache, confusion, and depression.

Dietary supplements are categorized as neither a food nor a drug, so they are exempt from FDA regulation. As a result, no proof of efficacy or warnings about side-effects (known or testing for the unknown) are required. There are also currently no standardization or quality assurance methods for herbal formulations. Even if there were, it would be very difficult to identify the active ingredient(s) of a herbal product for the often more than one ailment it is claimed to benefit. Added to this is the possibility of contamination, mislabeling, and misidentification of herbs. Assuming that herbs are 'natural,' and therefore safe, can be a wrong assumption. The long-term hepatotoxic effect and other side-effects of many herbs are unknown and may not be elucidated for a long time. As with many compounds, herbal supplementation is not recommended during pregnancy or lactation.

Summary

A moderate, well-balanced diet with emphasis on the stress-related nutrients and regular but not excessively large meals is probably one approach that can be recommended. There is no evidence that any one special dietary preparation or plan is more effective than any other in coping with stress, but specific recommendations concerning energy and nutrients exist in the literature that may benefit certain conditions.

SUCROSE

Contents

Properties and Determination

J Huberlant, Waremme, Belgium

Occurrence in Foods

Among the sugars found in nature, sucrose (also named saccharose, beet sugar, or cane sugar) plays a dominant role in food processing and agriculture, as well as in international economics and politics.

It is naturally present in many plants, in varying quantities. In some plants, it serves as a storage product, although, in other plants, the storage product comprises different sugars such as fructose (fruit), or complex carbohydrates such as starch (corn, potatoes) or inulin (Jerusalem artichoke, dahlia, chicory). (*See* **Carbohydrates**: Classification and Properties.)

There are many plants from which sucrose is commercially extracted, including the date palm, sorghum (*Sorghum vulgare*), sugar maple (*Acer saccharum*), carob or locust bean, and of course, the two most important worldwide sources: sugar cane (*Saccharum officinarum*) and sugar beet (*Beta vulgaris*). (*See* **Date Palms**; **Sorghum**; **Sugar**: Sugarcane.)

Nowadays, because of the improvements in selecting varieties, sugar cane may have a sucrose content of 17–20% and produce as much as 10–12 tonnes of sucrose per hectare, and sometimes even more, depending on numerous factors such as soil, climate, irrigation, etc. The sugar content of the sugar beet varies normally between 14 and 18% with a mean yield of more than 8 tonnes of sucrose per hectare in good conditions (western Europe).

The use of sucrose is extensive, both for homemade preparations and for processed foods, including chocolate and sugar confectionery, baked goods, soft drinks, canned, frozen and dairy products, various preserves (jams, jellies), beers and wines, and so on.

The apparent total sugar consumption based on 'disappearance data' (i.e., the total supply to food industries, wholesalers, and retailers, without considering losses, wastes, or other uses) varies considerably from country to country, according to the standard of living, the climate and dietary habits, and may amount to more than 40 kg per capita per annum (high-income countries) to less than 8 kg (developing countries).

Chemical and Physical Properties

Chemical Properties

Sucrose is a carbohydrate of the general formula $C_{12}H_{22}O_{11}$ and has a molecular weight of 342.30. Its systematic chemical name is α-D-glucopyranosyl-β-D-fructofuranoside. Sucrose is a disaccharide and is easily split by hydrolysis into the two monosaccharides (hexoses) glucose and fructose (eqn (1)). It is a nonreducing sugar, in contrast to the two sugars produced by the inversion reaction. (*See* **Fructose**.)

$$C_{12}H_{22}O_{11} + H_2O \rightarrow 2C_6H_{12}O_6. \qquad (1)$$

In solution, it is present mainly in the cyclic form, which may be represented in various ways, e.g., the Fisher projection (**Figure 1a**) or as a Haworth-type structure (**Figure 1b**).

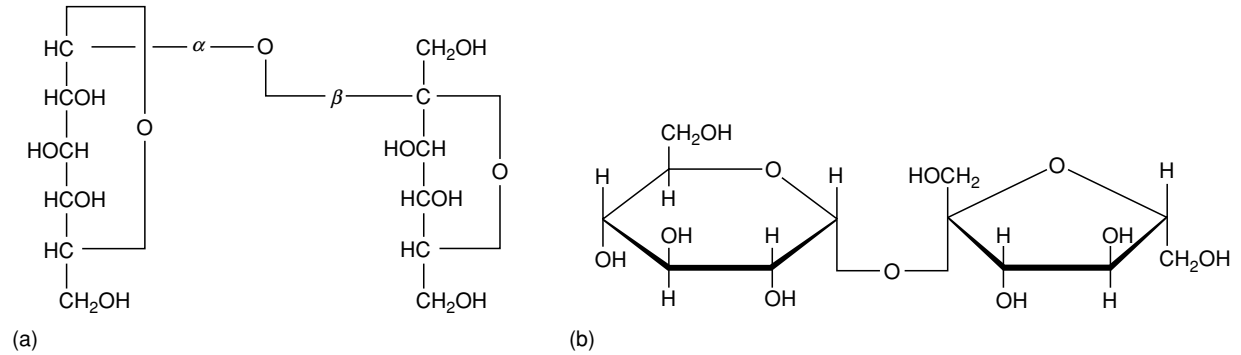

Figure 1 Structural representations of sucrose: (a) Fisher projection; (b) Haworth-type structure. Reproduced from Sucrose: Properties and Determination, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Physical Properties

Crystalline sucrose Sucrose in a pure state crystallizes in a monoclinic system, forming transparent, colorless, and odorless sphenoidal prismatic crystals, the form of which may be strongly affected by impurities (needle-like shapes).

Sucrose has a characteristic sweet taste without any other flavor or aftertaste; it is the standard reference for sweetness. If sucrose is given a sweetness rating of 100, the relative sweetness of fructose is between 105 and 125 and that of glucose between 65 and 75, depending on the conditions (acidity, pH, temperature, etc.).

The crystal density (D_4^{15}) is 1.5879, but the apparent specific gravity of high-grade white sugar varies between 0.72 and 0.88 kg dm^{-3}, depending on the crystal size and humidity, the storage duration, and the thickness of the layer in the storage silo.

Sucrose decomposes at about 186–188 °C to form brown products (caramel) and, finally, chars, but impurities and the products of thermal decomposition significantly lower the temperature of decomposition.

The heat of combustion is 1351.3 kcal mol^{-1} or 3.95 kcal g^{-1}. Sucrose is thus less caloric than fat (9.3 kcal g^{-1}) and protein (4.1 kcal g^{-1}).

Sucrose solutions Sucrose is readily soluble in water, and its solubility increases with temperature. By cooling or evaporating a saturated sucrose solution, a metastable supersaturated solution is obtained. Sucrose is sparingly soluble in ethanol and practically insoluble in ether.

The solubility of sucrose has been calculated at different temperatures. In 1978, the International Commission for Uniform Methods of Sugar Analysis (ICUMSA) officially adopted the tables of Vavrinecz and of Charles. Table 1 gives example solubilities at various temperatures, which have been taken from the Charles tables.

Table 1 Solubility of sucrose at four example temperatures according to the ICUMSA

T (°C)	*Solubility of sucrose (g) in*	
	1 g of water	*100 g of solution*
10	1.884	65.32
20	1.994	66.60
50	2.576	72.04
90	4.262	81.00

Sucrose in aqueous solution has the property of rotating the plane of linear polarized light, and the angle of rotation is proportional to the concentration and to the path length of the solution traversed by the light beam. This angle is measured by means of polarimeters. In the sugar industry, special polarimeters, called 'saccharimeters,' are directly calibrated in 'degrees sugar' (°Z). The ICUMSA adopted a new definition of the international sugar scale as from 1 July 1988. The basis of the 100 °Z point of the international sugar scale is the optical rotation of a 'normal sugar solution' at the wavelength (λ) of the green line of the mercury isotope ^{198}Hg ($\lambda = 546.2271$ nm *in vacuo*) measured at 20.000 °C in a 200.000-mm polarimeter tube. The 'normal sugar solution' corresponds to a concentration of 26.000 g sucrose weighed with brass weights in air under normal conditions (1013 hPa pressure, 20 °C, 50% relative humidity) in 100.000 cm^3 of solution at 20 °C. On this new international sugar scale, the optical rotation of the 100 °Z point is 40.777 ± 0.001 °.

The density of sucrose solutions is a function of the mass concentration and of the temperature. The density values universally used are those of Plato (first published in 1900) giving D_4^{20} for the solutions

between 0 and 95 degrees Brix (grams per 100 g of solution).

The refractive index of sucrose solutions is a function of the amount of dissolved material and also of the temperature. The ICUMSA has published refractive index tables for sucrose solutions from 0 to 85 degrees Brix at 20 and 27 °C, as well as temperature correction tables.

There are many other properties that have been measured, such as viscosity, osmotic pressure, specific heat, boiling point elevation, and equilibrium relative humidity, the knowledge of which is very useful in food technology.

Structural Properties

In addition to its use in food processing as a sweetener and an energy source, sucrose has other functions. Thus, it is not sufficient to replace sucrose by artificial noncaloric sweeteners and expect simply to obtain similar products with the same sweetness but without the calories. (*See* **Sweeteners**: Intensive.)

Sucrose acts as a preservative by its ability to reduce water activity and to increase osmotic pressure to a level where the growth of even the most osmophilic microorganisms is no longer possible (as in jams, jellies, fruit syrups, concentrated milk).

Sucrose acts as a bulking agent and a texturizer in confectionery, baked goods, and soft drinks. Owing to its high solubility and viscosity, it gives body and mouth-feel to various preparations. It influences the pore size distribution, softness, and structure of pastry.

Sucrose also has properties of humectancy, i.e., it assists the ability of products to withstand changes in moisture content, and so extends the shelf-life of goods such as cakes.

Sucrose is an antioxidant, preventing the oxidation of flavors in fruit preserves. (*See* **Antioxidants**: Natural Antioxidants.)

Sucrose can fulfill the role of a diluent or carrier for flavoring or coloring additives and, at the same time, act as enhancer for natural food flavors, balancing sweetness, sourness, and bitterness. Sucrose alone can also give a caramel flavor and a browning of the products in baking, as a result of partial degradation.

Inversion on Storage and Processing

Sucrose, in a solid crystallized form, is one of the most chemically pure food products available in the world with a purity of $99.97 \pm 0.05\%$. It can be stored unchanged almost indefinitely under ideal conditions. To avoid caking or, conversely, attraction of moisture or even liquefaction in the silo, the sugar produced, prior to storage, must be dry and cold and must have undergone a conditioning process.

Freshly produced crystals are surrounded by a thin film of supersaturated mother liquor and possibly contain syrup inclusions. It takes a few days to achieve crystallization and to release free moisture, and, if this water is not allowed to escape, serious storage problems can occur, such as chemical or microbiological inversion, and, with the lowering of the pH, an accelerated degradation with formation of colored products. It is thus useful to store sugar initially in a holding bin aerated with cold dry air before storage in the final silo.

Fermentation of Sucrose

Sucrose may be readily fermented by several microorganisms and is a good starting material for the microbial production of many chemical products such as ethanol, butanol, glycerol, citric acid, levulinic acid, dextran, and many others. Molasses, a byproduct of the sugar industry that no longer contains crystallizable sucrose, is often used as a cheap source for these processes.

The most important fermentation process known from time immemorial is probably alcoholic fermentation by yeasts used to produce beverages such as beer and wine. The first stage of alcoholic fermentation is an enzymatic hydrolysis of sucrose to glucose and fructose by invertase.

Analysis, Extraction, and Isolation

The term 'sucrose analysis' can include numerous determinations depending on the purpose of the analysis.

Sucrose in the Solid State (Commercial Sugars)

The purity of sucrose can be determined by polarimetry or, indirectly, by determining the amount of nonsucrose material present, i.e., water content and other compounds (organic or inorganic).

The water content can be determined by direct methods, such as the Karl–Fischer titration or the conventional 'loss on drying' method.

Inorganic compounds can be evaluated gravimetrically by incineration of the sugar. The result is the sum of the water-soluble and water-insoluble residues or 'ash' in the form of 'carbonate ash' or 'sulfated ash,' according to the method chosen. Ionized soluble salts ('conductivity ash') can be determined conductimetrically. This method is easier and less time-consuming than incineration, but does not have precisely the same significance as 'gravimetric ash.'

Among the so-called organic nonsugars, there may be small amounts of 'invert sugar,' a mixture of reducing sugars. There are numerous methods to

determine reducing sugars in the presence of sucrose, based on the reduction of a copper(II) complex with tartaric acid in alkaline solutions, e.g., Lane and Eynon titration, in addition to the Emmerich method for the determination of traces of reducing sugars in pure sucrose.

It is also possible, when required, to determine individual ions such as copper, lead, iron, calcium, chloride, arsenic, sulfite, and organic nonsugars such as aminonitrogen, betaine, lactic acid, citric acid, and so on.

In addition to the above purity evaluations, buyers require other quality criteria according to the specific uses intended for the sucrose. These may include particle size and uniformity, visual appearance, color and turbidity in aqueous solution or in alcoholic solution, insoluble matter or the presence of visible extraneous impurities, filterability, foaming properties, and floc formation in soft drinks. Some industries have special requirements concerning microbiological quality. For instance, the canning industry has a procedure for determining spore-forming thermophilic bacteria, and in the soft drinks industry, procedures are carried out for the detection of mesophilic bacteria, yeasts, and molds.

Sucrose Solutions and Technical Sugar Juices

Polarimetry may be used to determine the sucrose content of pure sucrose solutions and of intermediate liquid sugar products. In the latter case, it will often be necessary to eliminate many impurities to obtain a clear solution to allow passage of light through the polarimeter tube. This clarification is normally achieved with basic lead acetate solution, but the present trend is to replace this toxic reagent with nontoxic clarifying agents such as aluminum salts.

It is also possible to measure the densities or refractive indices of pure sucrose solutions to determine the sucrose content, since these values are functions of the sucrose concentration. For impure sugar juices, the influence of the soluble nonsucrose compounds on these parameters is almost the same as that of the sucrose. Consequently, the measurement represents the total soluble dry matter of the solution and allows the determination of the degree Brix (or degree Balling), i.e., the percentage of dry matter in the solution. The ratio of sucrose content (Pol) to total soluble dry matter (Brix) is called the quotient of purity (Q):

$$Q = \frac{\text{Pol}}{\text{Brix}} \times 100 \qquad (2)$$

The density can be measured by pycnometers or hydrometers, possibly calibrated in degrees Brix (formerly in degrees Baumé). However, these densitometric methods require many precautions and are time-consuming. It is much easier to measure the refractive index, but because the influence of the nonsugars is not the same, a distinction must be made between densitometric Brix and refractometric Brix, giving a slightly different purity quotient. (*See* **Rheological Properties of Food Materials**.)

Sugar-containing Products (Sweet Foods, Molassed Feeds)

Considering the high solubility of sucrose in water, the first step in analysis will often be an aqueous extraction followed possibly by clarification (or sometimes an aqueous alcoholic extraction). As glucose or invert sugar will also be frequently present in this extract, a double polarization or a double reducing sugars determination should be made, one before and one after inversion of the sucrose present in the extract. By calculation, the total sugars and sucrose content of the product can be determined.

In the sugar industry, the sugar content of beet or cane has to be determined, as this is the basis of payment for the raw material and allows calculation of the amount of sugar entering the factory. For this purpose, there are conventional methods specific to the sugar industry.

Traces of Sugars

It can be important to detect traces of sugar in some products, such as the presence of sugar in the feed water of boilers as a result of the use of condensed water from the sugar juice evaporation, and to control the losses of sugar in the waste water. This is carried out by qualitative or semiquantitative methods (α-naphthol with sulfuric acid) or by automatic apparatus based on chemical reactions or physical properties (conductivity or fluorescence).

Methods of Analysis

Polarization This method is based on measurement of the rotation of polarized light of a solution containing the normal weight (i.e., 26 g in 100 cm^3) of a sugar sample or of the unknown sugar solution to be examined (after clarification if necessary) by means of a saccharimeter calibrated to give 100 °Z with pure sucrose. Calibration of the saccharimeter is carried out with standard quartz plates. The result is given as the percentage of sucrose in the sugar sample or of the unknown sugar solution to be analyzed.

Loss on drying Instead of speaking of water content in this indirect method, it is more correct to speak of 'loss on drying.' The principle of this method is the determination of the loss in weight of a sugar sample placed in an oven at 105 °C for 3 h and cooled

afterwards in a desiccator under uniform conditions. The loss in weight for a high-grade white sugar is normally between 0.02 and 0.05%.

Conductivity ash The specific conductivity of a solution containing 28 g of sugar per 100 g is measured at 20 °C. The water used will have a conductivity of less than 2 $\mu S\,cm^{-1}$. The concentration of 28 degrees Brix has been chosen because the conductivity curve shows a flattened peak in this concentration region. The measured conductivity corrected for the water used is converted by a conventional factor into the percentage of conductivity ash in the sugar.

Visual appearance The visual grade of crystalline white sugar is assessed by comparing the sample with standard color types numbered from 0 to 6, made up of sugar artificially colored and of a defined particle size. The comparison is made by eye under well-defined conditions. Some instruments are now on the market that are intended to replace the eye and so yield a better reproducibility. (*See* **Sensory Evaluation**: Appearance.)

Color and turbidity in solution A solution of 50 g of sugar in 50 g of a buffer solution at pH 7 is filtered through a 0.45-μm membrane filter, and the absorbancy of the deaerated filtered solution is measured by means of a spectrophotometer at a wavelength of 420 nm. The final result is expressed in ICUMSA color units as a percentage of the dry sample.

Turbidity is measured by means of a turbidimeter calibrated with a formazin turbidity standard. The result is expressed in nephelometric turbidity units.

Floc test The soft-drink industry uses various tests to check the appearance of a floc during the shelf-life of a bottled beverage. This floc formation, in acid conditions, may be due to the presence of polysaccharides (gums).

Sulfur dioxide The level of sulfur dioxide in sugar is often limited by national legislation. A method of determining low levels of sulfur dioxide in white sugar is based on a colorimetric determination of the sulfite/rosaniline complex, as measured by spectrophotometry at a wavelength of 560 nm after reaction with formaldehyde.

Particle size The particle size of crystalline sugar can be characterized by the mean aperture (MA) and coefficient of variation (CV). The MA is the theoretical mesh aperture, in millimeters, of a sieve that retains (and also lets through) 50% of the sugar. The CV is the standard deviation expressed as a percentage of the MA. It is an evaluation of the dispersion of the crystal size around the MA.

Chromatographic methods High-performance liquid chromatography (HPLC) and gas–liquid chromatography (GLC) techniques for the analysis of commercial sugar products have been developed in recent years. (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography.)

Sucrose in beet and cane molasses can be determined by GLC. Molasses samples together with trehalose as an internal standard are silylated using a trimethylsilyl (TMS) reagent to convert the sugars into a form in which they are volatile. The TMS ethers of sucrose and trehalose are separated from each other and from other volatile components using a low- to medium-polarity column. Detection is carried out using a flame ionization detector, and accurate estimation of the sucrose content can be achieved by measurement of the peak areas with the use of an electronic integration system. Sucrose, glucose, and fructose in cane molasses can be determined by GLC according to the method described above by introducing an oxime formation step prior to the silylation.

Sucrose in beet and cane molasses can also be determined by HPLC. The separation column is a cation-exchange resin converted to a metal ion form. The diluted sample is filtered prior to injection on the column. The hydroxyl groups of the different sugars interact with the cations to varying extents, resulting in different elution times. Detection is achieved by differential refractometry of the column eluant. The peak area or height for sucrose is obtained by an electronic integration system, which is compared to that obtained for standards.

White Sugar or Refined Sugar

Irrespective of whether a sugar is a product of the 'first strike' or has actually been refined by remelt, decoloration, and recrystallization, the EC has defined a number of criteria to which a sugar must correspond, to be called 'white sugar' or 'refined sugar.' The criteria are based on the results of some of the analyses described above – polarization, loss on drying, conductivity ash, visual appearance, color in solution, invert sugar, and sulfur dioxide content.

Dietary Importance

G H Anderson, University of Toronto, Toronto, Ontario, Canada

Introduction

For centuries, sucrose has played an important role both in nutrition and in making foods palatable. Sucrose, in many natural and refined forms, has been widely used in the diet since its first recorded use in India in 500 BC, when a rough sugar was produced from boiled cane. This product was called gur, meaning 'nice, sweet, sticky stuff.' Sugar began to be used in the Middle East in 600–700 AD and reached widespread usage in Europe by 1000 AD. From the eighteenth century onward, relatively inexpensive brown sugar was available for the average family. The Industrial Revolution and large-scale food processing brought refined white sugar to everyone's table, and consumption increased rapidly. Since the mid-1920s sugar consumption has remained relatively constant, except during the Second World War, when rationing led to a decrease in consumption.

Sucrose consumption has declined since the 1970s when nutritive sweeteners from corn became available. Corn sweeteners are available as corn syrups, other saccharides, or as high-fructose corn syrup, which is produced by enzymatic conversion of some of the dextrose to fructose. To avoid confusion in this presentation, 'sucrose' will be used when sugar from cane and beet sugar is being discussed and the word 'sugars' will be used when all added free sugars, including corn sweeteners, are discussed.

The facts about sugars today are often distorted, producing incorrect public perceptions; therefore a discussion of the metabolism, health implications, and current consumption levels of dietary sugars follows.

Digestion and Metabolism of Sucrose

Sucrose is hydrolyzed by the enzyme sucrase, an α-glucosidase in the human small intestine, to its component monosaccharides fructose and glucose. About 10–25% of the fructose is converted to glucose in the brush border of the upper gastrointestinal tract. The monosaccharides are absorbed and transported to the liver via the portal vein and subsequently transported to all tissues.

Within the liver fructose may be converted to glucose; it may enter the glycolysis pathway, or provide acetate units for the synthesis of fatty acids. Glucose can be stored in the liver as the glucose polymer glycogen; it can be used in glycolysis to produce energy; or it can provide acetate units for the synthesis of fatty acids.

Glucose is made available to other body tissues via the blood stream and is the primary form of carbohydrate used as energy by the tissues. Under circumstances reflected by normal consumption of sucrose or high-fructose corn syrups, little fructose appears in the blood because it is rapidly metabolized by the liver for synthesis of glucose and primarily fatty acids and triglycerides, and possibly by metabolism in the kidney. The utilization of fructose by peripheral tissues seems to be negligible, perhaps because glucose, which is always present in the blood, inhibits both its uptake and entry into the metabolic pathway of glycolysis.

As a result of insulin release in response to sucrose ingestion, blood glucose is maintained within a closely regulated range, a requirement for normal functioning of the central nervous system. Sugar does not cause abnormal insulin and blood glucose responses. In fact, the effect of ingesting sucrose on

insulin release and blood glucose is less than when an equivalent amount of carbohydrate is consumed from bread. The excess of glucose above the energy requirements of the tissues can be stored to some extent as glycogen in muscle. The remainder is used to synthesize fatty acids and glycerol, which allow efficient storage of energy in the form of triglycerides in adipose tissue.

The effect of sugars on blood glucose can be captured by measuring the total glycemic response over time. To compare the response produced by different carbohydrates, the glycemic index (GI) was developed. The GI compares the incremental area under the blood glucose curve produced by 50 g of a carbohydrate test food to that produced by 50 g of a standard food (white bread or glucose). The glycemic indices of sugars depends on their composition. For example, sucrose has a GI which is only 87% of the white bread standard. This glycemic response is explained by its components glucose and fructose. Glucose alone has a GI relative to white bread of 138%, whereas that of fructose is only 32%. Relative to many common starchy foods, both sucrose and fructose have lower GI values (Table 1).

Nutritional Properties of Sucrose

Sucrose has two important nutritional properties. It provides energy at 3.8 kcal g^{-1} and, through its sweet taste, it increases the palatability of foods.

Table 1 Glycemic index of selected foods[a]

Foods	*Glycemic index (GI)*
White bread	100
All Bran	60
Cornflakes	119
Oat bran	78
Apple	52
Banana	83
Cornmeal	98
Rice, white	81
Rice, brown	79
Rice, instant	128
Rice, parboiled	68
Baked potato	121
Boiled white potato	80
Milk, whole	39
Spaghetti, white	59
Chocolate (various)	84
Sucrose	87
Fructose	32
Glucose	138
Soya beans	23

[a]Selected from FAO/WHO (1997) *Carbohydrates in Human Nutrition. FAO/WHO Expert Consultation on Carbohydrates in Human Nutrition*. Rome, Italy: FAO/WHO.

Sucrose, in the form that it reaches the table of the consumer, is the purest of common foods and free of contaminating chemical residues. As a result, it provides only one nutrient, carbohydrate, which is readily converted to energy by the body. It is this aspect of sucrose that has led to the concept of 'empty calories.' Clearly, sucrose can be used to manufacture foods that are low in essential nutrients and, if consumed in excess, may lead to nutrient-deficiency syndrome. However, there is no objective evidence that sugar intake leads to nutrient deficiencies at current consumption levels, nor that its widespread use has compromised the food supply so that nutritionally adequate meals and diets cannot be obtained from the marketplace.

Diets containing too much sugar are theoretically possible, and examples based on readily available foods can be easily constructed. For the majority of people, however, consumption of sugar falls well within a safe range of intake.

The probable reason why sugar does not lead to nutrient-imbalanced diets is because it is used to enhance the intake of many nutrient-rich foods which may not otherwise be readily eaten. For example, small amounts of sugar are added to many fruits, vegetables, and cereals. Increasing the palatability of these foods with sugar makes them more likely to be consumed.

Many reviews have examined the role of sugar in health and indicate that, other than contributing to dental caries, which is a consideration for all carbohydrates, the amounts consumed in the average diet produce no deleterious health effects. However, perceptions that sugar is the cause of hypertriglyceridemia, diabetes, and hyperactivity in children still persist.

Hypertriglyceridemia is the elevation of triglycerides in the blood and is believed to play a role in heart disease. It has been recognized for years that large amounts of dietary sugars, particularly fructose, can raise triglycerides. Thus, sugars that contain fructose, such as sucrose and high-fructose corn syrups, also have this potential. The potential effect of fructose consumption on blood lipids is explained by its unique metabolic pathway in the liver and evidence that it is a better substrate than glucose for lipid synthesis. Therefore, it should not be a surprise to find an elevation of blood triglyceride concentrations in some subjects given excessive quantities of fructose or sucrose. However in studies in which amounts of sugars typical of the western diet were provided, such responses are not usually observed.

Diabetes mellitus is a condition in which an insulin deficiency or decreased insulin sensitivity results in

hyperglycemia. The most prevalent form of diabetes is noninsulin-dependent diabetes mellitus (NIDDM), which most often has its onset in adulthood and is associated with obesity. All reviews on the subject have concluded that there is no evidence that sugar intake is related to the incidence of diabetes or mortality. In fact, as with obesity, an inverse relationship between sugar intake and diabetes has been found.

The belief that sugar causes hyperactivity in children is one of the most persistent and widespread myths about sugar. However, the link between sugar and hyperactivity has been based largely on subjective observations made by both parents and teachers. Recent well-controlled challenge studies clearly indicate that sugar does not affect hyperactivity, attention span, or cognition in children. In fact, studies have shown that children are calmer and more sedate following sugar preloads.

Sugar Consumption versus Sugar Disappearance Data

A great deal of confusion surrounds sugar consumption statistics. This is because there are two types of consumption being interchanged in discussion of the statistics. One consumption statistic is based on economic concepts and refers to national usage or availability of sugar for use in the food supply, whereas the other consumption statistic is an estimate of the amount eaten by humans and is a physiological concept.

Estimates of the total amount of nutritive sweeteners available for use within a country are assembled on an annual basis by statistics or economic branches of the government. The figures are reported as per capita consumption, but they do not represent per capita intake by individuals. They indicate availability of added sugars to the marketplace, after consideration of production, imports, and exports, and beginning and ending stocks. No allowance is made for losses or wastage in food manufacturing or in other aspects of usage. Thus, while these consumption statistics have proved useful in describing trends in national availability of added sugars, they have proved to be misleading in predicting actual intake by humans. For example, in 1980–85, total caloric sweeteners available for consumption in the USA averaged 155 g (620 kcal) per person per day and 17% of the energy content of the available food supply. However, much of the sugar available is destroyed in production processes such as making bread, pickles and alcoholic beverages, or wasted during distribution, storage, and usage, or consumed by animals.

Added sugar consumption in the USA was estimated to average only 53 g day^{-1}, or 30% of estimated availability (155 g) derived from disappearance data in 1977–78. Consumption data for sugars added to the food supply were derived from the 1977–78 (US Department of Agriculture (USDA)) Nationwide Food Consumption Survey. Average daily intake of sugars for this population sample of 30 677 subjects was 53 g day^{-1}, or 11% of the daily intake of calories. Younger age groups had a higher intake than older age groups. The highest consumers, those in the 90th percentile of daily intake of added sugar, ranged from 1.5 to 2.5 times the mean value for the 14 age/sex groups. For the total population the 90th percentile of daily intake of added sugar was 104 g day^{-1} or 20% of calories.

More recent (1999) economic estimates of per capita consumption show that availability of caloric sweeteners averages 196 g (745 kcal) per person per day. This increase of 29%, since the early 1980s, is somewhat less than the increased per capita availability of total flour and cereal products (36%) and is greater than the increase in total fat availability (19%). When total added sugars availability is related to the availability of calories in the food supply it now approximates 20%, slightly up from 17% in the early 1980s. In contrast, more recent dietary surveys estimate consumption of sweeteners to be close to 80 g day^{-1} or nearly 18% of the energy consumed. These data suggest that the amount of added sugars eaten has risen by almost 50% from 20 years ago and is 42% of the added sugar availability. However the majority of this reported increase in intake can be accounted for by a change in the approach and definition of sugars used by USDA in reporting dietary survey data.

By definition, sugars are mono- and dissaccharides and this definition was used in the earlier survey estimate of sugar intakes. In more recent surveys all high-fructose corn syrups are included as added sugar, which does not adjust for the 70% of these syrups that are made up of polysaccharides. This fact, plus the failure to consider loss of sugars in baking and other processes, and the inclusion of high-intensity sweeteners in the calculation, account for most of the calculated increase in added sugar consumption. Thus at present it is uncertain the extent to which the modest increase in availability of added sugars as a portion of the energy content of the available food supply has influenced dietary intakes.

Since the mid-1970s there has been a considerable replacement of sucrose with corn sweeteners, including high-fructose corn syrup, glucose syrups, and dextrose. At the present time, corn sweeteners account for about 50% of the total added

sweetener that is available in the USA. Because the most commonly used high-fructose corn syrups contain 52% or less of fructose, their availability has done little to affect fructose consumption compared with the consumption of sucrose which is 50% fructose.

Due to changing lifestyles since the early 1900s, the major use of sugars has shifted from direct use by consumers in households to use by the food industry in baked goods, processed foods, and beverages. In 1925, consumer use accounted for about two-thirds of total sugar disappearance, whereas the food industry used only one-third. Today these figures are reversed. In addition to the use of sugar as a sweetener, it is widely used for its functional properties, such as providing bulk in baked goods and inhibiting spoilage microorganisms in jams and jellies. These functional uses are the same whether they occur in the home or the industry, and are essential to achieving a safe and tasty food supply. Therefore the shift to use by the food industry of a greater proportion of sugar disappearance does not suggest that the consumer is eating more sugar than in previous decades.

Dietary Goals and Guidelines

Primarily because of concern with chronic disease, developed countries have produced statements of dietary goals and guidelines aimed at improving the dietary pattern of their populations. The assumption is that nutritional factors are important in the development of chronic disease and that corrective actions in terms of diet will prove to be beneficial.

Sucrose has appeared prominently in dietary guidelines. Recent nutrition recommendations of the governments of Canada and the USA have taken a more liberal view of the nutritional role of sugar in the diet. The American and Canadian Diabetes Associations recommend that sugars and sugar-containing foods do not need to be restricted by people with diabetes and should be considered in the context of the total amount of carbohydrates consumed. The Canadian dietary guidelines for healthy people are silent on the subject, based on the conclusion of the scientific advisory committee that there was no basis on which to advise reduction of sugar intake to the population. Similarly, the guidelines for the USA are no longer punitive and have shifted from 'avoid too much sugar' to 'choose beverages and foods to moderate your intake of sugars.' This advice emphasizes the requirement of individuals to select diets that are based on variety and moderation. Avoidance of refined sugars is no guarantee of a healthy diet.

Sucrose and Food Intake

Sucrose, through its sweetness and other functional properties, makes foods more appealing and raises the probability that they will be selected over foods that are not as palatable. It is well known that the hedonic value of a food is a major determinant of its consumption. However, there is a natural response to sweetness and palatability of foods that tends to be self-limiting. Sensory-specific satiety, which refers to the decreased pleasantness of a food or beverage as it is consumed, occurs for all foods and tastes. Thus increasing the pleasantness of a food may influence its choice but does not necessarily lead to excess consumption.

The role of a varied and palatable diet in the etiology of obesity is currently of great interest because of the high prevalence of obesity in western populations. In the past 40 years, the incidence of obesity has increased fivefold. It is unlikely that sucrose can be rationalized as a causative factor, for several reasons. First, on a strictly correlative basis, the increase in obesity does not associate with the constant intake of sugars occurring during this same period. Second, obese subjects do not show a disproportionate intake of sweet foods compared with normal-weight individuals.

In contrast to hypotheses that sugars bypass appetite-regulatory systems, experimental studies indicate that consumption of sugars suppresses subsequent energy intake. Both children and adults compensate for energy provided by sucrose preloads when given within 1 h before a test meal. Similarly, compensation is also observed for other sugars, which produce higher glycemic responses, including glucose and polycose. Therefore, a rapid increase in blood glucose following ingestion of rapidly digestible carbohydrates does not negatively impact food intake regulation. In general, ≥ 50 g of sugar within 20–60 min of a meal is sufficient to reduce meal intake.

Mechanisms controlling the regulation of food intake remain poorly understood. It seems clear, however, that the cause of obesity is an excess of energy intake over expenditure. It is far too simple to attribute its origin to the composition of the food supply or of a particular food. Many foods and many dietary habits probably contribute to this imbalance, but for most the causative factor of greatest impact is reduced energy expenditure in the form of physical activity.

SUGAR

Contents

Sugarcane

M A Godshall, Sugar Processing Research Institute, New Orleans, LA, USA
B L Legendre, US Dept of Agriculture, Houma, LA, USA

Introduction

During the decade of the 1980s, word sugar production held steady at around 100×10^6 t, with cane sugar accounting for 60–64% of the total, and beet sugar for the remainder. The decade of the 1990s was characterized by a steadily increasing output of sugar, so that total world sugar production was forecast to reach 121.5×10^6 t in 1999–2000. Cane sugar now accounts for about 70% of total world sugar production. Although most tropical and subtropical countries produce cane sugar, 10 countries account for 74% of global cane sugar production, as shown in **Table 1**.

Taxonomy and Origin

Sugarcane is a large perennial tropical grass belonging to the tribe Andropogoneae of the family Gramineae and the genus *Saccharum*. The Andropogoneae

Table 1 Raw cane sugar production for the 10 leading producing countries (1997–98 crop)[a]

are characteristically tropical or subtropical with a high concentration of genera in two geographical areas: India and Indonesia. The genera *Saccharum, Erianthus* (sect. *Ripidium*), *Sclerostachya*, and *Narenga*, most cited in the origin of sugarcane, constitute an interbreeding group that, along with three species of *Saccharum* (*S. officinarum* L., *S. barberi* Jeswiet, and *S. sinense* Roxb) were used for commercial sugar production. *Saccharum officinarum* is a progenitor of all modern sugarcane cultivars. However, the presence of the interbreeding *Saccharum* complex of the three sugar species as well as its wild relatives, *S. spontaneum* L. and *S. robustum* Brandes and Jeswiet ex Grassl, has provided a genetic pool of unparalleled diversity, allowing for the development of thousands of cultivars that are adapted to the areas where sugarcane is grown. Today, most cultivars of sugarcane are interspecific hybrids of two or more of the five *Saccharum* species.

Description

The sugarcane plant is a large, jointed grass 2.5–4 m in height, with robust stems up to 5 cm in diameter and a tendency to tiller profusely in clumps called stools (Figure 1). The stem is made up of 10–40 internodes with leaves borne at the nodes. The inflorescence (Figure 2) is a large, terminal panicle, feathery in appearance, white to purplish in color.

History

The evolution of sugarcane is postulated to have had three foci – Polynesia, China, and India – and must have started many thousands of years ago. Sugarcane is a readily transported food plant and capable of germination several weeks after cutting from the parent stool. The 'noble' cultivars (clones of *S. officinarum*) were undoubtedly grown in native gardens of Polynesia as a food plant since earliest times. They were also carried throughout the Pacific Island archipelago by Polynesian navigators more than 1000 years ago.

There are well-documented records of sugarcane in both China and India several centuries before the Christian era. Sugarcane was carried from India to Persia in the sixth century, after which the Arabs took it to the Mediterranean littoral. The Egyptians were the first to refine sugar.

Sugarcane reached Spain and Portugal in the eighth century and was subsequently brought to the Canary Islands, the Azores, and East Africa. The first

Figure 1 Example of sugarcane growth habit. Courtesy of Mary An Godshall and Alfred D French.

Figure 2 Flowering sugarcane in Cairns, Australia. Courtesy of Mary An Godshall and Alfred D French.

introduction to the New World was made by Columbus, who carried the cane from the Canary Islands to what is now the Dominican Republic on his second voyage in 1493. By 1550, sugarcane was introduced to Mexico, Brazil, and Peru.

Because of its scarcity and expense, for much of human history, sugar was considered a valuable medicine and later a spice. It was not until the mid to late eighteenth century that practical methods for sugar extraction were developed, making cane sugar widely available and less expensive.

Breeding Programs

The productivity of any sugarcane industry is constantly threatened by diseases, insect pests, and climate. To insure consistent, economical production, new and improved, high-yielding sugarcane cultivars are constantly needed to replace those removed from production. Further, most sugarcane cultivars have a finite life span of useful productivity. Prior to the early 1990s sugarcane was improved mostly by cultivar substitution, making use of naturally occurring clones (mainly *S. officinarum*). This gave improved yields owing to better adaptation or greater inherent disease resistance. In 1888, the fertility of sugarcane seed was discovered in Java, Barbados, and Brazil, and before the end of the century, organized breeding programs were established in six countries. Initially, improvements were realized using a procedure termed 'nobilization,' whereby the hardy and disease-resistant, but otherwise inferior wild cane types, i.e., *S. spontaneum* and *S. barberi*, were crossed and back-crossed with the noble canes, *S. officinarum*, which are characteristically higher in juice quality.

Today, most sugarcane cultivars grown around the world are trispecies hybrids that can be traced to only a relatively few clones of the three species mentioned above. The major objectives of most breeding programs are to combine high-yield potential and improved juice quality with disease resistance and other important agronomic characteristics. Recurrent breeding and selection programs based on yield potential have generally been highly successful. Most of the economically important characteristics in sugarcane are quantitative ones controlled by multiple genes. Therefore, large seedling populations are required when attempting to develop new, high-yielding sugarcane cultivars when selecting for as many as 20 or more individual characteristics.

In an effort to broaden the narrow genetic base, a basic or prebreeding program has been established in many countries with its objective to broaden the genetic base upon which contemporary cultivars are bred. This base-broadening program makes most cultivars less vulnerable to disease and insect pests and increases their agronomic worth. However, the basic breeding program is long-term and high-risk, and has had success in only a few countries. It has had a dramatic impact upon the sugar industry of Louisiana in recent years with the release of three superior, high-yielding cultivars for commercial planting. One of

these cultivars, a BC_4 progeny of the *S. spontaneum* clone US 56-15-8, now occupies approximately 70% of the planted area. This cultivar alone has increased productivity by over 30%, leading to a record yield of sugar per unit area during the 1999–2000 harvest season that approached 8.16 t of sugar per hectare for a crop season which averages only 7–9 months.

To augment traditional selection strategies, researchers in various countries have developed species-specific markers in recent years that allow for the accurate selection of true hybrids of these different species at the early seedling stage. In the past, it was only through morphological traits that apparent true hybrids were selected in the basic breeding programs. However, in many cases it was later found that what was thought to be a true hybrid was, in fact, a self or a contaminant. This new molecular approach has given plant breeders a powerful tool to select only those genotypes that carry the desired markers.

Each program is tailored for the needs of its specific location, which can be quite different from country to country. For example, in Louisiana, breeding goals include development of early maturing cultivars with cold tolerance suited for the very short growing season of 9 months. These goals would be meaningless in a more tropical climate where other needs predominate. Further, rarely will a cultivar selected for one environment be adapted to the environment of another area.

Augmenting traditional approaches with new molecular techniques fills a critical need in developing these improved cultivars through wide hybridization and genetic transformation. In recent years, researchers in several countries have been successful in inserting genes into sugarcane plants that express resistance to various diseases, insects, and herbicides. Because of the great potential gains that can be realized from molecular approaches in the development of superior new cultivars, this long-term, high-risk research also offers opportunities for the twenty-first century. However, it is not envisioned that these molecular approaches will replace traditional breeding and selection in the development of future high-yielding cultivars.

Diseases and Pests

Sugarcane plants are subject to a number of bacterial, fungal, and viral diseases. At any one time in any given location, there are usually three or four prevalent diseases of major concern. The severity of infestations increases and decreases in various parts of the world depending on factors such as types of cultivars grown and other control measures. The most recent diseases to appear in the western hemisphere are: leaf scald, caused by the bacterium *Xanthomonas albilineans* (Ashby) Dowson, which arrived in USA (Florida) in 1967; smut, caused by the fungus *Ustilago scitaminea* Sydow, in 1978; rust, caused by the fungus *Puccinia melanocephala* H. & P., in 1979; and yellow-leaf syndrome, caused by a virus, in 1993.

Other important diseases include sugarcane mosaic, a viral disease which caused severe losses throughout the world in the earlier part of the century, and ratoon-stunting disease, caused by the bacterium *Clavibacterium xyli*. Red rot, caused by the fungus *Collectotrichum falcatum*, was once severe in many parts of the world but now appears to be a problem mainly in India.

Pests include rats – a severe problem in some areas – nematodes, and a number of insects. The most severe insect pests are the various types of borers, i.e., the sugarcane borer, *Diatrea saccharalis* (F.), and the eldana borer, *Eldana saccharina*, which cause damage first by boring into the cane stalk, then by providing entry points for other diseases and, finally, by reducing cane and juice quality.

Various weeds cause problems in sugarcane culture by competing for nutrients and crowding or overgrowing the young plants. Perennial grasses are the most serious weeds, harboring insects and diseases. Preemergent herbicides are commonly used for control.

Control Measures

In recent years, detection of several of these diseases has been made easier with the development of DNA-based molecular diagnostic protocols. Timeliness of diagnosis is important to the management of all diseases; however, cultivar resistance through traditional and molecular approaches still remains as the primary control mechanism.

Very little chemical treatment with fungicides or other agents is used. Such measures are largely ineffective because the leafy canopy of the cane plant prevents proper application, and such large amounts would need to be applied as to be prohibitively expensive and environmentally unsound. (*See* **Fungicides**.)

For some diseases, especially ratoon-stunting disease, the seed cane is treated with hot water.

In recent years, experiments have progressed on the use of biological control agents for long-term control of insects. Examples include the *Cordyceps* fungus to control white grubs, parasitization with the wasp *Apanteles flavipes* to control borer, and the fungus *Metarhizium anisopliae* for leaf hopper control.

The sugarcane borer, *Diatraea saccharalis* (F.), and the Mexican rice borer, *Eureuma loftini* (Dyar), are

major insect pests of the mainland USA sugarcane industry. However, in 1986 a recurrent selection program was initiated in Louisiana to develop sugarcane cultivars with resistance to these two stalk borers. Plant resistance as well as biological control have become increasingly important as tactics used in integrated pest management (IPM), thus reducing the need for chemical pesticides and increasing profit margins for farmers. During the past 10–15 years, the need for chemical pesticides has been reduced from four applications per unit area per year to less than one application per unit area per year, with the use of more resistant cultivars and IPM.

Culture

Sugarcane grows in the warm, humid tropics and subtropics. It needs at least 600 mm of annual rainfall but responds well to irrigation where rainfall is limited.

Propagation is asexual, accomplished by cuttings known as sets or 'seed cane' which contain at least one bud. It is also propagated sexually by pollination, but this is usually seen only in breeding programs since sugarcane is a polyploid hybrid and does not breed true.

Sugarcane normally requires large inputs of chemical fertilizer, especially nitrogen, in order to maximize yields; however, excellent yields can be obtained with minimum cultivation.

Types of cane harvesting are determined by terrain, soil types, and the availability and cost of labor. Methods range from manual cutting to full mechanical harvesting, which includes whole-stalk and billet-cane (combine) harvesting. In some parts of the world, the cane is briefly burned to remove the dry, trashy leaf residue. Burning also helps to reduce the number of field pests, such as snails, rats, and insects. The cane may be topped or not, burned standing or lying cut in the field, or taken green (unburned) to the mill.

Harvest seasons vary with location, ranging from mid-June to December in Queensland, from mid-October to March in Texas and Florida, and early October to the end of December in Louisiana, which is one of the shortest harvest seasons in the world. In a few tropical areas, the cane may be harvested all year around. Table 1 shows the harvest dates for several countries.

Maturation and Use of Ripeners

In nature, the cane ripens, or matures, when growth slows and the synthesis and storage of sucrose occur. Ripening is influenced by many factors, with the most important being the age of the cane, incident sunlight, temperature, and rainfall. Cultivars differ in their optimum ripening time, some being considered early-maturing and some late-maturing.

The use of chemical ripeners has increased since the introduction of glyphosine in 1972. Glyphosine, glyphosate, mefluidide, and ethepon are the compounds most widely used. The harvest is timed to coincide with the maximum level of sucrose in the mature stalks, and chemical ripeners are used to maximize the sucrose-producing potential of the cane stalks, especially under adverse ripening conditions. Ripeners are not able to induce the production of more sucrose than is inherent to the cultivar, nor are they economically effective when natural ripening conditions are optimum.

Production of Raw Sugar

The harvested sugarcane cannot be stored for very long without deteriorating, so it is converted to raw sugar with as little delay as possible. The sugar is contained in the stalk juice, ranging in concentration from 15% to 20% sucrose. The juice also contains a number of other constituents, such as starch and other polysaccharides, bits of fiber, flavonoid and anthocyanin pigments, protein, amino acids, aconitic, and other organic acids and salts. The purpose of sugar manufacture is to separate the sugar from these other components and to crystallize it in as pure a form as economically feasible.

The first stage of sugar manufacture is the production of raw sugar, which occurs in the sugar mill or factory. Juice is extracted from the stalks by either of two processes: milling, which is the more common, or diffusion. In either process, the cane tissue is sufficiently disrupted by cutting, shredding, grinding or 'fiberizing' to achieve 95–97% extraction of available sucrose. (*See* **Sucrose**: Properties and Determination.)

The raw cane juice is turbid and acidic, with pH in the range of 5.3–5.7. The first stage of sugar production is clarification (or purification) of the juice, designed to remove soluble and insoluble impurities and to inactivate enzymes that hydrolyze sucrose (invertase). Clarification is carried out by the addition of lime and flocculents to the heated cane juice. This coagulates and precipitates insoluble and colloidal material and raises the pH to near neutral. Increasing the pH of the juice helps to stabilize the sucrose against acid hydrolysis. After filtration, the clarified juice is concentrated by evaporation into crystalline raw sugar. In recent years, several variations on the above process have been developed to improve yield and product quality. Among these are the use of

enzymes to reduce problematic polysaccharides. For example, dextranase enzyme is used to reduce the amount of dextran, which is caused by infection with the bacterium *Leuconostoc mesenterioides*, and amylase is sometimes used to decrease the amount of starch in the juice from some high-starch cultivars. Expensive enzymes such as these are used only on an 'as-needed' or emergency basis.

During processing, the cane juice changes color from dark green to golden brown owing to various color-forming reactions, the most important ones being enzymatic and nonenzymatic browning and polymerization of polyphenolic acids, the Maillard browning reaction between reducing sugars and amino acids, and the caramelization reaction caused by thermal degradation of sugars. Manufacturers try to maximize sucrose yield and minimize the reactions that produce color or cause sucrose loss. (*See* **Browning**: Nonenzymatic; **Caramel**: Properties and Analysis.)

In the USA and some European countries, raw sugar is considered inedible because it is not made according to the strict sanitary codes established in those countries. However, in many other parts of the world, raw sugar is sold directly to the consumer. The composition of raw sugar is shown in Table 2. A special type of raw sugar, called turbinado sugar, is produced for the edible market in Europe and North America.

In terms of bulk, the major coproduct of milling is bagasse, the fibrous residue of the stalk. Although some of it is used in paper-making, as a chemical feedstock and in cattle feed, its principal use is as an energy source for the mills, allowing most cane factories to be partially or totally energy-self-sufficient. In some areas cogeneration of electricity is also possible.

Raw sugar is a commodity sold on the world market. Many rules and regulations control its sale, its cost, and its transport around the world. Raw sugar is exported from producing areas to refineries in industrialized countries for conversion into highly purified white sugar.

Table 2 Composition of raw sugar

Component	*Range of concentration*
Sucrose	96–99%
Glucose	0.3–0.6%
Fructose	0.3–0.6%
Moisture	0.1–0.5%
Ash	0.1–0.5%
Starch	50–400 p.p.m.
Other polysaccharides	800–1500 p.p.m.
Insoluble matter (soil and vegetable particles)	200–500 p.p.m.
Color	800–3000 ICUMSA units[a]

[a]ICUMSA, International Commission for Uniform Methods of Sugar Analysis. It is the absorbancy index of the solution × 1000:

$$\frac{A_{420} \times 1000}{\text{cell length (cm)} \times \text{Conc. (g ml}^{-1})}$$

Specialty Products from Sugarcane

While the major product from sugarcane is white, granulated sugar, the process also lends itself to the production of several specialty sweeteners. Sugarcane is uniquely suited, by virtue of trace components present in the juice and the reactions that occur during processing, to produce sugars with desirable flavors and colors. The latter range from light yellow to dark brown, and flavors include a range of molasses and browned/caramelized types.

The specialty sweeteners from sugarcane include factory (mill) products such as turbinado sugar, edible molasses, Demerara sugar, muscovado sugar, plantation white sugar, sugarcane syrup, and dried cane juice. In the last 5 years or so, organic sugar has come on the market in various locations. Specialties from refineries include brown sugar, yellow sugar (popular in Canada), golden syrups, refinery syrups, and molasses. Less common specialties include canned or packaged, pasteurized cane juice, canned cane stalks, dehydrated molasses, and liquid brown sugar.

Brown sugar, which is produced in refineries, is a very fine grain sugar which is enveloped in a thin film of dark syrup and may range in color from light yellow to very dark brown. It is produced in either of two ways. The traditional method is to crystallize it from a refinery syrup selected for its color and flavor. The second, more energy-efficient way is to coat white sugar crystals with cane syrup or molasses. The latter method can be used to produce brown sugar from beet sugar.

The last decade has also seen great changes in the production of plantation white sugar, which is a white sugar produced directly at the mill, in lieu of raw sugar. This sugar is not of as high quality as refined sugar, having slightly higher color, ash, moisture, and reducing sugar content, but it is acceptable for almost all domestic applications. It has the advantage that its production is much less expensive than that of refined sugar, and it can be made in existing raw sugar mills with a minimum of redesign of equipment. Currently, most plantation white sugar is used within the country of production, but several countries, notably Brazil, have in recent years developed a worldwide trade in plantation white sugar.

Sugarbeet

M A Clarke, Sugar Processing Research Institute Incorporated, New Orleans, LA, USA
M F G Cleary, Holly Sugar Corporation, Colorado Springs, CO, USA

Introduction

Total world sugar production in 1990–91 was 112.6 $\times 10^6$ t, of which 41.2 $\times 10^6$ t were produced from sugarbeet, and the rest from sugarcane. Some 35% of world beet sugar is produced in the EC, and 9% in the USA. **Table 1** lists areas, yields, and sugar yield for the 10 major sugarbeet-producing countries based on (1989 to 1991 data). Sugarbeet is grown in many climates, from temperate (southern California, Spain, Italy) to relatively cold climates (North Dakota, Finland). In general, sugarbeet is converted directly to white sugar, refined quality, although some eastern European areas still make an intermediate raw sugar because of lack of processing facilities. Costs of production vary widely with climate, yield, and socioeconomic factors. Average production costs (grower cost) and factory cost (processor cost) are shown in **Table 2** for the USA, an intermediate-cost producer.

Composition

The composition of sugarbeet is shown in **Table 3**. Sugarbeet, being a root, has a much higher level of nitrogen compounds than does sugarcane, and beet processing is geared to removing these, and preventing them from contributing to color and odor compounds. Composition is of vital importance to sugar yield because soluble nonsucrose constituents impede crystallization of sucrose by complexing with sucrose and carrying it into residual molasses. Each kilogram

of nonsucrose constituents in sugarbeet juice can carry 0.65–0.85 kg of sucrose to molasses, removing it from the yield of crystalline sugar. Plant breeders have bred for high sucrose in beet to the point where selection for lower specific nonsucrose components (sodium, potassium, amino nitrogen) can generate greater total sucrose yields. (*See* **Sucrose**: Properties and Determination.)

Origin, Plant Breeding, and Cultivation

Sugarbeet has been grown for sugar (sucrose) production only since the late eighteenth century, when Achard in Europe identified the 'white Silesian beet' as a source of sugar, and Napoleon encouraged breeding and processing research, to provide a home-produced alternative to cane sugar, which required shipment from the West Indies.

Sugarbeet, grown from seed, is a biennial plant which accomplishes vegetative growth in its first year and seed production in the second. For sugar production it is harvested at the end of the first year of growth, after a frost-free (preferably) period of 5–6 months, in areas with annual rainfall of some 20 cm. Irrigation is used in some areas, e.g., north-western USA. Sugarbeets are often used in crop rotation, as their deep roots bring up nutrients from lower levels of soil, to become available for alternate crops, and because they cannot be planted in the same field more than once every 3–4 years without risk of attack by nematodes. Beets for seed are grown in nonsugar-producing areas, notably in Oregon, where most US and European companies operate joint-venture seed companies with the purpose of maximizing germplasm resources.

Seed is, and has been since the 1940s, all monogerm hybrid, which permits mechanical planting and harvesting. The selected monogerm, male-sterile, inbred line and the multigerm pollinator (chosen for other desirable characteristics) are initially multiplied separately; the former is planted in strips together with the fertile monogerm complementary line. Foundation seed produced by the male-sterile inbred furnishes the seed parent for the hybrid variety, which again is grown in strips with foundation seed of the pollinator. Monogerm hybrid seed is harvested only from the male-sterile parent, while the pollinator is destroyed soon after flowering.

The major varieties currently grown in the USA are shown in Table 4. Varieties must be tested in semicommercial or commercial trials for several years after development to receive test market approval.

Harvest Practice

Clean, unbroken beets, free of leaves, trash, and rocks, are the primary objective. Grower contracts can penalize noncompliance and usually include a right of refusal for beet not fit for processing. This option is rarely exercised in North America, except when beets are so severely degraded as to stop the process completely.

Harvest dates are normally agreed upon prior to planting, with premiums for early and/or late harvest deliveries to compensate the grower for beet low in sugar content and tonnes per hectare (immature), or at risk from weather, respectively. Harvesting normally

takes place in September to November, except in some areas of California where a second crop is harvested in the spring. The combined harvest and processing strategy accounts for both the 'optimum harvest window' for the grower, and the beneficial impact of increased throughput on processor profitability.

Commonly used machines can harvest four to six rows simultaneously, and up to 1000 t per day. None the less, smaller machines (one and two rows) are abundant, and there are still areas where beets are harvested by hand at a rate of less than 10 t per worker per day. The harvester is normally pulled behind a tractor which dumps the harvested beet into an open lorry alongside. Three basic operations are performed: removal of the beet from the ground; removal of the leaves and, perhaps, a portion of the top of the root; and a modest separation of dirt and trash from the root.

Complete removal of leaves is essential, whether before the beet is taken from the ground, or after the beet is lifted. Further removal of a portion of the top of the root is arguably of benefit. The portion that is removed typically displays 67% of the sugar concentration of the main root and has a higher impurity load; its inclusion would reduce both grower payment and processing profitability. On the other hand, a sizable wound is inflicted, which may lead to sugar losses between harvest and processing.

Effect of Ambient Temperature

The technical value of the beet decreases exponentially if the root is subjected to repeated freeze–thaw

cycles, with ambient temperature falling below −5 °C. Irreversible tissue damage occurs, the vascular system collapses, and secondary infections consume the sugar. The first hard freeze will normally kill the leaves while the root remains undamaged, and, if the soil temperatures are reasonably high and a variety has been chosen which 'sits down' in the soil, the crop can withstand several nights of −5 °C to −10 °C temperatures. Some cold-temperature growing areas target this period to accelerate the daily delivery rate to the factory, from about 1% of the crop to up to 10% of the crop per day.

Similar phenomena occur in beets which have been subjected to temperatures in excess of 40–45 °C for a number of days. Since the respiration rate has already been accelerated by heat, and soilborne infections and diseases thrive in warm soils, tissue degradation and technical losses occur much more rapidly. Autumn harvests around the Mediterranean and spring harvests in California are occasional victims of this plague.

Sampling

As beets are delivered and received by the processor, a representative sample is taken in order to determine, ultimately, the amount that will be paid to the grower. The sampling procedure varies from elaborate cross-sectioning of the lorry and subsequent sample-splitting, to a simple 'grab sample' of the falling stream of beet. Samples are evaluated in a laboratory usually operated by the processor but open to inspection by the grower. Parameters normally include sugar content, percentage dirt and trash (tare) and, occasionally, other analyses.

The tare is the portion of the delivery which, by contract, the processor is not obliged to pay for. It always includes rocks, leaves, and trash, but may also include a portion of the top root which the grower had agreed to 'scalp' from the beet. Once the percentage is determined in the laboratory, the delivered weight is adjusted accordingly. Dirt and trash typically contribute 1–2% to the tare value, but difficult harvest conditions may drive this contribution to over 10%. 'Top tare,' if applicable, will normally fall into the 3–5% range.

Sugar content of mature, healthy beet is between 10% and 22% (Table 3) depending on agricultural inputs: variety, disease pressure, climate, and harvest conditions. Grower payment is linearly tied to sugar content, with a multiplier based on the market value of sugar. The typical participating payment scale in the USA returns 60% of the net market value of the recovered sugar to the grower. Some contracts include a premium for exceptionally high sugar concentrations based on the assumption that recovery will increase accordingly.

Analyses for nonsucrose components may be run to estimate the amount of impurities which affect yield on crystallization. Most common are sodium, potassium, and amino nitrogen; they are used ubiquitously in breeding beet varieties, and occasionally in both Europe and North America to adjust the grower payment.

Storage of Beet

After beets are removed from the ground, they can be processed immediately, stored for a few weeks, during which time normal respiration losses are tolerated, or put into long-term storage which requires special equipment and/or techniques to maintain the beet for several months. Respiration losses during the storage of healthy beet are typically 0.15% sugar per week. Another strategy is to increase the beet-processing capacity of the factory and store an intermediate syrup.

When beets are stored in piles for up to 160 days, special precautions may range from simply orienting the pile to minimize exposure to sunlight, to the use of fully enclosed ventilated sheds which can contain 90 000 t of beet. Between these extremes are the use of straw or plastic to cover the piles, and the use of half-round ducts to ventilate beet piles. Typical piles contain 50 000–100 000 t of beet, with a trapezoidal cross-section 50–65 m wide at the base and a height of 6–9 m, depending on storage conditions.

Clean, unbroken beets, with a root temperature below 10 °C, are required to assure the proper air flow and cooling which prevent the natural respiration of the beet from heating the pile. Piles are monitored to detect such hot spots. Ideally, storage should minimize respiration rate without freezing the tissue but, in practice, the outer layer of the pile often suffers severe deterioration to a depth of about 50 cm. Forced-air ventilation may be used intentionally to freeze the entire pile where the climate allows this to be accomplished continuously over a period of a few days: this requires daily temperatures below −10 °C for 4 or 5 days. Such beets are not subject to respiration losses, but must remain frozen until they are processed.

Regardless of storage conditions, beets enter the factory process in a flow of water through the flume during which, allowing for the natural buoyancy of the root, rocks and trash are separated. Some washing is effected during this process, but all processes are supplemented with a beet washer, prior to slicing the beet. Water from the washer is returned to the flume loop, which typically includes a system to remove

suspended solids, lower biochemical oxygen demand (BOD) and chemical oxygen demand (COD), and reuse the water.

Factory Processing

Sugarbeet processing is illustrated in Figure 1. The complete sugarbeet-processing operation involves a number of unit operations, including the following:

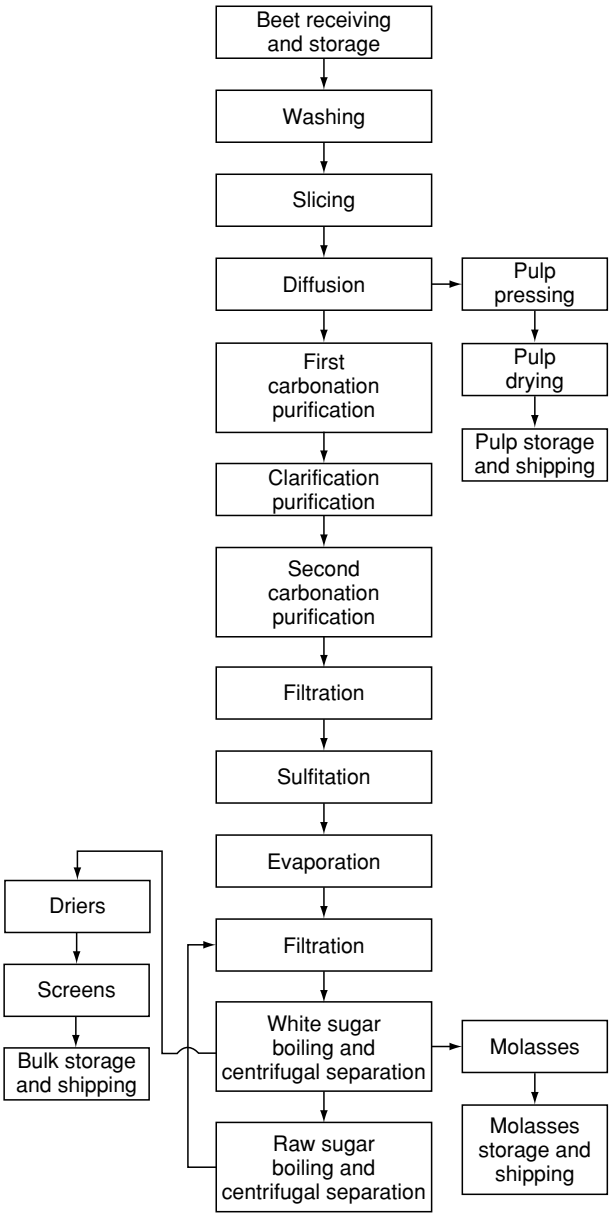

Figure 1 Outline of sugarbeet factory process. Source: Holly Sugar Corporation, a subsidiary of Imperial Holly Corporation, Colorado Springs, USA. Reproduced from Sugar: Sugar Beet, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

1. Diffusion (dried beet pulp – animal feed coproduct).
2. Carbonation (purification).
3. Evaporation (concentration).
4. Crystallization (saleable white sugar; also molasses coproduct used as animal feed and fermentation feedstock).

After washing, beets are sliced into V-shaped cossettes, about 3 cm by 4.5–7.2 cm. This shape ensures maximum surface area for sugar extraction. Cossettes are introduced into a countercurrent continuous diffuser that may be one of several designs: horizontal drum, sloped vat, or vertical-cylindrical tower. All designs involve a mechanism to transport sugarbeet cossettes in a direction against the flow of hot water extractant, and extract some 98% of the sugar (sucrose) in the beet. Sugarbeet cell walls are heat-denaturedto enhance diffusion of sugar from the plant cells to the lower concentration of sugar in the aqueous extractant. Wet beet pulp, discharged from the diffuser at approximately 92% moisture, is pressed mechanically to reduce beet pulp moisture to approximately 76%, and either air-dried under ambient temperatures (in California) or dried in direct gas, oil, or coal-fired rotary drum driers to a moisture content of approximately 10%. Pulp has long been sold as an animal feed, but in recent years it has been purified and sold as a food fiber, for breakfast cereals. Juice from the diffuser (diffuser juice or raw juice) contains approximately 12% sucrose by weight, together with 2% soluble impurities, soluble and semisoluble colloidal proteins, pectins, and saponins extracted from the cossettes; it is heated to 85 °C prior to purification with lime and carbon dioxide, called carbonation.

In this carbonation clarification, semisoluble colloidal materials are coagulated and precipitated as insoluble salts. Potassium and sodium salts of oxalic, malic, and citric acids, and phosphates and sulfates are precipitated as insoluble calcium salts. Milk of lime (a suspension of calcium hydroxide) and carbon dioxide are added continuously and concurrently to a diffusion juice in a carbonation tank, with a retention time of 12–15 min at 85–88 °C. Treated juice is then sent to a clarifier for separation of the precipitated impurities. Thickened underflow mud from the clarifier is filtered on vacuum, rotary drum filters and washed to minimize sugar loss.

Lime and carbon dioxide are produced from limerock (calcium carbonate) at each factory in a coke or natural-gas-fired, vertical-shaft Belgium-type lime kiln, or in a gas-fired, horizontal, rotary drum-type kiln where waste lime is reburned. Carbon dioxide is reclaimed from the kiln for direct use in the

lime–carbon-dioxide first carbonation purification tank. Approximately 2% of lime on sugarbeets is used for purification and clarification.

Clarified overflow juice (thin juice) is then subjected to a second treatment with carbon dioxide to reduce residual lime salts concentration. Calcium carbonate precipitate is filtered from the juice by use of pressure filters. Sulfur dioxide is added to the filtered juice to minimize color formation during subsequent processing steps. The thin juice, after all colloidal impurities and approximately 35% of the soluble impurities have been removed, is concentrated from about 13% dissolved solids (13° Brix) to approximately 60–65% dissolved solids in energy-efficient quintuple-effect evaporators.

Steam at all beet sugar factories is produced in relatively low-pressure (17.5–28 $kg\,cm^{-2}$) boilers. This steam is passed through a turbine to produce electricity for factory use. Exhaust steam from the turbine is used for heating, evaporation, and crystallization of sugar in the latter stages of the process.

Thick juice from the evaporators is concentrated and sugar is crystallized in a three-stage process. The first vacuum-pan crystallization produces white sugar, separated from mother liquor (massecuite) in basket-type batch centrifuges, in which crystals are washed with hot water. Second and third vacuum-pan crystallizers produce lower-purity raw sugars, which are redissolved after separation of the massecuite in continuous conic-basket centrifuges developed specifically for the sugar-processing industry.

White sugar, discharged wet from the batch centrifuges, is dried in rotary hot-air driers (granulators) to a moisture content of approximately 0.02%. The white refined sugar produced is 99.96% pure as a result of successive purification by diffusion, lime–carbon-dioxide purification, and triple crystallization in the batch vacuum-pan crystallizers.

The mother liquor recovered from the last three vacuum-pan crystallizers is exhausted of further raw sugar crystals under standard atmospheric conditions. The massecuite reclaimed from this process is a molasses coproduct, and approximately 60% of the solid material is sucrose. The ratio of nonsugar impurities to sugar prevents further crystallization of sugar using conventional processing technology.

Sugarbeet processing is a seasonal operation, beginning with beet harvest, which must be completed before beets freeze in the ground, and continuing through processing of stored beets. Some factories process additional beets to syrup, or thick juice, which is then stored in tanks and processed after beet input is complete. A longer operating season reduces the fixed costs of a factory.

Molasses Desugarization

In the last decade, a new process has been developed and widely applied in the North American, Japanese, and Finnish beet sugar industries. Molasses desugarization, accomplished by ion exclusion in which the final molasses is passed over ion exchange resins which separate sucrose from other molasses components, allows continuous production of a high-sucrose product stream and a desugarized molasses stream, and can increase a factory's sugar production by 10%, with no increase in incoming beet.

Problems of Waste Disposal

Leaf and root material which have been removed in the field during the harvest are normally reincorporated into the soil as green manure. Occasionally, livestock are allowed to forage directly on this material. Trash and beet pieces recovered from the flumes are also used as cattle feed, either directly or chopped with pulp for drying.

Most factories operate a self-contained system to handle the vast amounts of water used for beet transport and cleaning. Two to four million liters of water per day for a factory processing 5000 $t\,day^{-1}$ are settled to remove suspended solids and to reduce the COD and BOD, usually through an extensive lagoon system, and reused. (*See* **Effluents from Food Processing**: Composition and Analysis.)

Precipitated calcium carbonate, which contains 10–15% organic and phosphate impurities, is produced at a rate of about 4–5% (w/w) of beet. The most up-to-date processes yield material which can be directly used for soil amendment or as an animal feed supplement. Less modern factories will allow this material to dry outside before sale.

Palms and Maples

L W Doner, Eastern Regional Research Center, Wyndmoor, PA, USA

Introduction

The sucrose content of sap from palm trees is extensively variable, but it often exceeds 10%. This is a higher level than can be obtained from any other tree family. Sucrose is produced in parts of tropical Africa and Asia by evaporating water from the sap of a variety of palm species. Sap from the North American sugar maple contains a lower level of sucrose (1–3%). Its natural range includes south-eastern Canada and north-eastern USA, where maple syrup and maple sugar are produced by evaporation of water from the sap. (*See* **Sucrose**: Properties and Determination.)

Palm Species which Serve as Sucrose Sources

The palm family (Palmae) consists of over 2700 species. The coconut palm (*Cocos nucifera*) is widely distributed, but others have a limited natural range. Most palm species are trees, and in tropical areas they are second only to grasses in economic importance. Among the many food and fiber products that are obtained is palm sugar, also known as jaggery. This is unrefined sucrose, obtained by boiling water from, in some cases, tree sap, and in others the sweet juice obtained from unexpanded blossoms.

A small number of the palm species account for most of the sucrose production. The major sources and some productivity parameters are listed in Table 1. Some less utilized Asian sources of sucrose include the buri palm (*Corypha elata*; the Philippines), the nipa palm (*Nipa fructicans*; Malaysia), and the gomuti palm (*Arenga pinnata*; Malaysia and Java). In tropical Africa, sap from the oil palm (*Elaeis guineensis*) and from palms of the genus *Raphia* contains sucrose at about the 10% level.

Production and Utilization of Palm Sucrose

Potential exists for expanding the palm sugar industry in all growth areas. Palm sugar production remains largely a village industry because of the difficulty in mechanizing both the collection and the processing of the sap. Even so, the annual production of palm sucrose in India approaches 70 000 t, in Cambodia 35 000 t, and in Burma 20 000 t. Collection vessels must be effectively sterilized in order to prevent microbial contamination of the sap and conversion of sucrose to glucose and fructose, its constituent monosaccharides. This is often accomplished by elevating the pH by the addition of lime. Collapsed sap is most often filtered before lime addition to remove debris, and is then evaporated over a wood fire while being stirred in open pans.

Palm sap, which is produced at many Asian and African locations, is often consumed as such or as fermented beverages, which are sometimes distilled. In India, for example, although raw sugar would be the most valuable product from palm sap (neera), it is not usually manufactured on a large scale. Instead, most is allowed to ferment and is then consumed as a beverage called toddy. People in India, Sri Lanka, and other parts of South-east Asia have consumed both toddy and distilled toddy for centuries.

Burma has become self-sufficient in cane sugar. In central Burma, however, a large segment of the population depends on palm jaggery production for its livelihood, and about 50% of the sucrose consumed is derived from palm. It is refined to white, crystalline sucrose in order to compete with cane sugar. However, since unrefined palm jaggery possesses flavor characteristics preferred by many people, a portion should perhaps be marketed in this form. This would

be analogous to the relationship in North America between maple sugar and cane sugar, with the former being desired for certain specialty uses because of its distinctive flavor.

In many palm sugar production areas, forests are being destroyed in order to provide firewood as an energy source for evaporation of the palm sap. More efficient means for evaporation are being tested, including the use of solar energy.

Maple Trees as Sucrose Sources

Maple sugar and syrup were high-value barter items among Native Americans. The production area was then, and remains, from Maine west to Minnesota and from Quebec south to Indiana and West Virginia. This is the natural range of the sugar maple (*Acer saccharum* Marsh.), the maple species which accounts for about 75% of the production. The sugar maple and the black maple (*A. nigrum* Michx. F.) are the only two of the 13 maple species native to North America which are used to produce maple syrup. These species are favored because their sap is much sweeter (higher in sucrose) than the sap from the other species.

The early North American colonists found cane sucrose to be both expensive and difficult to obtain. As a result, they learned how to produce maple sugar. This was increasingly relied upon during the eighteenth century, when coffee and tea were being consumed in greater quantities. Later, when both cane and beet sucrose became more readily available, production of maple syrup steadily declined, especially in the USA. At the present time Canadian production exceeds $(11 \times 10^6\,\text{l})$ $(3 \times 10^6\,\text{gal})$ per year, nearly double that of the USA.

Production of Maple Syrup

Optimal flow of sap from maple trees occurs during late winter and early spring, when consecutive days with freezing temperatures at night and thawing temperatures during the day are most common. Tapholes of 95 mm diameter are drilled into the tree at a distance of 60–90 cm from the ground. The tapholes are drilled to a depth of about 8 cm, and each tree can accommodate up to four tapholes, depending on its diameter.

Traditionally, sap was collected by hanging 15-quart (14.19 l) buckets on the tap spout. This continues to be a common practice among many hobbyists, but since about 1970, commercial operations have used networks of plastic tubing to transport maple sap to evaporating plants. A germicidal pellet is often inserted into tapholes in order to inhibit microbial growth and to insure that the tubing remains clean and sterile. Much of the hard labor has been eliminated by using the tubing collection system, and production costs have been reduced by about 40%. A typical taphole yields 5–15 gallons (19–57 l) of sap each season. Forty gallons (151 l) of typical sap is required to yield a gallon (3.785 l) of maple syrup; thus an average taphole yields a quart (0.946 l) of syrup. The syrup is produced by boiling water from the sap until the solids (mostly sucrose) content has increased to 67%.

Table 2 Composition of maple syrup

Component	*Amount (%)*
Sucrose	65–66
Water	32–33
Hexoses	0–7.9
Malic acid	0.093
Citric acid	0.010
Succinic acid	0.008
Fumaric acid	0.004
Soluble ash	0.30–0.81
Insoluble ash	0.08–0.67
Calcium	0.07
Silica	0.02
Manganese	0.005
Sodium	0.003

Sucrose in Maple Sap and Syrup

Maple sap typically contains about 2% solids, of which sucrose constitutes about 97%. The remainder includes a variety of other organic compounds and some inorganic salts. The composition of a typical maple syrup is given in Table 2. Numerous other compounds have been identified in trace amounts, and some of these provide maple syrup with its unique color and flavor. These compounds are generated during the sap evaporation process, which is conducted by atmospheric boiling in open-pan evaporators, using fuel oil as the energy source. Maple sugar is produced by continuing boiling until the sucrose level exceeds 68%. Cooling this mixture results in the rapid crystallization of maple sugar. Maple sugar is heavily flavored and consists of sucrose and all the other substances which were present in the syrup.

Considerable research effort has been aimed at increasing maple syrup production. Recently, this has included the application of high-vacuum pumping to increase sap flow, and the genetic modification of the sugar maple with the aim of increasing the sucrose concentration in the sap.

Refining of Sugarbeet and Sugarcane

M Donovan, Tate and Lyle Sugars, Reading, UK

Introduction

Sugars, such as sucrose, glucose, and fructose, are produced naturally in a number of fruit-bearing plants. Sucrose is only produced commercially, however, from sugarcane or sugarbeet. Sugarcane is a grass that grows in tropical regions; sugarbeet is a root crop grown in temperate climates, such as Europe and North America. Sugar refining is the process by which white granulated sugar is produced from these crops. (*See* **Fructose**; **Sucrose**: Properties and Determination.)

The production processes are in principle the same, but differ quite considerably in detail. The sugar from the two sources is virtually identical. Both processes will be described here, with separate sections where the two processes differ.

The main demand for white refined sugar has traditionally been in the developed world. Cane is grown in tropical regions, typically in Third World countries and remote from major markets. This has resulted in a two-stage process. The first-stage product, raw sugar, is a part-purified, brown, crystalline material produced in the factory. This is then transported to the refinery, which is sited close to the consumer and from which the product is typically pure crystalline white sucrose, henceforth called sugar. Sugarcane is a perishable material and must be processed almost immediately it is cut, whereas raw sugar can be stored and transported relatively easily.

Sugarbeet is grown in temperate climates, usually close to the consumer, and beet sugar-processing factories are conveniently close to the farms. These factories usually produce refined white sugar from beet without the intermediate raw sugar stage.

The principal steps in both cases are the extraction of sugar from the cane or beet by water to form an impure sugar solution, followed by purification by a number of techniques to remove suspended solids and many of the dissolved impurities. The purified sugar solution is then evaporated and crystallized to give granulated white refined sugar. These key steps are shown in **Figure 1**.

Preparation of Sugar Solution

SugarBeet Juice

Beet sugar processing is an operation in which sugarbeets are the raw material and white sugar is the primary product, and the complete process takes place in the one factory operation.

Sugarbeet processing is a seasonal operation, usually operating in Europe and North America for 3 or 4 months during the period August to February; this is the harvesting period for beet. About 7.5 tonnes of sugarbeets are required to produce 1 tonne of refined sugar, and the logistics and equipment to handle these large quantities of beets are quite complex. Even a medium-sized beet factory can process 7000 tonnes of beet a day.

The sugarbeets are transferred into the plant using a water flume system, where various devices remove most of the foreign materials such as weeds, straw, stones, and rocks. The final removal of foreign material and soil is carried out in beet washers.

Diffusion The beets are passed through a slicer, which produces long, thin strips called cossettes. These are passed into a diffuser, where sugar is continuously extracted in a stream of water. A common type of diffuser is a vertical drum. In this type the cossettes are transported upwards by a scroll, while the water passes down the drum, leaching sugar out of the cossettes as it passes through them. The temperature used in the diffuser is usually about 65 °C, and the pH is maintained at about 6.5. The juice from the diffuser is around 15% solids, and most of the sugar in the beets is extracted. Effort is made to keep the extraction level as high as possible, around 98%. The cossettes after sugar extraction are called pulp, and this is processed for animal feed.

Cane Sugar Liquor

The cane is shredded by knives and passes into a series of mills where water is used to extract sugar from the crushed cane. The sugar juice is clarified using lime to

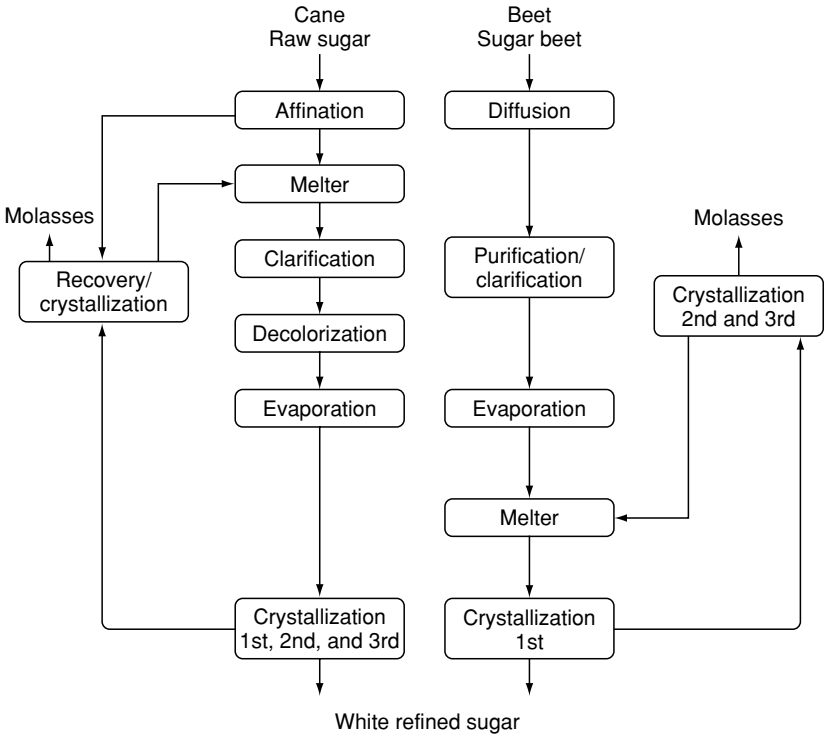

Figure 1 Process flow diagram for refining of cane and beet sugar. Reproduced from Sugar: Refining of Sugar Beet and Sugarcane, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

precipitate impurities, concentrated, and then crystallized. The product is termed raw sugar and is shipped to form the raw material for the cane refinery.

Raw sugar as received and processed in a cane refinery is really quite a pure compound, although not pure enough, and generally not prepared and transported in sufficiently hygienic conditions to be acceptable as a food ingredient. Raw sugar delivered to the UK is on average 98.0% sucrose, on a dry basis. Refined sugar, on the other hand, is 99.95% pure. At first sight the difference between the purity of raw and refined sugar would suggest a relatively straightforward process, but the impurities, including color which in weight percentage terms is very small, are quite difficult to remove. This is especially true at the throughputs required for economic, modern processing.

Affination The first step in refining raw cane sugar is affination. Raw sugar is a crystalline material, and crystals are generally quite pure. In fact, most of the impurities in raw sugar are in a syrup layer on the crystal surface. The raw sugar is mixed with a hot syrup that is at about its saturation point, in a piece of equipment called a mingler. This is a large trough with a horizontal helical screw, that mingles the raw sugar and the syrup. This mixture is then centrifuged. The most common machine is a batch basket centrifuge, centrifuging from 750 to 1500 kg in one batch, each batch being processed in about 2 min. During centrifugation a small amount of wash water is sprayed on to the cake of sugar in the basket to wash off some of the final layers of syrup. The amount is kept to a minimum to prevent dissolution of too much sugar.

This centrifugation produces two streams, a washed raw sugar, and a syrup stream containing most of the impurities from the surface of the raw sugar. This low-purity syrup is sent to a process called recovery. As the name implies, most of the sugar in this stream is recovered and sent back to the main stream for refining.

The washed raw sugar is about 99.6% sucrose, showing that affination removes the bulk of the impurities. This sugar is then sent to the melter where it is dissolved in water to about 65% solids, called 65° Brix.

Comparison of Beet Sugar Juice and Cane Sugar Liquor

The terminology used is that a low-concentration solution is called a juice, and a high-concentration solution is called a liquor. At this stage in the process,

beet sugar is in a dilute form and relatively impure. It normally contains 85% sucrose on a dry basis, called 85% purity, and is at a concentration of about 14% solids. The cane liquor on the other hand is at a higher solids, usually about 64° Brix. It has a higher purity than beet juice, that is, 99.65. This is because it has already been crystallized once. Both solutions are fairly highly colored; both solutions need to be subjected to a purification process before they can be crystallized to white sugar.

Purification of Beet Juice and Cane Liquor

Beet Juice Purification

The juice from the diffuser contains a number of impurities, both dissolved and as suspended solids, and the sugar represents about 85% of the total solids present. The purification is carried out with lime and carbon dioxide in a series of operations which increase the purity of the juice. The first step in some factories is a pre-limer, where a portion of the lime is added with control of time and temperature to precipitate much of the colloidal matter. This step is not always used, but in all cases the balance of the lime is added and then carbon dioxide is introduced through the juice to precipitate calcium carbonate crystals. Many of the impurities become absorbed on or react with the calcium carbonate, creating precipitates, and are thus removed. In the next step the calcium carbonate with the impurities is sedimented and removed by filtration. This is termed a first carbonatation stage. More carbon dioxide is then introduced through the juice to remove the remainder of the lime in a second carbonation, and the solution is filtered. A number of different types of filter can be used, but the filter leaf type is the most common. The calcium carbonate 'mud' from the two carbonatations is desweetened with water and filtered again on a rotary vacuum filter. The mud is then discarded.

Cane Liquor Purification

This is carried out in two stages: clarification to remove suspended solids and some color, followed by decolorization.

Clarification Cane liquor contains the impurities that were present in the raw sugar crystal, and the clarification step is designed to remove the suspended matter that is present. There are three processes than can be used for clarification, and two of them are also effective systems for the removal of about half of the color in the liquor. The three different systems are:

- Carbonation, combined with pressure filtration
- Phosphatation, with a clarifier using air flotation of the scum
- Pressure filtration using a filter aid

Carbonatation uses the addition of lime and then bubbling of carbon dioxide through the limed sugar liquor to precipitate calcium carbonate. In principle it is the same as beet carbonatation, but carried out at higher concentration and using less lime. The calcium carbonate crystals agglomerate into a form that is an effective filter aid and the suspended solids can be removed on pressure filters. During the precipitation of the calcium carbonate, the suspended solids, such as waxes and gums, are combined into the agglomerates and readily removed by filtration on pressure leaf filters. Some of the color also reacts with the calcium, and over 50% is removed.

Phosphatation also uses lime, but in this case the precipitate is formed with phosphoric acid to make calcium phosphate. Calcium phosphate is very difficult to filter, unlike calcium carbonate, but can be floated off as a scum. This allows the use of a clarifier, where air is introduced into the suction of a pump, and the tiny air bubbles attach themselves to the flocs of calcium phosphate, which rise to the surface. The scum can then be removed using a scraper arrangement at the top of the clarifier tank. When using a clarifier it is not possible to obtain 100% removal of solid, and a clarifier is often followed with a polish filter to prevent small quantities of solid fouling the next step, the decolorizing system.

Some refineries use pressure filtration with filter aid. This is a relatively straightforward system, but gives little color removal.

Decolorization Cane sugar liquor at this stage is actually less colored than beet sugar liquor, but because of the difference in the types of color, cane is always passed through a decolorizing step, whereas beet is only rarely decolorized.

Color can be removed from cane sugar streams by the use of carbon, or by special resins. Often a high degree of color removal is required, sometimes in excess of 80%. There are several forms of carbon decolorizer. A traditional method is to use bone char. This is a granular material prepared by grinding cattle bones, and roasting them in a kiln. Bone char is 90% hydroxyapatite, and 10% carbon.

The bone char is loaded into large vertical cylinders called cisterns. The clarified syrup is passed downwards through one, and sometimes two of these cisterns, with the second being a polish. When the char is exhausted, after perhaps 60 h, the flow of syrup to the cistern is stopped. The char is washed clear of

sugar, emptied from the cistern, and sent to the drier and then a kiln, where it is regenerated by heating to 550 °C for a few minutes with a limited quantity of air. The regenerated char is returned to a cistern and the process is repeated.

Another type of carbon decolorizer is granular carbon. This is usually manufactured from coal by kilning in the presence of steam. It contains 60% carbon and it has 10 times more decolorizing capacity than bone char. This allows the use of smaller and generally more automated plant. A granular carbon cistern may be run for 30 days; when it is exhausted it is flushed with water and the carbon is kilned at about 900 °C with a limited amount of oxygen.

A more recent method of decolorizing sugar is by the use of resins. These are in the form of small beads, and the liquor is passed through cells containing these beads. The color in sugar liquors is largely negatively charged; thus by using an anionic resin in the chloride form, color can be absorbed on to the pore walls of the resin beads. The color replaces the chloride. Once the ability of the resin to remove color has been exhausted, it can be regenerated with common salt. Two types of resin are commonly used, acrylic or styrene. A resin cell can be used for up to 60 h before needing regeneration. It is then taken offline to be desweetened, washed, treated with salt, and put back online.

Evaporation

Both liquors need to be evaporated prior to crystallization. The beet sugar juice is at 14 ° Brix and thus more water needs to be removed from beet than cane liquor.

Beet Sugar Juice Evaporation

The thin juice, as it is now called, is evaporated in a multiple-effect evaporator. This can often have as many as five effects or stages and raises the solids from about 14% to over 60%. A multiple effect is used to give economic use of steam. Live steam is used on only one of the effects, with vapor produced in that effect boiling the liquor in another effect at reduced pressure, and so on. In this way the amount of steam used is reduced by a factor of up to four. Some of the vapor is used for other heating jobs around the factory, such as heating the juice prior to carbonatation, and boiling vacuum pans used to crystallize sugar. The use of this vapor often dictates the temperatures and pressures used in the evaporator.

The product from the evaporator is about 62% solids and 89% sucrose on a solids basis, and is called thick juice. This is sent to a melter where crystal sugar from second and third boilings is dissolved in it. This is then filtered and is known as standard liquor, and is about 74% solids and 92% purity. This is the liquor that is sent to the vacuum pans to be crystallized to white refined beet sugar.

Cane Sugar Liquor Evaporation

After decolorization, the cane sugar liquor is at 60–64 ° Brix, and at a color low enough to be crystallized to white granulated sugar. However, it first needs to be evaporated at about 75 ° Brix for crystallization. The traditional evaporator used in the sugar industry has been a calandria type, i.e., a vessel with a submerged bundle of tubes. More recently both falling-film and plate-type evaporators have been used effectively. Cane liquor evaporators are usually run as double- or triple-effect, and vapor from the evaporator can be used to provide the heat for the melter, where the sugar is dissolved in water.

Crystallization

The evaporated sugar liquor is sent for crystallization, although some cane liquor can be sold in this form as liquid sugar, as it is very pure. (*See* **Crystallization**: Basic Principles.)

Crystallization is essentially the same for beet and cane. The purity of the syrup used to crystallize beet sugar is lower and this, combined, with the use of lower pressure steam, means that beet crystallizations are slower than cane crystallizations. In the sugar industry the term used for crystallization is boiling.

Sugar is crystallized in batch vessels called vacuum pans. These can crystallize up to 70 t of sugar in one batch, and a batch cycle can take from 2 to 4 h. In vacuum crystallization the sugar liquor is boiled under a vacuum until it just exceeds its saturation point. It is then supersaturated, and crystals will grow provided this supersaturation is maintained by continual boiling of the liquor. In order to have some control over the size of the crystals, the liquor is usually seeded at a predetermined supersaturation with a small amount of milled sugar crystals in alcohol. These crystals are about 10 μm in size, and 0.5–1 l is generally added. As these crystals grow, the deposition of sugar on them from the solution will reduce the supersaturation. However, by heating and evaporating the solution, water is removed and the supersaturation is carefully controlled. If this supersaturation becomes too high, nucleation can occur, and the extra crystals formed will cause the size of the final sugar to be too small. If the supersaturation is allowed to become too low, crystal growth will slow down or stop. Maintaining the growth of crystals at the correct rate, and obtaining a batch of sugar at the correct crystal size, and size dispersion has been the

skill of the pansman. Nowadays, modern measurement techniques, and computer control can boil sugar pans as well as a skilled pansman.

The key features of a vacuum pan are shown in Figure 2. The pan has a heating surface consisting of vertical tubes or plates called a calandria, and is heated by steam. Most pans have an agitator to assist in circulation of the massecuite (see below). A vacuum is maintained in the pan during the boiling to keep the sugar in the temperature range 65–85 °C. This is to prevent color formation during the crystallization. The yield of sugar is in the range 50–60%, and the final mixture of crystals and concentrated sugar liquor is called massecuite, or masse. This masse is extremely viscous, and at the end of the crystallization period the vacuum is released and the masse is allowed to drop by opening a large valve at the bottom of the vaccum pan. It is dropped into a receiving vessel, and from there it is fed to centrifuges to separate the sugar crystals from the syrup.

Continuous pans have been developed for white refined sugar, and a few are used. However, difficulties in obtaining a narrow size distribution, cost, and some other problems mean that the vast majority of refined sugar is boiled in batch pans.

At this point there is a difference between beet and cane. The high purity of the cane syrup at this point means that the mother liquor from the first boiling can be used again for another crop of white refined sugar. In fact a total of three or four batches, including the first batch described above, can be boiled. With beet, only one batch can be boiled and used directly for refined sugar. The subsequent batches, as described below, are dissolved and put back into the process.

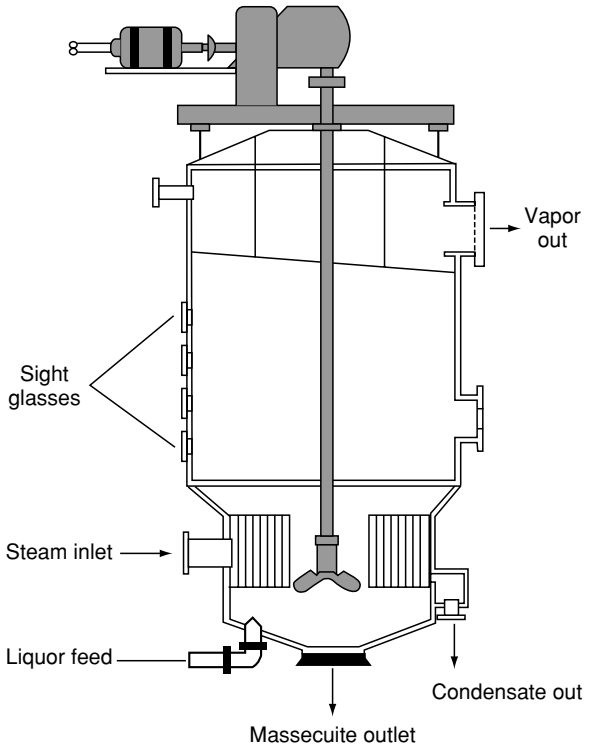

Figure 2 Vacuum pan for crystallizing sugar.

The steam used to heat a beet vacuum pan is generated in one of the effects of the evaporator, and is often around 100 °C. In recent years a lot of effort and capital have been spent in factories to reuse the steam vapors generated in a number of applications around the plant, and pans are now being boiled with steam or vapor at quite low temperatures. Pressures less than 1 bar abs and less than 100 °C are quite commonly used to boil beet sugar. This has required pans to have a larger heat-transfer surface and to have a lower hydrostatic head of liquor above the calandria.

Vacuum pans for boiling cane sugar take steam from the boiler or steam turbine backpressure at pressures of 1–2 bar gage, and sometimes up to 4 bar gage.

Centrifugation

White sugar is separated from mother syrup in batch centrifuges. The massecuite is fed into a basket which is then accelerated up to speeds in excess of 1000 rpm, where it forms a wall of sugar that is 150–200 mm thick. The sugar is then washed with a spray of hot water, which dissolves a small amount of sugar from the surface of the crystals, but assists in removing most of the impurities such as color, ash, and invert from the surface of the sugar crystals. The first two need to be removed to reach purity specifications, and removal of invert is important to prevent the sugar from caking in storage. The centrifuge is then slowed down, and a plough is inserted into the cake, which discharges from the bottom of the centrifuge.

Drying

The moisture content of the sugar crystals from the centrifuge is quite low, at about 1%, but this moisture is concentrated on the surface of the crystals. It is removed in a rotary drier, where the sugar is gently tumbled in a stream of warm air for a residence time of about 20 min. The most common type of sugar drier is an inclined rotary drum, fitted with blades or paddles to lift the sugar. The air flow can be either cocurrent or concurrent. The final moisture is extremely low, at 0.02%. This sugar is scalped to remove oversized lumps, usually agglomerates of

crystals that have built up. (*See* **Drying**: Theory of Air-drying.)

Other Boilings

Beet Sugar

In a beet factory white sugar is only produced from the first crystallization. A second and third crystallization are carried out; the crystal sugar from both of these boilings is sent to the melter to be mixed with thick juice (as mentioned earlier). The crystals are not pure enough to be sold as white sugar, but are considerably purer than thick juice, and thus raise the purity of this to provide standard liquor which can be crystallized to produce white sugar. A variety of names are used for these boilings, such as raw and after product or high and low raw.

The raw boiling is carried out with the mother liquor from the white sugar boiling, i.e., the liquor separated from the white sugar crystals in the centrifuge. The afterproduct boiling is the mother liquor of the raw boiling, although the liquor that is seeded is usually of a higher purity. This is because it can be difficult to get small seed to grow at low purity. The masse from this afterproduct boiling is very viscous, but it is still possible to crystallize more sugar from it. The complete masse is sent to a cooling crystallizer where it is cooled over a period of 48 h. This long period of time extracts as much of the sugar as is economically possible. This masse is centrifuged and the liquor is molasses.

There is still 60% sugar in beet molasses, but owing to the solubility of sugar it is not possible to separate any more by crystallization. New large-scale chromatographic techniques have been developed to separate sugar from molasses; these are not used extensively in Europe, although there are a number of operations in the USA.

Cane Sugar Recovery

The recovery process consists of a number of crystallization and centrifuging steps, and is designed to extract as much sugar as possible from low-purity syrups. The final products are molasses and a low-purity sugar, the latter being remelted and returned to the main stream of the refining process, following affination. In cane processing there are two feed streams of low-purity syrup; the main stream is from affination where the syrup from the surface of the raw sugar is removed, and the other stream is from the white crystallization process, where the syrup that, after three or four boilings, is too impure for extraction of white sugar is sent to recovery. The recovery process is a series of crystallizations, usually three, and each with a yield of 40–55%. As these crystallizations are carried out at low purity, they can be slow, and quite difficult. There are a number of ways of carrying out these boilings and the schemes can become quite complex. In one scheme the crystals grown in the third boiling are used as the seed for the second boiling, and the crystals from this boiling are used as the seed for the first. However, there are almost as many schemes as there are refineries.

Brown sugar can be boiled from the first, or purest of the recovery boilings. Adjustments are made to the purity and color of the syrup in order to obtain the appropriate flavor and color.

Beet and cane molasses are sold for animal feed or fermentation. The beet sugar industry blends a portion of its molasses with the dried pulp, and makes pellets for animal feed.

Storage

The drier produces a very dry sugar, with a moisture level of about 0.02%. Nevertheless, even at this low level there can be problems in storage, and if sugar has to be stored for an extended period of time then it is usually conditioned. This is carried out to prevent the sugar caking. Conditioning is essentially a holding period of perhaps 24 h in which any moisture released from the crystal can pass into the surrounding air, and be blown away from the sugar. It is usually carried out in a silo. In some cases dehumidified air is passed through the sugar in the silo, and in others the sugar is passed into the silo, and out again in perhaps a 24-h period; the movement of the sugar allows moisture to escape without the crystals sticking together and caking. The reason that even such a small amount of residual moisture can cause a problem is that it is all concentrated on the surface of the crystal. The water is in the form of a saturated syrup, and as this syrup crystallizes it releases moisture. If the surrounding air is not kept moving, this moisture can humidify the air to such an extent that any cooling can cause it to condense. This condensed moisture can dissolve the surface of the crystals and allow them to stick together. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

Packaging

White sugar is quite free-flowing and packaging in the standard 1-kg pack can be carried out at very high speeds in modern equipment. This equipment takes preprinted rolls of paper, folds and glues this paper to form bags, fills and seals them. Brown sugars are more difficult to package, owing to their sticky nature, and are packaged at much lower speeds. Bulk deliveries

are typically made in tankers, 1-tonne containers and 25-kg or 50-kg bags. (*See* **Packaging**: Packaging of Solids.)

Analysis

Analysis is required of intermediate products to ensure that the process is running correctly, and of final products to ensure that they meet customers' specifications.

During the process a close watch is kept on concentration of sugar. This is measured as Brix, which is weight of sugar solids per weight of syrup, and in the laboratory is measured by a refractometer. Color is also closely monitored, measured by an absorbance of light at 420 nm in a spectrophotometer. The ash content is monitored in cane, and in beet the purity is followed. Purity is the amount of sucrose per unit dry weight of substance. In both cane and beet the pH is also measured at key points of the process. Too high or low a pH leads to degradation of sucrose to color byproducts or invert.

The product may need several other measurements to ensure quality and conformance to customer requirements. The color and ash measurements are routine requirements. For liquid sugar a Brix value would be required. Others include a sieve analysis to measure both the size and size distribution of the sugar crystals, expressed as mean aperture (MA) and coefficient of variation (CV). A test is also carried out to measure suspended solids, which in white sugar are extremely low.

SUGAR ALCOHOLS

A Rapaille and J Goosens, Eridania Béghin-Say, Brussels, Belgium
M Heume, Eridania Béghin-Say, Krefeld, Germany

Introduction

Sugar alcohols are white crystalline, non- to slightly hygroscopic powders and clear syrups. They are generally stable to heat, and do not take part in Maillard-type browning reactions. Chemically, sugar alcohols are hydrogenated mono-, di-, and oligosaccharides. The more important compounds in these groups have the structures shown in **Figure 1**. and their main physical properties are summarized in **Table 1**. Erythritol is discribed separataly further in the text.

Sensory and Nutritional Properties

Compared to sucrose, sugar alcohols have slightly reduced sweetness values, as shown in **Table 2**. Sugar alcohols produce a characteristic mouth-cooling effect which is directly related to their heats of solution and their solubility in water (**Table 1**). Sugar alcohols, also known as polyols, may give particular advantages with regard to diet control and dental health (**Table 3**). The benefits that polyols can give in reducing caloric intake is due to their different metabolic behavior after oral ingestion compared to other carbohydrates. Because polyols may have a mono-, di-, or oligosaccharide carbohydrate structure, small differences can occur with regard to their metabolic fate in the human body.

Except for maltitol-containing syrups (55–75% maltitol), in which a small fraction of oligomeric structures occurs, polyols are not degraded by saliva enzymes (amylases) upon oral ingestion. In the stomach slight acid hydrolysis of the di- and oligosaccharide polyols may occur. However, once the small intestine is reached, extensive hydrolysis by α-amylases of the mucosa occurs and up to 60–80% of the maltitol and isomalt is hydrolyzed. A 50% glucose/50% sorbitol or a 50% glucose/25% sorbitol/25% mannitol mixture respectively is obtained. The other disaccharide polyol lactitol is almost unchanged because the required β-galactosidase is only present in trace amounts. Sorbitol, mannitol, and

xylitol reach the small intestine unchanged. (*See* **Isomalt**.)

In the small intestine the monosaccharide polyols are partly absorbed into the blood stream by a passive diffusion process at rates depending upon their molecular weight (Table 3). Also, the applied dose and the actual intestinal transit time affect the rate of absorption. The absorbed fraction of sorbitol and xylitol is channeled into the normal liver metabolism and contributes energy to the same extent as glucose.

The unabsorbed polyols finally reach the large intestine where the microflora ferments them almost completely to volatile fatty acids (VFAs). From the energy contained in the fermented fraction, 20% is used by the bacteria for growth. The remainder is absorbed from the gut as VFAs which are then

Table 2 Sweetness values of sugar alcohols

Compound	*Relative sweetness*

Isomalt	35–45	0	< 1	55–65	3.0

transported in the blood to be metabolized by the liver into fat constituents. In total, about 50% of the energy of the fermented polyols is available to the human body.

Based on the above metabolic behavior, the calorific value of polyols can approximately be calculated (Table 3). However, depending upon the methodologies used, values vary over a wide range. Therefore, and because many polyols are used in combination with each other, a European Union Directive has laid down an average calorific value of 2,4 kcal g^{-4} for all polyols.

Because of the reduced digestibility of polyols, their intake level is recommended to be restricted to 40–50 g day^{-1} (adults) and 30 g day^{-1} for children in order to avoid gastrointestinal discomfort. Higher doses may cause an osmotic diarrhea or increased flatulence due to slow absorption and extensive fermentation, respectively, but tolerance levels improve upon adaptation. On the other hand polyols are very suitable for diabetics, because rapid glycemic or insulinemic response is avoided. For the same reason sorbitol and xylitol are often applied in parenteral nutrition to provide a more controllable carbohydrate energy source compared to glucose or fructose.

Concerning dental health, polyols have long been known to have no adverse effect on teeth. This is due to the fact that mouth bacteria are unable to ferment polyols, thereby avoiding the production of enamel-solubilizing acids. With the intraplaque pH telemetry test, it was shown that eating polyol-based sweets did not decrease the plaque pH below the critical value of 5.7. Additionally, for xylitol, there is ample proof of a cariostatic effect. In several studies, of which the Turku study (Finland) is most famous, the incorporation of xylitol in a normal diet was proved to reduce the occurrence of dental carics. Most probably, xylitol selectively discriminates against the growth of *Streptococcus mulans*, the major organism involved in dental caries. (*See* **Dental Disease**: Role of Diet.)

Occurrence and Methods of Production

Polyols like sorbitol, mannitol, and xylitol have been well known over the last 30 years due to their occurrence in a number of fruits, vegetables, and cereals. Although they occur in nature, their concentration in plant material is too low for a simple, economic commercial extraction, as practiced with sucrose. A more complicated process is therefore needed for the production of sugar alcohols.

Several techniques have been described to produce polyols but only a few of them are of industrial importance. These are mainly based on catalytic hydrogenation of easily accessible carbohydrates, e.g., dextrose, glucose syrups, maltose syrups, invert sugar, isomaltulose, xylose, and lactose. These carbohydrates are obtained either by hydrolysis or isomerization of natural raw materials like starch, sucrose, milk (whey), and straw (Figure 2).

The carbohydrate raw material is hydrogenated in an aqueous solution at elevated temperatures (120–190 °C) and hydrogen pressure (20–200 bar) using an activated nickel catalyst. Hydrogenation can be performed either in a batch or a continuous process, and results in the addition of hydrogen to the carbohydrate precursor. Hydrogen pressure, temperature, pH value, and type of catalyst are the most important parameters influencing reaction time and selectivity. They have to be well adjusted to obtain a high-purity product in high yield. Purity of the raw material is also of importance in this respect. The hydrogenated carbohydrate (polyol-containing) solution is subsequently refined by filtration, carbon, and/or ion exchange resin treatment to remove salts as well as colored byproducts formed during hydrogenation.

Sorbitol and maltitol are available as aqncous solutions and also as crystalline material. Mannitol, xylitol, lactitol, and isomalt are available as crystalline material. All crystalline polyols are produced by crystallization, solidification, or spray-drying of an aqueous solution at an appropriate concentration.

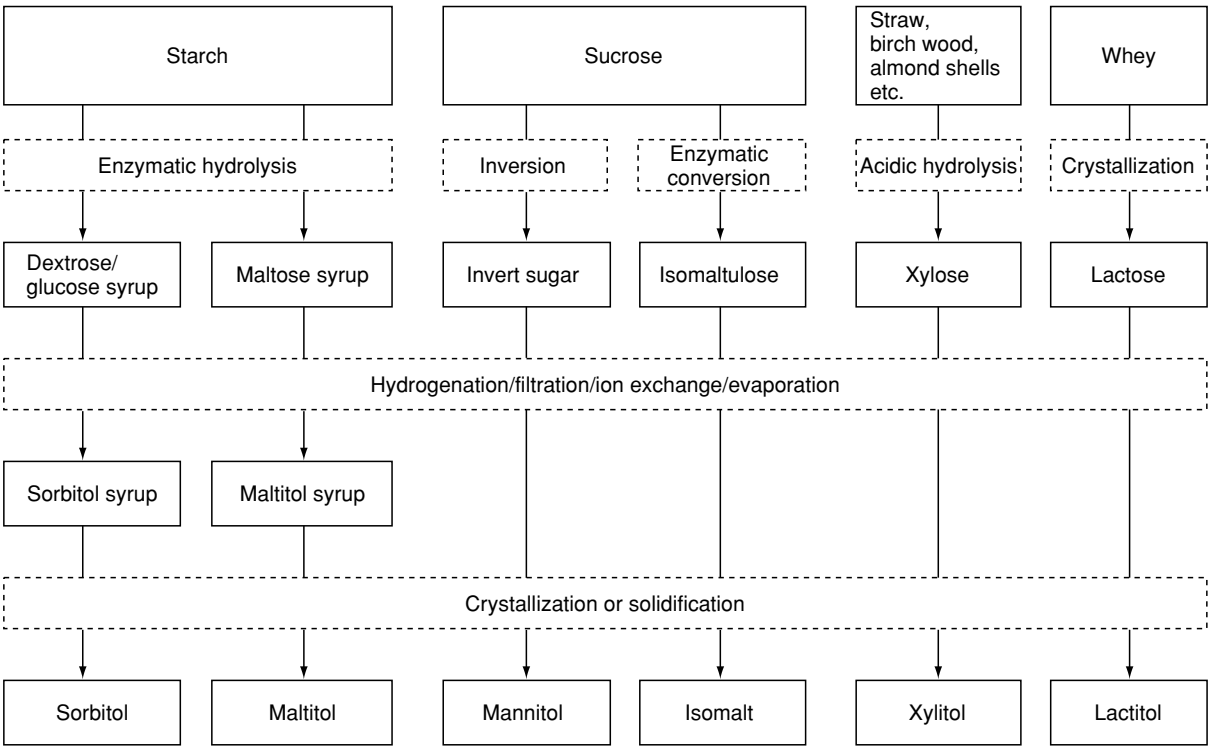

Figure 2 Commercial production of sugar alcohols. Reproduced from Sugar Alcohols, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Uses in Foods

Substitution of sugars in food to achieve specific nutritional objectives is not a new practice. Initially, polyols like sorbitol and mannitol were used to sweeten food for diabetics. To cope with sensorial and technological requirements for noncariogenic food, the range of polyols has been extended to include products such as maltitol, xylitol, isomalt, and lactitol.

For the production of polyol-based foods, most conventional types of food-manufacturing equipment are used. However, manufacturing conditions (temperature, vacuum, etc.) very often need to be adapted. As some polyols are moderately hygroscopic, the relative humidity of air during production and storage conditions require careful control. It is also necessary to assure good protection by careful wrapping and/or packaging. When neccessary, sweetness of polyol-based foods can be enhanced by adding the neccessary amounts of intense sweetners like aspartame, accsulphame K, cyclamate, and saccharin. (*See* **Sweeteners: Intensive.**)

In addition to the production of sugarless foods, polyols, e.g., sorbitol, can also be used in conventionally sweetened food products in order to give specific sensorial effects such as texture and reduced color. There are also technological advantages such as plasticity, workability, and shelf-life. In particular, sorbitol is widely used for its humectancy power to extend food products shelf-life.

The main uses of polyols in food products are outlined below.

Sugar-Free Confectionery

This is the most important application field for polyols.

Hard Confectionery

Hard confectionery is produced by boiling polyol solutions or syrups to a very high dry-matter content (98–99.4%) followed by cooling, molding, and wrapping. The boiling temperature for such polyol confectionery varies between 155 and 170 °C depending on the type of polyol. Severe vacuum conditions are needed. With the exception of mannitol, all the polyols can be used alone. However, for technical and economical reasons very often combinations of polyols are applied. It should be kept in mind that the solubility of polyols strongly influences crystallization and graining.

Soft and Chewable Confectionery

The main component in this application is a polyol or a polyol blend (65–70% dry matter) which is

presolubilized and cooked together with vegetable fat (about 6%), emulsifier (about 0.8%), gelatin (about 1.4%), and other minor components, e.g., food-grade acid, flavor, and color. After cooling, the mass is formed and wrapped. Chewability of the sweets can be obtained by acration of the cooked mass after partial cooling using conventional acration techniques such as pulling and continuous foaming.

Gums and Pastilles

Maltitol syrups, alone or in combinations with either lactitol or isomalt, are very suitable for the production of gelatin gums. For some compositions it is necessary to adapt the gelatin type and level as well as the cooking conditions in order to obtain gum properties equivalent to those obtained with conventional sweetened gums.

In pastilles a gum arabic/polyol ratio of 50/50 on a dry-weight basis is advised. This composition is cooked to 70–72% dry-matter content, molded in starch, and dried to 90% dry matter. After demolding, the gums are waxed. Maltitol syrups give good pastilles with optimal shelf-life properties.

Tubletting

Although all powdered polyols can be compressed on rotary machines to give tablets, sorbitol is the most common polyol used in this field.

Powdered sorbitol has excellent flow properties for tabletting. Good flowability is very important to provide a uniform tablet weight. Compared to other directly compressible materials, powdered sorbitol gives a high increase of tensile strength as a function of compression force and is therefore very suitable for direct compression. Due to their rather high hygroscopicity, sorbitol-based tablets should be protected or stored under relatively dry conditions in order to avoid softening due to moisture pick-up. The priability of sorbitol tablets, even those compressed at low pressure, is extremely low and is improved further by storage at close to equilibrium relative humidity (ERH). The overall performance of sorbitol powder in tabletting depends upon different factors, such as particle size and distribution, crystal morphology, and compression conditions.

Chewing Gum

The main components of sugar-free chewing gums are gum base (25–30%), polyol powder as solid phase (45–63%), and sorbitol or maltitol syrups as liquid phase (10–30%). The solid phase can be sorbitol powder, but more often a combination of sorbitol and xylitol is used. The main advantages of xylitol are its excellent cariostatic propertics, high sweetness, and a pleasant cool taste due to its negative heat of solution. Addition of a small quantity of glycerol improves the plastifying properties; mannitol addition prevents stickiness.

Chocolate

Total replacement of sucrose by polyol powder both in bitter or milk chocolate is possible providing the powder has an optimum purity, crystal morphology and granulometry. A bitter chocolate consists of 40–50% cocoa mass, 40–50% polyol powder, and 5–10% cocoa butter.

Originally only sorbitol was used for sugar-free chocolate. Recent trends are towards the use of maltitol, isomalt, and lactitol.

Dragee Coating

Coating consists in covering cores, e.g., chewing gum with a syrup which is close to its saturation point, then inducing crystallization by evaporation. Generally a lot of layers (40–50) are needed. The temperature of polyol syrups, drying air, centers, and core bed are very important processing parameters. Sorbitol is the most common sweetener for sugarless coating, but maltitol, xylitol, isomalt, and lactitol can also be used.

Bakery Products

Polyols can be used in bakery products due to their specific properties which are lacking in many other bulk sweeteners. The sugar alcohols contribute to softness and storage capacity. They also regulate moisture, taste, and sweetness. A combination of polyols or a polyol combined with another sweetener is preferred. If browning is too light, the baking temperature can be raised or a small amount of fructose can be added.

The baking industry uses crystalline sorbitol and sorbitol solution in products for special dietary use. It is also employed as a humectant to extend the shelf-life of baked goods. The stability of baked products can be improved by partial substitution of sucrose by sorbitol, e.g., in cakes. Sorbitol is used in sponges and cakes at between 5 and 8% of flour weight. In biscuits and cream fillings it is used up to 10%. The freshness of gingerbread is improved by adding only 5% sorbitol. It is also used to substitute sugar in classical formulations for low-sugar products. (*See* **Cakes**: Nature of Cakes.)

The use of the other polyols in bakery is rapidly developing. The level of sugar replacement with these sweeteners depends on the type of polyol and the application objective. While, for some polyols, rather

high usage levels can be achieved, e.g., for maltitol, lactitol, and isomalt, for others, e.g., xylitol and mannitol, usage levels are generally low. These differences are also related to the specific sensory and physicochemical properties of the polyols used. An important contribution of the other polyols is, as for sorbitol, the humectant properties which control the moisture level in bakery products when stored for long periods. In some cases, combinations of polyols can give interesting complementary effects. The main applications in the bakery field are cakes, biscuits, pastry, fillings, and icings. In the last two products, xylitol and mannitol can be an asset due to their perceptible cooling effect. (*See* **Biscuits, Cookies, and Crackers**: Nature of the Products; **Pastry Products**: Types and Production.)

Other Areas of Application

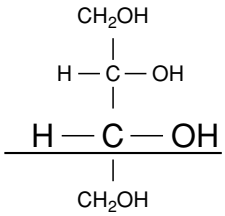
Polyols can also be used in sugarless jams and ice-creams. Sorbitol-containing jams and preserves have a clear taste and good texture. A sufficiently high solids content can be obtained in order to inhibit microbiological activity, thereby protecting the jams against mold development. In order to avoid crystallization during storage, the solubility of the polyol(s) should be checked before formulating the food.

Erythritol

Chemical and Physical Properties

Erythritol is a linear carbohydrate molecule of four carbon atoms, each carrying one hydroxyl group. The molecular structure is shown in Figure 3.

Chemically, erythritol therefore belongs to the class of monosaccharide polyols like sorbitol, mannitol, xylitol, and glycerol. Erythritol is also a symmetrical molecule and therefore it exists in only one form, the mesoform. It forms anhydrous crystals with a moderately sweet taste without off-taste or odors. The powder has a transparent white brilliant appearance and dissolves in water to give a colorless nonviscous solution. Crystals melt at 122 °C to form a colorless and brilliant nonviscous melt.



1,2,3,4-butanetetrol

Figure 3 Molecular structure and chemical formula of erythritol.

Erythritol's chemical properties are similar to those of other polyols in that it has no reducing end groups and thus has excellent heat- and acid-stability. It differs in having a low solubility (37% ww at 25 °C), a property which among these simple polyols it shares with mannitol and isomalt. Heat of solution is very low ($-181\,J\,g^{-1}$), a property shared with xylitol. However, compared to the group of polyols presently used as sugar-replacers, erythritol has the lowest molecular weight (122) which of course provides different properties, such as higher osmotic pressure and lower water activity in solution. It has also a high freezing-point depression and boiling-point elevation.

Compared to sucrose, erythritol has a sweetness value of 60–70%. It has a clean, sweet taste, similar to sucrose, a strong cooling effect, and shows many synergies with intense sweeteners.

Occurrence and Methods of Production

Erythritol occurs in several foods at levels up to 0.13%. It is also present in human and animal tissue and body fluids.

Briefly, erythritol is produced from wheat or corn starch by enzymatic hydrolysis yielding glucose, which is fermented by a safe and suitable yeast-like fungi, *Moniliella pollinis*. Once erythritol is separated from the sterilized fermentation broth, it is purified by ion exchange resin, active carbon, ultrafiltration, and crystallization. The final crystalline product, which looks very similar to sugar, is more than 99.5% pure.

Uses in Foods

The main uses of erythritol in food products are outlined below.

Tabletop Sweeteners

In tabletop applications, erythritol will be used at levels up to 99.9% as a noncaloric, noncariogenic carrier for intense sweeteners. In these applications, the sensorial profile-modifying properties of erythritol are of great importance, resulting in sweetness synergy, improved mouth feel, and masking of off-flavors. In addition, due to erythritol's crystalline structure and nonhygroscopic property, it offers excellent flowability and stability as carrier.

Beverages

The synergies which erythritol shows when used in combination with intense sweeteners are also very useful in low-calorie beverages. Also, at use-levels of 3.5% or less, erythritol can mask certain off-flavors in beverages like coffee, tea, and grapefruit juice.

Chewing gum

Good-quality noncaloric and noncariogenic chewing gum can be formulated by using solely erythritol (use-level up to 60%).

Most of the sugar-free chewing gum produced today has a tendency to become brittle and harder during aging. This can be avoided and a sugar-free chewing gum with softer texture, greater flexibility, and improved shelf-life can be obtained by partial replacement of the other sugar alcohol(s) using erythritol.

Chocolate

The use of erythritol in chocolate compositions allows a dry conching process at high temperatures. Due to the good heat-stability and low-moisture pick-up of erythritol, it is even possible to work at higher temperatures than traditionally used. This results in enhanced flavor development.

Erythritol-based chocolate is not only easy to produce, it can also be considered a true 'reduced-calorie' product.

Candies

Sugar-free fudge with texture and shelf-life properties equivalent to conventionally sweetened fudge can be produced using erythritol (up to 40%) in combination with maltitol syrup (75% maltitol) to control crystallization.

Depending on the cooking temperature and seeding level with erythritol, texture can be varied from soft to hard. In hard candies, erythritol in its crystalline form is used up to 50% for its cooling effect as sherbet filling in die-formed hard candies, or 'sandwiched' in between two layers in deposited hard candies.

Fondant

Using erythritol, it is possible to obtain sugar-free low-calorie noncariogenic fondant with identical technical properties to classical products. Previously this was impossible with the other low-calorie bulking agents currently available. Pure erythritol induces too high a crystallization, but 60% erythritol in combination with maltitol syrup as a liquid phase helps to control this phenomenon.

Lozenges

Research has shown that lactitol, crystalline maltitol, and erythritol are the only suitable materials to produce a lozenge with a lower calorie content than the conventional sugar-based lozenges, but which are otherwise identical. In addition to the lower calorie content and pronounced cooling effect, erythritol has the added advantage over lactitol and crystalline maltitol of requiring a shorter drying time to obtain the required texture at low residual moisture content. Lozenges based on solely erythritol (up to 99%) have excellent shelf-life properties, even when stored under high humidity conditions.

Bakery (Pastry) Products

In fat cream, a very good texture is obtained with erythritol at a use-level of 60% and a particle size distribution below 300 μm. The manufacturing process and shelf-life properties of the erythritol-based fat cream are similar to those for conventional fat/sucrose compositions. Erythritol has an effect of masking the fatty mouth feel, giving a more refreshing and attractive product. In addition, the calorie content of the composition is also reduced.

Reduction of calories in bakery products is particularly difficult if only the sugar moiety is replaced. Erythritol can reduce the caloric content by more than 30% (dependent on the application) without introducing undesirable side-effects. Additionally, erythritol improves the shelf-life of bakery products. Erythritol can be applied successfully in cookies, biscuits, and cakes, where it improves baking stability and shelf-life at an addition level of about 7%.

SUNFLOWER OIL

F J Sánchez-Muniz and C Cuesta, Universidad Complutense de Madrid, Madrid, Spain

Origin and Systematics

The cultivated sunflower (*Helianthus annus* L.) is a plant of the family Asteraceae (Compositae). The term *Helianthus* is derived from the Greek *helios*, meaning sun, and *anthos*, meaning flower. The property of this flower 'turning with the sun' is clearly expressed by the Spanish and French languages when naming this plant.

Hypothesis suggests that the wild *H. annus* of the western USA became a camp-following weed of North American Indians. In time it was introduced into the central part of the country where it was domesticated for use primarily as food. Archeological evidence indicates the occurrence of heads and achenes of domesticated types of sunflower as early as the first millennium BC, and it has been suggested that cultivation began as early as 3000 BC. During the early sixteenth century European visitors to America introduced the sunflower to Europe, principally to Spain, from where it spread throughout the continent. It was grown initially as an ornamental plant and later for food and medical purposes. The sunflower was developed as an important source of oil during the early 1800s in Russia. More recently, wild species have been used in breeding programs. They have been found useful in improving disease and insect resistance of cultivars. The success of breeders (most from the Former Soviet Union) in improving the oil content of seeds from less than 30% to over 50% was a major factor in the development of the sunflower as a major world oilseed crop.

The plant is generally grown to obtain oil, but meal and hulls are also used or present potential uses (see below).

World Sunflower Crop

Sunflower ranks among the most important annual field crops grown in the world for production of edible oil. During the last decade, the total production of sunflower has increased. Thus, in 1989–91 it was estimated at about 22.3 million metric tons. In 1998–99 world production was about 26.7 million tons (Table 1).

Sunflower grows well in most regions of the world, with significant production occurring in each of the six crop-producing areas (Figure 1). Europe and America (North, Central, and South America) are the leading producers of sunflower seed, accounting for about 50% of the world's total production. In Figure 1 production efficiency (kg ha^{-1}) in the six world crop-producing areas is also presented. Recent data show that the ex-USSR and Argentina are the largest producers (Table 1). Other leading producers are also presented in Table 1. However, because production depends on cultivars and in many countries efficiency is determined by the weather, the leading order can change. For example, in Spain, one of the leading producers, a high percentage of sunflower comes from dry-ground cultivars, thus sunflower seed production may change dramatically from a wet year to a dry year (by about half a million tons).

Although sunflower is grown primarily for its oil, there is limited production of certain cultivars grown for nonoilseed or confection purposes.

Table 1 World sunflower crop and sunflower oil production (Million Tons)

World Sunflower Oil Production

World edible oil and fats production has increased in the last years with a total seed production in the year 2001 of 306.9 million metric tons. The sunflower oil production since 1998 is presented in Table 1. World production of sunflowerseed in the season 2002/03 is currently forecast at 23.8 million metric tons. World

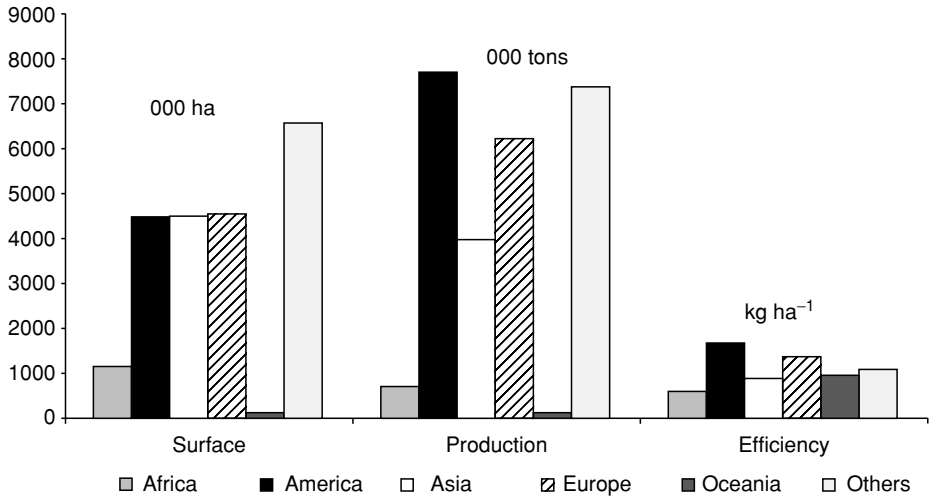

Figure 1 World crop production of sunflower. Data from Anuario de Estadística Agraria (1997) pp. 148–150. Madrid: Ministerio de Agricultura, Pesca y Alimentación; Unilever Food. España (2000) Statistics. Personal Communication. Bilbao, Spain: Agra.

production is thus seen recovering by about 2.6 million tons from last season but still this season's global sunseed crop is expected to remain approximately 3.4 million tons below the harvested amount in 1998/99. Oil production is highly dependent on the crop and thus is changeable from season to season.

Although sunflower oil is considered a premium oil, with a correct equilibrium between linoleic acid and tocopherols the benefits of monounsaturated fatty acids to health has encouraged the production of new oils with a high level of oleic acid, such as high-oleic-acid sunflower oil, high-oleic-acid rapeseed oil, high-oleic-sunflower oil (HOSO), etc. Thus, recently several new variants of sunflower have appeared with the aim of catering for the demand for oils richer in oleic acid and with a lower price than olive oil. Because they have greater oxidative stability than conventional sunflower oil, high-oleic-oil sunflower oils are expected significantly to expand food and industrial uses of sunflower oil all over the world.

Market and Prices

Sunflower derives most of its economic value from the oil extracted from the seeds; the remaining value is from the meal. The oil is considered to be of very high quality and generally sells for a premium in world markets, over soybean, palm, and rapeseed oils. In the period 1999–2001 sunflower oil price range between US $400 and 600. The year 2002 estimate price for crude and refined sunflower oils are 699 E/metric ton and 733 E/metric ton, respectively. However, due to unfavorable weather conditions further rise of prices for the sunflower oil can be expected for the next 9–10 months.

Reduced crushing of sunflower seed, as crushing margins remained inadequate, forced most crushers to process rapeseed as an alternative. However, increased arrivals of Argentina sunflower oil prevented the oil price from rising sharply.

Sunflower oil initially maintained a high and justified premium over soybean and rapeseed oil but as the lower Spanish crop was more or less compensated by higher yields in Eastern Europe and France, the market could not sustain the high premium. Currently the premium has eroded to US $80 from US $100. Sunflower seed supplies from Russia and the Ukraine have recently become uncertain as governments announced export taxes.

Oil Extraction

Before oil extraction, sunflower seed (*c.* 30% hulls) is usually dehulled to 8–12% because of the high wax content in the hulls. An outline of the extraction process is shown in Figure 2. Before pressing, other manipulations are necessary, such as delinting, cracking, breaking, conditioning, and structuring. Nowadays, the only presses used on an industrial scale are screw presses or expellers. The pressure applied in pressing can be as high as 300 000 kPa but is commonly around 150 000 kPa. Capacities of expellers used for prepressing are usually 100–200 tons per day, but equipment exists that can handle up to 500 tons per day. The solvent extraction is mainly carried out by percolation through the platelets of prepared seeds using nontoxic solvents that are powerful solvents for oils and nonsoluble in

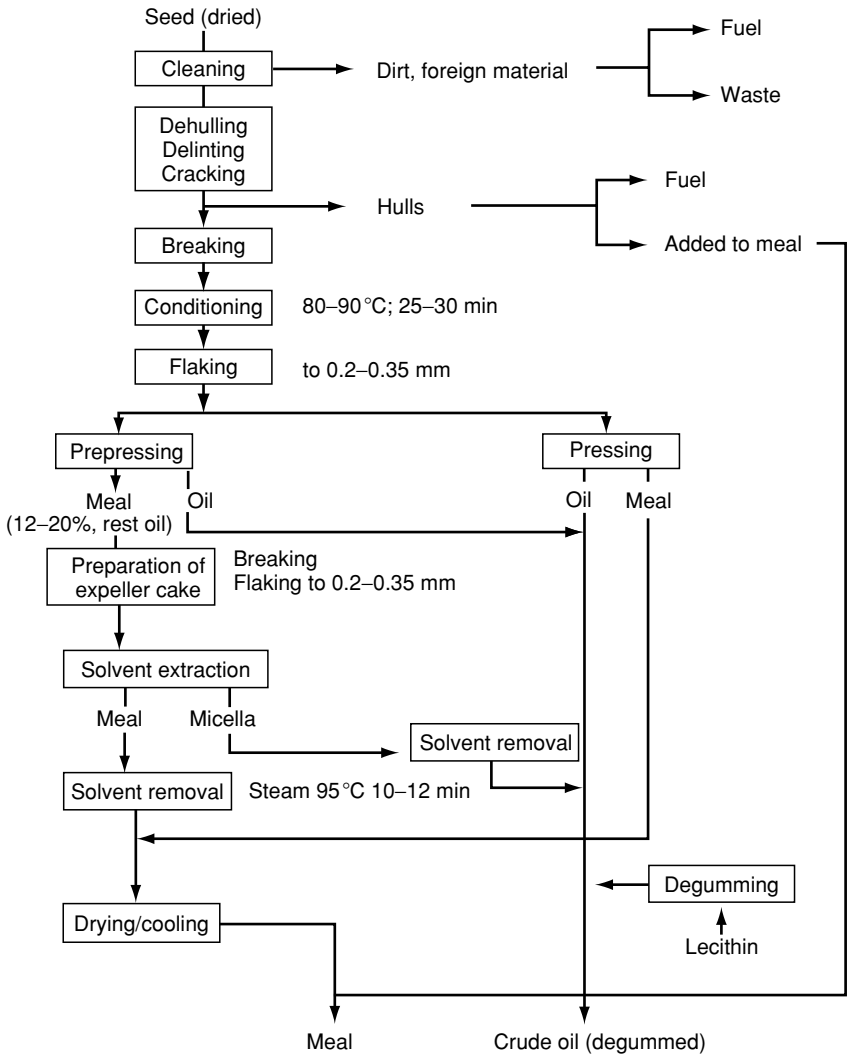

Figure 2 Sunflower oil extraction scheme. Modified from Dupont J (1999) Vegetable oils. In: Macrae R, Robinson RK and Sadler MJ (eds) *Encyclopedia of Food Science, Food Technology and Nutrition*, pp. 4686–4714. London: Academic Press.

water, low in price, and also nonflammable and nonexplosive.

Treatment of Crude Oil

In some countries the oil from the first pressing of seed is used directly. However, to refine the oil to change its color, odor, flavor, and physical properties, it has become a common procedure to satisfy consumer demands.

Refining

Fats and oils contain minor compounds which must be removed because they confer taste and smell that can diminish consumer acceptance. Steps in the chemical and physical refining of sunflower oil are similar to the ones processed in other vegetable oils.

Degumming

The degumming process is necessary to eliminate gums from the oils of some seeds. The oil is heated, the phosphoric acid (85%) is added and, after a reaction time, the gum-water sludge is filtered off or separated by centrifugation.

Neutralization

After harvesting or during ripening, lipolytic enzymes start to split the triacylglycerols contained in the oil and the free fatty acids are originated; this increases rapidly the acidity value. Because of this, it must be removed. Neutralization of these fatty acids can be performed by extraction, distillation, and chemical processes. Another action is reesterification of the free fatty acids with glycerol. Neutralization is carried out by alkalis or ammonia.

Bleaching

Among others, chlorophyll and carotenoids are colored substances. They are removed in the bleaching process by employing bleaching earth that adsorbs and removes these particles.

Deodorization

In this process odorous substances, mainly oxidation products, are eliminated. Deodorization can be considered to be a water vapor distillation, and must be carried out under vacuum, because the vapor pressure of ketones and aldehydes at 200 °C is of the order of 30 kPa, about 300 times higher than that of fatty acids. The process is generally carried out for seed oils at temperatures of about 240 °C for deodorization or 270 °C if distillative neutralization includes centrifugation.

However, the deodorization temperature for sunflower seed oil is 220 °C under ~400 kPa. Nevertheless, depending on the application, it may be necessary to modify the sunflower oil by means of hydrogenation, interesterification, or fractionation and winterization in order to change the melting point or improve clarity.

Composition

Triacylglycerol Species and Fatty Acid Composition

The chemistry and reactivity of natural fats and oils are mainly dependent on their overall composition and especially on the relative composition of the fatty acid constituents. Furthermore, the structure of the fats in terms of the relative proportions of different molecular species or of the sterospecific distribution of fatty acids on the glycerol moieties have a bearing on their properties. Table 2 presents the fatty acid profile of these two sunflower oil variants. The HOSO shows a fatty acid composition similar to other monoenoic oils, such as olive oil. The triacylglycerol composition of sunflower and HOSO is shown in Table 3. The former is rich in trilinolein, while the latter is rich in triolein.

Table 4 shows the characteristics that sunflower oil has to have in order to be an acceptable edible oil according to European Community regulations. The different fatty acid fraction contained in this oil may be quite variable, as shown in Table 2. Nevertheless, polyunsaturated fatty acids predominate. The percentage of oleic acid (C_{18}:1, *n*-9) plus linoleic acid (C_{18}:2, *n*-6) is rather constant (85–87%) because both fatty acids originated in the same biosynthesis chain. The linoleic acid is produced from oleic acid by desaturation carried out by the Δ^9 desaturase enzyme. The major *n*-6 fatty acid is linoleic acid, ranking 50–72%. This edible oil also contains about 11–12% of saturated fatty acids (mainly palmitic and stearic acids). Oleic acid represents about 16–25% and only minor amounts of α-linolenic acid are present (Table 4).

Sunflower oils from cold climates are poor in oleic acid and very rich in linoleic acid (about 15% and 75%, respectively) with an iodine value of 125–136, and do not require winterization. Southern oils have been found to contain over 50% of oleic acid and as little as 35% of linoleic acid with an iodine value of ~106.

Minor components

In the last decade certain minor constituents of oils have been extensively studied, because of their antioxidant properties, and also because they can modulate the dietary cholesterol absorption, the fatty acid metabolism and thus the serum cholesterol levels. Table 2 shows a typical composition of sunflower oil's minor components. Large amounts of phytosterols and tocopherols, and relatively high amounts of squalene are present. Table 4 shows some admitted limits for tocopherols and phytosterols in sunflower oil.

Applications

Catering

Contrasting with other vegetable oils, such as soybean, corn, and cotton, the oil extracted from the sunflower seed contributes about three-fourths of the total value of the crop. Sunflower oil is appreciated among vegetable oils because of its bland flavor, light color, high smoke point, high level of linoleic acid, and very poor linolenic acid content.

Sunflower oil is primarily used as a salad dressing and cooking oil. Furthermore, it is extensively used as a major ingredient in some margarine and shortening products. The use of sunflower oil in salad is less frequent than olive oil in Mediterranean countries. Nevertheless, sunflower oil is prominently used in deep-fat frying throughout the world. At present, Spaniards and others, particularly those who live near to the Mediterranean coast, continue buying and consuming a relatively large quantity of olive oil, mainly for frying purposes. However, other oils, mostly sunflower oil, have largely substituted the use of olive oil. This situation is particularly acute in the Spanish institutional sector (hospitals and welfare centers, prisons, military bases, teaching institutions, company dining facilities, government establishments, etc.). Economic reasons have promoted the production and consumption of sunflower oil.

Deep-Fat Frying

Deep-fat frying, a quick elaboration procedure of food, improves the palatability of food as well as providing flavor and nutritive value. This culinary technology can be defined as a complex process of controlled dehydration and browning with hot oil as the heat transfer medium.

Many factors are at work:

1. The process itself: temperature, time, frying method, and vessel material.
2. The type of fat: chemical and physical properties of the fat, additives, and contaminants.
3. The food size and form: rate surface/volume, battered, floured, direct action (on thermolabile nutrients improving nutrient interactions, nutrient interchange between the foodstuff and the frying fat).

During deep-fat frying a wide variety of chemical reactions take place. The steam from a moist food will cause hydrolysis of triacylglycerols, resulting mainly in the formation of free fatty acids and diacylglycerols (monoacylglycerols and glycerol are produced in small quantities during controlled frying), while the air released into the frying system will initiate a cycle of oxidation involving the formation of free radicals. These oxidation processes will involve fatty acids in intact triacylglycerols as well as the products of triacylglycerol hydrolysis. The fatty acid residues of triacylglycerols formed can react to form polymers and other complex reaction products. On the other hand, the food being fried can influence the type and quantity of breakdown products in the frying medium.

The substrate can influence the process in three ways:

1. By releasing natural antioxidants or prooxidants into the frying oil. These products can also be absorbed by the frying substrate.
2. By the absorption of lipid oxidation products on to the substrates
3. By the catalytic effect of various functional groups present in the food.

Frying with sunflower oil Sunflower oil is one of the most important vegetable oils employed for deep-frying. It has been used in the cooking of food such as French fries and frozen prefried foods at home, in fast-food restaurants, and in the industry. The frying process can also be used to produce cardio-health foods because during frying the exchange of fat between the frying medium and the food occurs. Thus, the level of linoleic acid in the food can be deeply increased when frying is performed in sunflower oil. Moreover, after frying some minor components from the oils, such as tocopherols, are present in the fried food.

The degradation must be ascribed to a lower turnover of fresh oil during frying, but in industrial cooking, where a high turnover of fresh oil is used, sunflower oil can be used successfully. The thermal oxidation of sunflower oil used in frying (as with other oils or fats) can be evaluated by measuring the percentage of total polar content by column chromatography. The level of 25% polar content has been accepted as critical for oil discarding. Frying potatoes in sunflower oil following domestic conditions shows that polar content increases in oil and fried potatoes. However, when frying is performed with frequent oil turnover, the amount of polar material in sunflower oil is substantially below the critical level (**Figure 3**).

The amount of polymers and dimers of triacylglycerols formed in sunflower oil through deep-fat frying is also lower in the frequent turnover of fresh oil than in the null turnover one. The benefit of the high turnover of sunflower oil has also been found in the frying of frozen foods (potatoes, fish fingers, croquettes, pastries, etc.) under domestic conditions.

HOSO seems to be a rather stable oil and has been recently studied. Experiments using HOSO to fry potatoes following a domestic frying model suggests

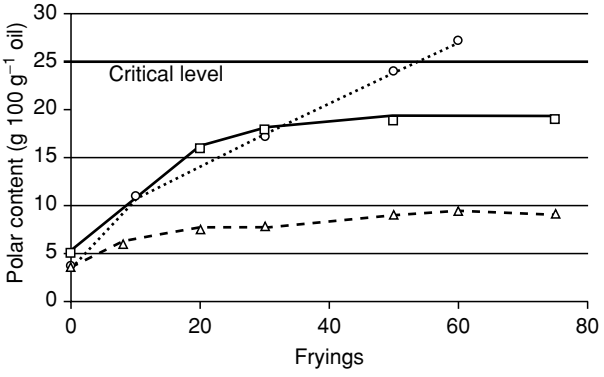

Figure 3 Sunflower oil and high-oleic-acid sunflower oil behavior in frying potato. Polar fraction (mg 100 mg^{-1} oil) change. Open circles, sunflower oil used in discontinuous frying of French fries without replenishment with fresh oil. Open squares, sunflower oil in discontinuous frying of French fries with frequent replenishment with fresh oil. Open triangles, high-oleic-acid sunflower oil in discontinuous frying with frequent replenishment of French fries with fresh oil. Modified from Cuesta C and Sánchez-Muniz FJ (1998) Quality control during repeated fryings, *Grasas y Aceites* 49: 310–318 and Sánchez-Muniz FJ, Cuesta C, López-Várela S, Garrido-Polonio MC, and Arroyo R (1993) Evaluation of the thermal oxidation rate of sunflower oil using various frying treatments. In: Applewhite TH (ed.) *Proceedings of the World Conference on Oilseed Technology and Utilization*, pp. 448–452. Champaign, IL: AOCS Press.

that frequent replenishment of used HOSO with fresh HOSO permits the frying of sets of fresh potatoes at a very high rate (Figure 3). Moreover, HOSO performs much better than conventional sunflower oil in the frying of prefried frozen foods. This occurred using the frequent and the null turnover techniques, commented on before. The triacylglycerol and fatty acid composition and the ratio of antioxidant to unsaturated fatty acids explain the different stability and frying behavior of these two variants of sunflower oil.

Among natural sunflower oil antioxidants, tocopherols seem to be more relevant. In this way, it is interesting to note that, in continuous frying operations, a regular turnover of fresh oil maintains the level of antioxidant in the oil.

However, data from some publications suggest that addition of the antioxidant exerts little influence in extending frying life of the oil used in frying but it can extend the shelf-life of the food by reducing the rate of oxidation of the absorbed oil. Nevertheless, data from the AIR (The Agriculture and Agro Industry Research) project have shown that peroxidative degradation of frying oils occurred when there was a lack of tocopherol content.

Oleochemistry

Margarines Margarines were originally obtained from lard and other fat sources, and were widely consumed through the world until the 1970s and 1980s. However the association of saturated fats with coronary heart disease led to the development of new margarine products of vegetable origin. These new margarines, with high-polyunsaturated-fatty-acid content, include soft margarines and diet spreads. Sunflower oil is one of the oils employed in the formulation of fat blends to achieve an adequate product. Typical fat blends for margarines are shown in Table 5.

In margarines the level of polyunsaturated fatty acids should not be less than 45% of *cis, cis* linoleic acid or less than 50% of total polyunsaturated fatty acids; the sum of saturated fatty acids and *trans* fatty acids should not exceed 25% and the level of cholesterol should not exceed 15 mg kg^{-1}. Considering these facts, in order to reach 45–50% in polyunsaturated fatty acids, it will be necessary to use 70–80% sunflower seed or soybean oils.

Table 5 Fat blends for polyunsaturated fatty acid margarines

	PUFA 1(%)	*PUFA 2(%)*
Hydrogenated vegetable oil (melting point 55 °C)	5	
Hydrogenated vegetable oil (melting point 46–48 °C)		20
Hydrogenated vegetable oil (melting point 40 °C)	15	
Sunflower oil	80	80

PUFA, polyunsaturated fatty acids.

Other Uses

The sunflower meal, obtained after the oil is extracted from the seed, has a high protein percentage (28% for meal from hulled seeds to 42% for dehulled seed meals) and is used primarily in food rations for livestock and poultry. Compared to soybean, sunflower meal contains lower energy and lysine but higher fiber and methionine content.

Variants of sunflower seeds with low oil content (nonoilseed sunflower) are primarily used as a snack food, an ingredient in baked foods, salads, and candies, and for feeding birds and small animal pets. During the last decades a flowering market has grown round these seeds.

Finally, sunflower hulls present a potential use as litter for livestock or poultry, and as a source of roughage in animal feeding. Building or insulation boards and, fireplace logs are other interesting potential applications.

However, the relatively higher price of sunflower oil in respect to other seed oils explains why it is not widely used for industrial purposes. Nevertheless, some paints, varnishes, and plastics take advantage of its semidrying properties without the yellowing problems associated with oils rich in linolenic acids. In some eastern European countries the oil is also employed by detergent and soap manufacturers. Like other vegetable oils, it has potential value for use in the production of adhesives, agrochemicals, surfactants, additional plastics and plastics additives, fabric softeners, synthetic lubricants, coatings, and other products.

HOSO has potential value in industrial products where oleic acid and related chemicals are currently utilized. This new oil is of initial interest in food use (primarily in frying of snack foods to enhance the shelf-life of retail products), and as an ingredient in infant food formulas which require stability, bland flavor, and specific fatty acid composition. The high level of oleic acid together with the high oxidative stability is valuable for cosmetic and pharmaceutical manufacture.

Dietary Importance and Health Effects

Sunflower Oil as Energy Source

While protein and carbohydrates provide 17 kJ g^{-1} (4 kcal g^{-1}), long-chain triacylglycerols provide 38 kJ g^{-1} (9 kcal g^{-1}). The fatty acids are used for

energy production in the cell mitochondria and peroxisomes. Present recommendations for fat are about 30% of total energy intake (80–90 g day^{-1} in a 2200–2450 kcal/diet). Due to a large proportion (more than 50% of total fat, in Mediterranean countries) that comes from cooking oil, the fatty acid composition of a diet depends largely on the culinary oil used.

Recent knowledge suggests that a unit of energy from fat may be more fattening than a unit of energy from carbohydrate. This fact can be related to the limited body capacity to convert carbohydrate into fat and the faster adaptation to oxidize excess carbohydrate than excess fat. Moreover, body capacity for storing carbohydrate as glycogen is limited, whereas in adipose tissue, fat storage is virtually unlimited.

Sunflower Oil as Essential Fatty Acid Source

Linoleic and linolenic acids are the two first (parent) members of ω-6 (*n*-6) and ω-3 (*n*-3) fatty acid families, respectively. Both are essential and must be supplied by the diet because humans and many animals have lost the ability to synthesize them. Moreover, other fatty acids of the *n*-6 family such as γ-linolenic acid (18:3, *n*-6), dihomo-γ-linolenic acid (20:3, *n*-6), and arachidonic acid (20:4, *n*-6) cannot be formed.

The major *n*-6 fatty acid in the western diet is linoleic acid. Although other oils are very rich in linoleic acid, sunflower oil appears to be the primary source of this fatty acid. The importance of linoleic acid consumption in humans and animals is detailed elsewhere. (*See* **Essential Fatty Acids**.)

Deficiency of this fatty acid is called essential fatty acid (EFA) deficiency; it is well documented in the rat and can be produced in several animals, including humans. The disease is characterized by skin symptoms such as dermatosis. Growth is retarded, reproduction is impaired, and there is degeneration or impairment of function in many organs of the body. EFA deficiency is characterized by changes in the fatty acid composition of many biological membranes, depending on how much vegetable oil, such as sunflower oil, is consumed in the diet; the intake of this fatty acid generally varies from 4–10%. Overt EFA deficiency is only seen when it provides less than 1–2% of dietary energy (about 2–5 g d^{-1} for adults).

Sunflower Oil as Antioxidant Source

As commented on before, sunflower oil contains valuable amounts of minor compounds such as α-tocopherols, γ-tocopherols, and phytosterols. The correct equilibrium between polyunsaturated fatty acids and antioxidants protects membranes from oxidative stress. Among other properties, phytosterols act not only as free radical scavengers but also as antipolymerization agents in frying oils.

Influence of Polyunsaturated Fatty Acids *n*-6 on Cholesterolemia and Lipoproteinemia

It is currently recommended that dietary total fat, saturated fatty acids, and cholesterol should be reduced while the intake of unsaturated fats should be increased. As a result of these considerations the consumption of unsaturated oils has been recommended and margarines rich in polyunsaturated and monounsaturated fatty acids, called health margarines, have been developed. Linoleic acid has been considered for many years to be the unique fatty acid that had a hypocholesterolemic effect at serum and lipoprotein particle level.

Recent investigations suggest that oleic acid also presents such an effect on low-density lipoprotein particles. However, a large intake of linoleic acid decreases high-density-lipoprotein cholesterol while oleic acid has no effect on high-density-lipoprotein cholesterol levels.

Influence of Polyunsaturated Fatty Acids *n*-6 on Other Physiological Processes

n-6 fatty acids have been proven to exert other important roles in cytokine production and monocyte quimiotactism, and in eicosanoid production.

Platelet aggregation, inflammation, and cellular immunity are processes modulated by metabolic products derived from *n*-6 polyunsaturated fatty acids. Because sunflower oil contains large amounts of linoleic acid (the fatty acid mother of other *n*-6 fatty acids), the intake of this oil should be adequate, avoiding low and very high intakes that would produce an EFA deficiency or *n*-6 fatty acid saturation.

Like other fats, sunflower oil may modulate all these previous cited processes because of its ability to change the fatty acid composition of membrane phospholipids. As a consequence, membrane fluidity may change and also, when cytokines act on target cells, the amount and types of prostaglandins and leukotriens originated are modified. Dihomo-γ-linolenic and arachidonic acids derive from linoleic acid, and are precursors of eicosanoids. These fatty acids can be metabolized via different enzymatic pathways, giving rise to thromboxanes, prostacyclins, prostaglandins, leukotriens, and hydroxy-fatty acids and oxygenated metabolites, which have been proved to modulate inflammation, cellular immunology, thrombosis, cardiovascular disease, and cancer.

The recommendation for the polyunsaturated fatty acid contribution to total energy is 7.5%, with a total of 6% as linoleic acid. Other scientific societies recommend that linoleic acid should contribute 3–6% of

total energy in the diet. However, because cardiovascular disease and cancer have been defined as a consequence of oxidative damage, vegetable oils consumed in correct amounts would add benefits in reducing such degenerative diseases, because they contain antioxidant and flavonoids and an adequate linoleic-acid-to-vitamin-E ratio. Immune response can be improved by consuming unsaturated fatty acids; however large quantities of *n*-6 fatty acids could suppress cellular immunity.

SUPERCRITICAL FLUID EXTRACTION

E Reverchon, University of Salerno, Via Ponte Don Melillo, Italy

Background

Many food and nutrition ingredients are traditionally produced by organic solvents extraction. This process is relatively simple to perform and is firmly established in industrial practice; however, it has several drawbacks: it is a polluting process, since organic solvents can be released to the atmosphere, they remain in starting material, and they have to be eliminated from the extracted products. Owing to the increasing demand for nonpolluting processes and product purity, alternative processes are intensively coming under scrutiny. The most promising alternative to organic solvent processing is supercritical fluids extraction (SCFE); several SCFE produced compounds are already commercialized.

A supercritical fluid (SCF) is, as a rule, a gas under room conditions that is heated and compressed above its critical temperature and pressure. When it is under supercritical conditions, the SCF is in the gas state and maintains its related properties, but, depending on the operating pressure, it can assume variable densities from gas-like to liquid-like. Therefore, SCFs are sometimes called 'variable geometry' solvents. This characteristic makes them suitable for selective extraction processes. Indeed, it is possible to modulate the solvent power of a SCF to perform intensive or selective extraction processes. After the extraction, owing to pressure reduction, the SCF is immediately and completely eliminated from the raw material and from the extracts.

Table 1 lists some SCFs proposed for extraction processes, together with their critical temperatures and pressures. It is evident that only some of them can be applied to food extraction, since their critical temperatures are often too high for the stability of thermolabile compounds that are characteristic of food.

The large majority of the extraction applications proposed for SCFE use carbon dioxide (CO_2) as the SC solvent because CO_2 is cheap, nonflammable, nonpolluting, and available in large quantities. Its critical temperature and pressure are readily obtainable in an industrial process, and the SCF process temperatures that can be set (for example from 35 to 50 °C) are compatible with the thermal stability of most food-related ingredients. The general behavior of SC-CO_2 is similar to a nonpolar solvent, i.e., it has strong affinity with lipophylic molecules. Also, since supercritical CO_2 is used during the process, but not produced during extraction, it does not contribute to the so-called 'greenhouse effect.' Thus, the only drawback of SC-CO_2 extraction is the requirement of a pressurized plant to perform the process.

SCF extraction has been successfully performed in many cases on the laboratory scale, but only a few industrial-scale applications have been developed until now. However, the potential of SCFE is very high, and many industrial applications are expected to be developed in the next years.

Table 1 List of supercritical fluids proposed for the extraction process

Supercritical fluid	T_c(°C)	p_c(bar)
Carbon dioxide	31.1	73.8
Nitrogen protoxide	36.5	70.6
Propane	96.7	42.4
Ethanol	243.4	72.0
Isopropyl alcohol	235.3	47.6
Trifluoromethane	26.0	46.9

Extraction Processes

From the point of view of the process arrangement, SCFE can be divided into three major areas, according to the physical state of the compounds to be extracted or of the raw material to be treated:

- *Extraction from solid matrices* is used to extract one or more compounds from a solid matrix, for example, to extract oil from seeds, essential oils, etc.
- *Extraction from liquid mixtures* is used when liquid compounds are to be extracted from a liquid mixture. It is used, for example, to eliminate hexane from seed oil and alcohol from wine, and for milk fat fractionation.
- *Spray extraction* is used to extract solid compounds from a liquid mixture. In this case, the previous process arrangements cannot be used. It can be used to extract lecithin from seed oils.

This classification underlines the similarities among the various extraction processes and can be useful for choosing the process arrangement to apply SCFE to products different from those described in the scientific and technical literature.

Extraction from Solid Matrices

This is the most studied SCFE application, since the most frequently required process is the extraction/elimination of one or more compound families from a solid (natural) matrix. The base extraction scheme is represented in Figure 1. It consists of an extraction vessel filled with the raw matter to be extracted. As a rule, the raw matter is dried and finely ground to facilitate the extraction process. It is loaded in a basket located inside the extractor to allow rapid charge–discharge of the extraction vessel. Metallic frits at both ends of the extractor allow the SCF to go through the bed of solid material to extract the required compounds. The SCF at the exit of the extractor flows through a depressurization valve to a

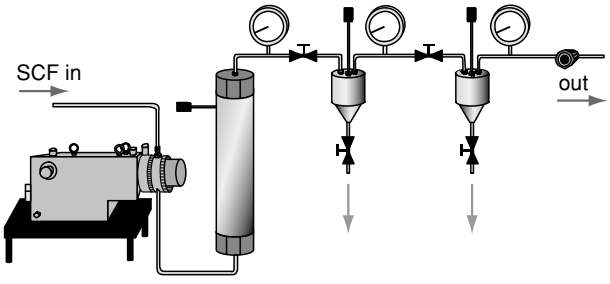

Figure 1 Extraction scheme for extraction from solid matrices.

separator in which, because of the lower pressure, the extracts are released from the gaseous medium and collected. More sophisticated extraction schemes (such as that shown in Figure 1) contain two or more separators. In this way, it is possible to fractionate the extract in two or more fractions of different composition by setting suitable temperature and pressure values in the separators.

Other possible variations of the SCFE scheme are multistage extraction and cosolvent addition. The multistage extraction strategy can be used when several compound families are to be extracted from the same matrix, and these are characterized by their different solubilities in SC-CO_2. It takes advantage of the fact that the solvent power of SC-CO_2 strongly increases with pressure at a fixed temperature. Therefore, it is useful to perform a first extraction operating at a low CO_2 density (e.g., 0.29 g cm^{-3}, 90 bar, 50 °C) followed by a second extraction step at a high CO_2 density (e.g., 0.87 g cm^{-3}, 300 bar, 50 °C). The most soluble compounds are extracted during the first stage (e.g., essential oil) and the less soluble compounds are extracted in the second one (e.g., antioxidant compounds).

A liquid cosolvent can be added to SC-CO_2 to increase its solvent power towards polar molecules. Indeed, as previously mentioned, SC-CO_2 is a good solvent for lipophilic (nonpolar) compounds, whereas it has a low affinity with polar compounds. Various authors have added small quantities of liquid polar solvents (for example, ethyl alcohol) that are readily solubilized by SC-CO_2 owing to their low molecular weight but, when in solution, modify the solvent power of the SC solvent. The only drawback with this strategy is that the cosolvent is a liquid and is collected in the separator together with the extracted compounds that have to be processed later for solvent elimination. Therefore, one of the advantages of the SCFE, i.e., the complete solvent elimination, is lost.

Selection of the Operative Conditions

The selection of the operating conditions depends of course on the specific compound or compound family to be extracted. Molecular weight and polarity have to be taken into account case by case, but some general rules can be applied. First, the SCFE temperature for food compounds is fixed between 40 and 50 °C, e.g., in the vicinity of the critical point and as low as possible to avoid thermal degradation. The increase of temperature reduces the density of SC-CO_2 (for a fixed pressure), thus reducing the solvent power of the SC solvent, but it increases the vapor pressure of the compounds to be extracted and, therefore, their tendency to pass in the fluid phase. However, the most relevant process parameter is the extraction pressure that can be used to tune the selectivity of the SCF. The general rule is: the higher the pressure, the greater the solvent power and the lower the extraction selectivity. Frequently, the solvent power is described in terms of the SC-CO_2 density under the operating conditions. CO_2 density can vary from about 0.15 to 1.0 g cm^{-3} at the operating conditions useful for SCFE and is connected to both pressure and temperature. Its variation is strongly nonlinear, so the proper selection requires the use of accurate tables of CO_2 properties (for example, the International Thermodynamic Tables of the Fluid State CO_2).

The other crucial parameters in SCFE are CO_2 flow rate, the particle size of the matrix, and the duration of the process (extraction time). The appropriate selection of these parameters leads to complete extraction of the desired compounds in a shorter time. These are associated with the thermodynamics (solubility) and the kinetics of the extraction process in the specific raw matter (mass-transfer resistance).

The proper selection depends on the mechanism that controls the process (the controlling mechanism is the slower mechanism and determines the overall process velocity). For example, particle size plays an important role in extraction processes controlled by the mass-transfer resistance, since a reduction in the mean particle size reduces the length of diffusion of the solvent. However, if particles are too small (for example, smaller than 0.2 mm), they can cause problems of channeling inside the extraction bed: part of the solvent flows through channels formed inside the extraction bed and does not contact the material to be extracted, thus causing a loss of efficiency and yield in the process. Moreover, the production of very small particles by grinding could lead to a loss of volatile compounds.

Applications of Solid Matter Extraction

Many solid matrices have been processed by SCFE. Some relevant categories of products are listed in Table 2. Some well-established industrial processes

Table 2 Some food and food ingredients processed by solid matter SCFE

Essential oils (spices, citrus, etc.)
Seed oils, fats, and waxes
Fatty acids, fatty acid methyl esters
Natural colorants, pigments
Vitamins
Antioxidants (licopene, tocopherols, etc.)
Alkaloids (caffeine)

use SCFE to produce hops extracts and several food nutritional substances that also offer some aspects of therapeutic protection to the human body (nutraceuticals). One of the largest industrial applications is coffee decaffeination, which is performed on green coffee beans presoaked in water. Green coffee beans are used to prevent coextraction of aroma compounds that are formed during roasting. The use of water in the preliminary treatment allows the release of caffeine from the natural substrate where it is linked in the form of sodium salts. Very large plants that operate at pressures between 280 and 300 bar at 40 °C are used in this process with internal volumes larger than 10 m^3. Caffeine is recovered during the SCFE with a purity of around 96% by weight; the final caffeine content in coffee beans can be lower than 0.05% w/w.

Two examples of SCFE are now described in detail: essential oil isolation, which represents a good example of extraction, followed by fractional separation, and seed oil extraction.

Essential oil isolation Essential oils are mainly formed by hydrocarbon and oxygenated terpenes and by hydrocarbon and oxygenated sesquiterpenes. They are commonly extracted from seeds, roots, flowers, herbs and leaves using the so-called hydrodistillation. This is a very simple process but has many drawbacks: thermal degradation, hydrolysis, and solubilization in water of some compounds that alter the flavor and fragrance profile of many essential oils extracted by this technique. (*See* **Essential Oils**: Isolation and Production.)

From the point of view of SCFE, essential oil isolation is an example of extraction followed by fractional separation. Indeed, this extraction process can be optimally performed at mild pressures (from 90 to 100 bar) and from 40 to 50 °C, which correspond to relatively low CO_2 densities. However, even under these operating conditions, essential oil components are extracted together with cuticular waxes, i.e., paraffinic compounds located on the surface of vegetable matter with the aim of controlling its perspiration. Paraffins have a relatively low solubility in SC-CO_2 but are located on the surface of the vegetable matter, whereas essential oil compounds are readily soluble in SC-CO_2 but are partly located inside the vegetable structure. Therefore, extraction of waxes is controlled by their solubility, and essential oil extraction is controlled by mass-transfer resistance through the vegetable structure. As a result of these different interactions, the two compound families are coextracted even under the optimum extraction conditions. Since coextraction is unavoidable, it is possible to take advantage of the fact that at the same pressures, but at low temperatures (from −5 to +5 °C), waxes are practically insoluble in CO_2, whereas essential oil compounds are still very soluble. Therefore, fractionation of the extract is possible by operating a first separation, for example at 0 °C and 90 bar and operating a second separation at 20 °C and 30 bar. In the first separator, the selective precipitation of waxes is obtained, and in the second, essential oil is recovered. This concept has been applied up to the industrial scale, and to date, two companies operating in Germany and in Italy use this process to isolate essential oils.

It is worth noting that it is not possible to perform the CO_2 extraction directly at 0 °C and 90 bar, since the vegetable matter contains many other compound families (antioxidants, colors, etc.) that are very soluble under these process conditions.

XSeed oil extraction Vegetable oil from seeds is traditionally produced by liquid-solvent extraction; as a rule, hexane is used to extract the oil from ground seeds. The process is very efficient, but its major problem is hexane elimination after extraction. Three distillation units in series have to be used, operated under vacuum. The drawbacks of this process are the high costs, the possible thermal degradation of the oil, and the incomplete hexane elimination (from 500 to 1000 p.p.m. residue).

Therefore, several authors have proposed substituting the traditional process by SC-CO_2 extraction of oil from seeds. Indeed, tryglicerides forming seed oils are readily soluble in SC-CO_2 at 40 °C and at pressures higher than about 280 bar. The main parameters to be taken into account for this process are particle size, pressure and residence time. Small particles (1 mm mean diameter or less) and high pressures (300–500 bar) can strongly reduce the extraction time. After the extraction, the SC-CO_2-tryglicerides solution is sent to a separator working at a subcritical pressure. This operation reduces the solvent power of CO_2 to almost zero and allows the recovery of oil. The complete elimination of gaseous CO_2 from oil is also carried out in the separator. The SCFE of several seed oils has been successfully performed up to the pilot scale. An alternative process has also been proposed, in which the operation is performed at a fixed pressure, and only temperature variations are used to recover the oil.

A comprehensive mathematical model of oil extraction has also been validated in which the oil-bearing seed structures, their characteristics, and the experimental data from several authors have been considered to obtain a general validity representation of the process. (*See* **Vegetable Oils**: Oil Production and Processing.)

Extraction from Liquid Mixtures

When liquid compounds have to be extracted from a liquid mixture, it is not possible to use the fixed-bed extractor. In this case, a packed tower operating in continuous mode has to be used. The packing is formed by an inert material characterized by a large surface area that facilitates the contact between the liquid and the supercritical fluid that are sent to the tower in the countercurrent. Typical packings are Rashig rings, perforate saddles, etc. Note that while the extraction from solids is a discontinuous operation, the packed tower is capable of a continuous steady-state operation, which allows large quantities of liquid mixtures to be processed in a relatively small apparatus and in a short time.

Selection of Operating Conditions

The typical extraction apparatus used in this case is shown in Figure 2. Two pumps deliver the liquid solution and SC-CO_2 to the packed column. SC-CO_2 flows along the column from the bottom to the top, whereas the liquid solution is usually added to the top, though it is also possible to feed it at an intermediate position along the column.

The process is based on the different solubilities of liquids to be treated in SC-CO_2. The ideal case is obtained when only the compounds to be extracted are soluble in SC-CO_2, whereas all the other liquid components are completely insoluble. However, this case is rare, and as a rule, the limited solubility of the other liquid compounds forming the mixture has to be taken into account. For this reason, the appropriate pressure and temperature of the process have to be chosen to select the conditions under which there is a maximum difference in solubility among the compounds to be extracted and all the other compounds in the mixture. Also, in this case, CO_2 density is frequently used as a criterion to find the conditions of maximum selectivity.

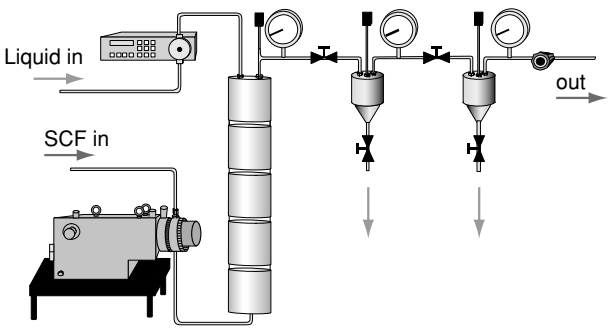

Figure 2 Extraction scheme for extraction from liquid mixtures.

The difference in density between the liquid and SCF is in this case another parameter to be taken into account: to allow the countercurrent operation, the SCF density has to be lower than that of the liquid.

The traditional operation of packed columns requires that the liquid flow rate will be greater than the minimum amount that ensures complete wetting of the packing. The feed ratio is also selected to avoid the massive entrapment of the liquid in the fluid phase (flooding). Of course, these conditions have to be respected also when a supercritical fluid is used as the fluid processing medium. The classical calculation in terms of the number of theoretical equilibrium stages required for separation can also be applied.

A possible variation of this processing scheme can involve the adoption of a temperature profile along the column with the aim of optimizing the separation temperature with respect to the composition of the mixtures at different levels inside the column.

The extraction of liquid mixtures is controlled by the relative solubilities in SC-CO_2 of the various compounds forming the mixture, that is, the thermodynamic limitation of the process. Mass transfer between the two phases represents the kinetic limitation. The distance from the equilibrium condition represents the driving force for the separation along the column.

Applications of Liquid Extraction

The fractionation of a liquid mixture by SCFE has been proposed for various applications. A selection of the most relevant examples is given in Table 3. Two examples will be discussed: hexane elimination from vegetable oils, representing a new approach to seed oil extraction, and citrus essential oil deterpenation, used to extend the shelf-life of these products.

Hexane elimination from traditionally extracted seed oils This process represents a different approach to seed oil extraction by SC-CO_2. Indeed, the supercritical extraction applied directly to seeds has the drawback of high costs owing to the use of large pressurized vessels and the discontinuous operation.

If the approach is to treat the liquid–hexane oil mixture after traditional hexane extraction, it is

Table 3 Applications of liquid fractionation by SC-CO_2

Wine dealcoholation
Milk fat fractionation
Deterpenation of citrus oils
Recycling of frying oils (fatty acid methyl esters and peroxide elimination)

possible to use a smaller apparatus and a continuous operation that allows large quantities of raw mixture to be processed.

Hexane and triglycerides are both soluble in SC-CO_2, but at a temperature of 40 °C, hexane is completely miscible at pressures higher than about 100 bar, whereas, at the same temperature, tryglicerides show a nonnegligible solubility in SC-CO_2 only for pressures higher than 250 bar. Therefore, these compounds can be separated if the operation pressure is considerably lower than 200 bar.

For example, the fractionation of soybean oil–hexane mixture has been successfully performed using a 1.8-m-tall packed tower, charged with stainless steel perforated saddles with a very large specific surface. The extraction has been performed at 120 bar and 40 °C using different starting concentrations of soybean oil in hexane up to 70:30 hexane–oil concentration by weight, which corresponds to the composition of the mixture at the exit of the traditional liquid extraction vessels. With a single passage in the packed tower, it has been possible to obtain a bottom product formed by soybean oil containing down to 20 p.p.m. of hexane residue and to recover pure hexane at the top of the column.

Citrus essential oils deterpenation Citrus essential oils are produced by cold pressing the peel of citrus fruits. These contain very large quantities of hydrocarbon terpenes (mainly limonene) up to 99% in some cases, and small quantities of oxygenated terpenes. Whilst limonene undergoes degradation and produces an unpleasant flavor, oxygenated terpenes make a large contribution to the characteristic citrus flavor and fragrance. Therefore, in order to prolong the shelf-life of these products and concentrate their fragrance, hydrocarbon terpene elimination (deterpenation) processes have been proposed. The most commonly used processes to deterpenate peel oils are vacuum distillation, extraction with alcohol, and partitioning between two solvents. The disadvantages of these processes are contamination with organic solvents and thermal degradation of the products.

The alternative to traditional processes is SCF deterpenation in a packed tower operating in continuous mode, taking advantage of the different solubilities of hydrocarbon and oxygenated terpenes in SC-CO_2 to fractionate the mixture. This separation is more difficult to perform than that described in the previous paragraph for soybean oil, since both hydrocarbon and oxygenated terpenes are very soluble in SC-CO_2, and their solubilities are very similar.

Successful processing has been proposed, operating at 40 °C and at pressures near the critical value of CO_2 (from 75 to 90 bar) to obtain the maximum possible selectivity (the maximum difference in solubility between two compound families can be obtained in this range). Nevertheless, no operating conditions exist at which the less soluble oxygenated terpenes are not soluble in SC-CO_2. Thus, fractionation is possible only using very tall columns and with a fractionation efficiency lower than 100%.

For these reasons, some authors have proposed another SC processing scheme, based on the adsorption of the citrus oil on an adsorbent (silica gel) and the fractional desorption by SC CO_2. The process is very similar to SCFE; it has the advantage that it is an enhanced separation owing to the different strength of the adsorption of hydrocarbon and oxygenated terpenes on silica-gel active sites.

Spray extraction

A liquid mixture can also be formed by a liquid that contains one or more solid solutes. The extraction of these compounds from the liquid cannot be performed using a packed tower, since the solid matter will precipitate inside the tower. It cannot be recovered, and the internal packing is made dirty by this material. Therefore, in the case of solid-containing liquid mixtures, a supercritical spray extraction process has to be adopted. The preconditions to apply spray extraction are that the liquid solvent has to be very soluble in SC-CO_2, whereas the solids have to be insoluble in the SC fluid. These conditions can be frequently obtained, since many organic solvents are readily soluble in SC-CO_2, even under mild operating conditions (e.g., a CO_2 density lower than 0.6 g cm^{-3}), and many high-molecular-weight solids have negligible solubilities in SC-CO_2, especially at low CO_2 densities.

The supercritical spray extraction process consists of a precipitation vessel previously charged with SC-CO_2 (and in which the supercritical fluid continues to flow), in which a spray of the liquid solution is continuously injected. If the process conditions have been properly selected, the liquid is rapidly dissolved in the SC fluid, whereas the solid precipitates at the bottom of the precipitation vessel. A possible representation of the process is shown in Figure 3; two pumps deliver the liquid solution and SC fluid, respectively. A precipitation vessel is used to collect the solid, and a liquid solvent recovery vessel located downstream the precipitator and operated at lower pressure (for example, 30 bar, 25 °C) is used to recover the liquid.

Selection of the Operative Conditions

One of the key steps in this process is the spray formation. The aim of this operation is to produce a

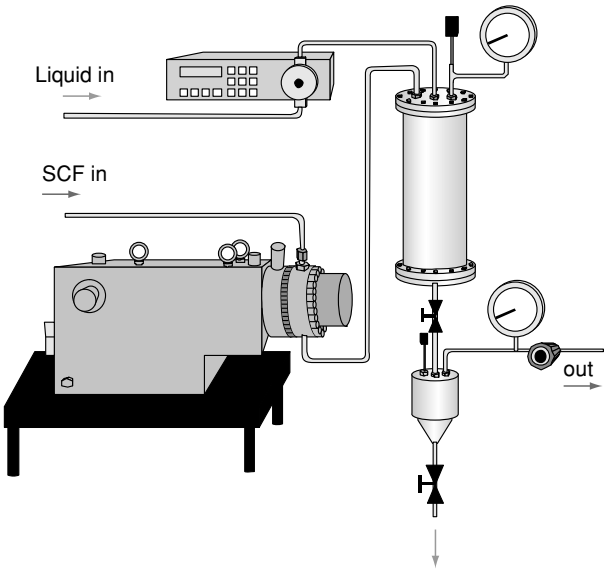

Figure 3 Apparatus used in spray extraction.

very large liquid surface forming small liquid droplets. The large surface area between the liquid and SCF strongly enhances the solubilization of the liquid phase in the supercritical medium and reduces the time required for the complete elimination of the liquid phase to a few seconds or less. For this reason, the process is performed under operating conditions at which the liquid is completely soluble in SC-CO_2. Knowledge of the solubility data on the liquid solvents and of the solids in SC-CO_2 is mandatory for this process for the appropriate selection of process temperature and pressure.

Also, in the case of SC spray extraction, there is the interaction between thermodynamics constraints and mass-transfer mechanisms that control the process performance. The enhanced mass transfer that characterized SC fluids is again a distinctive advantage in their adoption as extraction media, together with the rapid and complete separation by simple depressurization between the SC solvent and the liquid.

A limitation of this process is the possible formation of a ternary liquid–solid–SC-CO_2 mixture. Indeed, the liquid can induce a nonnegligible solubility of the solid compounds in SC-CO_2. In this case, the liquid can act as a cosolvent from the point of view of the solid solubilization. When this phenomenon occurs, the part of solid retained in the fluid phase obviously does not precipitate and is lost in the liquid recovered in the separation vessel. However, this liquid can be used to solubilize the solid compound again before the SC spray extraction. The limit case is represented by the complete entrapment of the solid in the fluid phase that produces the process failure.

Applications of Spray Extraction

Until now, spray extraction has been used in a limited number of processes, but it has a great potential for future applications. Several possible applications are listed in Table 4.

Two examples will be described in detail: lecithin extraction from seed oil and citric acid purification. The first example is a classical spray extraction with the solid solute that is completely insoluble in SC-CO_2. Citric acid purification introduces a multistep spray extraction in which different compounds are precipitated in sequence.

Lecithin extraction from soybean oil Lecithin is formed by a mixture of phospholopids and is a valuable nutraceutical compound. Its major source is soybean (1.1–3.2 wt%). It is an important natural emulsifier used in food and pharmaceutical industries and can be extracted from soybean oil. However, as long as the oil is extracted, the liquid becomes very viscous because of the concentration of lecithin. (*See* **Phospholipids:** Properties and Occurrence.)

Some authors have proposed using a spray extraction process and using SC-CO_2 as the spray extraction solvent, since seed oils are soluble in SC-CO_2 (though at pressures higher than about 280 bar, as previously specified), and phospholipids are completely insoluble in this medium.

Thus, the proposed process consists of a precipitation vessel pressurized with SC-CO_2 (at 400 bar and 40 °C, for example), in which CO_2 flows continuously and an injection system that sprays the lecithin-containing oil into the precipitator in the form of small droplets. The oil solubilizes very rapidly in SC-CO_2 and is extracted and recovered in a separator operating at low pressure. Lecithin precipitates in the precipitation vessel as a solid powder and is collected when the vessel is discharged.

Citric acid purification Citric acid is an important compound that is used in food and beverages as an acidulant. It is generally produced by fungal fermentation, and the purification process includes several treatments with chemical reagents. The spray extraction process has been proposed to purify citric acid after extraction from the fermentation broth using an organic solvent (e.g., ethanol or acetone). Two kinds

Table 4 Applications of SC-CO_2 spray extraction

Citric acid extraction and purification
Phospholipids from soybean oil and egg yolk
β-Carotene from oxides
Protein purification
Di- and triglyceride fractionation

of impurities are coextracted by acetone: sugars and by product organic acids like oxalic and malic acid. Therefore, the process involves the fractional precipitation of sugars that precipitate at low pressures (about 20 bar), the pressure is then increased, and citric and malic acid precipitate in the same range of pressures. Oxalic acid is retained in the solution and precipitated only at very high pressures (higher than 120 bar). Therefore, the purification of citric acid is not complete: the only residual impurity being malic acid, which has a very low concentration in the starting solution. Intensive

A Bassoli and L Merlini, Università di Milano, Milan, Italy

Background

The sensation derived from tasting a sweet substance is a pleasant one for most of the contemporary mankind. It is debatable whether this is an innate character or built on the millenary use of honey and sugar as foods. Sugar plays an important role in the human diet, being widely distributed in nature and accounting for a large portion of total nutrient intake, at least in the developed countries. The necessity, or interest, in substituting the whole, or part of, sugar in foods while maintaining the sweet taste, derived first from the requirement of reduction of sucrose in the diet of diabetics, who comprise up to 2% of the world population. Later on, from the attempt to avoid risks connected with obesity or overweight caused by the excessive caloric intake in developed countries, and to prevent dental caries. Sweeteners can be used to produce foods that are sweet yet have no sugar.

A sweetener is a substance that can be added to foods to confer a sweet taste. Sweeteners belong to two main classes: intensive and bulk sweeteners. Intensive sweeteners are substances so sweet that minute amounts can substitute substantial amounts of sucrose, with a greatly reduced caloric intake. However, this change can create difficulties in the preparation of traditional sweet foods, such as cakes or confectionery, in which sugar, often used in large amounts, confers very important properties besides sweetness, such as structure and absorbance of water. This problem can be solved using so-called bulk sweeteners, which have a chemical structure, sweetening power, and mechanical and physical properties very similar to those of sucrose.

From a nutritional point of view, sweeteners are often classified as caloric, low-caloric, and noncaloric. However, there are no great differences in the amount of calories produced by the complete consumption of similar amounts of different sweeteners. Low-caloric sweeteners owe their definition to the fact that they are not absorbed as much as sugar, and therefore, while their sweetening potency is maintained, only a part of their caloric value is utilized by the consumer. Similarly, noncaloric sweeteners are so called because they are so much sweeter than sugar, that only a minute amount is required to impart the sweetness required, and the energy produced is negligible. It should be noted that these definitions are not strict and are used randomly by different authors.

Intensive Sweeteners

The first sweetener to be used was saccharin (q.v.), the production of which began in 1884, and in the first half of the last century, production was directed almost exclusively to diabetics. In the 1950s, the demand for sweeteners, mostly for soft drinks, led to the discovery of other sweet compounds, first of all cyclamates (q.v.). These were used mainly in nonalcoholic drinks, and in the USA, in 1968, production rose to 9500 tonnes corresponding to about 300 000 tonnes of sugar. In the meantime, concern about the possible dangerous consequences of the systematic use of food additives became increasingly widespread, with calls for more accurate toxicological tests. Indeed, the results of studies aiming to demonstrate the innocuity of cyclamates were used by the Food and Drug Administration (FDA) to ban cyclamates from soft drinks in the USA in the 1970s. However, the controversy surrounding the interpretation of such studies meant that their use has continued, with repeated applications to reapprove the use of cyclamates, and they are still being used in many other countries, albeit with restricted daily intake doses.

In the last two decades, the market has called for new sugar substitutes with sensorial properties as similar as possible to those of sugar, and with unquestionable safety. At present, the introduction of a new sweetener on to the market is regulated by laws or directives of the authorities (FDA, European Community), who require, among other data, a dossier with acute and long-term toxicity studies. As a consequence of the different regulatory laws or procedures in different countries, it is possible that the use of a sweetener may not be allowed in all countries, or that the

procedures to put it into the market are much longer in one country than in others. For those approved for use, regulatory authorities, such as the FDA, Scientific Committee for Food of the European Commission (SCF), or Joint Expert Committee on Food Additives (JECFA) of the FAO/WHO, have established an acceptable daily intake (Table 1).

Design of a New Sweetener

Research on new sweet compounds for use as sugar substitutes has been constantly growing.

According to Hough, a new sweetener:

1. should be at least as sweet as sugar, colorless, odorless, with a pleasant sweet taste, and as similar to sugar as possible;
2. should be soluble in water, and chemically and thermally stable;
3. should have no toxic effect whatsoever, an expected metabolism, or be excreted unmodified;
4. should be easy to produce; if it is a synthetic compound, its purity must be guaranteed; if it is a natural compound, its sources of supply must be guaranteed;
5. should be compatible with production or application technologies; and
6. should be cheaper than those already in use, even if a better taste or other advantages can counterbalance a higher cost.

One of the major problems in the research of new sweet compounds is a lack of information on the mechanism of sweet-taste perception. Experimental evidence from biology, chemistry, physiology, psychology, and neurology supports the hypothesis of the existence of one or more receptor proteins on the taste buds that should mediate the chemoreception mechanism. The first results in cloning candidate genes for sweet taste receptors appeared in 2001, but the molecular details of the entire biological process are still unknown, and so the question of 'how to design a new intensive sweetener' is still open. The rational design of new molecules generally starts from known sweet natural compounds or synthetic sweet molecules. Most of the commercially successful intensive sweeteners (such as aspartame and saccharin) have been discovered by chance and/or designed from a rational and systematic modification of known molecules. In this case, the first step is the identification of those molecular fragments that are important in the receptor–sweetener interaction, the so-called glucophores. This aim is obtained *via* a systematic process of structural modification by synthesis and a critical comparison of the structure–activity relationships of the derivatives obtained. Successful examples of this procedure are sucralose and neotame.

Perceptual Characteristics of Sweeteners

Perceptual characteristics, which include sensory and hedonic, i.e., pleasant aspects of sweeteners, play a major role in food selection and intake. Beyond intensity of sweetness, other characteristics, such as the time–intensity profile, bitterness, other aftertastes (metallic, sour, etc.), fragrance, 'body' (viscosity), and freshness, influence the perception and therefore the acceptability and/or the preference for a sweet material. These characteristics are evaluated by sensory analysis (q.v.), performed by a trained panel of tasters, following established procedures, and with statistical treatment of data. In tasting a sweetener, the form in which it is presented, concentration, temperature, and pH of the solution, are important factors. Important characteristics are those related to mouth feel. A sweetener with a negative heat of solution gives a sensation of cool if tasted as a solid, that is not given by its aqueous solution. A diluted solution of an intensive sweetener has a low 'body,' which, on the contrary, is perceived when tasting a more concentrated (and more viscous) solution of a sugar alcohol, with a sweetness comparable with that of sucrose. The overall description of the taste quality of a sweetener is usually reported as a 'spider web' diagram (Figure 1), representing the mean scores for different attributes as determined by the sensory analysis.

The onset of the sweet taste and the change of its intensity over time, i.e., the temporary profile of a sweetener, is very important in determining the overall quality of the substance. The taste perception is a time-dependent phenomenon related to the time after which the sweetness is perceived (lag time), duration, and speed of the increase and decrease of the stimulus itself. These parameters are described in a time–intensity profile (Figure 2), which is characteristic and different for each sweet substance.

In the example, the time–intensity profile of sucrose and an intensive sweetener are compared. The two substances have similar lag times, and the sweet taste is immediately perceived; but in sucrose, the rate of increase and especially the decrease of the stimulus are higher than in the intensive sweetener. An intensive sweetener usually shows a longer duration of the stimulus, i.e., a prolonged onset of the sweet sensation (or lingering) that can sometimes be an undesirable side-effect. The maximum intensity of the sweet taste (I_{max}) is similar, but the overall effect on the taste of the two substances is quite different. Each sweetener has its own taste profile, which depends also on the presence of other sweeteners, taste modifiers, or flavors in the same mixture.

Table 1 Characteristics of various sweeteners

Sweetener	*RS*[a]	*Limitations*	*Status (updated to spring 2001)*	*ADI*[b] *(mg per kilogram of body weight)*	*Notes*
Acesulfame K	130–200	At high concentrations, may have a slight aftertaste	Approved by SCF[c] and JECFA[d]. Approved in more than 90 countries world-wide	15 (JECFA); 9 (SCF)	Flavor enhancer. Good shelf-life; thermal resistance. Synergistic with other sweeteners
Alitame	2000–3000	On long-term storage, can impart an off-taste	Approved in Australia, Chile, Colombia, Indonesia, New Zealand, Mexico, and the People's Republic of China. Approval is also being sought in the USA, Europe, and other countries	0.1–1	Clean sweet taste. Sweetness profile close to that of sugar. Heat stability; synergistic
Aspartame (q.v.)	200	Limited stability to acidic pH and high temperatures	Approved by SCF[c] and JECFA[d]. Approved by the US FDA	40	Produces phenylalanine during metabolism: consumption limited for people suffering from phenylketonuria. Synergistic, flavor enhancer for citrus and other fruits
Cyclamate (q.v.)	30–50		Approved by SCF[c] and JECFA. A petition for the reapproval of cyclamate is under review by the US FDA	11 (JECFA); 7 (SCF)	Good shelf-life; synergistic; economic
Neotane	7000–13 000	Slow degradation at very low pH	Approved by FDA and ANZA[e]	6	High quality sweetness, flavor enhancer, excellent stability
NHDC	400–600	At high concentrations, exhibits a long-lasting sweetness associated with a menthol- or licorice-like aftertaste	Approved by SCF[c]. Approval for food use in countries outside the European Union has been granted or is being sought	0–5 (SCF)	Obtained from bitter flavonoids in orange peels. Remarkable synergy with acesulfame and aspartame. Flavor enhancer, bitter taste inhibitor
Saccharin (q.v.)	300–500	Metallic aftertaste	Approved by SCF[c] and JECFA[d]. Approved in more than 90 countries world-wide	5 (JECFA, SCF)	The first calorie-free sweetener discovered in 1879
Stevioside	100–150	Licorice aftertaste	*Stevia* extracts are approved for food use in several South American and Asian countries, but lack approval in Europe and North America and at the international level	Not determined	Extracted from the leaves of the *Stevia rebaudiana* plant
Sucralose	600	Sucralose can hydrolyze slowly in solution, under extreme conditions of acidity and temperature	Sucralose is currently approved for use in foodstuffs in more than 35 countries, including the USA and Japan	0–15	High-quality sweetness, good water solubility and excellent stability in a wide range of processed foods and beverages
Thaumatin	2000–3000	Delayed perception of sweetness; perception lasts a long time leaving a licorice-like aftertaste at high usage levels	Approved as a sweetener by SCF[c] and JECFA[d]. Approved as a flavor enhancer in Europe. Classified as generally recognized as safe by the FDA in the USA	Not specified (JECFA)	A mixture of three proteins of molecular weight 22 000, extracted from the fruit of West African plant *Thaumatococcus daniellii*

[a]RS, relative sweetness with respect to sucrose. This value is determined by a sensory analysis of aqueous solutions of sucrose (usually at 3, 5, or 10% by weight) taken as standard references compared with solutions of the sweetener at different known concentrations.
[b]ADI, acceptable daily intake. The ADI is the amount of a food additive, expressed on a body-weight basis, that can be consumed in the diet every day throughout life without any appreciable health risks. It is in fact a safe intake level.
[c]SCF, the Scientific Committee for Food of the European Commission. Reference legislation is contained in the *European Parliament and Council Directive 94/35/EC of 30 June 1994 on sweeteners for use in foodstuffs*.
[d]JECFA, the Joint Expert Committee on Food Additives of the FAO/WHO.
[e]ANZA, Food Standards Australia New Zealand.

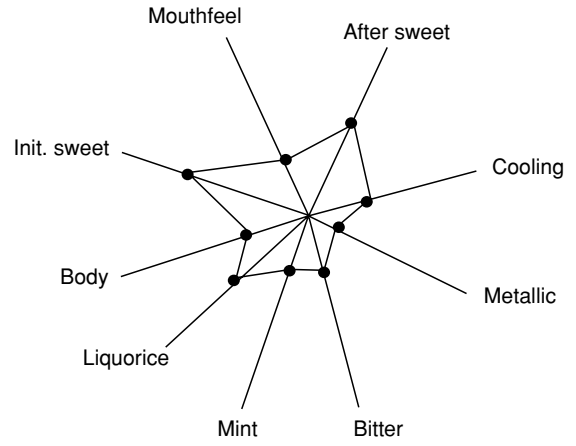

Figure 1 A 'spider web' representation of some perceptual characteristics of an intensive sweetener as determined by the sensory analysis.

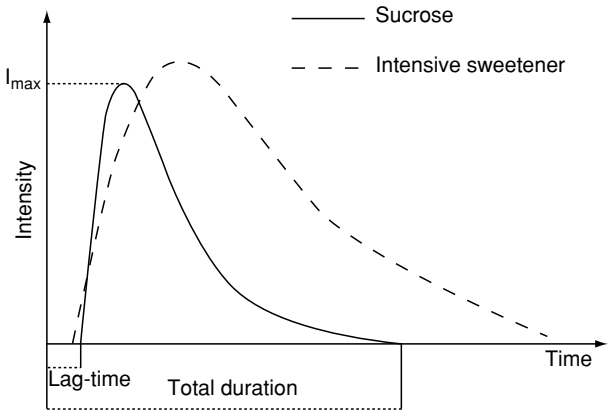

Figure 2 Schematic time–intensity profiles of sucrose and of an intensive sweetener.

Synergy

Many sweeteners show a synergistic effect when used in mixtures, i.e., the taste intensity of the mixture is higher than the sum of the intensities of the single components. This phenomenon is of practical importance, since it offers several advantages. First, the use of mixtures of intensive sweeteners helps in approaching the optimal sucrose taste, which can be mimicked by varying the components' concentrations in order to approach the desired time–intensity profile of the mixture. Sweetener mixtures can also have lower costs, especially if synergy is at play, resulting in a lower daily consumption of the individual additives in food. Manufacturers can overcome the limitations of individual sweeteners by using them in blends; mixtures of saccharin and cyclamate have been used in a number of commercial products.

Table 1 and Figure 3 provide details and structures, respectively, of the intensive sweeteners currently used in many countries.

Acesulfame K

Discovered in 1967 by Hoechst, acesulfame K is structurally related to saccharin. When used in high concentrations above normal use, it may have a slight aftertaste.

Applications Acesulfame K has a good shelf-life and is very stable with normal preparation and processing of foods; it is heat-resistant and therefore suitable for cooking and baking.

Safety Acesulfame K is not metabolized by the body and is excreted by the kidneys unchanged. A large number of safety studies have been conducted, and no adverse effects have been reported.

Status Acesulfame K has been approved for a variety of uses in more than 90 countries. In 1998, the FDA broadened the US approval of acesulfame K to allow its use in nonalcoholic beverages.

Alitame

Discovered by Pfizer Inc., alitame is a high-intensity sweetener formed from the amino acids L-aspartic acid and D-alanine, and an amine derived from thietane. The aspartic acid component is metabolized normally, and alanine amide is not hydrolyzed any further.

Applications Alitame has the potential to be used in almost all areas where sweeteners are presently used. It has an excellent stability at high temperatures, and so it can be used in cooking and baking. During long-term storage, some soft drinks sweetened with alitame can develop an off-taste.

Safety Extensive animal and human studies have supported the safety of alitame.

Status Alitame has been approved for use in a range of foods and beverages in Australia, Chile, Columbia, Indonesia, New Zealand, Mexico, and the People's Republic of China. Approval is also being sought (2000) in the USA, UK, Canada, Brazil, Europe, and other countries.

Aspartame (q.v.)

Aspartame, discovered by Nutrasweet in 1965, is the most commonly used intensive sweetener of the new generation. The compound is made by coupling two

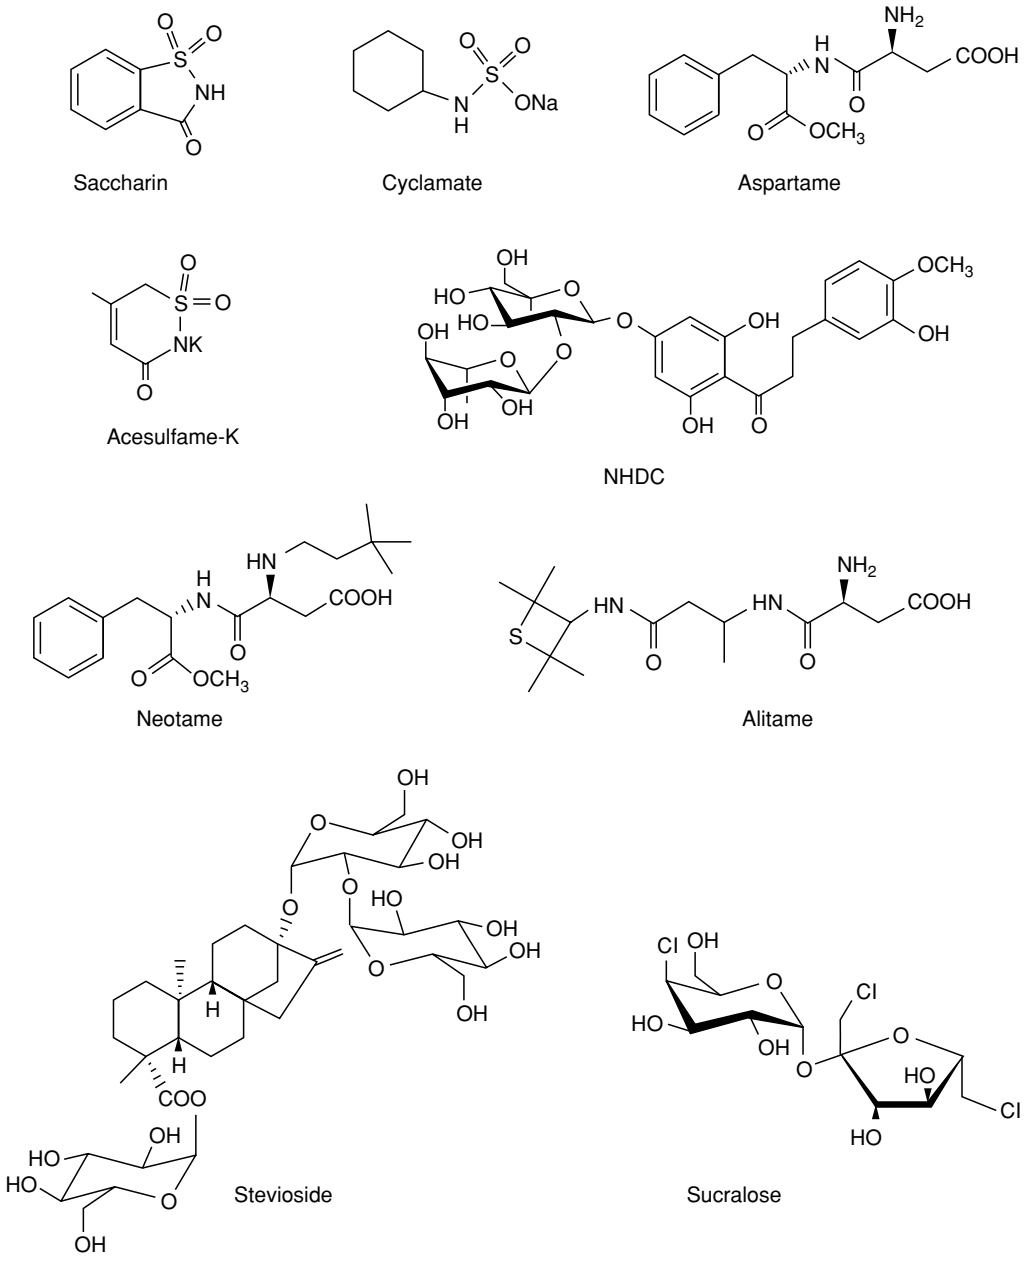

Figure 3 Structure of the most common sweeteners.

essential amino acids, aspartic acid and phenylalanine, found naturally in most protein-containing foods, including meats, dairy products, and vegetables. Upon digestion, aspartame breaks down to phenylalanine, aspartic acid, and a small amount of methanol, this last in levels that are insignificant compared with those of many natural foods. Aspartame enhances and intensifies flavors, particularly citrus and other fruits.

Applications Aspartame is used to sweeten a variety of foods and beverages, and as a table-top sweetener. It is currently used in well-known brands of a great variety of foods and drinks.

Safety Aspartame is one of the most thoroughly tested food ingredients. Aspartame is safe and approved for people with diabetes, pregnant and nursing women, and children.

Status Aspartame has been approved in more than 90 countries and is widely used throughout Eastern and Western Europe, the USA, Canada, South America, Australia, and Japan.

Cyclamate (q.v.)

Cyclamate was discovered in 1937. It is metabolized to a limited extent in the gut by some individuals, shows limited absorption by the body, is excreted unchanged by the kidneys, is stable at high and low temperatures, has a good shelf-life and pleasant taste profile, and is suitable for cooking and baking.

Applications Cyclamate, particularly in combination with one or more other low-calorie sweeteners, has a wide range of applications in foods and beverages.

Safety The SCF confirmed the safety of cyclamate in 1994, as did the Cancer Assessment Committee of the FDA in 1984 and the US National Academy of Sciences in 1985.

Status Cyclamate has been approved in more than 50 countries world-wide. A petition for the reapproval of cyclamate is still (as at July 2001) held in abeyance by the FDA.

Neohesperidinedihydrochalcone (NHDC)

NHDC is a low-calorie sweetener and flavor enhancer that can be produced by hydrogenation of neohesperidine, a flavonoid occurring naturally in bitter oranges. At high concentrations, NHDC exhibits a long-lasting sweetness associated with a menthol- or licorice-like aftertaste. NHDC is not absorbed to any significant extent, but it is metabolized by the intestinal flora, yielding the same or similar breakdown products to its naturally occurring analogs.

Applications NHDC is typically used in combination with other sweeteners, with remarkable synergistic effects. Even at very low concentrations (5 p.p.m.), NHDC can still improve the overall flavor profile and mouth feel of certain foods, acting as a flavor enhancer and modifier rather than as a sweetener. It also has bitterness-reducing properties. NHDC is stable in solid form and in aqueous solutions of pH 1–7. It is heat-stable and therefore can be used in foods requiring pasteurization or UHT processes.

Status NHDC is a permitted sweetener in Europe. Approval for food use outside the European Union has been granted, or is being sought.

Neotame

It is a derivative of a dipeptide, structurally related to aspartame. Its relative sweetness is much higher, being 7000–13 000 times that of sucrose and c.40 times that of aspartame. Neotame has been developed by Monsanto.

Applications Neotame can be used across many food categories, including beverages, dairy products, frozen desserts, baked goods, and gums. It also has flavor-enhancing properties, especially for mint.

Status In July, 2002, FDA approved neotame for use as a general-purpose sweetener. Its use is also permitted in Australia and New Zealand.

Saccharin (q.v.)

Discovered in 1879, saccharin has been used commercially to sweeten foods and beverages since the turn of the twentieth century. It is absorbed slowly, not metabolized, rapidly excreted unchanged by the kidneys, highly stable with a long shelf-life, suitable for cooking and baking, does not promote tooth decay, and is suitable for diabetics.

Applications Saccharin has the widest range of applications and is used in a great variety of foods.

Safety Saccharin has a history of a century of safe human use and is probably the most thoroughly researched of all food additives. Its safety was questioned in a 1977 Canadian study that found bladder tumors in male rats, albeit given unrealistically high doses. All scientific research conducted since then has shown that this effect is only seen in male rats at extremely high doses and has supported the safety of saccharin for human use at the levels currently consumed. Several human studies have shown no overall association between saccharin consumption and cancer incidence.

Status Saccharin has been approved in more than 90 countries. In the USA, the FDA proposed a ban on saccharin in 1977, on the basis of the aforementioned high-dose rat studies. The proposed ban was formally withdrawn in 1991, but saccharin and foods and drinks containing saccharin were still required to carry a warning label. In 2000, legislation gave saccharin a clean bill of health and removed the label.

Stevioside

Stevioside is extracted from the leaves of *Stevia rebaudiana* Bertoni, a plant growing in South America and several Asian countries. Stevioside is a glycoside consisting of the aglycone steviol (ent-13-hydroxykaur-16-en-19-oic acid) and three glucose molecules. The sweetness of stevioside is accompanied by a licorice-like aftertaste.

Applications Leaves of the stevia plant have been used for centuries in Brazil and Paraguay to sweeten

foods and beverages. Stevioside can be used in soft drinks, Japanese-style vegetable products, table-top sweeteners, confectionery, fruit products and seafood, and in some countries as stevioside-rich *Stevia* extracts.

Safety and status Stevia extracts have been approved for food use in several South American and Asian countries but lack approval in Europe and North America and on an international level. Safety studies on stevioside and *Stevia rebaudiana* have not been accepted internationally, owing to the lack of generally accepted specifications. In 1999, the SCF reiterated the opinion that "stevioside is not acceptable as a sweetener on the presently available data." The JECFA reviewed stevioside in 1998 but could not quantify an acceptable daily intake (ADI) because of inadequate data on the composition and safety of stevioside. In 2000, the European Commission refused a request for marketing authorization for *Stevia rebaudiana* plants and dried leaves. Stevioside, as a sweetener, is not permitted in the USA and may not be used or marketed in Europe.

Sucralose

Sucralose is the common name for 4,1′,6′-trichlorogalactosucrose, a high-intensity sweetener derived from ordinary sugar, developed jointly by McNeil Specialty Products and Tate & Lyle. Sucralose is not metabolized.

Applications Sucralose has a high-quality sweetness, good water solubility, and excellent stability in a wide range of processed foods and beverages. Like sugar, sucralose hydrolyzes in solution, but only over an extended period of time under extreme conditions of acidity and temperature.

Safety Extensive studies have shown that it is safe for human consumption.

Status Sucralose is currently approved for use in foodstuffs in more than 35 countries.

Thaumatin

Thaumatin is a low-calorie protein sweetener and flavor modifier extracted from Katemfe, the fruit of the West African plant *Thaumatococcus daniellii*, and is totally natural with an intense sweetness. A limitation of thaumatin is its delayed perception of sweetness, but perception lasts a long time, leaving a licorice-like aftertaste at high usage levels. It is metabolized by the body like any other dietary protein.

Applications Thaumatin is stable in freeze-dried form and is soluble in water and aqueous alcohol. It is heat- and pH-stable and synergistic when combined with other low-calorie sweeteners. Thaumatin has a wide range of applications in food and drinks and is particularly effective for its flavoring properties and because it adds mouth feel.

Safety A large number of animal and human studies have been conducted, showing no adverse reactions. Thaumatin is classified as generally recognized as safe by the FDA. The JECFA gave thaumatin an ADI of 'not specified.'

Status Thaumatin is a permitted sweetener and has been approved in all applications in the European Community as a 'flavor preparation.' Similar approval exists in Switzerland, the USA, Canada, Israel, Mexico, Japan, Hong Kong, Korea, Taiwan, Vietnam, Australia, New Zealand, and South Africa, and further approval is being sought elsewhere.

Uses

Food Intensive sweeteners have several practical applications. Their main use is in food, where they are used as additives in several products: table-top sweeteners, carbonated beverages (soft drinks), noncarbonated beverages (e.g., coffee drinks, alcoholic drinks, cider, juices, fruit nectars, shakes, ice tea, instant beverages), dairy products (yogurt, icecream), desserts (puddings, jellies, gelatins, flans), marmalade and jams, chocolate, fruit preserves, fruit spreads, baked goods (confectionery, biscuits, breakfast cereals), chewing gum, pickled vegetables, marinated fish, savories, sauces, and salad dressings.

They are also used in the preparation of dietetic products or functional foods such as vitamin- and mineral-fortified products, sport drinks, and low-fat products.

Pharmaceuticals and dental decay prevention In pharmaceuticals, sweeteners are used as additives in drugs for oral administration, especially to mask the bitter or unpleasant taste of certain active ingredients. They are widely used in the preparation of toothpaste and mouthwash, for improving taste and preventing dental decay. In fact, dental caries is the result of the interaction of sucrose or other carbohydrates with oral bacteria, leading primarily to dental plaque formation and secondarily to tooth decay, as a result of the alterations of dentin caused by acidic fermentation end products and inflammatory processes induced by bacterial toxins.

The potentiality of alternative sweeteners to reduce dental caries has attracted much interest and many

studies. All the intensive sweeteners and sugar alcohols (q.v.), such as xylitol, sorbitol, and mannitol, are noncariogenic, since they are not fermented by oral bacteria.

Economics

The world market for sweeteners has tended to increase broadly in line with the world economy. The average growth rate in the 1990s was around 2%. The world consumption of intensive sweeteners reached 12 million tonnes of sugar equivalents in 1997, with a share of the total sweeteners market of *c*. 9%. Asia accounts for 50–55% of the total, with the rest being shared almost equally between the Americas and Europe. More than 70% of the market by quantity (sugar equivalents) is represented by saccharin, aspartame having 18% and cyclamates 5%, whereas if the consumption is measured by value, aspartame accounts for 62%, saccharin 17%, cyclamates 5%, and others 16%. The high share of saccharin is due to its cheapness, making it suitable for use in many applications where only a generic sweetener is required, and for nonfood use, such as pharmaceuticals, animal feed, and toothpaste. Another reason is its stability under a wide variety of conditions, together with a high-quality sweetness. All this explains why it has a high share (90% or more) of the Asian market, whereas aspartame is mostly used in North America, followed by Europe. As for other, recently introduced, intensive sweeteners, the use of acesulfame-K is increasing, especially in blends for soft drinks, whereas the natural compound stevioside is mostly used in Asia.

Bulk Sweeteners

In sweet foods, sucrose provides not only sweetness but also, in many cases, structure, weight, and volume. This 'bulk' effect must be maintained in sugarless products to insure that those properties make the product acceptable to the consumer and to maximize the shelf-life. Moreover, the substitution of sugar must minimize the changes in the technological processes of production. In products where this bulk effect cannot be provided only by water (drinks) or partially by air (e.g., in icecreams), such as confectionery, chocolates, hard and soft candies, jellies, chewing gums, dragées, and jams, the so-called bulk sweeteners can be used. The most important of these are glucose, fructose, lactose, galactose, maltose (q.v.), and sugar alcohols (q.v.), these last obtained by hydrogenation of carbohydrates. They should have a relative sweetness and rheological properties at least as good as that of sugar. (*See* **Sugar Alcohols**.)

Background

Sweetness is one of the most important taste sensations for humans. Sucrose has been widely used for its

sweetness, functional properties such as texture and mouth feel, and as a bulking agent and preservative. However, the special dietary needs of diabetics and the health concerns about obesity and dental caries have prompted considerable efforts for the development of alternative sweeteners.

Sweeteners are widely used in the food, beverage, confectionery, and pharmaceutical industries throughout the world. Because of high consumer demand and acceptance of low-calorie products, the market of artificially sweetened foods has increased significantly and will continue to grow.

Sweeteners can be classified into two categories, bulk and intense. The bulk sweeteners are used as sweeteners and as bulking agents and can have a preservative and bodying effect. They are metabolized by the body and provide calories and include glucose, fructose, maltose, hydrolyzed products from starch and sugar alcohols. They vary in sweetness over a narrow range, from 0.3 to 1.2 times the sweetness of sucrose. Bulk sweeteners are permitted in a number of specified foodstuffs at *quantum satis* – as much as needed.

The intense sweeteners have a sweet taste but are effectively noncaloric. They can be natural or synthetic compounds, and they are intensely sweet, ranging from 30 to 3000 times the sweetness of sucrose, so the concentrations used for normal sweetness are very low. This category includes saccharin, cyclamate, acesulfame-K, aspartame, alitame, dulcin, sucralose, neohesperidin dihydrochalcone, glycyrrhizin, stevia sweeteners, and thaumatin. The first four compounds are the main sweeteners consumed and are presented in other sections. Dulcin (4-ethoxyphenylurea, $C_9H_{12}N_2O_2$, MW 180.20) was synthesized by Berlinblau in 1884. It is 70–350 times sweeter than sucrose. However, it should not be used as a food additive, since it has been reported to cause cancer in laboratory animals. The purpose of this chapter is to provide general information on the other intense sweeteners.

The sweeteners have different chemical structures (Figures 1–5) and, therefore, diverse properties (Table 1). Maximum levels have been established for intense sweeteners in different food categories, depending on the legislation in a particular country.

Alitame

Alitame [L-α-aspartyl-*N*-(2,2,4,4-tetramethyl-3-thioethanyl)-D-alaninamide] is an amino acid-based sweetener (Figure 1) developed by Pfizer Central Research from L-aspartic acid, D-alanine, and 2,2,4,4-tetraethylthioethanyl amine. A terminal amide group instead of the methyl ester constituent of aspartame was used to improve the hydrolytic stability. The incorporation of D-alanine as a second amino acid in place of L-phenylalanine has resulted in optimum sweetness. The increased steric and lipophilic bulk on a small ring with a sulfur derivative has provided a very sweet product and good taste qualities.

The formula of alitame is $C_{14}H_{25}O_4N_3S$, with a molecular weight of 331.06. It is produced under the brand name Aclame®. It is a crystalline, odorless, and nonhygroscopic powder, with a good solubility in most polar solvents such as water (130 g l^{-1} at pH 5.6) and alcohol (Table 1). Alitame is 2000 times sweeter than sucrose, 12 times sweeter than aspartame and six times sweeter than saccharin. It has a

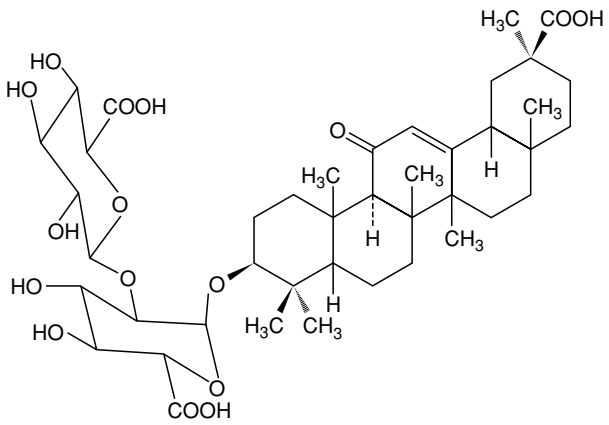

Figure 4 Chemical structure of glycyrrhizin.

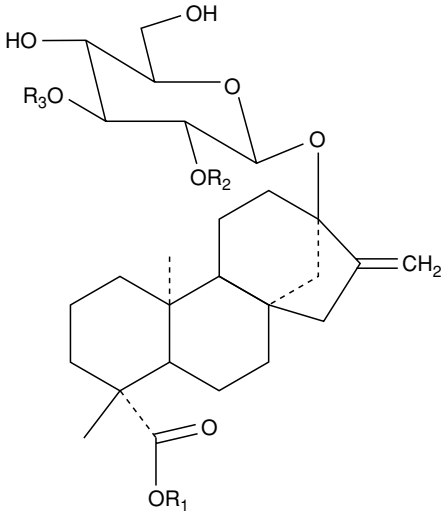

Figure 5 Chemical structure of the sweet glycoside of *Stevia rebaudiana* Bert.

clean sweet taste with no unpleasant aftertaste. It is blended with other sweeteners such as, saccharin, cyclamate, and acesulfame-K to maximize the quality of sweetness.

Alitame offers several benefits such as stability at high temperatures and a broader pH range. For instance, it is stable for over a year at pH 6–8 and room temperature and withstands pasteurization. However, prolonged storage of acidic solutions at high temperatures or in combination with certain ingredients (hydrogen peroxide or sodium bisulfite) may produce off-flavors. In the presence of high levels of reducing sugars, alitame can undergo Maillard reactions.

Alitame is noncariogenic. From an oral intake, 7–22% is unabsorbed and excreted in the feces. The remainder is hydrolyzed to aspartic acid and alanine amide. The aspartic acid is normally metabolized, and the alanine amide is excreted in the urine as a sulfoxide isomer, sulfone, or conjugated with glucuronic acid. The incomplete absorption and metabolism result in a core value of 1.4 kcal g^{-1}.

The Joint Expert Committee on Food Additives (JECFA) concluded that alitame was not carcinogenic and did not show reproductive toxicity. In 1996, an acceptable daily intake (ADI) of 0–1 mg per kilogram of body weight was allocated. It is approved for use in Australia, New Zealand, Mexico, and China. A food additive petition was submitted to the US Food and Drug Administration (FDA) in 1986, and approval is awaited. In the petition, the estimated daily intake is 0.34 mg per kilogram of body weight, which represents the amount if alitame is the only sweetener in the diet. The level at which no observed adverse effects occur in animals is 100 mg kg^{-1}. Potential uses include baked goods, baking mixes, hot and cold beverages, dry beverage mixes, table-top sweeteners, chewing gum, candies, frozen desserts, and pharmaceuticals.

Sucralose

Sucralose, 1,6-dichloro-1, 6-dideoxy-β-D-fructofuranosyl 4-chloro-4-deoxy-α-D-galacto-pyranoside or 4,1′,6′-trichloro-4,1′,6′-trideoxy-*galacto*-sucrose (Figure 2), is a chlorinated derivative of sucrose, discovered in 1976 by carbohydrate research chemists at Queen Elizabeth College and Tate and Lyle, UK. It is derived from a patented multistep process, involving selective chlorination of sugar at the 4, 1′, and 6′ positions substituting three hydroxyl groups on the sucrose molecule. It is the result of a study on a large number of related compounds, carefully synthesized and evaluated to determine the spatial structure and molecular configuration required for sweetness perception.

Ingredients and tabletop forms of sucralose are being marketed under the brand name Splenda®. Its chemical formula is $C_{12}H_{19}O_8Cl_3$ (MW 397.35). Sucralose is a white, odorless crystalline powder and is readily dispersible and soluble in water, methanol, and ethanol. At 20 °C, a 280 g l^{-1} solution of sucralose in water is possible. Sucralose presents Newtonian viscosity characteristics, a negligible lowering of surface tension, and no pH effects, and its solubility increases with increasing temperature. In ethanol, the solubility ranges from approximately 110 g l^{-1} at 20 °C to 220 g l^{-1} at 60 °C, and its solubility in ethanol facilitates in formulating alcoholic beverages and flavor systems.

Table 1 Properties of some intense sweeteners

Sweetener (INS)[a]	*Sweetness*[b]	*Sweetness characteristics*	*Synergism*[c]	*Solubility in water*	*Stability*		*ADI*[d] *(mg per kilogram of body weight)*
					In solution	*During heating*	
Alitame	2000	Clean, no unpleasant aftertaste	sac, cyc, aces	Good, 130 g l^{-1}, pH 5.6	Good, pH 6–8	Very good	0–1 (1996)
Sucralose (955)	400–800	slow onset, clean sweet sugar-like, prolonged sweetness	cyc, aces, nhdc	Good, 280 g l^{-1}, 20 °C	Good, pH > 3, loss of sweetness, pH < 3	Very good	0–15 (1990)
Neohesperidin dihydrochalcon (959)	250–2000	delayed onset, lingering licorice–menthol-like aftertaste	sac, asp, aces, cyc, sucral, sugar alcohols	Low, 0.5 g l^{-1}, 20 °C, 650 g l^{-1}, 80 °C	Stable, pH 2–6	Good	Not evaluated by JECFA, 0–5 (1987–SCF[d], EC)
Glycyrrhizin (958)	50–100	Slow onset, long aftertaste, licorice flavor	stev, thau, asp	Good	Stable, pH > 4.5	Good	Not evaluated by JECFA
Stevioside	100–300	Slow onset, menthol at high levels, bitter	asp, cyc, aces, glyc	Low, 0.8 g l^{-1}	Stable, pH 3–10	Good	Not evaluated by JECFA
Thaumatin–Talin (957)	2000–3000	Slow onset, persistent, licorice-like	sac, aces, asp, cyc, stev, glyc	Good, 600 g l^{-1}	Stable, pH 2.7–6.0	Stable, neutral to low pH	Not specified (1985)

Sucralose is 400–800 times sweeter than sucrose (Table 1). Although its sweetness varies with pH, sucralose has a clean sugar-like taste and a time–intensity profile like that of sucrose, albeit more persistent. It has an excellent taste profile and no bitter or objectionable aftertaste. It is a flavor enhancer and shows sweetness synergism with cyclamate, acesulfame-K, and neohesperidin dihydrochalcone.

Sucralose offers a broad pH, aqueous, thermal processing, and shelf stability. It does not interact with food ingredients and is stable in the dry form (4 years at 20 °C). It withstands high temperatures, thus making it well suited for use in pasteurized, aseptic processing, sterilized, cooked, and baked foods. However, under extreme conditions of pH, temperature, and time, sucralose may be hydrolyzed, producing 4-chloro-deoxy-D-galactose and 1,6-dideoxy-1,6-dichloro-D-fructose, or degraded with elimination of hydrogen chloride in basic medium.

Sucralose is noncariogenic. It resists hydrolysis in the human digestive tract, being excreted unchanged in the feces, and the very small portion absorbed is rapidly eliminated in the urine. Therefore, it produces no glycemic response and is virtually noncaloric. Following safety testing and toxicological studies in humans and animals, the FDA concluded that sucralose does not pose any carcinogenic, reproductive, or neurological risk. The JECFA reviewed it favorably and in 1990 recommended an ADI of 0–15 mg per kilogram of body weight. Sucralose is approved for use in a wide range of food products in Canada, USA, Australia, Mexico, Russia, Romania, China, the European Union, and Mercosur. It has been used as a table-top sweetener and in carbonated, still, and alcoholic beverages, frozen desserts, confectionery, bakery products, canned fruits and vegetables, fruit spreads, chewing gum, dry-mix products, dairy products, condiments, dressings, and breakfast cereals.

Neohesperidin Dihydrochalcone

Citrus fruits contain bitter flavanone glycosides, all derivatives of the disaccharide 2-*O*-α-L-rhamnopyranosyl-β-D-glucopyranose, neohesperidose. In 1963, Horowitz and Gentili found that catalytic hydrogenation of the chalcone form gave dihydrochalcone neohesperidosides, several of which were intensely sweet. Numerous dihydrochalcone derivatives were synthesized for taste and toxicity trials, from which neohesperidin dihydrochalcone (NHDC) emerged as a promising sweetener. It is prepared by alkaline hydrogenation of the biflavanoid neohesperidin present in Seville (bitter) oranges (*Citrus aurantium*).

NHDC is a semisynthetic nonnutritive intense sweetener. Chemically, it is 1-[4-[[2-*O*-(6-deoxy-α-L-mannopyranosyl)-β-D-glucopyranosyl]oxy]-2,6-dihydroxyphenyl]-3-(3-hydroxy-4-methoxyphenyl)-1-propanone with the molecular formula $C_{28}H_{36}O_{15}$ and a molecular weight of 612.60 (Figure 3). NHDC shows a slow buildup of sweetness, rising from 250 to 2000 times that of a 50 g l^{-1} sucrose solution, but more persistent (Table 1). It has a pleasant taste, flavor-modifying properties, ability to improve the sweetness quality and profile, and remarkable synergistic effects. Its flavor enhancement has been perceived in several products, specially fruit flavors. NHDC has the ability to decrease the perception of bitterness, saltiness, sharp, and spicy attributes. The sweetness intensity of NHDC depends on many factors such as concentration, pH, and the product to which it is added. As the concentration increases, the sweetness of NHDC decreases relative to the level of sucrose. Caffeine significantly enhances the sweetness of NHDC in certain soft drinks. At higher concentrations, NHDC has a lingering menthol or licorice-like aftertaste and a cooling sensation, which distinguishes it from other sweeteners. However, modifications of the sensorial properties of NHDC are possible by the admixture of bulk sweeteners, certain flavors, and other taste-modifying food additives such as gluconates, amino acids, or nucleotides. It also shows synergism with saccharin, aspartame, cyclamate, sucralose, acesulfame-K, and sugar alcohol.

NHDC is a nonhygroscopic colorless crystalline solid. It is sparingly soluble in water (0.50 g l^{-1}) at 20 °C but is highly soluble at 80 °C (650 g l^{-1}). It is also soluble in alcohol and aqueous alkali, but a higher solubility is achieved in ethanol–water mixtures than in water or ethanol alone. Where a higher solubility is required, monobasic salts may be used that are freely soluble in water and exhibit a shorter duration of sweetness than the parent compound. The solubility of NHDC may also be enhanced by dissolving it in glycerol and propylene glycol, as well as by using it in mixtures with readily water-soluble polyols such as sorbitol. Interestingly, these bulk sweeteners also act as taste modifiers of NHDC by reducing its menthol-like aftertaste.

NHDC presents high stability at pH 2–6. It is stable under most food-processing and storage conditions and withstands pasteurization, UHT processes, and the normal shelf-life of soft drinks. It is stable during fermentation of yogurt, but undergoes hydrolysis at high acidity and elevated temperatures, yielding hesperetin dihydrochalcone, hesperetin dihydrochalcone-4′-β-D-glucoside, rhamnose, and glucose.

NHDC is noncariogenic and has a caloric value of 2 kcal g^{-1}. Little of the compound is absorbed

unchanged from the small intestine. After cleavage of the glycosidic side-chain by intestinal mucosal or bacterial glycosidases, the residual primary metabolites are partly excreted unchanged in the bile and partly metabolized further. Standard toxicity tests have suggested its safety. In 1987, the Scientific Committee for Food of the Commission of the European Communities allocated an ADI of 0–5 mg per kilogram of body weight. It is currently approved for use in the European Communities, Sweden, Switzerland, Morocco, and Tunisia.

Owing to its highly intense and long-lasting sweetness, NHDC is normally used at concentrations of less than 100 mg kg^{-1}. Only in chewing gum are higher levels required because of its slow release from the gum base. For use in soft drinks, NHDC has been recommended in combination with other sweeteners at a concentration of 20 mg kg^{-1}. Owing to its ability to reduce bitterness and to its flavor enhancing properties, NHDC is an ideal sweetener for grapefruit or orange juice. Promising results have been reported from its use in fruit-flavored yogurts. In table-top products, the addition of small amounts of NHDC may result in significant savings because of its synergistic, sweetness enhancing effect. It has been used in juice, soft drinks, dairy products, desserts, confectionery, spreads, jams, chewing gum, chocolate based products, and icecream.

Glycyrrhizin

Glycyrrhizin is found in licorice root of a small leguminous shrub, *Glycyrrhiza glabra* L. from Europe and Central Asia. Glycyrrhizin or 20-β-carboxy-11-oxo-30-norolean-12-en-3β-yl-2-*O*-β-D-glucopyranurosyl-α-D-glucopyranosiduronic acid ($C_{42}H_{62}O_{16}$, MW 822.92), is a triterpenoide glycoside (saponin) with glycyrrhetinic acid, which is condensed with *O*-β-D-glucuronosyl-(1′→2)-β-D-glucuronic acid (Figure 4). After harvest, the roots are dried to 10% moisture, shredded, extracted with aqueous ammonia, concentrated in vacuum evaporators, precipitated with sulfuric acid, and crystallized with 95% alcohol providing a crude ammonium glycyrrhizin (AG). Further treatment yields a white, crystalline mono-ammonium glycyrrhizin (MAG). Both derivatives have the same sweetness but differ in solubility and sensitivity to pH. AG is relatively stable and highly soluble in hot or cold water and in alcohol. It withstands temperatures above 105 °C for a short period of time, and precipitates at pH values below 4.5. MAG is used in applications where low pH and color rule out AG.

Glycyrrhizin is 50–100 times sweeter than sucrose and has a slow onset of sweetness followed by a lingering licorice-like aftertaste (Table 1). It exhibits a sweet woody flavor, which limits its use as a pure sweetener. Glycyrrhizin enhances food flavors, masks bitter flavors, and increases the perceived sweetness level of sucrose. It has the potential for providing functional characteristics, including foaming, viscosity control, gel formation, and possibly antioxidant characteristics.

Studies have focused on the pharmacological effects of glycyrrhizin as antiulcer, antiinflammatory, antiviral, anticariogenic, and antispasmodic. It also has corticoid activity, influencing steroid metabolism to maintain blood pressure and volume and to regulate glucose/glycogen balance. Glycyrrhizin can be hydrolyzed by human intestinal microflora to 18-β-glycyrrhetinic acid and two molecules of glucuronic acid. After release of the acids, the compound binds to plasma protein, enters the enterohepatic circulation, and is almost completely metabolized. However, side-effects, typically involving cardiac dysfunction, edema, and hypertension have been reported among subjects receiving high doses of glycyrrhizin-based pharmaceuticals or consuming large amounts of licorice-containing confectionery or health products over a prolonged period.

The ammonium salt of glycyrrhizin is approved as a flavoring and flavor enhancer in the USA. It is on the FDA 'generally recognized as safe' (GRAS) list. The use of glycyrrhizin is permitted in Japan and Taiwan. In Japan, it is used as a flavoring for hydrolyzed vegetable protein, soy sauce, and bean paste to control saltiness. At levels of 30–300 mg kg^{-1}, it enhances the flavor of cocoa and chocolate-flavored products, flavors and sweetens candy, confectionery, and beverages, and masks the bitter taste of pharmaceuticals. Because of its pharmacological action, it should be used in moderate amounts as a sweetener.

Stevia Sweeteners

Stevia rebaudiana Bertoni (Compositae) is a herb native to Paraguay but cultivated in South-east Asia, Japan, Paraguay, Brazil, Israel, and USA. Stevia sweeteners are extracted from the dried leaves, clarified and crystallized. The sweet constituents of stevia include eight diterpene glycosides: stevioside, steviolbioside, rebaudiosides A, B, C, D, and E, and dulcoside A, which collectively are 100–300 times sweeter than sucrose. They are similar in structure in that a steviol aglycon is connected at C-4 and C-13 to mono-, di-, or trisaccharides consisting of glucose and/or rhamnose residues, as shown in Figure 5. Stevioside is the major constituent, whereas dulcoside A and rebaudiosides A and C are the other main components. Stevioside is 300 times sweeter than

sucrose (Table 1). It shows a sweetness profile similar to that of sucrose, except that it has an unpleasant, persistent, menthol, and bitter aftertaste. However, the development of new cultivars, derivatization and incorporation of cyclodextrin, L-histidine, potassium phosphate, glucono-δ-lactone and maltose in formulations has eliminated undesirable aftertastes. Rebaudioside A is more stable, sweeter, and has a better taste profile than stevioside. The remaining diterpene glycosides are not as sweet as stevioside.

Stevioside is a white powder, highly soluble in water, ethanol, and methanol, and is nonfermentable. When heated at 100 °C for 1 h, solutions of stevioside at pH 3–9 show little loss in sweetness and no change at 22 °C for 5 months. However, considerable decomposition occurs at pH 10. Some degradation of stevioside and rebaudioside has been observed in carbonated beverages acidified with phosphoric and citric acids during storage at 37 °C. Heating at 60 °C for 6 days has resulted in 0–6% loss of sweetness. Exposure to 1 week of sunlight does not affect stevioside, but results in 20% loss of rebaudioside A. The high stability of stevioside makes it a suitable sweetener for cooked and baked foods and for beverages.

Stevioside suppresses the growth of oral microorganisms, and both stevioside and rebaudioside A provide very few calories. In Paraguay, *S. rebaudiana* is used for the treatment of diabetes because of its hypoglycemic activity. Studies have suggested that stevioside is not toxic, mutagenic, or teratogenic in a number of animal species. In addition, the product has been used for more than 10 years in South America and Japan, but there are contradictory reports on the *in-vivo* metabolism to steviol, which is mutagenic for *Salmonella typhimurium* TM677.

Stevioside is available in three purity ranges: crude extract, and 50% and 90% purity. Since 1970, stevia sweeteners have been used in a wide range of food and beverage applications in Japan, including soft drinks, candies, chocolate, chewing gum, icecream, yogurt, jam, pudding, and table-top sweeteners. It is commonly used in combination with sucrose and fructose and also with other sweeteners such as aspartame, cyclamate, and acesulfame-K, but not with saccharin. It is currently approved for use in Japan, Taiwan, and Mercosur. An acceptable daily intake of stevioside for humans of 7.94 mg per kilogram of body weight has been suggested.

Thaumatin

Thaumatin is a mixture of sweet proteins originally isolated from the fruit of the West African plant katemfe (*Thaumatococcus danielli* Benth.). There are at least five thaumatins, which are obtained by extraction with water, concentration, and ultrafiltration. Tate and Lyle Ltd. manufactures a mixture of two as talin. These are proteins with isoeletric points of 11.5–12.5. Thaumatin consists of a single chain of 207 normal amino acid residues with eight disulfide bonds and has a molecular weight of about 22 000. It is very soluble in water ($600\,g\,l^{-1}$) and is stable at pH 2.7–6.0 and under pasteurization conditions (Table 1). At higher pH values, the protein becomes more heat-labile, despite its stability at pH values up to 8 under ambient conditions. The stability of solubilized thaumatin requires careful monitoring of pH, time, temperature, and other processing parameters. In addition, protection of the protein against yeasts and molds in solutions is also critical for stability. Thaumatin can associate with negatively charged compounds such as synthetic colors and acidic gums like xanthan, pectin, carrageenan, alginate, and carboxymethylcellulose, resulting in a loss of sweetness. Association with synthetic colorants may also cause color loss.

Thaumatin is 1600–3000 times sweeter than sucrose. However, it has unusual taste profile, slow in onset, followed by intensification to lingering sweetness with a licorice-type aftertaste. It masks metallic or bitter tastes. To achieve a taste closer to that of sucrose, thaumatin must be blended with other intense sweeteners or with sugars. Synergism has been observed with saccharin, acesulfame-K, and stevioside, but not with aspartame and cyclamate. By combining thaumatin with alanine and organic acids, there is a doubling in sweetness and a reduction in aftertaste and in the delay in sweetness. At subsweetness levels, thaumatin functions as a flavor enhances. It has the ability to enhance certain flavors and aromas, such as those in peppermint, spearmint, coffee, and ginger. The synergistic effect noted with monosodium glutamate enhances the aroma and improves the flavors of processed meats and fish products when used at levels of $0.5–2.0\,g\,l^{-1}$.

Thaumatin can be metabolized to its constituent amino acids, contributing the same calories as protein. However, because of its high sweetness, it has a low-calorie value per unit of sweetness, less than 0.002 kcal. It is noncariogenic and has undergone safety tests indicating that it is not allergenic, mutagenic, or teratogenic. Furthermore, it has a long history of use without any adverse effects. In 1985, a 'not specified' ADI was allocated by the JECFA. It has been approved for use in Japan, the UK, Australia, Canada, South Africa, Mexico, the European Union, Switzerland, Taiwan, Morocco, and Tunisia. In the USA and Switzerland, it is permitted as a flavor enhancer in chewing gum, and in the USA, it has been classified as GRAS.

The major uses include chewing gum, beverages, coffee, savory flavor, dairy products, dental and pharmaceuticals, animal and pet foods. However, because of its high cost, it is used on a small scale. Biotechnological alternatives to eliminate uncertainties and variability associated with agricultural production and to lower costs are being investigated.

Blends of Sweeteners

Today, there is an increasing tendency to explore the use of blends of sweeteners. When two or more sweeteners are combined, blends with an increased stability, longer shelf-life, lowered production costs, improved taste and flavor, and decreased side- and aftertastes result, as well as a positive impact on taste quality, flavor-enhancing, and flavor-modifying properties. Also, mixtures of sweeteners can exhibit additive and synergistic effects, and since lower amounts of each sweetener can be used, the average daily intake of each sweetener is low, thus minimizing the health risk from any one sweetener.

Since food laws in most countries regulate the use of intense sweeteners, analytical control for the presence and levels of sweeteners in food is essential. According to the JECFA, it is also important to know the level of additives in food products in order to estimate the actual consumption by the population. This information shows the average intake in relation to the ADI over a period of time. Based on this knowledge, regulatory authorities can propose regulations to insure intakes below the ADI. Furthermore, some sweeteners undergo decomposition during processing and storage of food products, forming a variety of degradation products that may have sensory and toxicological significance.

Several types of methods have been described for the analysis of intense sweeteners, among them, spectrophotometric, enzymatic, titrimetric, capillary isotachophoretic, thin-layer chromatography, liquid and gas chromatographic methods. High-performance liquid chromatography (HPLC) is by far the most frequently used technique. However, with the increased number of sweeteners available and their use being approved in specified food products and beverages by different countries, methods capable of separating several sweeteners simultaneously are still required.

SWEETS AND CANDIES

Sugar Confectionery

W P Edwards, Bardfield Consultants, Gt. Bardfield, UK

Background

The confectionery industry is not a science-based industry: it is an industry that has been built on the confectioner's craft. Confectionery is normally divided into three classes: flour confectionery, chocolate confectionery, and sugar confectionery. Flour confectionery covers products that are made from flour and are baked. Chocolate confectionery consists of chocolate. Sugar confectionery covers the rest of confectionery.

Confectionery making does share some technologies with the pharmaceutical industry, specifically tabletting, panning, and lozenge making. Most of the knowledge available to early confectioners was empirical rather than scientific.

Sugar confectionery making is an international industry. Some of the terms in use are clearly French in origin such as fondant (from *fondre* to dissolve), dragees, and pastilles. Unlike chocolate confectionery, sugar confectionery has few legal definitions. In some jurisdictions, caramel has a higher milk content than toffee, but in others, the two terms are used interchangeably. The types of product known as gums were undoubtedly originally made from the gum from *Acacia senegal* but are now made from any suitable ingredient. Because sugar confectionery has a long shelf-life and does not need controlled temperature storage, an international trade in confectionery had developed by the nineteenth century.

In general, the important concepts in sugar confectionery are water activity, colligative properties, solubility, and the need to use a mixture of sugars. Toffees depend on the Maillard reaction. High boilings require a sugar glass to form. Gums, jellies, and licorice need the right rheology. Panned coatings depend on crystallization. Chewing gum is a chewable piece of polymer chemistry. Aerated products are based on stabilizing and setting a foam.

Stability

Sugar confectionery products keep well compared with most food products. The long life of confectionery products occurs because spoilage organisms are unable to multiply rather than because the product is kept sterile.

Water Activity

The relevant parameter is not only the water content but the water activity. Water activity is a thermodynamic concept that was invented to explain why materials with different levels of water content did not behave in the same way chemically or biologically. The water activity reflects the ability of the water to be used in chemical or biological reactions. It is the concentration corrected for the differences in the ability of the water to undertake chemical reactions. If a nonvolatile solute were dissolved in water, the vapor pressure should decrease in a certain way for a perfect mixture. A thermodynamically ideal substance would always have a water activity of 1. If a product is held at its own water activity, it will neither gain nor lose weight.

Equilibrium Relative Humidity (ERH)

This term is normally abbreviated to ERH. The ERH is the relative humidity that matches the water activity of the product. The ERH has practical importance, since it is an indication of the conditions under which the product can be stored without deterioration.

Colligative Properties

Boiling Points

Colligative properties are defined as those properties that depend on the number of particles present rather than the nature of the particles. In sugar confectionery, the most important of these is the elevation of the boiling point. Because sugars are very soluble, very large boiling point elevations are produced, e.g., as large as 50 °C. Remembering that the elevation of the boiling point is proportional to the concentration of the solute, it is not surprising that the boiling point is used as a measure of the concentration and hence as a process control.

The boiling point of a liquid is the temperature at which the vapor pressure is equal to the atmospheric pressure. If the pressure is increased, the boiling point will increase, whereas reducing the pressure will reduce the boiling point. Most sugar confectionery is made by boiling a mixture of sugars to concentrate them. The use of a vacuum has several advantages.

The energy consumption is reduced, browning is reduced, and the process is speeded up. A common practice is to boil a mixture of sugars under atmospheric pressure to a given boiling point. A vacuum is then applied. This causes the mixture to boil under reduced pressure. This not only concentrates the mixture while the latent heat of evaporation cools it rapidly but also speeds up the production process, since the product will ultimately have to be cooled to ambient temperature.

Solubility

Sucrose is insufficiently soluble, at ambient temperatures, to lower the water activity sufficiently to give a microbiologically stable solution. A stable product can only be made by mixing the sucrose with other sugars. The ingredient that is most used as a source of nonsucrose sugars is the starch hydrolysate known variously as glucose syrup or corn syrup. Neither name is entirely accurate as the major ingredient is normally maltose rather than dextrose, but the product can be, and is, manufactured from wheat or potato starch as an alternative to maize starch. The degree of hydrolysis is characterized by the dextrose equivalent (DE), which is a measure of the equivalence of the solids in the syrup to dextrose in the Fehlings titration. The type of syrup normally used is referred to as confectioners' glucose and has a DE of around 40.

In this work to avoid confusion between glucose syrup and chemical dextrose, glucose will only be used to refer to the syrup, and the pure sugar will be referred to as dextrose.

Originally, the starch was hydrolyzed by using acid, which is a random process. Now, hydrolysis can be carried out by enzymes or a mixture of enzymes and acid. Using enzymes, it is possible to control which bonds are broken to allow the composition of the product to be varied as needed. In principle, the starch could be hydrolyzed to produce any combination of dextrose oligomers from dextrose through maltose and maltotriose to higher oligomers.

The proportion of glucose syrup used in different types of sugar confectionery varies for a number of reasons. Commercial pressure would encourage the use of a maximum amount of glucose syrup solids, but technical considerations restrict the proportion to be used. As glucose syrup inhibits crystallization, the highest proportion is used where crystallization is undesirable, e.g., in boiled sweets, and the lowest where crystallization is desirable, e.g., fondant. Figure 1 shows the ratio of sugar to glucose used for different products.

Maillard Reaction

A major feature of sugar confectionery manufacture is ensuring that the Maillard reactions occur where they are wanted in products like toffees and do not occur in products like high boilings.

Maillard reactions are nonenzymic browning reactions. In practice, any browning in foods is a Maillard reaction except where it is enzymic, e.g., the browning of a cut apple is enzymic; hence, it is not a Maillard reaction. The Maillard reaction is not a name reaction where all the details can be found in a text book. The term covers a whole range of reactions that occur in systems ranging from food to life sciences. The name of the reaction goes back to Louis Camille Maillard, who heated amino acids in a solution with high levels of dextrose. The chemistry of the Maillard reaction is easily described as complex. It is complex not only because the reaction can give complex products but because the starting materials are themselves complex. Most model systems involve studies of one reducing sugar being heated

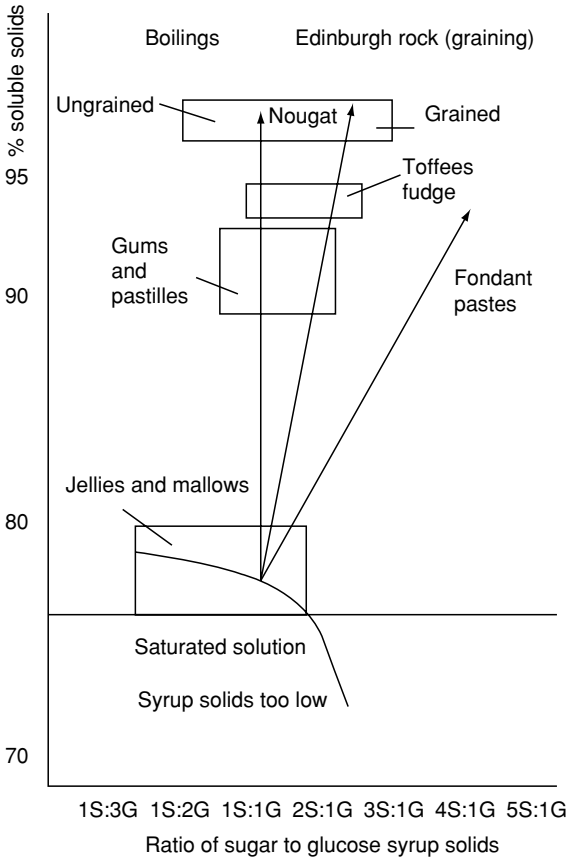

Figure 1 Sugar and glucose composition of confectionery.

with one amino acid. A typical confectionery system like a toffee would involve heating a mixture of proteins, usually from milk with a mixture of reducing sugars and fats. In sugar confectionery, the conditions of the reaction are likely to be a high temperature but a low water activity. In the early stages of the reaction, the free amino group of an amino acid, usually in a protein, condenses with the carbonyl group of a reducing sugar. The resulting Schiff bases can rearrange by Amadori (Figure 2) or Heyns rearrangement (Figure 3), the products being an N-substituted glycosylamine (if dextrose is the sugar) or an N-substituted fructosylamine for a ketose such as fructose. The *N*-glycosylamine can degrade to fission products by a free-radical mechanism. In the advanced stages of the reaction, the Amadori and Heyns rearrangement products degrade by one of three possible routes. They break down via deoxysones, fission, or Strecker degradation (Figures 4 and 5). The 1-deoxyglycosones and 3-deoxyglycosones can form reactive α-dicarbonyl compounds such as pyruvaldehyde and diacetyl by a retro-aldization reaction. These reactive intermediates are then available to react with ammonia and hydrogen sulfide.

At the end of the reaction, brown nitrogenous polymers and copolymers form. It is known that protein gels form when proteins are heated with carbonyl compounds. This could occur in toffees.

Sulfur-containing Amino Acids

Whereas sulfur free amino acids are broken down to amines via decarboxylation, the sulfur containing amino acids such as cysteine can undergo more complex reactions.

Products from Proline

Various schemes have been proposed to explain the production of nitrogen-containing heterocyclic compounds such as pyrrolidines and piperidines from proline. Nitrogen heterocyclic compounds are commonly found to be potent flavoring chemicals.

Strecker Aldehydes

These chemicals are produced by the Strecker degradation of the initial Schiff base (Figure 5). An α-amino carbonyl compound and Strecker aldehyde are generated by rearrangement, decarboxylation, and hydrolysis.

Sugar Glasses: The Chemistry of Boiled Sweets

In these products, which are variously called high boilings, hard boilings, hard candy, or boiled sweets, the sucrose is in the glassy state. The glassy state of matter is not a thermodynamic phase but a super-cooled liquid. Glassy materials are common in a number of products, whereas both natural and

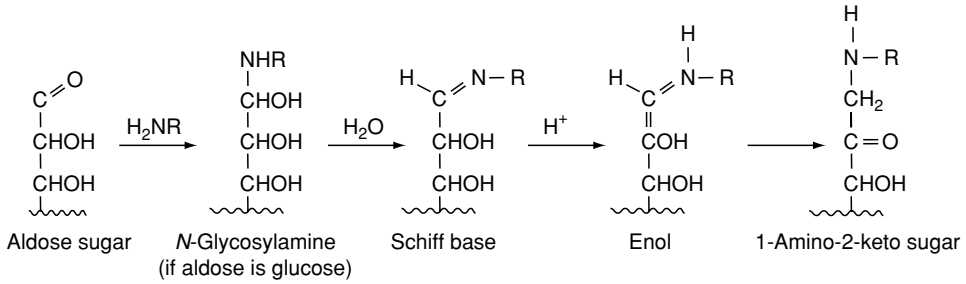

Figure 2 Amadori rearrangement.

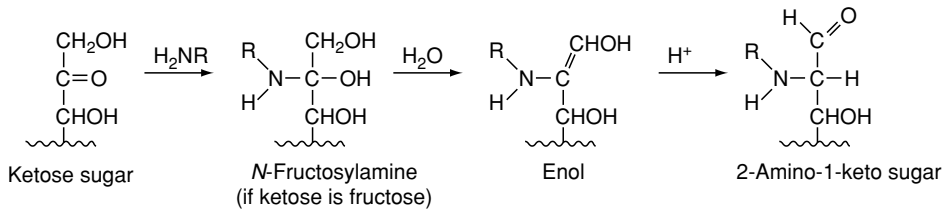

Figure 3 Heyns rearrangement.

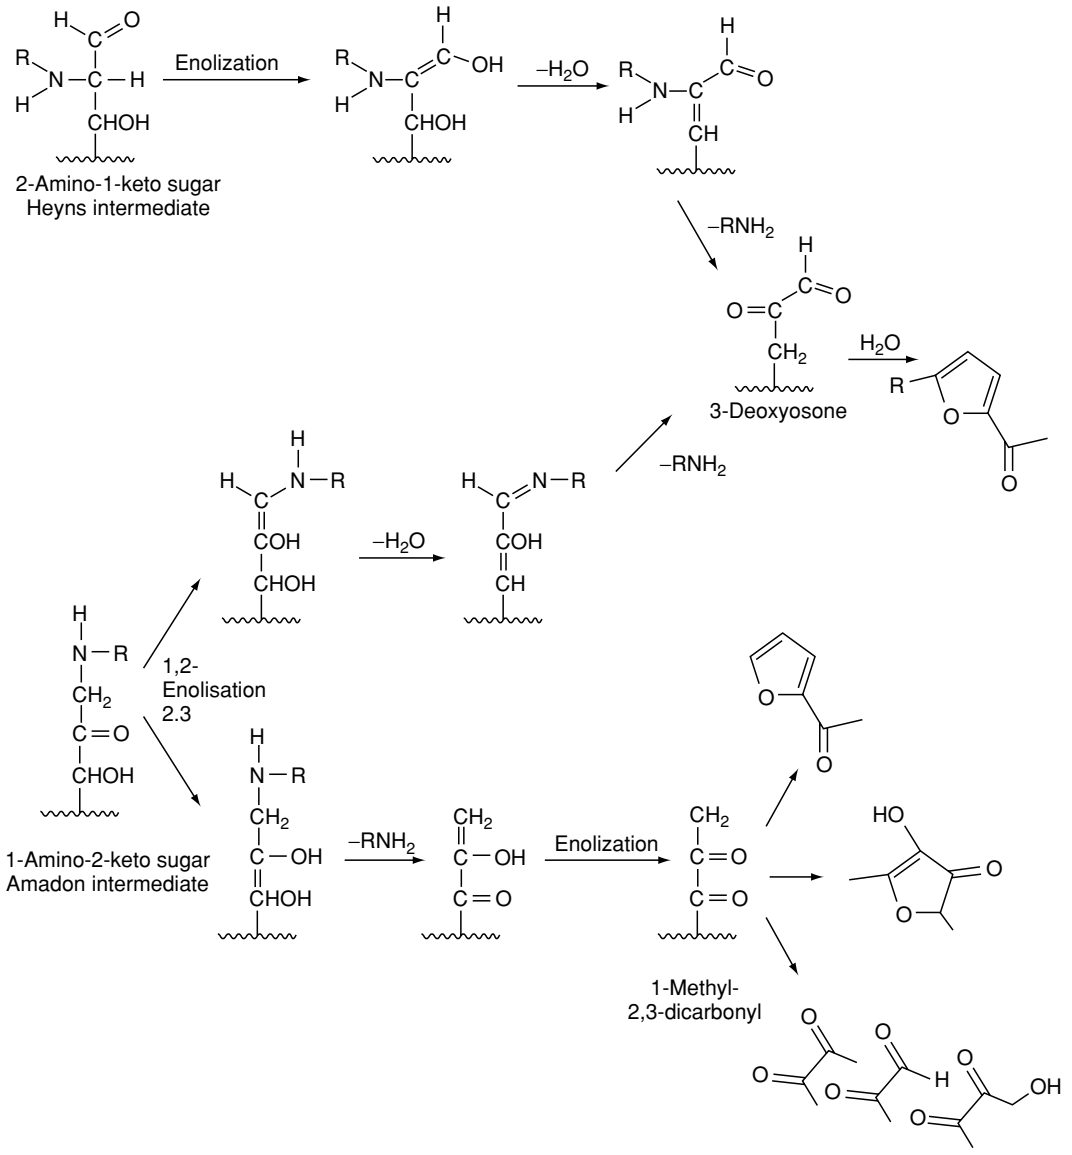

Figure 4 Formation of furans and dicarbonyls.

man-made substances can form glasses. Confusingly, although a glass is not a thermodynamic state of matter, glasses do exhibit a sharp transition temperature between the glassy and the rubbery state. Many methods have been used to determine the transition temperature between the rubbery and the glassy state. One popular method is differential scanning calorimetry (DSC). In these instruments, the sample and a blank are subjected to a change of temperature up or down at a controlled rate. The instrument measures the difference energy input or energy extracted between the sample and the control. A plot of difference gives the variation of heat capacity, C_p, with temperature. The glass transition is associated with a discontinuity in C_p. Unfortunately, there are a number of different ways in which the output from the DSC can be analyzed. Some workers would advocate integrating the result from the DSC, i.e., measuring the area under the curve. This then gives the variation of the enthalpy with temperature. The variation in several other physical parameters with temperature such as the refractive index and the dielectric constant have been used to measure glass transitions. In general, the glass transition temperature obtained depends on the method of measurement. In confectionery, the important point is that a product that is intended not to crystallize should be in the glassy state at ambient temperatures. Most sugars will form a

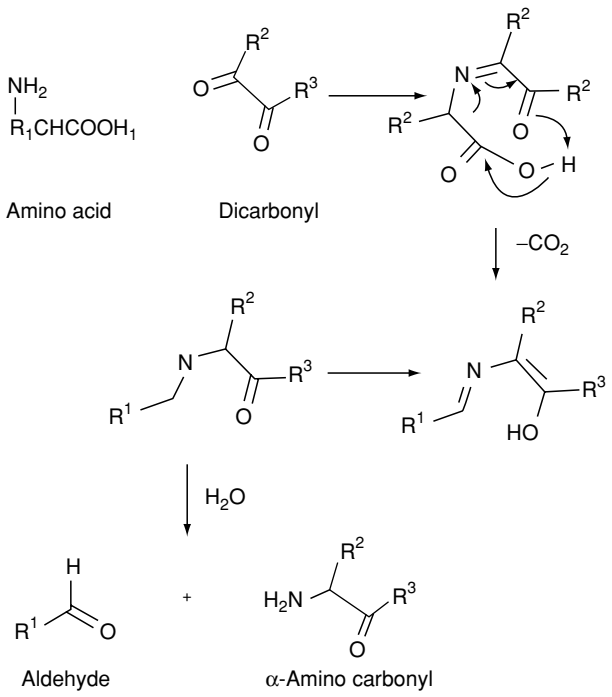

Figure 5 Strecker degradation.

glass, but pure sucrose will not form a glass. Commercial sugar glasses are always made from sucrose and some other sugar. Initially, invert sugar was used but has now been largely replaced by glucose syrup. Glucose syrup is a much better stabilizer of sugar glasses than invert sugar. In practice, boiled sweets become unstable by absorbing water. Initially, the product becomes sticky then soft, followed ultimately by crystallization. The rate at which high boilings can absorb water is diffusion-limited. The high-molecular-weight fraction in glucose syrup inhibits the migration of water into the sweet. This gives a markedly more stable product than invert sugar does. Glucose syrup also gives the boiled mass a plastic consistency when warm, which makes it much easier to handle.

Formulation of Boiled Sweets

The manufacture of stable boiled sweets depends on obtaining a product with a low moisture content. The higher the glass transition temperature, the more stable the product is. As water can be regarded as a plasticizer, it reduces the viscosity of the system and thus reduces the glass transition temperature. The water content of the finished product depends on the cooking temperature. The important parameter at the formulation stage is the ratio of sugar to glucose syrup. The situation to avoid is ending up with a product that is excessively hygroscopic, which will reduce the shelf-life by making the product sticky. Increasing the proportion of glucose syrup increases the proportion of dextrose and the high-molecular-weight dextrose oligomers. Increasing the proportion of dextrose makes the product more hygroscopic, which increases the tendency of the product to become sticky. As the proportion of high-molecular-weight material is increased, the viscosity of the liquid mass increases. These viscosity and hygroscopicity problems restrict the proportion of glucose syrup that can be used. If a conventional acid converted syrup is used, using a different DE only makes one problem or the other worse. Boiled sweets are made with ratios of sucrose to glucose of from 70:30 to 45:55. The common proportions are 60:40 and 50:50.

The high-maltose syrups break away from these restrictions, as the spectrum of carbohydrates present is modified to increase the maltose while reducing the dextrose and the high-molecular-weight fraction. Using these syrups, a high boiling can be made with approximately sucrose to glucose 35:75 with the properties of a product of a 55:45 product.

Science of Gums, Jellies, and Licorice

In these products, a colloid is incorporated to obtain the desired texture. Most of these colloids are gelling agents, e.g., gelatine, but some such as gum acacia and certain modified starches do not gel. The substances used (see Table 1) are chemically quite disparate, but they all have the ability to self-associate. An important difference is between those like gelatine, which gel thermoreversibly, and other gelling agents, which gel irreversibly, e.g., pectin. Licorice is slightly different from the other sweets in that it is made from wheat flour directly rather than with a purified starch. The important science is the texture of the product, which can be studied as rheology. If a sample is placed between the two plates (Figure 6), and one plate is oscillated, the structure of the sample will not be destroyed, but a transducer on the other element will produce an output wave form. This wave form can be analyzed in terms of an elastic and a viscous component.

Grained Products

In some products, the sucrose is intended to grain or crystallize. Examples are fondant, fudge, and montelimar. In these products, there is a high proportion of sucrose, as opposed to other sugars.

Fondant

Confectionery fondants are normally made by boiling a mixed sucrose and glucose syrup to concentrate it.

Table 1 Properties, chemistry, and sources for gums and gelling agents

Agent	*Properties*	*Chemistry*	*Source*
Gelatine	Thermoreversible gelling agent	Protein	Bovine or porcine hides or bones
Starch	Irreversible gelling agent	Carbohydrate	Maize or wheat or potatoes
High-amylopectin starch	Nongelling starch	Carbohydrate	Waxy maize
Gum acacia	Gum	Polysaccharide	Trees of the species *Acacia senegal*
Agar agar	Thermoreversible gelling agent	Polysaccharide	Red seaweeds
Alginate	Irreversible gelling agent	Polysaccharide	Brown seaweed
Carrageenan	Thermoreversible gelling agent	Sulfated polysaccharide	Red seaweeds
Gellan gum	Thermoreversible or irreversible gelling agent	Polysaccharide	*Pseudomonas elodea*
Guar gum	Thickener exhibits synergy with some gelling agents	Galactomannan	Seeds of *cyamopsis tetragonolobus*
Pectin – high methoxyl	Irreversible gelling agent	Polygalacturonic acid	Citrus peel or cider apple pomace
Pectin – low methoxyl	Thermoreversible gelling agent	Demethoxylated pectin	Citrus peel or cider apple pomace
Gum tragacanth	Gum or mucilage	Polysaccharide	*Astragalus* shrub
Locust bean or carob gum	Thickener exhibits synergy with some gelling agents	Galactomannan	Endosperm of locust beans from *Ceratonia siliqua*
Xanthan gum	Thickener exhibits synergy with locust bean gum	Polysaccharide	Aerobic fermentation of *Xanthomonas campestris*
Egg albumen	Whipping agent and irreversible gelling agent	Protein	Egg white
Enzyme-modified soy protein	Whipping agent	Protein	Soy beans

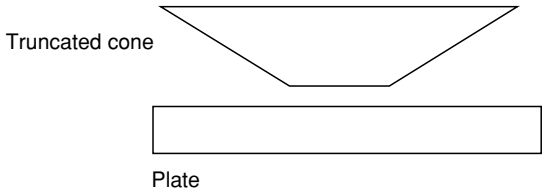

Figure 6 Cone and plate geometry.

The mixture is then cooled with beating to produce fine sucrose crystals. It is possible to make a fondant using dextrose instead of sucrose. Crystalline dextrose has a positive heat of solution, i.e., heat is absorbed. This produces a marked cooling effect, which goes well with a peppermint flavor, but it is not appreciated in other flavors. After a fondant has been made, the crystals undergo Ostwald ripening.

Fudge

A fudge-like product can be made by adding either a fondant or milled sugar to a toffee; alternatively, a sugar-rich caramel can be induced to grain.

Panned Products

In these products, one or more layers of sugars have been laid down. There are two different processes used, hard panning and soft panning. These processes involve building up a coating of sugar and sometimes other things layer by layer. This is one of those processes that the confectionery and pharmaceutical industries have in common. The normal modern small-scale method is to use a rotating dragee pan (Figure 7). These pans are traditionally made of copper but now more commonly stainless steel. The pan is equipped to be rotated, and usually, there will be a system for supplying and extracting air and possibly with a system for spraying in sugar syrup.

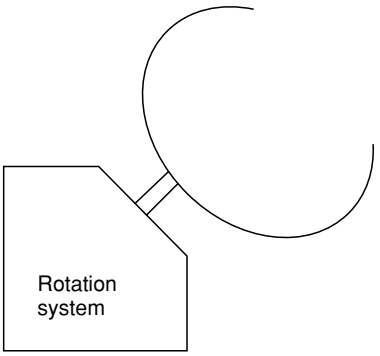

Figure 7 Dragee pan.

Hard panning

Hard-panned coatings are purely sucrose, whereas soft pan coatings are a mixture of sucrose and glucose syrup. Sugared almonds, mint imperials, nonpareils (hundreds and thousands), as well as sugar-coated chocolate lentils or eggs are normally hard panned. It is possible to soft pan some of these products, e.g., almonds. In hard panning, the centers are tumbled in the pan, and a sugar syrup is applied. The rotation

of the pan and the tumbling of the centers spread the syrup out into a thin layer. The water is evaporated, which causes the sugar to crystallize. The process is inevitably slow. The water can evaporate only at a certain rate, and the rate of crystallization of the sugar cannot be accelerated. The rate of evaporation can be increased by increasing the temperature and the air flow as well as reducing the humidity of the air. Increasing the temperature will reduce the rate of crystallization. The layers applied are only 10–14 μm thick. As the layers are so thin, they follow the contours of the product. If the center can be damaged by heat, heating the pan may not be possible. An air supply and extraction speed up the panning process considerably. In an unventilated pan, the process would slow down as the air became saturated with water vapor. In general, hard panning is done in large pans, whereas soft panning is done in small pans. Small products such as nonpareils tend to be made in small pans, whereas large items are produced in larger pans.

Soft panning

Soft panning involves applying a syrup to the centers, as does hard panning, but the soft panning syrup is intended not to crystallize. Instead of evaporating the water, as in hard panning, milled sugar is added, which dissolves in the water in the syrup. The syrup used in soft panning would be either all glucose syrup or a 50:50 mixture of sucrose and glucose syrup. This process is carried out in the cold and without using drying air. Dust extraction is needed for reasons of health and safety. Soft panning is a much more rapid process than hard panning. It can be applied to soft centers that would be unsuitable for hard panning. As the coating is thick, the shape of the center tends to be lost. Typical soft panned products are jelly beans and dolly mixture components.

Process Control Systems

Attempts to automate panning initially concentrated on the time and temperature. A more modern approach is to measure the absolute humidity to control the drying cycle. This is claimed to be an improvement on systems that rely on temperature and the elapsed time. In particular, because the actual humidity is measured, process parameters can be optimized to maximize throughput. In a time–temperature system, in order to avoid under-drying, the time set would have to be the maximum necessary.

Toffees and Caramels

In these products, the Maillard browning reaction between reducing sugars and proteins is essential to the taste and color of the finished product. The proteins used are from skim milk solids. Inefficient cooking pans promote this reaction at the heating surface to give a good product. If the same ingredients are cooked in an efficient continuous system, the reaction is suppressed to such an extent that the product is unacceptable. In practice, holding vessels known as caramelizers are used to promote the Maillard reaction.

In addition to skimmed milk solids and sugars, toffees contain fat. Originally, toffees were made from full cream milk solids, and the fat was milk fat. Now, a total or partial replacement with vegetable fat is possible. If sufficient milk protein is present, the fat disperses easily in the toffee, leaving a fatty layer on the surface that facilitates cutting. If insufficient milk protein is present, other emulsifiers will have to be added.

Chewing Gum

Chewing gum is a flavored and sweetened rubber, originally natural, but now usually synthetic. It is a product where confectionery becomes involved with polymer chemistry. The gum base in chewing gum is technically a rubber. The original ingredients were the natural products chicle and jelutong-pontianak, which were used alone or in a mixed gum base. The synthetic polymers used are mainly vinyl esters in particular polyvinyl acetate. Butadiene styrene rubber, isobutylene–isoprene copolymer, and polyisobutylene can be used. As in other fields of polymer chemistry, plasticizers such as glycerine esters of hydrogenated or polymerized resin, lanolin, and potassium, and sodium stearates are used. Different gum bases are used for chewing gum and bubble gum. Bubble gum base will contain either higher levels of polymers or polymers with a higher molecular weight. The higher level or molecular weight of the polymer makes the gum base more extensible and hence able to form bubbles.

Sugars

In order for a product not to have a gritty feel in the mouth, the sugar has to have a very fine particle size. Individuals differ in their response to particle size, but particles above 20–40 μm are normally found to be gritty.

Dextrose

Dextrose monohydrate is sometimes used as an alternative to sucrose in chewing gum. The endothermic heat of solution of dextrose gives a cooling sensation in the mouth that goes well with mint flavors but not with others.

Aerated Products

Technically, the problems in producing aerated products are in making and stabilizing a foam. Typically, aerated confectionery products involve making a foam and then causing it to set. A popular ingredient is egg albumen, which is a whipping agent and can be set irreversibly by heat. Some products are made with the combination of egg albumen and a gelling agent, e.g., gelatine. The only aerated confectionery products that work differently are those that are a high boiling that is chemically aerated and relies on the product passing through the glass transition before the bubbles collapse. These products sometimes contain material like gelatine to enhance foaming. Examples are bonfire toffee, honeycomb crunch, and peanut brittle.

Tabletting

Tablets are made by compressing a powder in a die. Under the pressure in the die, the powder fuses and is ejected as tablet. Tabletting requires a free-flowing powder that will flow freely when poured into the die but bonds satisfactorily when compressed.

Lozenges

Lozenges are one of the oldest forms of sugar confectionery. Lozenges are cut from a sheet of dough and then dried. Lozenge manufacture is one of the areas in which sugar confectionery is related to pharmaceutical products.

Lozenge manufacture

Lozenges are made by taking a milled sugar and making it into a dough. The best textures are achieved by using the smallest possible sizes of sugar. Lozenges are normally made with a binder. The traditional binder is gum tragacanth, which is probably the best material. Other materials that are used are gum acacia, gelatine, and xanthan gum. A mixture of gum acacia and gum tragacanth is sometimes used. Gum arabic used alone gives very brittle sweets that break easily.

Drying The stamped pieces are then spread on to trays where a slight crust of dry sugar forms on the surface. The lozenges are then dried at 35–40 °C until the moisture content is around 1.5%. If the lozenges are dried too rapidly, the lozenges shrink and crack. Extended drying times lead to loss of flavor and yellowing. A trace of blue color is often added to give a blue–gray color rather than a yellow–gray color. Flavor is a problem in lozenges, as the flavor must be volatile to be perceived in the finished product, but volatile flavors are often lost during drying. The reason why drying cannot be accelerated is that the moisture has to migrate from the center of the sweet to the surface.

Conclusion

Sugar confectionery is an area where the product came first and the science arrived afterwards. The science, however, is challenging.

SYRUPS

M A Clarke, Sugar Processing Research Institute Incorporated, New Orleans, LA, USA

Introduction

Syrups, which are sweeteners in liquid form, usually of high viscosity, have been used as food sweeteners since the early days of humanity, e.g., honey. This article includes information on the source and production, composition and properties, and use of cane and golden syrups, molasses, sorghum syrups, corn-, glucose-, fructose- and starch-derived syrups, fruit-based syrups, and maple syrups. (*See* **Honey**.)

Cane Syrups, Golden Syrups, and Molasses

Cane syrups are usually made from sugarcane juice, concentrated by evaporation, after clarification, before any sugar is crystallized out or otherwise removed. (*See* **Sugar**: Sugarcane.)

Cane Syrup

The term 'cane syrup' as applied to consumer products has a regional orientation to southern USA and other sugarcane-processing areas, where cane syrups and blends are sold for use on pancakes, biscuits, and cereals and in cooking. For food industry use, cane syrups are produced at sugarcane factories in Louisiana and Hawaii, or at refineries, where a blend of brown and golden-colored streams are combined to produce syrup. Cane syrups are dark golden brown in color, with medium flavor intensity (caramel, butterscotch, cane and green flavors; no heavy molasses flavor), and are partially inverted. (Inversion is the process in which sucrose is converted by hydrolysis to an equimolar mixture of glucose and fructose.) A factory evaporator syrup is often completely inverted, and mixed with uninverted syrup, to give a product of approximately 85° Brix, 25–30% sucrose and 50–52% invert. This is a relatively clear and low-ash material. (*See* **Carbohydrates**: Classification and Properties; **Fructose**; **Sucrose**: Properties and Determination.)

Cane sugar refineries make liquid sucrose, a watery, colorless solution of 67–70° Brix (percentage on a solids basis) sucrose, generally prepared by redissolving granulated sugar, but in some special refineries, e.g., in Brazil and Canada, by extensive ion exchange resin decolorization and carbon treatments. This product is often sold to beverage companies and canners because the high quality of color and clarity are immediately apparent.

Liquid invert sugar, which includes a range of liquid products of sucrose, glucose, and fructose of 75–77° Brix, was, until the late 1970s, a major product (15% of market) in the USA. It has been replaced by the cheaper starch-based syrups, most notably high-fructose corn syrup. Liquid products are still made in the UK, other parts of Europe, South America, and other areas.

Golden Syrup

Golden syrup is most popular in the UK, Canada, South Africa, and Australia (countries in which it is manufactured). It is a high-Brix (77–82°), partially inverted syrup, filtered several times over bone charcoal to give it a special golden color, very mild flavor, and high clarity. The syrup is generally inverted with sulfuric acid and neutralized with calcium carbonate, so that no soluble salt will remain as a reaction product to affect the special flavor. Typical analysis (courtesy of Tate and Lyle Sugars) is as follows: invert, 50%; sucrose, 32%; ash, 1.4%, and solids, 82.6%. The syrup is used directly on cereals, breads, and baked goods, and in home baking, e.g., in syrup pudding or tart. Golden syrup tends to crystallize on storage and is therefore usually sold in cans.

The obvious advantages, in many applications, of handling sugar in dissolved form have led to the extensive distribution and use in bakery products of sucrose and invert sugar syrups. Liquid sugars can be roughly classified into sucrose types, invert (or mixed) types, and refinery syrups or liquid brown sugars. Sucrose is available at 66.5–68% solids content. This is the limit of solubility of sucrose at ordinary temperatures. Two or three grades, varying for the main part only in color, are usually available.

If part of the sugar is inverted, the resulting syrup will retain higher concentrations of solids in solution. Common commercial types are syrups of 73% or 76% solids with 30% or 60% invert. Totally inverted syrups contain 72–73% solids, of which perhaps 5% is sucrose.

Because of the low water content, all of these syrups are quite resistant to microbiological spoilage. The invert syrups are probably somewhat superior in this regard because of their lower water activity. (*See* **Water Activity**: Effect on Food Stability.)

Molasses

Molasses (or treacle in the UK consumer market) is a general term for concentrated juice from sugarcane or sugarbeet, or raw cane sugar in concentrated solution after varying amounts of sucrose have been removed. Sugarcane molasses is the major food molasses. Both sugarbeet and sugarcane molasses are used for animal feed and as fermentation sources for ethyl alcohol and other chemicals. These uses are amply described in the literature and are not discussed here. Recent developments in technology have made possible some sugarbeet molasses food products; these are at present available in limited quantity. (*See* **Sugar**: Refining of Sugarbeet and Sugarcane.)

Several common terms for molasses are defined as follows. Blackstrap molasses is the byproduct from a sugarcane factory or raw sugar refinery; it is the heavy, dark viscous liquid remaining after the final stage of sugar crystallization from which no further sugar can be crystallized economically by the usual methods. Types of blackstrap are further defined by the US Department of Agriculture (USDA) as superior, normal, or utility, but these are ready definitions for feed-grade material.

High-test molasses is the product obtained by concentrating clarified cane juice to approximately 85° Brix; it is partially inverted with either acid or invertase enzyme. High-test molasses is produced from cane juice instead of sugar, not as a byproduct of sugar production. High-test molasses, also known as fancy molasses, cane invert syrup, or cane juice molasses, is a premium product, higher in sugars content and of a more aromatic flavor than blackstrap. It has been subjected to less heat than blackstrap, and so contains relatively fewer sugar decomposition products, which can add bitter flavor.

Sulfured molasses is the byproduct of raw sugar manufacture in which sulfur dioxide has been added to the molasses to bleach color. Sulfured molasses may be lighter in color, but it is higher in ash of the insoluble sulfate type. The term 'unsulfured' is more common. The approximate composition of cane molasses (blackstrap) is given in Table 1. (*See* **Preservation of Food**; individual constituents.)

Most commercially available molasses, for consumer purchase or food industry use, is made by blending various cane factory and refinery molasses and syrups for desirable – and constant – flavor and quality.

Physical properties of molasses vary with composition. Viscosity can vary over several orders of magnitude depending on inorganic and polysaccharide composition and temperature. Cane molasses has an acid pH, usually between 5 and 7. The salts content (2–8%) can contribute buffering capacity, to stabilize flavors and prevent hydrolysis, and can also provide flavor for feed use.

Color and flavor are the major properties besides nutrition that molasses contribute to food processing. Molasses always contributes some sweetness, to a degree which usually decreases as color darkens. The range of flavors is broad, ranging from caramel, cane flavor in light high-test molasses, to heavy, bitter notes, sometimes with licorice characteristics. Extensive research has shown that molasses flavor is a complex mixture. Because of this wide range of flavors, molasses can be used to mask or disguise other, less pleasant flavors, e.g., bitterness of bran in wholewheat (wholemeal) products; as an enhancer in sauces and licorice products. Molasses can also be used as a coloring agent, for golden to dark brown colors, especially in baked goods, and as a color enhancer, or masking agent, to disguise gray or gray-brown tones. Molasses displays humectancy, colligative, and water absorption (lowering of water activity) properties that would be expected of a sucrose syrup of similar solids composition; these properties lead to wide application in intermediate-moisture foods and in baked goods with extended shelf-life. However, nonsugars in molasses apparently have some effect on humectancy: molasses has been shown to be more effective in retaining a high moisture content than either sucrose or corn syrups. Molasses nonsugars also exhibit an antioxidant effect, significant when this fraction is used at some 3% of the fat level in the food product, and important for health foods. Inclusion in whole-grain products is one potential role for this fraction. (*See* **Antioxidants**: Natural Antioxidants; **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Molasses is a food product that has often been claimed to be a secret of youthful behavior and appearance (e.g., to inhibit hair graying). Technological investigations, such as the isolation and characterization of the antioxidant fraction, may provide a scientific basis for what formerly appeared to be myths.

A dried molasses product, usually mixed with corn syrup solids to absorb water, is also available for use in dry mixes.

Syrups and molasses products sold to the food industry represent the result of blending various molasses and syrups to produce products of consistent color, flavor, and functional properties. Table 2 lists several typical blends, their composition, flavor characteristics, and potential applications. These blends are typical of material sold directly to the consumer as molasses in the USA, and as treacles, syrups, or blends in, other countries.

Table 1 Approximate composition of cane molasses

Main constituents	*Components*	*Normal range*
Water		17–25%
Sugars	Sucrose	30–40%
	Glucose (dextrose)	4–9%
	Fructose (levulose)	5–12%
	Other reducing substances (as invert)	1–4%
	Total reducing substances (as invert)	10–25%
Other carbohydrates	Gums, starch, pentosans, also traces of hexitols; myoinositol, D-mannitol, and uronic acids	2–5%
Ash	As carbonates[a]	7–15%
	Bases:	
	Potassium oxide (30–50%)	
	Calcium oxide (7–15%)	
	Magnesium oxide (2–14%)	
	Sodium oxide (0.3–9%)	
	Metal oxides (as ferric) (0.4–2.7%)	
	Acids:	
	Sulfur trioxide (7–27%)	
	Chloride (12–20%)	
	Phosphorus pentoxide (0.5–2.5%)	
	Silicates and insolubles (1–7%)	
Nitrogenous compounds	Crude protein (as N × 6.25)	2.5–4.5%
	True protein	0.5–1.5%
	Amino acids, principally aspartic and glutamic acids, including some pyrrolidine carboxylic acids	0.3–0.5%
	Unidentified nitrogenous compounds	1.5–3.0%
Nonnitrogenous	Aconitic acid (1–5%), citric, malic, oxalic, glycolic	1.5–6.0%
	Mesaconic, succinic, fumaric, tartaric	0.5–1.5%
Wax, sterols, and phosphatides		0.1–1.0%

Sorghum Syrup

Sweet sorghum (*Sorghum bicolor*) is a giant grass, somewhat similar in appearance to sugarcane, but able to withstand cooler climates. In the Midwest and parts of the southern states of the USA, the juice of sweet sorghum is heated, clarified by skimming, and concentrated into a syrup. Sorghum juice tends to be higher in invert sugars than cane juice; it is therefore difficult to crystallize sweet sorghum sugar, and syrup is the product of choice. Sorghum syrup is produced by small plants in Tennessee, and northern Mississippi and Alabama (further information is available from the National Sweet Sorghum Producers Association, PO Box 1071, Knoxville, TN 37901-1071, USA). (*See* **Sorghum**.)

The light-brown-colored syrup has a distinctive, pungent odor and flavor, in addition to its sweetness and molasses-like flavor. It is often blended with other (sugar- or starch-based) syrups, but is seldom sold industrially. Production is a cottage industry at present.

Starch-Based Sweeteners and Syrups

Starch is a polymer of glucose and, upon hydrolysis by acid or by amylase enzyme, it yields glucose and a variety of maltooligosaccharides. The process has been employed in the USA to produce sweetener syrups since the 1840s, at first on potato starch and some 20 years later on corn, or maize, starch. Crystalline glucose, more often called dextrose in the corn refinery industry, and glucose syrup remained the major starch-based sweetener products until the 1960s. Enzyme-catalyzed isomerization of glucose to fructose, a sweeter sugar, then made possible

high-fructose syrups, with ratio of sweetening power to energy equivalent to that of sucrose. The corn-refining industry in the USA now makes available a wide range of sweeteners, with crystalline fructose as the newest addition. Corn-based starch hydrolysis products are also manufactured in Argentina, Canada, Japan, and eastern Europe. In the EC, the starch base for these sweeteners is usually potato, increasingly wheat, and, in at least one factory in Finland, barley. Products are similar in composition, properties, and use to those made from corn; thus cornstarch-based products are used as examples here. (*See* **Dextrins**; **Starch**: Structure, Properties, and Determination; **Sweeteners**: Intensive.)

In general, corn-based sweeteners are classified into the following seven categories:

1. Corn syrup (glucose syrup) is the purified, concentrated, aqueous solution of nutritive saccharides obtained from edible starch and has a dextrose equivalent of 20 or more.
2. Dried corn syrup (dried glucose syrup) is a corn syrup from which the water has been partially removed.
3. Dextrose monohydrate is purified and crystallized D-glucose containing one molecule of water of crystallization with each molecule of D-glucose.
4. Dextrose anhydrous is purified and crystallized D-glucose without water of crystallization.
5. Maltodextrin is a purified concentrated aqueous solution of nutritive saccharides obtained from edible starch, or the dried product derived from the solution and having a dextrose equivalent less than 20.
6. High-fructose corn syrup is a purified, concentrated, aqueous solution of nutritive saccharides obtained from edible starch in which a portion of the dextrose has been isomerized to fructose.
7. Crystalline fructose is a purified and concentrated D-fructose obtained from edible starch in either dry crystal or remelted liquid form.

Products in 2, 6, and 7 are of direct interest as syrups; the others are listed for explanation of the processes involved.

Composition of the typical range of syrups is outlined in Table 3.

Starch-Based Syrups Manufacture

Common methods employed in the commercial production of corn syrups are the acid process, the acid–enzyme process, and multiple enzyme process. In the acid conversion process, a starch slurry of the appropriate dry substance is acidified to pH of about 2 and pumped to the converter. After neutralization, liquor is clarified and concentrated by evaporation to an intermediate density. The resulting syrup is further clarified, decolorized, and finally concentrated in evaporators to the final required density. Some syrups are treated with ion exchange resins for further refinement.

The acid–enzyme process is similar except that the starch slurry is only partially converted by acid to a given dextrose equivalent (DE), then treated with an appropriate enzyme or contribution of enzymes to complete the conversion.

In multiple enzyme processes, starch granules are gelatinized and the preliminary starch-splitting or

depolymerization is brought about by an α-amylase enzyme, rather than by means of acid.

Various intermediate syrups of differing composition may be further converted with enzymes having specific modes of action or providing particular types of end product, such as high-maltose syrups, high-fermentable syrups, and others.

High-Fructose Corn Syrup

Dextrose or glucose solutions or high-DE substrates produced from starch by acid–enzyme or dual enzyme processes are refined by carbon and ion exchange systems and treated enzymatically with isomerase in an immobilized enzyme system. Isomerization is usually carried to a point where the substrate contains 42% fructose. Following this step, the product is refined again through carbon and ion exchange systems and is evaporated to a dry solids level of 71%. (*See* **Enzymes**: Uses in Food Processing.)

In the production of syrups with a fructose level above 50%, the original 42% fructose feedstock is passed through separation columns of cationic ion exchange resins which retain fructose and dextrose. Fructose is removed; dextrose is recirculated for further isomerization. In a standard moving-bed system, the fructose fraction is generally recovered at an 80–90% concentration, and blended with 42% fructose feedstock to produce 55% fructose content, at a dry solids level of 77%. The high-level feedstock may also be refined and evaporated to produce 90% high-fructose syrup.

High-Maltose Syrups

Enzyme technology has been developed to produce syrups that are higher in maltose than an acid-converted syrup of similar DE. These syrups are used for fermentation (brewing) and for applications in icecream and confectionery where physical properties are more important than sweetness. The low dextrose concentration allows control of color development in a heated product. The 65% maltose syrup is a fine material for catalytic reduction.

Chemical and Physical Properties of Corn Syrups

Corn syrups all have pH values on the acid side, minimum 3.5–5.5, to minimize color and flavor development. Ash (mainly sodium chloride) levels in corn syrups are low. Although sulfur dioxide is used extensively in the preparation of starch from corn, processing, especially those processes using ion exchange resins, can remove residual sulfur dioxide so that products contain acceptably low levels of sulfite and its oxidation product, sulfate. Fermentability of corn syrups is another useful chemical property; fermentable extract is defined as the percentage of carbohydrates, on a dry-weight basis, fermented by bakers' yeast under controlled conditions. The higher the DE, the higher the fermentability.

The reducing sugars characteristics of glucose, fructose, and maltose allow participation in Maillard, or browning, reactions, for brown crust formation in baking and production of caramel color. (*See* **Browning**: Nonenzymatic; **Caramel**: Methods of Manufacture.)

Density of corn syrups is usually measured in degrees Baumé instead of Brix. Syrups content (e.g., 55% high-fructose corn syrup) is always expressed on a solids basis.

Corn syrups, because of their solids content, have colligative properties similar to those of sucrose invert syrups as regards boiling point elevation and freezing point depression: the latter is an important factor in icecream hardness and melting. Osmotic pressure increase is a measure of control against spoilage in jams and preserves. The syrups' very high viscosities are an important property in food processing, controlling handling characteristics, and air retention.

The humectant, or hygroscopic, properties of corn syrups vary with their carbohydrate composition. Lower-DE syrups are less hygroscopic, while maltotriose and maltotetraose may be the most hygroscopic sugars. Variation in this property may be

used to control the texture and keeping quality of baked goods, confectionery, and intermediate-moisture foods, where corn syrups are employed as moisture conditioners, food plasticizers, crystallization inhibitors, and stabilizers.

Applications and uses of starch-derived syrups include the following: baby and geriatric foods; bakery products; beverages, brewed, alcoholic, carbonated, and still; breakfast foods; cheese spreads and cheese-based foods; coffee whiteners; condensed sweetened milk; confectionery; eggs (frozen or dried); extracts and flavors; frosting and icings; fruits and vegetables; icecreams; industrial products (adhesives, chemicals, dyes and inks, explosives, paper, textiles, tobacco); jams, jellies, marmalades, and preserves; meat products (sausages, etc.); peanut butter; pharmaceutical and medical; pickles and pickle products; pork and beans; prepared mixes; seafood (frozen); syrups (table, chocolate, cocoa, fruit, medicinal, soda fountain, cordials, etc.); soups; toppings.

High-fructose corn syrup is also widely used in processed foods, bakery products, beverages (colas and other carbonated soft drinks, and still drinks), canned juices, canned fruits, condiments, confectionery products, frozen desserts, jams, jellies, and preserves, pickles, and wine.

Lycasin Lycasin, originally manufactured in Sweden by the Lykeby Starch Co., is a hydrogenated glucose syrup, which does not crystallize out, even at low temperatures, and has a viscosity similar to that of high-fructose corn syrups. It is a mixture of hydrogenated homologs of glucose and glucose polymers, said to prevent dental cavities, although not suitable for diabetics, and used in jams, preserves, drinks, and hard-boiled candies.

Maple Syrup

Maple sweetners, made by concentration of the sap of the sugar maple tree (*Acer saccharum*), are produced in eastern Canada and north-eastern USA. Heating of the sap causes flavor and color development, as well as concentration, and the characteristic maple flavor of the syrup and sugar (sold in granulated or in block form) is a major attraction. The pure product is more expensive, by an order of magnitude, than sucrose or starch-based sweetners, and, as a result, many blends of maple syrup with other syrups, or of other syrups with maple flavoring, are available, and nowadays are generally labeled as such; false labeling of maple products was common some years ago.

The composition of maple syrup is shown in Table 4. The carbohydrate make-up of fresh maple syrup is almost entirely sucrose. This will invert with time, but provides a means of detecting adulteration or replacement of maple syrup with cheaper, starch-based syrups: genuine maple product does not contain maltose, while starch-based products do.

Table 4 Composition of maple syrup

Component	*Amount (%)*
Water	34.0
Sucrose	58.2–65.5
Hexoses	0.0–7.9
Malic acid	0.093
Citric acid	0.010
Succinic acid	0.008
Fumaric acid	0.004
Soluble ash	0.30–0.81
Insoluble ash	0.08–0.67
Calcium	0.07
Silica	0.02
Manganese	0.005
Sodium	0.003

Physical properties of maple syrup are similar to those of sucrose syrups, making the product suitable for baking and confectionery, but, because of its cost, most maple syrup is sold directly, and used as pancake syrup or in home baking. Characteristic maple flavor has been shown to be a complex mixture of plant components (guiacyl acetone, vanillin) and products of thermal degradation of carbohydrates (isomaltol, acetol, α-furanone). (*See* **Carbohydrates**: Interactions with Other Food Components.)

Fruit Syrups

A new product has entered the sweetener syrup field in the USA, Europe, and South America: fruit syrup or fruit juice concentrate. Excess fruit crops, or damaged fruit unsuitable for its original destination as fruit, fruit products, or wine, is prepared in juice form. The juice is decolorized and the flavors removed, through proprietary processes, and the remaining material – usually a solution of invert sugar, because fruit sucrose is hydrolyzed to invert in the process – is concentrated to about 75 ° Brix at pH 4, and sold as a natural fruit sweetener. The product is designed for the natural foods market, so that the terms 'fruit sweetener', 'sweetened only with fruit' and 'no sugar added' can be displayed on the label, although the last statement is questionable. These fruit products, made in different places from apple, peach, pear, citrus, and grape juices, sell, on solids basis, at five to six times the price of sucrose.

TAINTS

Contents

Types and Causes

B D Baigrie, The Lord Zuckerman Research Centre, University of Reading, Whiteknights, UK

Background

British Standard 5098, 1974 defines a taint as a taste or odor foreign to the product, whereas the dictionary definition of an off-flavor is a flavor that is not natural or up to standard owing to deterioration or contamination. Often, the term taint is used specifically to describe a flavor defect that has arisen from extrinsic sources. Where a flavor defect has developed internally, e.g., via enzymically induced deterioration and not by external contamination, the term off-flavor is used. In practical terms, this differentiation is not particularly helpful or necessary, and hereafter, the term 'taint' will be used to describe any deviation of flavor from the accepted norm, irrespective of the cause.

The sources of taints in foodstuffs are manifold. They can arise through microbial spoilage (bacteria, yeasts, and molds), and many of the metabolites produced by these species will often remain in the food, even after extensive processing. They may also be formed by internal deterioration of food components through the intermediacy of enzymes, by other non-enzymic pathways (Maillard reactions, Strecker degradation, etc.), or by oxidative degradation. In addition, many food taints or precursors thereof arise from some source of external contamination. For example, airborne sources of taint are common. Water used in food processing, cleansing/sanitizing agents, and packaging materials are major vectors also for the transmission of taints to foods. This article discusses some of the more commonly occurring taints and their origins.

Microbial Metabolites

Microorganisms are a common source of taint in foods. Microbial activity can produce taints in several ways: by production of primary metabolites; by conversion of innocuous food components into species with a low odor threshold, or through residual enzyme activity after death of the organism. Fish is a food that is susceptible to tainting by all of these mechanisms. Fresh fish has little odor, but on storage, spoilage odors develop, primarily through bacterial action. *Achromobacter*, *Vibrio*, and *Pseudomonas* bacteria have been shown to be capable of producing sulfidic taint in fish by the production of volatiles such as hydrogen sulfide, methyl mercaptan, dimethyl sulfide, dimethyl disulfide, and dimethyl trisulfide. A metabolite of *Pseudomonas perolens*, 2-methoxy-3-isopropylpyrazine, was found to cause a potato-like taint in fish, whereas a fruity taint in fish muscle caused by ethyl esters of acetic, butyric, and hexanoic acids was produced by *Pseudomonas fragi*. The classic 'fishy' odor of aged fish has been attributed to the presence of trimethylamine, and it has been established that this volatile is produced by the action of bacterial enzymes on trimethylamine oxide, a natural constituent of fish muscle.

Metabolites from microbial species, including *Pseudomonas*, have also been implicated as the source of specific taints exhibited by various crustacea. Dimethyl trisulfide was responsible for an onion-like flavor, and indole a fecal-like flavor that had developed in red prawns. The compounds responsible for a distinctive garlic-like taint also in red prawns, namely bis-(methylthio)-methane and

trimethylarsine, were believed to arise from microbial activity. The former chemical was also the principal cause of an objectionable taint in sand lobster. 2,6-Dibromophenol was identified as the cause of an iodoform-like taint in prawns. Marine algae and bryozoa were found to contain this compound in concentrations comparable with that found in the prawns and were implicated as the primary source of the taint.

Freshwater crustacea (peneid shrimp) and fish (rainbow trout, catfish, bream) can often acquire earthy/musty taint via contaminated water. The compounds held to be primarily responsible for musty taint from these sources are geosmin ([*E*]-1, 10-dimethyl-[*E*]-9-decalol), 2-methylisoborneol (1,2,7,7-tetramethyl-exo-bicyclo [2.2.1] heptan-2-ol) and, to a lesser extent, 2-methoxy-3-isopropylpyrazine. In most cases, geosmin and methylisoborneol are found in eutrophic and hypertrophic waters, and it has been established unequivocally that the causal agents of these chemicals are actinomycetes (several species), cyanobacteria (blue–green algae), or certain species of fungi. The presence of geosmin or 2-methylisoborneol in water supplies, particularly that used for food processing, is the probable cause of earthy taints in some foods canned in brine (e.g., champignons) and syrups.

Food production systems that utilize microorganisms to produce flavor, e.g., dairy products, alcoholic beverages, and cocoa, are particularly susceptible to the development of taints via excessive microbial activity. A selection of some taints developed by these types of foods is shown in Table 1. Of course, many other foods can develop fermentation-like taints through adventitious infection by the appropriate microorganisms.

Enzymic Deterioration of Food

Foods containing lipids are particularly prone to the development of taints by enzyme-catalyzed degradation of lipid. Two main types of enzymes are involved in lipid degradation: lipoxygenase and lipase. The former are particularly common in plant tissues such as the legumes. For example, the beany flavor of soya beans and the reversion flavor of soya bean oil are due to lipoxygenase activity.

Lipoxygenase catalyzes fatty acid hydroperoxide formation in a manner similar to nonenzymic systems. Polyunsaturated fatty acids such as linoleic and linolenic acid are more susceptible to attack than monounsaturated or unsaturated acids. After initial formation of the hydroperoxides, decomposition by pathways similar to those occurring in autoxidation takes place. This is believed to involve homolytic cleavage of the oxygen–oxygen bond to yield an alkoxy radical that decomposes via carbon–carbon cleavage to give aldehyde or hydrocarbon products. Other pathways lead to the formation of hydrocarbons, alcohols, aldehydes, ketones, esters, and acids. There is a wide variation between these oxidation products with respect to flavor threshold values, concentration in the food, and flavor character. However, the *D*-value parameter, a measure of the relative intensity of flavor compounds extracted from a food, reveals that unsaturated aldehydes and ketones, namely (*Z*)-3-hexenal, 1-octen-3-one, (*Z*)-1,5-octadien-3-one, (*Z*)-2-nonenal, (*E*, *Z*)-2,6-nonadienal,

Table 1 Microbiologically produced taints in fermented foods

Food	*Microorganism*	*Tainting species*
Butter	Bacteria (*Streptococcus*)	Acetaldehyde
Cheddar cheese	Bacteria (Nonlactic)	Ethyl butanoate and ethyl hexanoate
Cheddar cheese	Yeast (*Candida*)	Ethyl acetate and ethyl butanoate
Munster cheese	Bacteria (*Pseudomonas*)	2-Methoxy-3-isopropyl-pyrazine
Yogurt	Fungi	1,3-Pentadiene
Wine	Yeast (*Brettanomyces*)	2-Acetyltetrahydro-pyridine

Malt distillate	Bacteria (Actinomycetes)	Geosmin
Rum	Yeast (*Saccharomyces*)	3-Ethoxypropanal and 1,1,3-triethoxypropane
Beer	Yeast (*Saccharomyces*)	Diacetyl and 2,3-pentanedione
Beer	Yeast (*Saccharomyces*)	Isoeugenol and other phenols
Beer	Yeast (*Saccharomyces*)	Methional
Beer	Bacteria (*Clostridium*)	Butanoic acid
		2-Methoxy-3-isopropylpyrazine and methylisoborneol
Coffee	Molds (*Aspergillus*)	2,4,6-Trichloroanisole

and 3-methyl-2,4-nonandione, are the most potent taints. Flavor descriptors for lipid oxidation volatiles range from rancid, fishy, painty, cardboard, and metallic to mushroom, green, and fruity.

Lipase enzymes can produce taint by hydrolysis of triglycerides and release of fatty acids. The longer-chain fatty acids have higher flavor thresholds, and so lipolytic taints are more common in products containing short-chain fatty acids. Dairy products such as butter, cheese, and milk powder regularly suffer from taints described variously as rancid, butyric, goaty, and unclean, which are caused by excessive concentrations of free fatty acids of chain lengths C_4–C_{10}. Products containing coconut or hydrogenated palm kernel oil (HPKO) are prone to soapy and bitter taints caused by hydrolytic release of lauric (C_{12}) and myristic (C_{14}) acids from the triglycerides of coconut oil or HPKO.

Nonenzymic Deterioration of Food

Autoxidation

Autoxidation of lipid is initiated by the formation of lipid radicals and, subsequently, lipid peroxy radicals and lipid hydroperoxides. Volatile taints are generated from the lipid hydroperoxides via the secondary reactions described in the previous section. High-energy (short-wavelength) light is an effective initiator of lipid autoxidation. However, many other factors also influence the rate of oxidation: the number and type of double bonds; the presence of trace metals such as copper, cobalt, and iron; water activity (low-moisture foods oxidize at higher rates), temperature, and the presence of antioxidants. While dry foods such as milk powder, crisps, and breakfast cereals are particularly susceptible, fish and meat products are also prone to lipid autoxidation. (*See* **Fatty Acids**: Properties.)

Nonenzymic Browning

The importance of nonenzymic browning, also known as the Maillard reaction, in the development of desirable food flavors is well established. However, it is also recognized that the Maillard reaction is a major route for the development of taints in food.

The formation of both desirable flavors and taints via the Maillard reaction starts with a condensation reaction between a carbonyl group, usually from reducing sugars, and an amino group, most commonly from peptides or proteins. A complex sequence of chemical rearrangement, fragmentation, cyclization, and polymerization reactions occurs, which generates the flavor volatiles and the characteristic brown coloration. The generation of specific flavor chemicals depends on factors such as time, temperature, water activity, pH, and sources of carbonyl and amino groups.

Any food that undergoes substantial heat treatment during processing can develop a Maillard reaction-type taint. Maillard chemistry can also proceed significantly at room temperature and often causes taint in low-moisture foods that have been stored for long periods. For example, staleness in stored dry milk powder was thought to be caused by 2-aminoacetophenone, a Maillard degradation product of tryptophan. The same chemical, together with some furanoid species, was thought to contribute to the gluey flavor of aged casein. The concentration of furfural, a classic Maillard reaction product, in canned citrus juices was found to increase during storage and could be correlated with the development of taint in these products. Similarly, heat-treated orange juice and blackcurrants were found to contain flavor compounds thought to be derived by Maillard reactions. (*See* **Browning**: Nonenzymatic.)

Direct External Contamination

Airborne

Airborne contamination is one of the most frequent causes of direct tainting of food, and many such cases have been documented. Growing crops have been contaminated by airborne industrial discharges. For example, grapes inadvertently contaminated in this way produced wine exhibiting a taint. Exposure of food during processing and packaging operations to contaminated air either from sources external to the factory or from localized sources within a factory has resulted in many incidents of taint. Baked goods and chocolate confectionery, products that are often cooled or set using chilled air, are particularly susceptible to tainting by this route.

In one example, chocolate confectionery was found to be contaminated with a wide range of alkyl phenols. The source of the phenols was traced to an area of flooring some distance from the cooling confectionery. The flooring was found to contain a phenolic-based bonding resin that was slowly releasing alkyl phenols to the atmosphere. These chemicals were subsequently adsorbed by the confectionery. Air diffusion within warehouses or transit containers contaminated by other commodities stored either contemporaneously or at some stage in the past often results in tainting. A good illustration of this source of taint is afforded by the case of white beans that acquired a disinfectant-like taint after being transported in containers. The primary taint was identified as 6-chloro-2-methylphenol. This

compound was an impurity in a herbicide, which, during a previous voyage, had contaminated the wooden floor of the container and subsequently transferred to the beans. Examples of taints arising by these routes are outlined in Table 2.

Water

Water is used extensively in the production or processing of many foods and can be a major source of taint. Waterborne, earthy/musty taints have been discussed in the section on microbial taints. However, another common type of waterborne taint is the disinfectant-like taint caused by phenolic compounds, particularly chlorophenols. Mono-, di-, and trichlorophenols can be formed by spontaneous reaction of phenol with free chlorine present in chlorinated mains water. Plastic fittings and hoses or phenol-based resins and paints used as protective coatings on processing plant often function as ready sources of phenol.

Boiler treatment chemicals have been documented as the source of free phenol that caused chlorophenol-like taints when the boiler water was used for direct steam injection of brines and syrups. Another documented example of chlorophenol contamination of food by water involved the accidental introduction of algaecide-treated water into the processing water supply. The algaecide was found to contain tri-, tetra-, and pentachlorophenol. Disinfectant solutions used as plant-sanitizing agents have been implicated in many cases as sources of chlorophenolic taints. Several documented cases of tainting by chlorophenols are listed in Table 2.

Packaging Materials

One of the primary functions of food packaging is to prevent the ingress of contaminants and taints into the product. Unfortunately, the reverse often occurs with packaging materials frequently functioning as abundant sources of tainting chemicals. This is due in part to the ever-expanding range of materials used to package food and the increasing sophistication of packaging construction, e.g., laminates, metallized films, etc. The most common examples of direct contamination from packaging involve solvent residues from printing inks, lacquers, resins, and adhesives.

Synthetic polymers frequently used in packaging such as polythene, polystyrene, polypropylene, polyvinyl chloride, and poly(ethyleneterephthalate) often impart chemical or plastic-like odors to foods. Residual levels of monomer are often the cause of the taint. Styrene-based polymers, for example, are known to transfer styrene monomer, which has a relatively low odor threshold and imparts an objectionable taste to foods. Other polymeric packaging materials have been found to contain a wide range of volatile organic compounds, many of which could cause taint.

Table 2 Taints from external sources

Food contaminated	*Compounds involved*	*Origin*
Biscuits	Chlorophenols	Airborne from nearby herbicide factory
Chocolate confectionery	Xylenols	Airborne from adjacent area of composite flooring
Chocolate crumb	2,4- and 2,6-dichlorophenol	Airborne from walls of metal container
White beans	6-Chloro-2-methyl-phenol	Airborne from wooden floor of metal container
Bakery and confectionery products	Petroleum hydrocarbons	Airborne from petrol spillages in warehouse
Canned vegetables	Tri-, tetra-, and pentachlorophenol	Algaecide in process water
Canned fruit	Di- and trichlorophenols	In-plant reaction of steam contaminated with phenol and chlorinated water
Fruit juice	2,4- and 2,6-dichlorophenol	Phenol from in-plant fitments reacting with chlorinated water
Distilled spirit	Di- and trichlorophenol	Phenol in spirit chlorinated by sanitizing agent
Jam filling	6-Chloro-2-methylphenol	Tanker with residual traces of disinfectant
Channel catfish	2-Methylisoborneol	Pondwater contaminated with phytoplankton
Water clams	Geosmin	Marshwater
Cocoa powder	Chlorophenols and chloroanisoles	Multiwalled paper sacks with glued seams
Milled flour	Various	Jute sacks
Chocolate assortments	Aliphatic hydrocarbons	Lithographic printed cartonboard
Icecream	2-Butoxyethanol	UV-cured printed cartonboard
Cereal	Terpenes	Resin in laminated liner
Sugar confectionery	Aliphatic aldehydes	Printed cellophane bag
Soft drink	2-Methylphenol	Can lacquer
Milk beverage	Isophorone	Can lacquer
Biscuits	Styrene	Polystyrene trays
Spring water	2-Ethylhexanol and hexanal	Liner of bottle closure

Another major route for contamination of food products with chlorophenols, apart from water as discussed previously, is via packaging materials and materials encountered during transport of foods. Cork closures, Kraft bleached paper sacks, cardboard boxes, jute sacks, fiberboard containers, and wooden pallets have all been shown to contain chlorophenols, which, in many cases, were the primary tainting species and, in others, precursors of the eventual tainting species.

Paper-based packaging materials, particularly those made from recycled paper and pulp, have recently been found to contain 2,4,6-tribromophenol in high concentrations. Given that it is a powerful taint with an odor threshold in water of $0.6\,\mu g\,l^{-1}$, this compound will also impart a medicinal taint if transferred to foods.

Tables 2 and 3 show that nearly all food packaging materials, except perhaps glass, can cause tainting of food products. Invariably, the tainting chemicals will be present in packaging materials at substantially higher levels than are found in the food. Therefore, monitoring of packaging for tainting chemicals by sensory evaluation or instrumental analytical methods may prevent any potential problems.

Indirect External Contamination

Polyhaloanisoles

The polyhaloanisole family contains some of the most potent odor compounds known and are notorious as the source of musty or moldy taints in foods and beverages. Unlike many of the other tainting chemicals discussed previously, the presence of polyhaloanisoles in food or food-associated materials is completely adventitious. As chemicals, they perform no known useful function, and their presence in food systems invariably occurs indirectly, since their genesis requires both a microbiological vector (to effect the methylation stage) and a source of halophenols. Timber-based packaging materials have been implicated in many of the documented cases of haloanisole taint. The first examples of a chloroanisole taint in food occurred in eggs and broiler chickens. It was shown that both tetra- and pentachloroanisole had been formed by microbial methylation of the corresponding chlorophenols present in wood shavings used as poultry litter.

A more recent occurrence has been the emergence of polybromoanisoles, and particularly 2,4,6-tribromoanisole, as powerful taints rivalling the polychloroanisoles in terms of potency. As with the chloroanisoles, timber-based packaging has been shown to be the primary source of the bromoanisole precursor, i.e., the corresponding bromophenol. Thus, the biocidal agent 2,4,6-tribromophenol can be readily converted by microbial methylation to 2,4,6-tribromoanisole.

As the sensitivity and selectivity of analytical techniques for the detection of polyhaloanisoles in food have improved, so the number of documented cases of taint by these chemicals has increased. Some of the more recent examples of foods affected by haloanisole taint are listed in Table 3.

Table 3 Foods tainted by haloanisoles

Food contaminated	*Haloanisoles detected*	*Origin*
Wine	2,4,6-TCA[a]	Cork closures containing the chlorophenols
	2,3,4,6-TeCA[a]	
Cognac	2,4,6-TCA	Cork closures
Dried fruit	2,4,6-TCA	Packaging adhesive containing chlorophenols
	2,3,4,6-TeCA	
	PCA[a]	
Raisins	2,3,4,6-TeCA	Paper/timer packaging materials
Cocoa powder	2,4- and 2,6 DCA[a]	Multiwalled paper sacks containing chlorophenols
	2,4,6-TCA	
	2,3,4,6-TeCA	
Desiccated coconut	2,4,6-TCA	Multiwalled paper sacks containing chloroanisoles
	2,3,4,6-TeCA	
Cheese	2,4,6-TCA	Wooden shelves containing chlorophenols and chloroanisoles
	2,3,4,6-TeCA	
Spring water	2,3,4,6-TeCA	Cardboard boxes used to store empty bottles
Canned beer	2,4,6-TBA; 2,3,6-TBA	Can lids
Skimmed milk	2,4,6-TBA	Unknown
Flour	2,4-DCA; 2,4,6-TCA	Jute sacks containing chloroanisoles and chlorophenols
	2,3,4,6-TeCA; PCA	
Wheat/wheat flour	2,4,6-TCA	Unknown – but not packaging materials

[a]DCA, dichloroanisole; TCA, trichloroanisole; TeCA, tetrachloroanisole; PCA, pentachloroanisole; TBA, tribromoanisole.

Catty Taint

The development of offensive catty odors in foods such as meat, canned vegetables, and cheeses is another example of indirect tainting. In these cases, a relatively innocuous substance was transferred to the food, where it was transformed into a powerful taint by reaction with a minor component of the food. The compound responsible for the catty taint was 4-mercapto-4-methylpentan-2-one, formed by the addition of hydrogen sulfide across the double bond of mesityl oxide. The latter was present in polyurethane paint, solvents used to dilute can lacquers and plastic packaging, and was presumed to have been transferred to the foodstuff from these materials.

Geranium Taint

The development of geranium-like taint in German wines occurred, as above, by reaction of two innocuous components to form the tainting substance. In this case, one of the reactants had been formed by acid-catalyzed rearrangement of a specific microbial degradation product of the preservative used in the fermentation. Sorbic acid (the preservative) was enzymically reduced to 2,4-hexadien-1-ol, which underwent rearrangement to 3,5-hexadien-2-ol. This product reacted with ethanol to form 2-ethoxyhexa-3,5-diene, the compound held to be responsible for the taint.

Medicinal Taint

Another good example of taint arising indirectly through a cascade of chemical reactions between ostensibly innocuous food components is afforded by the example of marinated herring that developed an offensive, medicinal taint. The taint was caused by 2-bromophenol. This chemical was formed by the reaction of bromine with phenol, the latter being present as a minor impurity in the acetic acid used for the marinade. The bromine was thought to be formed via the reaction of the hydrogen peroxide used to bleach the herring with bromide ion present as an impurity in the brine component of the marinade.

Analysis and Identification

B D Baigrie, The Lord Zuckerman Research Centre, University of Reading, Whiteknights, UK

Background

The wide diversity of chemical compounds that can cause taints and off-flavors in fresh and processed food, the various mechanisms and routes by which they may be imparted to foods, and the inherent complexity of food flavors all conspire to make the analysis and identification of taints and off-flavors a challenging and often time-consuming exercise requiring the application of a unique combination of scientific skills and analytical expertise.

Sensory Evaluation

Food manufacturers who operate to high standards of good manufacturing practice with a well-established quality assurance program and a proactive quality control scheme will normally detect grossly tainted product, usually by sensory evaluation, before it leaves the factory. However, some taints may occur intermittently within a production batch or only arise during the shelf-life of the product as a consequence of storage conditions or some other parameter. The manufacturer may then only be alerted to a taint problem indirectly through merchandise returns from retailers or directly via consumer complaints.

The first clues to the identity of the taint may come from the complainant's comments. Nevertheless, it is unwise to rely solely on untrained consumers for

an accurate description of a taint, even if large numbers of complaints about taint in a product have been received. Invariably, untrained consumers will generate a lengthy list of taint descriptors, which are often confusing, sometimes contradictory, and therefore of limited value to the analyst. The first stage in the analysis of a taint, therefore, is sensory evaluation of the foodstuff using a panel of trained experts.

It is important to use a panel of experts specifically trained to detect and describe taints, because, to any particular chemical, there will exist within a population of consumers a wide range of sensitivities. Taints are more likely to be detected by those in the most sensitive region of the distribution, and hence panels should comprise individuals with sensitivities considerably greater than that of the population mean.

For well-characterized types of taint, e.g., TCP, medicinal, antiseptic, panelists can be selected for their sensitivity to the taint species in question (usually halogenated phenols or halogenated alkylphenols). However, it should be recognized that sensitivity to a specific taint does not necessarily imply high sensitivity to taints in general.

Selection of a panel normally involves a measurement of their threshold to that taint. This requires the panelists to assess, in a specified medium, a range of stimulus concentrations ranging from zero to concentrations that can be clearly detected by all the panel. A threshold is usually defined as the concentration of taint that 50% of the panelists can perceive. For taints, two types of threshold are typically used, namely detection threshold and recognition threshold.

The ability of panelists to describe accurately the sensory properties of a taint and, if possible, to relate it to known standards is particularly useful, since it can provide vital information to the analyst or flavor chemist about the chemical structure of the taint. In practice, therefore, greater credence is placed on the comments of individual panelists who are known to be highly sensitive to certain taints, even if they constitute a minority opinion among the panelists.

Since most compounds responsible for taint are volatile, aroma assessment of the suspect food is mandatory. However, in some cases, for example taint caused by polychloroanisoles, the taint may only manifest itself when the food is held in the mouth or as a characteristic aftertaste after swallowing.

Once sensory evaluation has confirmed that a product is tainted and perhaps provided some clues to its nature, the next requirement is to establish its chemical structure and then to identify the source of the taint. This involves isolation of a concentrated flavor extract and separation of the individual flavor components. If the extract is particularly complex, fractionation into functional group classes followed by separation of individual components in each class may be necessary. Finally, identification of the taint is usually achieved using an appropriate spectroscopic technique. (*See* **Sensory Evaluation**: Aroma.)

Extraction of Taint

The first major challenge for the flavor analyst is to obtain a volatile flavor extract that represents the characteristic flavor of a food. There can be no absolute certainty that a valid extract (i.e., one characteristic of the food flavor) will be obtained. Nor is there any assurance that subsequently identified compounds were actually present in the food since artefacts can be introduced by many routes. However, with tainted foods, it is much easier to ascertain if an extract is valid, simply by assessing the odor or taste of the extract with a panel of assessors sensitive to the taint.

A wide variety of techniques exists for extracting taints from foods. Some of the isolation methods most frequently used are summarized in Table 1.

Where taints are volatile and readily detected by odor in a food or beverage, headspace sampling is often the technique of choice. Static headspace sampling is simple to perform and allows a truly valid flavor extract to be obtained. However, the quantity of the tainting species delivered to the analytical instrument is often too low to enable detection and identification to be achieved.

Table 1 Methods for isolation and/or concentration of taints

1. Headspace sampling
   - Static headspace
   - Dynamic headspace
     - Purge and trap
     - Closed-loop stripping
     - Solid-phase microextraction
2. Distillation
   - Steam distillation
   - Simultaneous steam distillation–extraction with Danish–Kuderna apparatus
   - Vacuum distillation
3. Liquid–liquid extraction
   - Discontinuous extraction with immiscible solvent
   - Continuous extraction with immiscible solvent and Kutscher–Steudel apparatus
4. Liquid–solid extraction
   - Solvent extract of solid in Soxhlet apparatus
   - Solid-phase microextraction
   - Stir bar sorptive extraction

Dynamic headspace methods such as purge and trap, closed loop stripping, and solid-phase microextraction (SPME) are used instead to overcome the problem of adequate detection limits inherent to static headspace sampling. In dynamic sampling, headspace volatiles are removed from the gas phase above the food and concentrated on a suitable adsorbent (activated charcoal, porous polymers, macroreticular resins, polymeric gas chromatography phases) and then desorbed either thermally or with a solvent.

As with static headspace, these dynamic collection techniques are simple and cause minimal artefact formation. SPME, which is a recent technological innovation, was introduced by Janusz Pawliszyn, University of Waterloo, Ontario as a solvent-free sample preparation technique. The method utilizes a fused silica fiber coated with an adsorbent polymeric phase. The fiber is mounted for protection in a syringe-like device, and by depressing the plunger of the syringe the fiber can be exposed to the headspace above the sample matrix. After partition of the headspace volatiles into the coating, the fiber is retracted into the needle and the device interfaced with the appropriate analytical instrument. SPME has been utilized extensively in the analysis of taints and other contaminants in foods. For example, it is used to monitor the presence of 2,4,6-trichloroanisole, the species responsible for cork taint in wines and distilled beverages.

Where the tainting species is only moderately or poorly volatile, headspace methods usually provide insufficient quantities for detection or identification. In these circumstances, quantitative removal of the taint from a larger sample size is a prerequisite, and the method most frequently chosen, particularly if the food matrix is solid, is simultaneous steam distillation-extraction (SSDE). This technique has the added advantage of being able to be operated under reduced pressure, thus minimizing possible thermal decomposition of the tainting species. SSDE has been used extensively to extract chlorophenol, chloroalkylphenol, and chloroanisole-type taints from various food matrices.

If the taint is not steam volatile, techniques based on direct extraction with solvents such as liquid–liquid, Soxhlet extraction, or extraction using the sorptive properties of gas chromatography (GC) polymeric phases, e.g., SPME in matrix immersion mode or stir bar sorptive extraction (SBSE), can be used.

Liquid–liquid and Soxhlet extraction are traditional methods with a long history of usage, but extracts obtained by these techniques may contain variable amounts of nonvolatile material, and additional separation techniques may need to be applied. SBSE is a recently developed extraction technique, similar in principle to SPME, but offering potentially much lower detection limits than SPME. In this technique, a glass magnetic stir bar coated with a polydimethylsiloxane (PDMS) stationary phase is stirred in the sample for several minutes. The analytes of interest come into contact with the PDMS phase and are extracted. Thermal desorption and online gas chromatography-linked mass spectrometry (GC–MS) analysis complete the analytical methodology.

Fractionation of Flavor Extracts

Fractionation of a flavor extract is best achieved using high-resolution GC on fused silica columns. However, despite recent advances in column technology in terms of stability, inertness, resolution, and sample capacity, major difficulties can still be encountered due to the inherent complexity of flavor extracts from many foods and the presence within the extract of only minute quantities of the tainting chemical relative to the other flavor components.

To minimize these difficulties, flavor extracts can be fractionated prior to analysis by GC. For example, flavor extracts, particularly those from SSDE, can be readily fractionated on the basis of chemical functionality into acids, phenols, bases, and neutrals. Fractionation of flavor extracts by conventional open column chromatography on silica gel is also well established. More recently, fractionation of food extracts by high-performance liquid chromatography (HPLC) has been utilized, but to date, this approach has found limited applicability.

An elegant way to optimize the separating power of modern GC capillary columns is fractionation of flavor extracts on two different columns – so-called multidimensional gas chromatography (MDGC). In this technique, initial separation is effected on a precolumn, and then selected fractions are introduced on to a second analytical column, where they are further separated into individual components. The columns can be located in the same oven or in two different ovens: the precolumn can be a packed column, a wide-bore capillary column, or even a high-resolution analytical capillary column coated with a different stationary phase from the second column. The selection of fractions of interest can be optimized by the introduction of a splitting device between the precolumn and detector so that GC effluent from the precolumn can be assessed at a sniff

port. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Detection and Identification of Taints

In addition to the superiority enjoyed by GC over other analytical techniques as a means of fractionating complex flavor extracts, it also possesses major advantages in terms of detection and identification of taints.

GC Detectors

The ubiquitous flame ionization detector (FID) is sensitive and is virtually a universal detector for volatile taints. It responds to most organic compounds but not to air, water, or light fixed gases. Complementing this detector are a variety of GC detectors, which are more specific and, in many cases, more sensitive as well.

The thermionic ionization detector (NPD) is specific for compounds containing nitrogen and/or phosphorus. Known fecal-like tainting compounds such as indole or skatole can be readily detected with the NPD, as can 2-acetyltetrahydropyridine, the cause of mousy taint in wines and cider. More recently, a nitrogen-specific detector based on chemiluminescence, which has a linear, equimolar response and is not quenched by hydrocarbons, has been developed. It has been used to monitor nitrogen-containing flavor volatiles in wine extracts.

The flame photometric detector (FPD) is a very selective and sensitive detector that measures chemiluminescence above a hydrogen-rich flame. By the use of filters and a photomultiplier, it can readily measure nanogram quantities of phosphorus or sulfur-containing compounds. It has been used successfully in many taint investigations and notably in the identification of taints in beer caused by sulfur-containing species.

Recent advances in the development of sulfur-selective detectors have culminated in a new sulfur chemiluminescence detector, which provides a linear and equimolar response to sulfur-containing compounds without interference from most sample matrices.

The photoionization detector (PID) can be used to analyze a wide variety of compounds, including aliphatic and aromatic hydrocarbons, amines, and organic sulfur compounds. Key features of the PID that make it suitable for detecting taints are its sensitivity, generally lower than an FID or FPD, and its wide linear dynamic range. It is also nondestructive and can be coupled in series with other detectors.

Several common tainting species containhalogen atoms, e.g., bromo/chlorophenols and bromo/chloroanisoles, and are therefore readily detected using an electron capture detector. This detector has probably the lowest detection limits of all the common GC detectors and is highly sensitive and selective for molecules containing electronegative atoms; it is, however, very limited in a linear range and requires extensive calibration for quantitative results.

The atomic emission detector is perhaps the most versatile of the selective detectors, since it can be tuned to detect virtually all of the elements in compounds eluting from a gas chromatograph (except helium). With an excellent sensitivity and selectivity, it can be used as a screen for elements to locate target or unknown peaks of interest in complex food matrices.

Despite the many advantages offered by this variety of electronic detectors, biological detectors such as the nose and tongue are probably best suited for detecting the presence of taints in food/flavor extracts. The technique of sniffing the effluent gas as it emerges from the GC – so called odor port gas chromatography (GC-O) – is commonly used in aroma analysis and is particularly useful for locating the position of tainting odorants in a gas chromatogram. The area(s) of the chromatogram that correspond to the taint can be identified, and the number and nature of the tainting species can often be ascertained. This greatly simplifies the primary task of the spectroscopist, which is to establish a chemical structure for each taint.

The usefulness of GC-O was readily illustrated in a recent study of a distilled beverage with an earthy, musty taint. Preliminary analysis of the flavor extract from the tainted beverage identified three members of the polychloroanisole family of taints, but all at subthreshold levels. Analysis by GC-O identified a region in the chromatogram with a strong musty aroma similar to that possessed by the beverage. The GC retention time was different from that of any of the three characteristically musty polychloroanisoles but identical to that of 2-methylisoborneol, a known powerful taint with a musty/camphoraceous odor and taste. Mass spectroscopic data were consistent with the presence of MIB in the tainted beverage. When the untainted beverage was spiked with MIB at $5\,\mu g\,kg^{-1}$, the taint was reproduced. (*See* **Chromatography**: Gas Chromatography.)

Mass Spectrometry

In view of the extremely low levels at which taint in food can be detected by the human sensory organs

and of the limitations on the quantity of taint that can be isolated for identification, the analytical technique best suited for detection and identification of taints is high-resolution GC-MS. Detection and identification of tainting compounds can usually be achieved using GC-MS operated in full scan mode. However, GC-MS operated in either the mass chromatography mode or selected ion monitoring mode is unparalleled in its ability to deliver both sensitivity and selectivity of detection.

Mass chromatography (MC) allows reconstruction of the ion current profiles of selected ions as a function of time from continuously collected data. One of the simplest uses of MC in taint studies is the location of certain classes of compounds in complex mixtures by looking for the presence of characteristic ions from the total ion current trace. For example, by examining at a resolution of 5000 the fragment ion *m/z* 45 (CHS^+) that occurs widely in both aliphatic and aromatic sulfur compounds, it is possible to separate this species from others of the same nominal mass (e.g., $C_2H_5O^+$) and, moreover, to detect those regions in the chromatogram where the sulfur-containing species occur.

With selected ion-monitoring (SIM), the peak selector of the mass spectrometer can record either single or multiple ion characteristics of any specific compound being searched for to provide a series of 'fragmentograms' from separated peaks during a GC run. By monitoring ions of one or just a few specific masses instead of the whole spectrum, a thousand-fold increase in sensitivity (picogram quantities) can be attained.

The successful application of GC-MS operated in the SIM mode to the identification of taints has been readily demonstrated by several groups of workers, and many case histories utilizing this technique have been extensively documented in the scientific literature. (*See* **Chromatography**: Combined Chromatography and Mass Spectrometry.)

Quantification of Taints

In many taint studies where only a limited quantity of tainted food is available for analysis, quantification of the taints by GC-MS is achieved by comparing the SIM responses for each ion monitored with those obtained with standard solutions of the tainting chemical. In these cases, it is usually assumed that complete extraction of the taint from the foodstuff has been achieved. This highlights the major difficulty in obtaining accurate quantification of odorants in general and taints in particular, namely the need to extract, enrich, and separate the taint without losses.

The isotope dilution assay is probably the most precise method for quantifying minor constituents of food such as taints. In this technique, the tainting chemical now labeled with deuterium or carbon-13 is used as an internal standard. Since the labeled standards have virtually the same chemical and physical properties as the taint, the overall efficiency of the extraction and enrichment stages does not influence the result. However, for a solid food, usually only the extract containing the volatile fraction, and not the food itself, is spiked with the labeled internal standard, and 100% efficiency of extraction is again assumed.

Despite the difficulties inherent in these methodologies, quantitative measurements are an essential part of taint studies. In tandem with sensory evaluation, they provide complementary data proving that the compound identified is responsible for the taint.

It is important to remember that taint in foods is a matter of perception: it is the taste/odor threshold level of an odorant, not its presence *per se*, that determines if it will cause taint.

TANNINS AND POLYPHENOLS

B G Swanson, Washington State University, Pullman, WA, USA

Background

Tannins are generally defined as soluble, astringent complex phenolic substances of plant origin used in tanning of animal skins or precipitation of proteins. Tannins are chemically defined as phenylpropanoid compounds often condensed to polymers of variable length. Phenolic compounds are chemically defined as compounds containing hydroxylated aromatic rings, the hydroxy group being attached directly to the phenyl, substituted phenyl, or other aryl group. Tannins and phenolic compounds are widely distributed secondary metabolites in plants, and play a prominent role in general defense strategies of plants, as well as contributing to food quality. The terms 'hydrolyzable' and 'condensed' tannins are used to distinguish between the two important classes of vegetable tannins, namely gallic acid-derived and flavan-3,4-diol-derived tannins, respectively. (*See* **Phenolic Compounds**; **Vegetables of Temperate Climates**: Commercial and Dietary Importance.)

Phenolic Compounds

Phenolic compounds are widely distributed in plant tissues, particularly contributing color, flavor, and astringency to fruits. The concentration of phenolic compounds may vary from 0.5 to 5.0 g per 100 g dry weight of plant tissues. Phenolic compounds are often considered secondary metabolites of plant metabolism that contribute little to the physiological or ecological functions of the plant. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Most phenolic compounds are believed to be byproducts of the metabolism of the aromatic amino acid phenylalanine. A major group of water-soluble phenolic compounds, the anthocyanins, contribute colors to fruits. Two identified anthocyanins, phloridzin in apples and arbutin in pears, occur only in plant tissues and are absent in associated fruits.

The greatest concentrations of phenolic compounds in plants are normally present as cinnamic acid derivatives and flavan monomers, dimers, and polymers.

Cinnamic Acid Derivatives

Cinnamic acids play key roles in the formation of other more complex phenolic compounds. The cinnamic acids (Figure 1) are rarely present in uncombined forms, occurring primarily as esters of quinic acid, but may also be esterified to malic or tartaric acids, or sugars. Chlorogenic acid (5-caffeoylquinicacid) (Figure 2) is perhaps the most important cinnamic acid observed in fruits, contributing 25% of the dry weight of the bilberry (*Vaccinium*) fruit. Chlorogenic acid can be isolated from green coffee beans, and forms a black compound with iron, believed to be responsible for the blackening of cut or cooked potatoes. Anthocyanin and flavonoid glycosides are also acylated by cinnamic acids through sugar hydroxyl groups, with *p*-coumaric acid the most common acylating agent. In addition to forming esters, hydroxylated cinnamic acids also form glycosides with sugars. (*See* **Coffee**: Green Coffee; **Fruits of Temperate Climates**: Fruits of the Ericacae.)

Cinnamic Acids in Fruits

The concentration of cinnamic acid derivatives declines as fruits mature. However, the total quantity

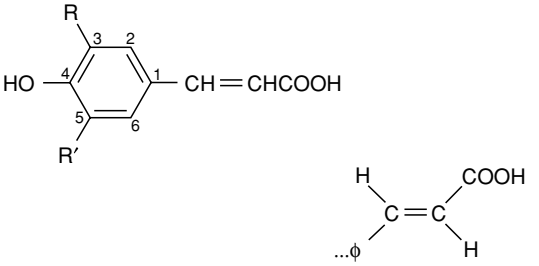

Figure 1 *Trans*-cinnamic acids: *p*-coumaric, R=R′=H; caffeic, R=OH, R′=H; ferulic, R=OCH_3, R′=H; sinapic R=R′=OCH_3.

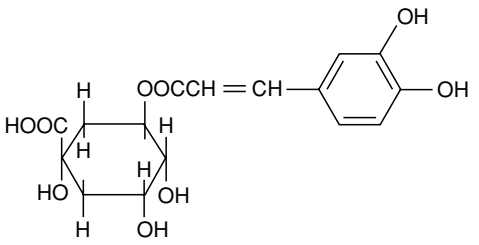

Figure 2 Chlorogenic acid.

of cinnamic acids increases as the fruits enlarge during the growing season. Cinnamic acids accumulate in the skin or peel of fruits. Cinnamic acids, especially chlorogenic acid, which is extensively destroyed during roasting, are important to the acceptability of coffee. (*See* **Ripening of Fruit**.)

Flavans

Flavans are widely distributed in nature and result from a double reduction of a flavanone. The general biochemical derivations of flavonoids are presented in Figure 3. Many natural flavans are lipid-soluble and are prominent in the skin or peel of fruits and in the cutin of leaf surfaces. A number of flavans are phytoalexins, which impart fungi or insect resistance to the plant tissues. Flavans are generally found in greater concentrations in immature fruits compared with mature fruits.

Flavans are not generally observed in plant tissues as monomers, glycosides, esterified, methylated, or in any heterogenous combination, except for galloyl esters in grapes and tea. Flavans generally are condensed to form 'condensed tannins,' more correctly referred to as 'proanthocyanidins.' Flavan-3-ols, catechin and epicatechin, are the largest class of monomeric flavans. A considerable number of flavan-3-ol glycosides can be isolated from plant tissues. (*See* **Tea: Chemistry**.)

The nomenclature of flavonoid and proanthocyanidin structures changes as the number and complexity of this group of plant metabolites expand. Leucoanthocyanidins are defined as monomeric flavonoids that produce anthocyanidins by cleavage of a carbon–oxygen bond on heating with mineral acid. Condensed proanthocyanidins are defined as flavan-3-oligomers, or more generally as proanthocyanidins that produce anthocyanidins by cleavage of a carbon–carbon bond. The isolation, structure, and properties of 'insoluble' proanthocyanins constitute a major unresolved problem for phytochemists, and enologists in particular.

Anthocyanidins and Anthocyanins

Anthocyanins are glycosides composed of the anthocyanidin aglycone plus one or more glycosidically bonded mono- or oligosaccharidic units. Anthocyanins are identified structurally by name (Figure 4). Six anthocyanins are water-soluble pigments common in flowers and plant tissues; although many other anthocyanins exist, they are rather limited among common food plants.

Color variations among the anthocyanins reflect structural differences in the number of hydroxyl groups, the presence or absence of methylation and glycosylation, as well as the distribution of positive charge about the aryl-substituted chroman ring system. Anthocyanins undergo structural alterations, depending upon the pH and ionic strength of the aqueous environment.

Tannins

Tannins are generally defined as polyphenolic compounds, with a molecular weight greater than 500, that precipitate proteins from an aqueous solution. Tannins precipitate proteins owing to functional groups that interact with two or more protein molecules, to form hydrophilic or hydrophobic complexes, building large cross-linked insoluble protein-tannin complexes. Hydrolyzable tannins are classified as gallotannins or ellagitannins on the basis of tannic acid structure relative to gallic or ellagic acids. Hydrolyzable tannins, including tannic acid, can be acid- or enzymatically hydrolyzed to yield glucose and gallic acid.

A second category of polymeric flavonoids, the condensed tannins are not hydrolyzed under physiological digestive conditions, but upon severe acid or alkaline treatment, yield less-soluble polymeric phlobaphanes or monomeric flavonoids such as catechin or epicatechin. Condensed tannins notably contain linkages between the 4-position of one catechin residue and the 6- or 8-position of another flavonoid. The condensed tannin structures are not to be confused with tannic acid, the representative structure of the hydrolyzable tannins.

Analysis of Polyphenolic Compounds

Extraction and separation of anthocyanin compounds generally involve maceration of plant tissue in methanol containing 1% HCl. Qualitative assays with thin-layer chromatography (TLC) have evolved to quantitative assays with high-performance liquid chromatography (HPLC), often utilizing selective absorption wavelengths to determine the identity and concentration. (*See* **Chromatography: Thin-layer Chromatography; High-performance Liquid Chromatography**.)

Much of the emphasis in contemporary natural products chemistry lies in the elucidation of the biological activity of plant metabolites, rather than in the intrinsic interest of the structures themselves. The rationale for the study of proanthocyanidins is to develop a knowledge of proanthocyanidins in plant

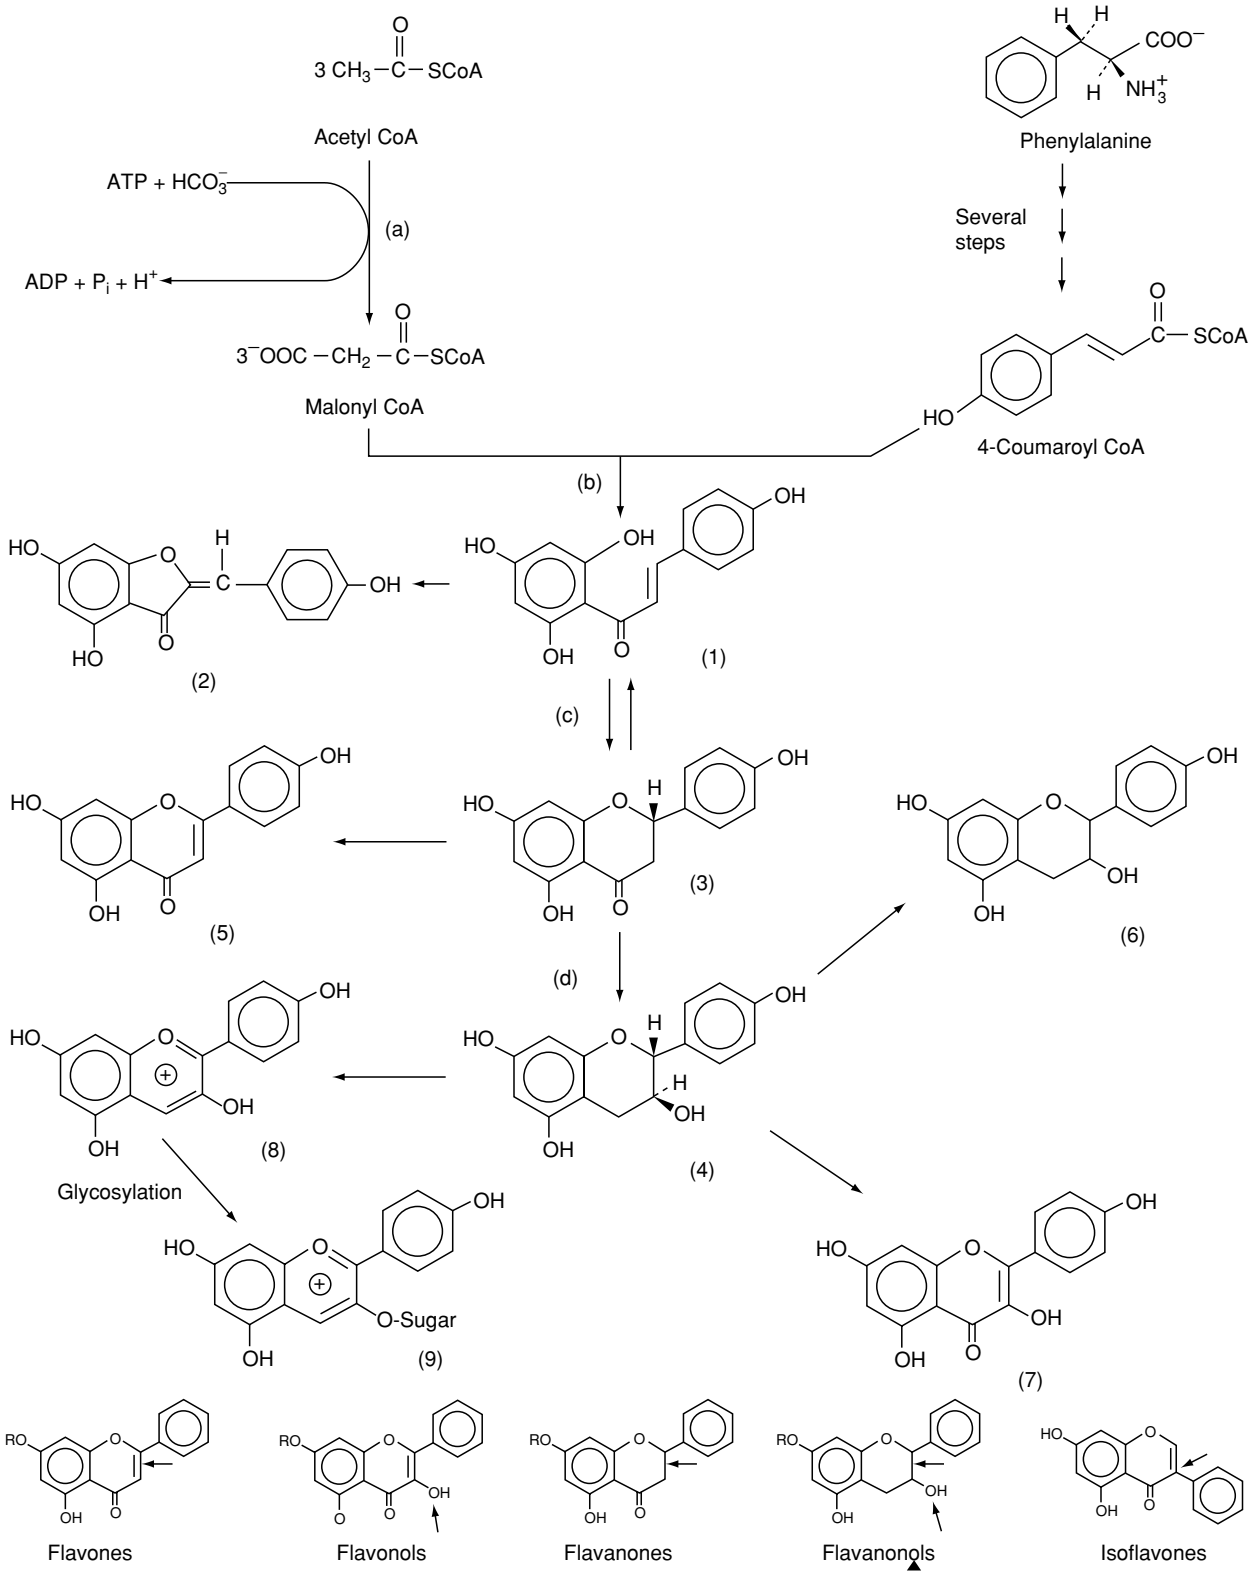

Figure 3 General biochemical derivations of flavonoids. A structural key for the group of compounds is indicated at the bottom of the figure: flavones, position 2,3 is unsaturated; flavonols, C-3 hydroxyl is present; flavanones, 2,3-site is saturated; flavanols, C-3 hydroxyl is present and site 2,3 is saturated; and isoflavones, C-3 phenyl ring substituent is displayed. Pathway key: (a) acetyl-CoA carboxylase; (b) chalcone synthase; (c) chalcone isomerase; (d) flavanone 3-hydroxylase; (1) chalcone; (2) aurone; (3) flavanone; (4) dihydroflavonol; (5) flavone; (6) catechin; (7) flavonol; (8) anthocyanidin; (9) anthocyanin. Isoflavone in the interim formation of chalcones (1) to flavanones (2).

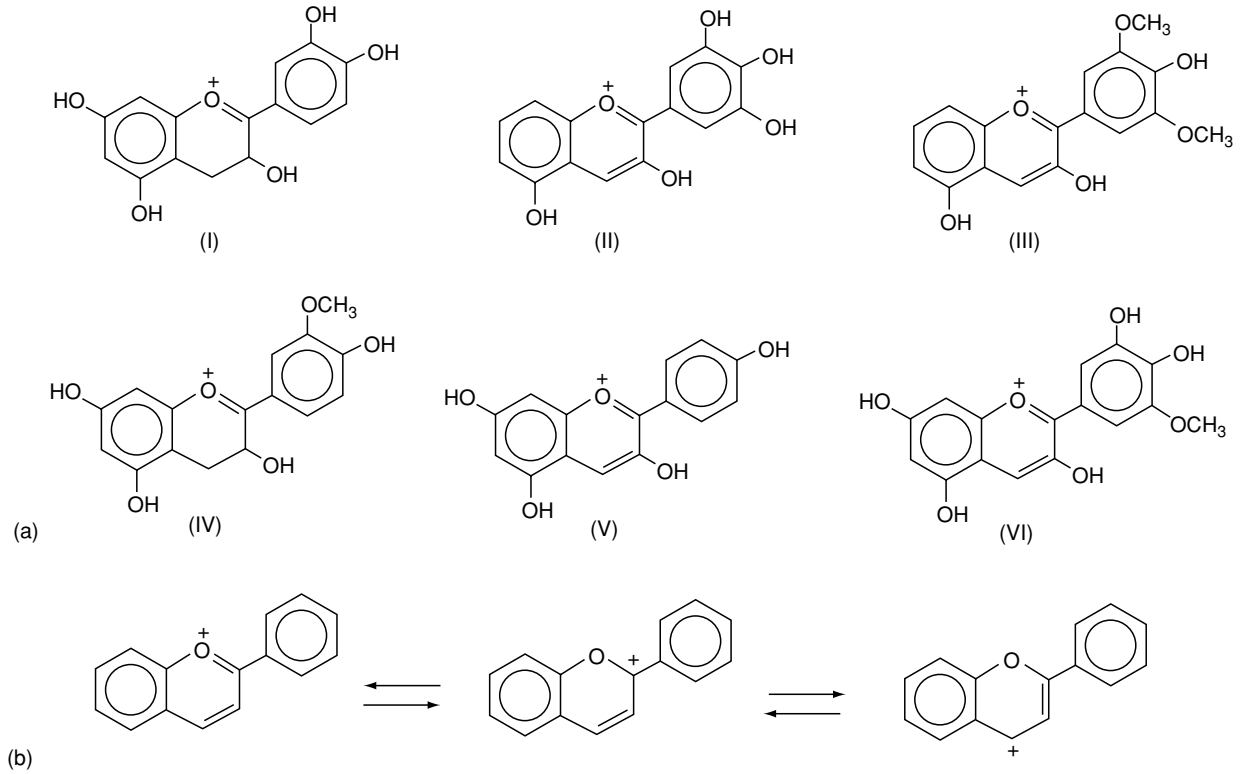

Figure 4 (a) Selected structures for six of the most common anthocyanidins. All anthocyanidins have hydroxyl groups in the 3-, 5- and 7-positions, although each structure may have its own characteristic hydroxyl or methoxyl groups on the so-called B ring: (I) cyanidin, (II) delphinidin, (III) malvidin, (IV) peonidin, (V) pelargonidin, and (VI) petunidin. These compounds occur in many species of fruits and vegetables: apple (I); blackcurrant (I, II); blueberry (I, II, III, IV, VI); cherry (I, IV); grape (I–VI); orange (I, II); peach (I); plum (I, IV); radish (V); raspberry (I); red cabbage (I); strawberry (V-major,I). (b) Possible positive charge distribution over a chroman ring system found in the structure of anthocyanidins.

biochemistry relative to structure and chemistry. To understand the biochemistry of physiologically active proanthocyanidins, the development of strategies to separate and purify proanthocyanidins in an unmodified state is necessary. Using alcoholic solvents, aqueous methanol or ethanol, mono-, di- and trimeric flavon-3-ols are separated from plant tissue with Sephadex LH-20 or a high-porosity polystyrene gel (CHP 20P). More recently, column chromatography on reversed-phase C8, C18 or CN supports has provided alternative separation techniques. HPLC on reversed-phase columns is used extensively for analytical and preparative separation of proanthocyanidins. High-resolution separation is achieved with solvent programming and dilute acid suppression of hydroxyl group ionization. Structural elucidation of proanthocyanidins may be readily determined with nuclear magnetic resonance and circular dichroism spectroscopy. (*See* **Spectroscopy**: Nuclear Magnetic Resonance.)

The condensed tannin content of plant tissues is generally determined by the traditional vanillin-HCl method or protein precipitation.

Physiological and Health Effects

Tannins are generally considered nutritionally undesirable, because they precipitate proteins, inhibit digestive enzymes, and have a detrimental effect on the absorption and utilization of vitamins and minerals. Tannin components have been implicated in incidences of cheek and esophageal cancers in specific regions of the world, and cited as antimutagenic and anticarcinogenic in other studies. Tannins are antimicrobial, inhibiting the invasion and growth of fungi, bacteria, and viruses in food plants. Tannins can theoretically serve as natural regulators of the microbial population in many habitats including the gastrointestinal tract. Tannins are also reported to produce other physiological effects such as immune response, hepatotoxicity, and lipid metabolism. Ingestion of large quantities of tannins may result in adverse health effects. However, the ingestion of small quantities of selected tannins may be beneficial to human health.

Polyphenols in herbal medicines, fruits, and vegetables are often presumed to play an important

physiological role in the maintenance of good health. Polyphenols generally exert their effects by associating with metals, their antioxidant and radical-scavenging activities, and interaction with other molecules, including proteins and polysaccharides. The antioxidant capacity of flavanoids is determined by a combination of the *O*-dihydroxy structure in the B-ring, the 2,3-double bond in conjugation with a 4-oxo function, and the presence of both hydroxyl groups in positions 3 and 5. Recent research efforts are highlighting the exciting and exceptionally dynamic role of polyphenolic components actions as antioxidants or agents of other mechanisms that contribute to their anticarcinogenic, antiviral, antiinflammatory, and cardioprotective effects derived from consumption of plant foods.

Sensory Properties

Flavonoids and anthocyanins contribute yellow, red, and blue colors to flowers, leaves, and fruits. Polyphenolic compounds also contribute sweet, bitter, or astringent flavors, depending on solubility and structure. Flavonoids such as rutin, a 3-rhamnosyl-D-glycosyl derivative of quercetin, contribute undesirable precipitates to processed foods. Tannins and tannin–protein complexes may give fruit juices a desirable body or consistency, or may contribute to undesirable hazing or loss of clarity or sparkle. (*See* **Sensory Evaluation**: Appearance; Taste.)

Pharmacological effects related to estrogen production and induction of infertility, enzyme cofactors beneficial to health, and counteracting of glucose resorption are attributed to consumption of specific polyphenolic compounds. Tannins are often related to astringency and bitterness in wines or foods, and are thought to play a significant role in the reduction of dietary protein digestibility by complexing with either dietary protein or digestive enzymes. (*See* **Coenzymes; Glucose**: Function and Metabolism.)

TASTE ENHANCERS

S S Schiffman, Duke University Medical School, Durham, NC, USA

Introduction

The term 'taste enhancer' is used in the food industry to describe a substance that enhances the sensations of food (or food ingredients) when introduced into the mouth. The use of the term 'taste' is colloquial and actually refers to flavor (both taste and smell) because chemicals from food activate receptors in the nose as well as the mouth. Enhancement of the taste and smell of food is desirable to improve palatability, increase total intensity, potentially reduce the cost of ingredients, and compensate for chemosensory (taste and smell) losses in vulnerable populations such as the elderly. Enhancement can be achieved in two ways: (1) by simply adding more molecules to the food or (2) by potentiating the intensity through synergism and/or alteration of receptor mechanisms without altering the total number of molecules.

Enhancement by Addition of Molecules

Many food ingredients, including monosodium glutamate (MSG), NaCl, and sweeteners have been termed 'taste enhancers' but their main effect is simply to add more molecules that generate additional taste or smell sensations. Tastants such as MSG, salt, and sweeteners don't actually boost other chemosensory properties but rather contribute additional meaty/savory, salty, or sweet properties respectively.

Experimental studies have shown that MSG at concentrations up to $0.005\,\mathrm{mol\,l^{-1}}$ does not alter the intensities of other food ingredients including salts, sweeteners, amino acids, acids, or bitter compounds. MSG is a taste enhancer strictly from the standpoint that it adds another taste quality to the food (called umami in Japanese) which improves palatability rather than altering the intensity of other ingredients. Similar conclusions pertain to the 'enhancing' effects of NaCl and sweeteners that add saltiness or sweetness to food, respectively; they also improve palatability by reducing bitter components of some food substances. Thus MSG, salt, and sweeteners are taste enhancers from the standpoint that they add additional tastes to the food and improve palatability rather than potentiate the taste intensity of other ingredients.

Analogous reasoning can be applied to flavors. Commercial flavors are often added to food for the elderly (called 'flavor enhancement') to compensate for losses in smell perception that occur in elderly individuals. Flavors consist predominantly of mixtures of odorous molecules that can be extracted directly from natural foods or can be synthesized after chromatographic and mass spectrographic analysis of natural products. Simulated flavors are flavor enhancers only from the standpoint that they increase the total number of molecules that interact with receptors on chemosensory membranes in the nose and mouth. Intensification of odor can improve palatability, induce more salivation, produce greater stimulation of the olfactory and limbic system of the brain, and promote immune function via mechanisms described below under positive health benefits of chemosensory enhancement.

Although odorants and tastants are perceived by two different senses, the perceived intensity of a tastant may also increase with the addition of odorant molecules. For example, perceived sweetness intensity is enhanced by the addition of odorants, especially for congruent taste/odor mixtures such as sucrose/strawberry and sucrose/lemon. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Enhancement by Synergism

Taste enhancement also occurs via synergism in which the total intensity of a mixture is greater than the expected intensity based on the concentration of the individual components. Two methods of calculating the degree of synergy have been used: one which simply compares the perceived intensity of a binary mixture (for example) with the sum of the intensities of the unmixed components, and a second which compares the intensity of binary blends to the average of the two pure components of the blends. The most common practical application of synergism occurs with the use of certain binary or ternary sweetener combinations in beverages. That is, when one sweetener is combined with certain other sweetener(s), it produces a synergistic sweetening effect. Synergism permits the blending of low concentrations of sweeteners such as saccharin or acesulfame-K, that are bitter at higher concentrations, with sweeteners without salient bitter components such as aspartame and fructose to achieve a desired level of sweetness. Synergistic effects are idiosyncratic and vary with the chemical structure of the individual ingredients. Synergistic effects can occur between two or more

high-potency sweeteners (such as aspartame and acesulfame-K), between a high-potency sweetener and sugars (such as acesulfame-K and fructose), and between combinations of sugars such as fructose and sucrose. The maximum synergy found for binary mixtures of sweeteners is about 74%; the maximum synergy found for ternary mixtures of sweeteners is as much as 99%. The precise mechanisms that produce synergism among sweeteners are not known at the present time. However, it is probable that multiple receptors as well as biochemical transduction mechanisms in taste cells play a role.

Enhancement by Modifying Receptor Mechanisms

A variety of compounds have been shown in a laboratory setting to enhance taste perception including: (1) caffeine (and other methyl xanthines); (2) 5′ ribonucleotides; (3) inosine; and (4) bretylium tosylate. However, only 5' ribonucleotides are commercially practical enhancers because the other compounds require pretreatment of the tongue to achieve potentiation.

Methyl Xanthines

Pretreatment (adaptation) of the tongue with methyl xanthines has been shown to enhance other taste stimuli. Methyl xanthines, including caffeine, theophylline, and theobromine, are found in coffee, tea, and chocolate, respectively. When the tongue was adapted to caffeine, theophylline, or theobromine at concentrations ranging from 10 μmol l^{-1} to 10 mmol l^{-1}, the taste intensities of acesulfame-K (a sweetener), sodium chloride, potassium chloride, and quinine hydrochloride were enhanced. Furthermore, 10 μmol l^{-1} caffeine potentiated the taste of moderate concentrations of other sweeteners, including neohesperidin dihydrochalcone, D-tryptophan, thaumatin, stevioside, and sodium saccharin. Sweeteners potentiated by caffeine had a bitter component; sweeteners without prominent bitter components, including aspartame, sucrose, fructose, and calcium cyclamate, were not potentiated by caffeine. It has been hypothesized that this enhancement by pretreatment with methyl xanthines may be caused by the antagonistic effect of methyl xanthines on adenosine receptors on the tongue surface. (*See* **Alkaloids**: Properties and Determination; **Caffeine**.)

Inosine-5′-Monophosphate (IMP)

The 5′-ribonucleotides, inosine-5′-monophosphate (IMP) and guanosine-5′-monophosphate (GMP), have been shown to enhance certain tastes. A mixture of 5′-ribonucleotides with MSG can potentiate the taste of suprathreshold concentrations of MSG. The nucleotides with the best enhancement capacity appear to be those having a purine nucleus with a hydroxy group in the 6-position and a ribose moiety esterified in the 5′-position with phosphoric acid, e.g., IMP and GMP. Addition of 0.1 and 1 mmol l^{-1} IMP to MSG also reduces the MSG taste threshold so that it can be perceived at lower concentrations (fewer molecules are needed for detection). Pretreatment of the tongue with 1 mmol l^{-1} IMP enhanced the taste of both sucrose and aspartame by approximately 60 and 40%, respectively. Biochemical studies indicate that the synergism between MSG and certain 5′-ribonucleotides is a peripheral event involving alterations in glutamate receptors on the taste bud. Inosine, a breakdown product of both IMP and of adenosine, has also been found to enhance moderate tastes of sucrose, aspartame, and sodium chloride when the tongue is pretreated with inosine.

Bretylium Tosylate

Pretreatment of the tongue surface with bretylium tosylate, a quaternary ammonium compound that is used as an antifibrillary drug, enhanced the taste of sodium chloride. Bretylium tosylate has been shown to open amiloride-sensitive sodium channels in other biological systems. Bretylium tosylate may act in a similar fashion on the human tongue by increasing sodium transport through the amiloride-sensitive channels on the tongue that are known to be involved with salty taste.

Positive Health Benefits of Chemosensory Enhancement

Enhancement of the sensory properties of meats, soups, vegetables, and other nutritious foods with food flavors and MSG not only compensates for taste and smell losses that occur in an elderly population but can also improve health status. Four clinical studies of frail elderly described here have shown that amplification of the flavor levels of foods to preferred levels is associated with increased total numbers of lymphocytes (including T cells and B cells), increased secretion rate of salivary immunoglobin A (IgA), and improved functional status. Furthermore, flavor enhancement resulted in improved immunity and functional status even when macro- and micronutrient intakes were uneffected.

Study 1: Flavor Enhancement Increases T- and B-Cell Levels in the Elderly

Flavor enhancement of table food for independent living residents at a retirement home has been

shown to improve immune status as determined by T- and B-cell levels as well as grip strength. In one study, 39 elderly residents were divided into two groups. Group 1 received food that was unenhanced by flavor for the first 3 weeks, and food that was enhanced by flavor for the second 3-week period. For group 2, the order was reversed; they received enhanced food for the first 3-week period and unenhanced food for the second 3-week period. The menu plan during the 3 weeks of flavor enhancement was identical to the menu plan during the unenhanced 3-week period. During the 3 weeks of flavor enhancement, six different flavors were added to selected nutrient-dense foods: roast beef, ham, natural bacon, prime beef, maple, and cheese. Flavors were added to some, but not all, foods at a meal in the flavor-enhanced condition. Analysis of the data indicated that the elderly subjects consumed the same macro- and micronutrients on the two arms of the study. This occurred because not all foods at a meal were enhanced during the 3-week experimental period of flavor enhancement; subjects simply ate less of foods that were not enhanced. This study was repeated with 4-week (rather than 3-week) food rotations in which MSG as well as flavors were added on the 4-week enhancement arm of the study. In both studies there was an increase in T- and B-cell levels and improved grip strength after flavor enhancement, even though macro- and micronutrient intakes were not affected.

Study 2: Flavor Enhancement Improves Secretion Rate of Salivary IgA

Taste and odor stimuli have also been shown to increase the secretion rate of IgA in the saliva of both young and elderly individuals. IgA is an antibody that protects mucosal surfaces. Flavors can either be dropped on the tongue from an eye dropper or delivered in food. The main finding of such studies is that chemosensory stimulation improves mucosal immunity in two ways: (1) by increasing saliva production and (2) by increasing the absolute concentrations of secretory IgA in the saliva. These results have important implications for the elderly, who often suffer from dry mouth and reduced salivary flow (and hence reduced mucosal immunity) due to normal aging, diseases, and medications they are taking.

Study 3: Sensory Enhancement of Foods Increases Intake in Sick Elderly

Enhancement of hospital food with a combination of flavors and MSG has been shown to improve intake in over 90% of patients. In addition, when sensory enhancement was performed for a week or more, there was improvement in plasma protein levels (including somatomedin-C/insulin-like growth factor I, albumin, and transferrin) and T lymphocytes in some patients.

Study 4: Flavor Enhancement of the Entrée at Dinner can Reduce Sodium Intake by 500 mg

Enhancement of an unsalted entrée with salt-free flavors can reduce the sodium levels in a meal without compromising ratings of satisfaction. This finding was obtained in a study at a retirement home performed over an 8-week period during which salt shakers were removed from the tables. During the study, two entrées (beef steak and chicken breast) were each served once a week. For the first 2 weeks (control period), the entrées (beef or chicken) were salted with 500 mg sodium (the minimum preferred level of table salt for this population). For the subsequent 6 weeks (experimental period), the flavor of the entrées was enhanced by marination in sodium-free beef or chicken flavor prior to cooking; no table salt was added to the beef or chicken. Two vegetables which were lightly salted in the kitchen accompanied the entrée. During the 6 weeks of flavor enhancement, the sodium content of the meal was reduced by 500 mg. Throughout the study, residents were asked to rate their satisfaction with the sensory properties of each meal after eating. Analysis of the data indicated no significant difference in the degree of satisfaction between meals with the salted version of the entrée and the flavor-enhanced (sodium-free) version. This suggests that enhancement of odor can replace salt in an entrée with no adverse affects on acceptability when two lightly salted vegetables accompany the meal. Thus, providing more sensory input in the form of odor can reduce the need for taste stimulation by salt, and could make it easier to comply with recommended daily intake of sodium (3000 mg or less).

Conclusion

Enhancement of the taste and smell of food can be achieved in two ways: (1) by adding more molecules to the food or (2) by potentiating the intensity through synergism and/or alteration of receptor mechanisms without increasing the total number of molecules. Taste (and smell) enhancement can improve palatability, increase total intensity, potentially reduce the cost of ingredients, compensate for chemosensory (taste and smell) losses in vulnerable populations such as the elderly, and improve a number of nutritional and health parameters.

TEA

Contents

Types, Production, and Trade

S Taylor, Natural Resources Institute, Chatham Maritime, Kent, UK

Introduction

Tea is one of the most popular beverages in the world, providing a valuable source of income to many producer countries. There are a number of factors accounting for the popularity of tea, including its sensory properties, relatively low retail price, and apparent health benefits. This series of articles on tea presents information on the types, trade, agronomy, processing, chemistry, analysis, and quality of tea.

Origin and Distribution

The probable center of origin of tea is in south-east China near the source of the Irrawaddy river. From there it spread to the southern portion of China, parts of India, Burma, Thailand, Laos, and Vietnam. From these main centers in South-east Asia, tea has spread into many tropical and subtropical countries. It is thought that tea was introduced into Japan around AD 600. In the early part of the nineteenth century, unsuccessful attempts were made to establish Chinese tea in India. Only when the native 'wild' tea plants found in Assam were used did tea production in India become successful. The main areas of production in India are the north-east and later the south. Tea was introduced into Indonesia as early as 1690, but commercial production began much later (1878), with the cultivation of Assam varieties. Extensive

plantings were started in Ceylon (now Sri Lanka) during the 1870s. The cultivation of tea has since spread to other Asian countries, such as Turkey, Iran, Taiwan, Bangladesh, and Malaysia. In the late nineteenth century, cultivation of tea spread beyond Asia to Africa and South America. Tea was first introduced into Malawi in 1886 and into East Africa at the beginning of the twentieth century. Production of tea in the former Soviet Union began on a large scale in 1892. Today, tea is grown in over 30 countries. The most northerly region in which tea is grown today is Georgia, in south Russia, and the southernmost is South Africa, and the Argentine in South America.

Classification

The tea plant, *Camellia sinensis* (L.) O. Kuntze, is the only important economic species of the family Theaceae. Two botanical varieties have been recognized.

China Teas (*Camellia sinensis* var. *sinensis*)

These teas are produced from slow-growing, dwarf trees (which grow to a height of 4–6 m if unattended), with small, erect, comparatively narrow, markedly serrated, dark green leaves which are smooth with a matt surface; the flowers are borne singly. The plant is relatively resistant to cold and, as a result, the variety is found in the more temperate producing regions such as China, Japan, the former Soviet Union, Turkey, Iran, and the northern, higher-altitude growing areas of India. It is known to produce delicately flavored tea when grown at high altitudes; it is, however, low-yielding, especially at very high altitudes, such as Darjeeling.

Assam Teas (*Camellia sinensis* var. *assamica*)

This variety is faster-growing and taller (12–15 m unattended) than the China variety with larger glossy elliptical leaves; flowers are found in clusters of 2–4. This variety is less resistant to cold than the China type and, as such, can only survive at high altitudes near the Equator. In general, it is a much higher-yielding plant than the China type, and produces a less delicately flavored beverage.

Numerous hybrids between China and Assam types are known. There is evidence that *C. irrawadiensis* was hybridized with *C. sinensis* var. *assamica* to produce the uniquely flavored Darjeeling tea. As tea is largely cross-pollinated, and much of the commercial crop is raised from seed, the crop is very heterogeneous.

The term 'jat' is used to indicate seed derived from different districts or plantations or to separate types on the basis of foliar characteristics.

Types of Processed Tea

Fermented or Black Tea

Black teas form the major proportion of tea consumed in the western hemisphere. They are produced by full fermentation and roughly classified as plain or flavory.

Plain black teas are produced and sold on the basis of the taste characteristics associated with the phenolic substances produced during fermentation. These teas are mainly produced and exported from Africa (e.g., Kenya and Malawi) and India (Assam). High-quality plain teas are often known as breakfast teas. (*See* **Phenolic Compounds**; **Tea**: Chemistry.)

Flavory black teas are sold on the basis of their aroma characteristics and should not be confused with flavored teas, to which fragrances have been added. They are primarily manufactured in areas of relatively high altitude in Sri Lanka and India (Darjeeling). In Sri Lanka, the very flavory teas are produced during January and February in the Dimbula district, and during August and September in the Uva district. In these areas, the desired aroma is produced during cool, clear, dry windy weather with day and night temperatures of about 20 °C and 6–10 °C, respectively. These conditions must last for at least two consecutive weeks and even slight rain will set the process back to the beginning. The famed first- and second-flush Darjeeling flavor is produced under similar conditions when growth is slow and the plants are under climatic stress.

Green Tea

Green tea is entirely different from black tea in its preparation. There are no fermentation products and the leaf remains green. It is generally produced from var. *sinensis*. When infused, the liquors are greenish, pale primrose, or lemon-yellow in color with no trace of red or brown. Green tea is produced and consumed mainly in China and Japan. Some is also consumed in northern Africa. Often, green tea production is a cottage industry, not only in the countries mentioned above, but also in other countries such as Malaysia, Thailand, Vietnam, and Indonesia. This processing is often undertaken by experienced Chinese tea makers. (*See* **Tea**: Processing.)

There are many different kinds of green tea produced, differing in style and cup characters. Some varieties of green tea include the following:

- Sencha, the most widely drunk grade of green tea in Japan.
- Kamaira-cha, made from young leaf, but differing from sencha in that the first process is parching and not steaming.

- Bancha, made from coarse leaf and stalk.
- Gyokuro, one of the finest green teas; it is grown under complete shade, hand-plucked and hand-sorted. It has a twisted dark green leaf.
- Matcha, a powdered tea also made from shade-grown leaf.
- Tencha, the ceremonial green tea. The beverage is a suspension of finely ground leaf.
- Gunpowder, made in the form of small compact pellets of Chinese green tea.
- Pilo chun, a small-leaved Chinese tea made from the first spring flush.

Partially Fermented Tea

Typical partially fermented teas include oolong and pouchong teas. These are partially oxidized so that their appearance is somewhat intermediate between that of green and black tea. Pouchong teas have a shorter fermentation time. They are manufactured primarily in China and Taiwan. Clones selected for oolong and pouchong tea production are characterized by the ability to impart a strong flowery aroma to the product. (*See* **Tea**: Processing.)

Instant Tea

Instant tea is the water-soluble extract of tea leaf, usually marketed as a powder, flake, or granule, either pure or as a part of flavored mixes. Iced lemon teas are the most popular examples of instant teas, particularly in the USA. Most instant tea is made from black tea, but some is made from green tea. It is manufactured in a number of tea-growing countries, e.g., Kenya and China, where the starting material may be fermented leaf that has not been dried.

Flavored Teas

Teas are sometimes scented with various plant essential oils such as lemon, bergamot, rose, and fragrant olive which impart sweet floral attributes to enhance the natural flavor of the tea. Other teas are blended with flower petals, spices, or dried leaf such as chrysanthemum, rosemary, camomile, and peppermint. Floral flavored teas are mainly consumed in the USA while herbal teas are popular in continental Europe. Many of these products are sold through health food stores and may not contain *C. sinensis*: the word 'tea' refers to their method of preparation. These products are often promoted on health grounds, particularly if they are caffeine-free. (*See* **Essential Oils**: Properties and Uses.)

Decaffeinated Tea

Decaffeinated tea has been popular in the USA since its introduction in 1983; however, in the UK the picture has been slightly different. Until the late 1980s it was primarily retailed through health food outlets; however more recently a number of specialist tea companies have launched decaffeinated tea bags into the mainstream grocery trade with considerable success.

Caffeine is removed from tea by treating it with one of three organic solvents: methylene chloride, ethyl acetate, or supercritical carbon dioxide. The caffeine is dissolved in the solvent and the tea is then treated to remove most of the solvent. (*See* **Coffee**: Decaffeination.)

Organically Grown Tea

Organically grown teas from Tanzania first entered the UK market in 1989 under the Natureland brand name from the London Herb & Spice Company. The tea bags were sold at a 20% premium price over other speciality teas and at more than double the price of regular tea bags. Since this time other organically grown tea products have appeared on the market. The major producers are India and Sri Lanka.

The attraction to the grower is substantially increased price for the crop and the saving of hard currency on chemical fertilizers and pesticides. It is believed that the average transition period from conventional to organic culture is 3 years, allowing time for chemicals to disperse.

World Production

According to statistics compiled by the International Tea Committee, tea production over the past decade (1988–98) increased from 2.48 million metric tons (mt) to 2.96 million mt. This represents an average annual rate of increase of 1.9%. The major producers are listed in Figure 1 along with their average production for the 1995–97 period and for 1998, the last year for which figures are currently available. The 3-year averages have been included to reveal the trend of changes in production through the smoothing of year-to-year fluctuations.

India is currently ranked as the world's largest producer of tea, followed by China, Kenya, and Sri Lanka. Kenya in particular had a record production for 1998 that represents an increase of over 33.3% from the 1997 drought-affected crop. Increases in both yields and planted area are likely to continue to support strong growth in tea production in African countries where the Kenyan output is expected to increase at an average annual rate of 2.8%. Malawi, Tanzania, and Zimbabwe are also expected

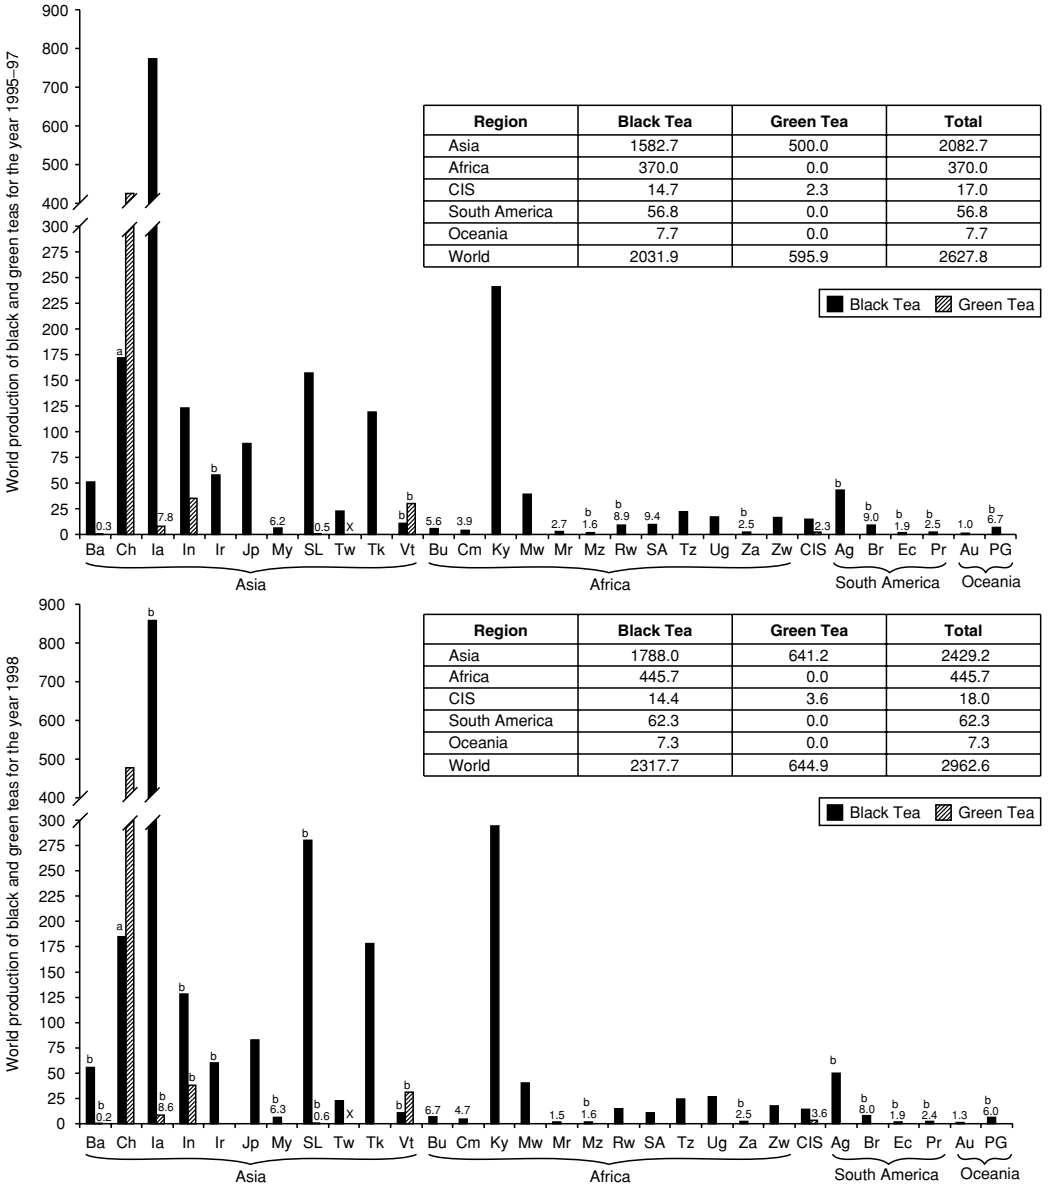

Figure 1 World production of black and green teas for the 1995–97 period and 1998 (× 1000 Mt). [a]Black and other teas, but not green teas. [b]Figures shown are provisional or estimated. Data from the Annual Bulletin of Statistics (2000).

to increase production significantly. The Intergovernmental Group (IGG) on Tea of the Food and Agriculture Organization (FAO) of the United Nations predicts that production in India will reach 1.02 mt in 2005. Economic reforms and the national plan to expand tea production in Sri Lanka could boost production to 285 000 mt, compared to 157 800 mt during the 1995–97 period. Other major tea-producing countries, including China and Indonesia, should also see significant growth in production, while in Bangladesh production is forecast to grow less rapidly.

Production expansion programs initiated by major exporting countries have contributed to previous increases in output of black tea in recent years, and the impact of these programs, particularly as bushes reach optimum production age, may continue.

The total tea area under production has increased from 1.4 million hectares in 1961 to 2.3 million

hectares in 1996. The average yield per hectare has increased by over 50% during the same period. However, it is questionable whether any large-scale increases will ensue from now on.

World Trade

Tea Retained in Producing Countries

In 1998, over 57% of the world's production of tea was retained in producer countries. In some countries it was much higher: Over 76% of the Indian and 74% of the Chinese production is retained for internal consumption. For India, in particular, the home market has increased greatly from 499 053 mt (1988) to 667 565 mt (1998). For a number of other countries, e.g., Iran, Japan, Malaysia, South Africa, Taiwan, and the Russian Federation, the majority, if not all, of their tea produced is consumed internally. African producer countries generally export the majority of their production, whereas most Asian producers do not.

Exports

World exports of tea, both black and green, for the 1995–97 period and for 1998 are reported in Figure 2. All major exporting countries maintained significant export volumes for 1998. The FAO projects that net export availabilities will reach 1.292 million mt in 2005 and predicts that China, India, Indonesia, Sri Lanka, and Kenya will account for 78% of this increased volume. Bangladesh, Malawi, Tanzania, Turkey, and Zimbabwe are also expected to increase their export capabilities significantly by 2005. Exports from India, the world's largest tea-producing and -consuming country, are expected to recover from the recent disappointing performance due to weather, while satisfying growing domestic demand.

The largest and most significant exporter of green tea is China. Major destinations for green tea include Morocco, the Russian Federation, Algeria, the USA, and Afghanistan. India exports small amounts of green tea to the USA, Afghanistan, and Japan. China also produces a number of other teas, e.g., partially fermented, and the major export destinations for these are Hong Kong and Japan. Taiwan produces and exports oolong, pouchong, and green tea, with Japan being the largest importer of these. The Japanese, in turn, export a small proportion of their green teas, primarily to the USA.

Imports

Imports for Consumption Figure 3 shows tea imports for consumption of major importing countries for the 1995–97 period and for 1998. The UK and the Confederation of Independent States (CIS) countries – particularly the Russian Federation – were the largest importers of tea for internal consumption. Other major destinations for tea include Pakistan, the USA, Egypt, Japan, Iraq, and Morocco. Growth in developed countries is expected to be largely concentrated in the CIS countries, the USA, and, to a lesser extent, western Europe. Consumption in the UK has been declining since 1961 when consumption per head was 4.5 kg, and reached its lowest point of 2.4 kg in 1995. The FAO reports that the apparent consumption per head has since stabilized and rose to 2.49 kg in 1996 and 2.58 kg in 1997. This is reflected in consecutive increases in net imports for these years.

Reexports of tea A proportion of the tea imported into the UK is reexported. The largest recipients of this reexported tea are Canada, Germany, Saudi Arabia, and France. The Netherlands also reexports a high proportion of its imports.

Marketing

Most of the world's black tea production is traded in either auction or forward markets. The former accounts for the largest proportion of the total tea traded. In 1997, 84% of the total tea traded was sold through auctions held in producer countries, namely: Mombasa (Kenya), Guwahati, (India), Siliguri (India), Calcutta (India), Cochin (India), Coimbatore (India), Chittagong (Bangladesh), Colombo (Sri Lanka), Jakarta (Indonesia), and Limbe (Malawi). The auctions take place weekly through the growing season.

Tea sold through forward contracts is gaining popularity. A significant advantage of this market over the auction market is that the participants can lock on prices they wish to trade in the future. In the forward market, a buyer and a seller buy/sell an agreed amount of goods for delivery on an agreed future date at a predetermined price. Prices in this market tend to be less transparent than auction prices (spot or cash markets).

Tea Consumption

According to the FAO, black tea consumption will increase from 1.97 million mt in 1993–95 to 2.67 million Mt by 2005 – an annual growth rate of 2.8%. Statistics collated by the International Tea Committee indicate that this is an underestimation, as the total world production for 1998 exceeds the FAO estimate for 2005. Developing countries are forecast to account for the largest part of the

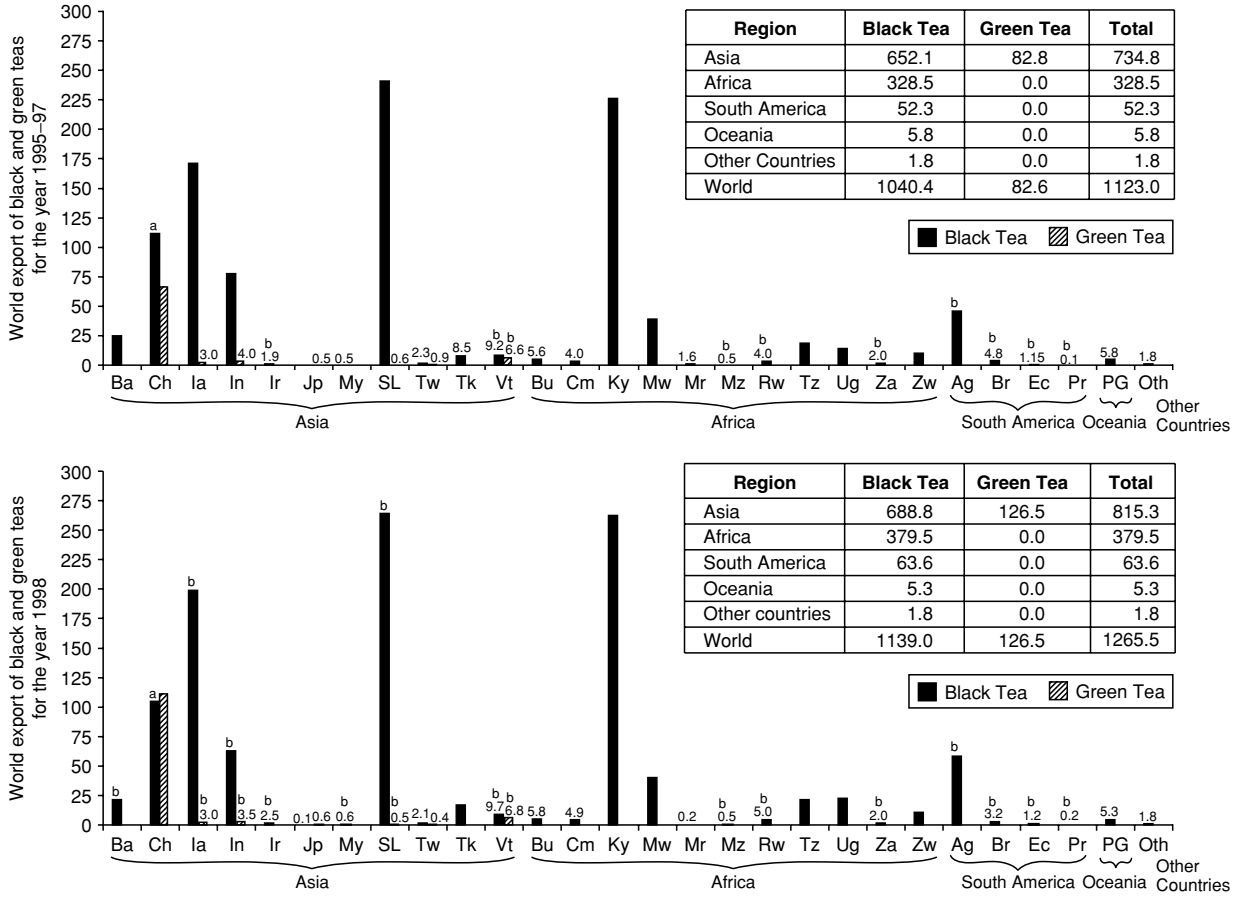

Figure 2 World export of tea (black and green) for the 1995–97 period and 1998 (× 1000 Mt). [a]Black and other teas, but not green teas. [b]Figures shown are provisional or estimated. Ba: Bangladesh, Ch: China, Ia: India, In: Indonesia, Ir: Iran, Jp: Japan, My: Malaysia, SL: Sri Lanka, Tw: Taiwan, Tk: Turkey, Vt: Vietnam, Bu: Burundi, Cm: Cameroon, Ky: Kenya, Mw: Malawi, Mr: Mauritius, Mz: Mozambique, Rw: Rwanda, Tz: Tanzania, Ug: Uganda, Za: Zaire, Zw: Zimbabwe, Ag: Argentina, Br: Brazil, Ec: Ecuador, Pr: Peru, PG: Papua New Guinea. Data from the Annual Bulletin of Statistics (2000).

prospective increase, with consumption rising from the 1993–95 average of 1.41 million mt to 1.95 million Mt by 2005 – an annual growth rate of 3%.

The FAO reports that black tea consumption in India will rise rapidly, reaching 832 000 Mt by 2005, annual growth of 3.2% from the 1993–95 average. In other major markets for black teas, such as Pakistan, the Islamic Republic of Iran, and Egypt, consumption is projected at 160 000 Mt, 122 000 Mt, and 90 000 mt by 2005, respectively. The reduction of import tariffs and declining prices could have a more pronounced effect on consumption in these countries.

Consumption in the European Community is projected to increase only slightly in the next decade since higher purchases by France, Germany, Italy, and the Netherlands would be largely counterbalanced by the decline in consumption in the UK that began in 1961. Consumption in the USA is projected to increase, though at a relatively slow rate of less than 1%. In the countries of the former Soviet Union, black tea consumption is projected to increase from 154 000 mt in 1993–95 to 250 000 mt in 2005, equivalent to an annual growth rate of 4.5%.

Trends in World Supply, Demand, and Prices

The FAO projections indicate that, by 2005, world black tea production and consumption could almost be in balance. Production gains are expected to come largely from higher yields, while the rise in consumption is from population and income growth. Developing countries are expected to account for most of the growth and their share in world consumption is expected to rise by 2% 2005. However, much will depend on the economic development of these countries.

Data from the Annual Bulletin of Statistics (2000).

The FAO projections suggest an imbalance in the international market, with a surplus of export availabilities over import requirements, reaching 24 000 Mt by 2005 from an almost balanced market in 1993–95. This possible imbalance implies that world market prices would be under downward pressure if there were no additional increase in demand and/or downward adjustments in production. One of the ways to narrow the trade deficit and improve prices is to expand consumption through promotion. Over the last few years, the IGG on Tea has made major efforts to create awareness of the health benefits of tea drinking and to work out a generic promotion program that would stimulate consumption of tea.

The FAO reports that auction prices of black tea rose significantly during the first quarter of 1998; however they failed to maintain this vigor during the remainder of the year. Tea prices were boosted in 1997 and early 1998 by reports of drought-induced damage to the crops in Kenya and Indonesia, as well as strong import demand in the former Soviet Union. However, following the production recovery in Kenya, and to a lesser extent in Indonesia, coupled with a sharp drop in import demand from the Russian Federation due to deterioration of economic conditions, prices weakened significantly during 1998.

Tea

Tea beverages are processed from the young tender shoots of *Camellia sinensis* (L) O. Kuntze. The plant biosynthesizes several chemicals during growth. **Table 1** summarizes the approximate chemical composition of dry tea leaves. The polyphenols, dominated by catechins (or flavan-3-ols) constitute up to 32% of the dry weight of young tender shoots. The tender tea plant shoots also contain both saturated and unsaturated fatty acids, either as glycosides or as

free acids. There are also methlyxanthines (mainly caffeine), amino acids and proteins, terpenes, and terpene glycosides, and many endogenous primary volatile flavor compounds. Although the biosynthetic pathways of these compounds are interesting, only the chemical and biochemical processes (after the young tender shoots have been plucked to make various kinds of tea beverages) are discussed here.

Of the many tea beverages, the most extensive chemical transformations occur during black tea processing. The article shall therefore reflect the chemistry of tea as represented by black tea manufacture, although, these chemical reactions partially occur to different degrees in the processing of other tea beverages.

Polyphenols

Polyphenols play a key role in the chemistry of the formation of the nonvolatile components of black tea. Although attempts to understand the chemistry of the formation of the nonvolatile black tea components started over half a century ago, to date, the chemistry is only partially understood. The young tender shoots of the tea plant used to process tea beverages contain high amounts of polyphenols, comprising flavanols (catechins), flavanol glycosides, leucoanthocyanins, and phenolic acids, etc.

The dominant polyphenols in green leaf are flavanol (Figure 1) comprising (+)-catechin (C), (+)-gallocatechin (GC), (−)-epicatechin (EC), (−)-epigallocatechin (EGC) and (−)-epigallocatechin gallate (EGCG). These compounds dominate the chemistry of nonvolatile compounds in tea. Several factors, including climate, genetic make-up, age of shoots and agronomic practices, cause variations in the total amounts and ratio of these compounds in young tea shoots. Although, recently, (−)-epicatechin-3,5-digallate and 3-methylgallates of (−)-epicatechin and epigallocatechin have been isolated in green tea leaves, their chemistry with respect to tea processing remains unknown. (+)-Catechin-3-gallate (CG) and (+)-gallocatechin-3-gallate (GCG) have also been isolated in manufactured teas, but not from fresh leaves. They are likely products of epimerization or racemization caused by firing (drying).

The other important component in the chemistry of nonvolatile components of tea is polyphenol oxidase. This is an *o*-dihidroxyphenolic oxygen reductase enzyme leading to the production of *o*-quinones. The enzyme is abundant in young tender shoots of green tea leaves, especially those cultivars suitable for making black teas.

The most noticeable chemical transformations/changes occur during the fermentation phase of black tea processing. Although this stage is called fermentation, in the true sense, the reactions that occur are those of oxidation. Following cell matrix destruction brought about by maceration, the catechins (flavanols) and other polyphenols undergo polyphenol oxidase initiated reactions, forming brown-colored products. The 1,2-dihydoxyphenols are oxidized to the quinones in the presence of oxygen, reacting further to form various brownish compounds. A simple catechin and a gallocatechin, for example, undergo oxidative reactions, which involve a loss of carbon dioxide to form a benzotropolone ring system. The compound formed is known as 'theaflavin.' Figure 2 outlines the formation of theaflavin.

From various combinations of the flavanols, it is possible to produce several theaflavins, as shown in Table 2. However, the dominant theaflavins found in black tea are theaflavin, theaflavin-3-gallate, theaflavin-3′-gallate and theaflavin-3,3′-digallate. The proportions of these four theaflavins in black tea vary with processing conditions and the composition of the individual precursor flavanols in green leaf.

Traces of epitheaflavic acid, theaflavin acid, and epitheaflavic acid-3′-gallate have also been found in black tea. Normally, there is very little gallic acid in green leaf. However, during fermentation, its levels

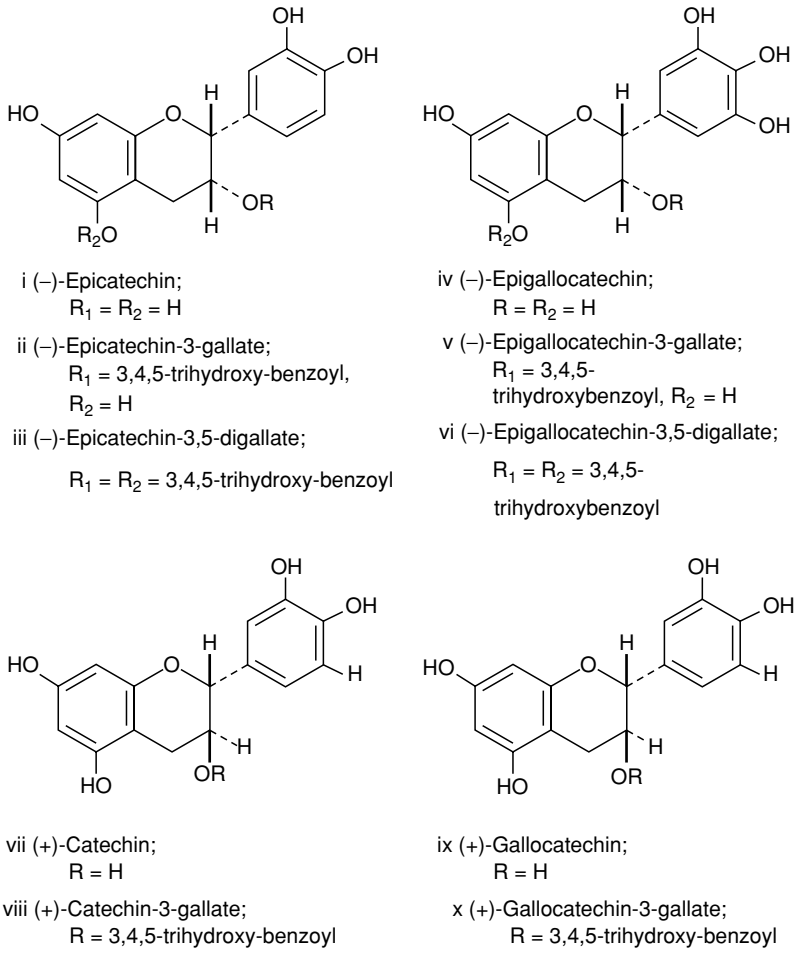

Figure 1 Structures of dominant flavanols in young tender shoots of tea plants.

increase, probably from the hydrolysis of galloyl esters from the catechins or gallated theaflavins. Although the rate of oxidation of gallic acid to the quinone acid is low, the presence of theaflavic acids is suspected to originate from gallic acid. Additional isomers of the theaflavins can also arise from racemization and epimerization of the flavanols. However, since racemization and/or epimerization of flavanols occur mainly during firing, very few isomers of theaflavins are normally found in black tea.

Theaflavins account for 0.3–1.8% dry weight of black tea and 1–6% of total solids in tea. They are

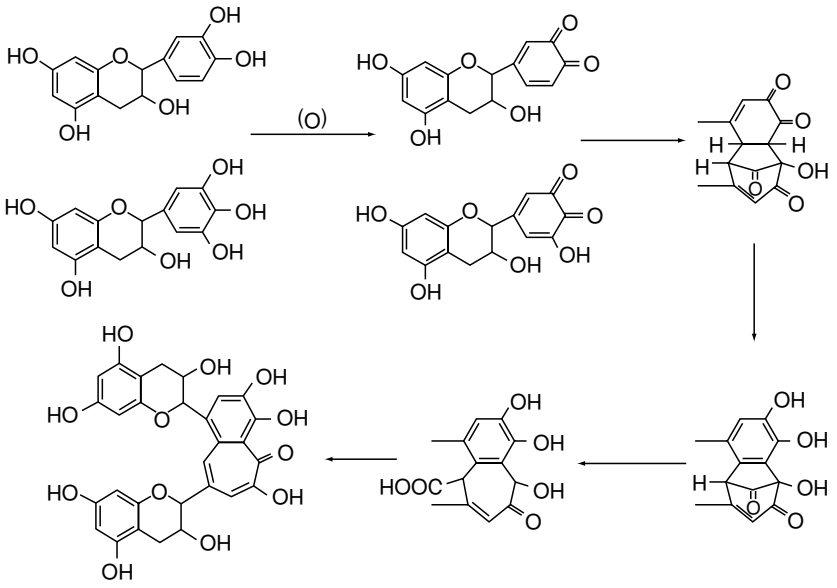

Figure 2 Mechanism of theaflavin formation. From Takino Y, Imagawa H, Horikawa H, and Tanaka A (1964) Studies on the mechanism of oxidation of tea leaf catechins – formation of a reddish/orange pigment and its spectral relationship to some benzotropolone derivatives. *Agricultural Biology and Chemistry* 28: 64–71, with permission.

bright red pigments that give the tea liquor its characteristic 'brightness' and 'briskness'. The contributions of the individual theaflavins to quality differ, with the gallated theaflavins being more astringent.

The other set of brownish compounds formed during black tea processing are called 'thearubigins.' Despite over 60 years' research, a full chemical characterization of thearubigins has yet to be achieved. Indeed, even their contribution to tea quality is not fully understood. The thearubigins are a group of compounds, of which some fractions have a large molecular weight and are nondialyzable compounds. The mixture of groups of compounds normally called thearubigins has been identified to have fractions of polysaccharides, proteins, nucleic acid anthocyanidins, cyanidin, and delphinidin. Indeed, the thearubigin structure could be a polymeric proanthocyanidin. The thearubigins are thought to be polymeric products of the various polyphenols. Indeed, a 4–8 interflavanoid bonding has been considered possible after oxidation of catechin. Over 40 peaks representing pigmented components have been separated by HPLC from black tea liquor, in the range of expected thearubigins. With prolonged fermentation, theaflavins undergo oxidative degradation. Thus, apart from thearubigins being formed directly from the catechins, and breakdown of thearubigins, theaflavin intermediates may also be involved in the coupled oxidation leading to more thearubigins. Thearubigins may not be a group of compounds with a common basic structure. They may be colored compounds resulting from catechin oxidation, catechin coupling without benzotropolone ring formation and catechin–anthocyanidin interactions. Other high-molecular-weight compounds formed by the interactions between flavanol quinones with other macromolecules such as proteins, carbohydrates, and nucleic acids are also classified as thearubigins.

The proposed strategy for the formation of theaflavins and thearubigins from flavanols is summarized in Figure 3. The formation of one theaflavin requires one molecule of a simple catechin and a gallocatechin. Tea shoots normally have higher amounts of the gallocatechins than of the simple catechins. This imbalance in the ratio affects the ability of particular leaves to make theaflavins, and may direct most gallocatechins to make thearubigins. The redox potentials of the individual flavanols to quinones also affect the amounts of the particular quinone available for reaction to produce theaflavin. The availability of a high polyphenol oxidase activity and oxygen are therefore critical in the direction of theaflavins to thearubigins formed under ideal conditions. However, even under ideal conditions, after some time, the formed theaflavins start degrading to thearubigins. Resultant thearubigins also degrade further or polymerize to other thearubigins.

Oxygen is required in three key steps: the oxidation of catechins to quinone, benzotropolone ring formation, and oxidative degradation of theaflavins. The first two are necessary for theaflavin formation. For the formation of high amounts of theaflavins, excess

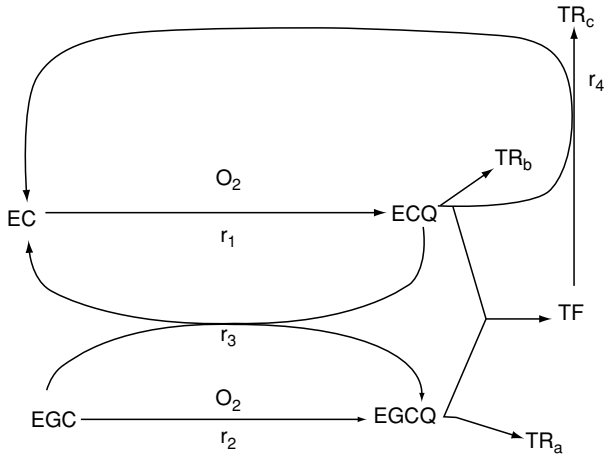

Figure 3 The formation of theaflavin and thearubigin from the catechin and possible role played by the simple catechins in coupled oxidations. EC, epicatechin; EGC, epigallocatechin; ECQ, epicatechin quinones; EGCQ, epigallocatechin quinone; TF, theaflavin; TR, thearubigin.

oxygen should therefore be available. The flavanols have a high affinity for oxygen. When oxygen is limiting, the benzotropolone ring system formation becomes inhibited, and fewer theaflavins are formed. However, during the theaflavin formation, there is also competitive degradation of theaflavins. With excess oxygen and/or when the catechin levels have been depleted, this reaction can be significant, reducing the amounts of theaflavins, but increasing thearubigins. However, this may not be the only way the thearubigins are formed. As in any chemical reaction system, the reaction temperature is critical. Fermentation of temperatures between 15 and 30 °C is beneficial to theaflavin formation. However, a higher temperature fermentation facilitates thearubigin formation at the expense of theaflavins.

Firing terminates the chemical reactions associated with the formation of the nonvolatile black tea components. Firing heat denatures polyphenol oxidase, reduces the moisture content to a product that can be stored, and enhances reactions responsible for black tea aroma. Firing black teas at temperatures above 100 °C increase the blackness, which may be due to pyrolytic reactions.

Thearubigins comprise 9–19% black tea dry weight and 30–60% soluble solids in black tea. They contribute to the 'liquor color' and 'thickness' or 'body.'

Methyl Xanthines

The caffeine is the major purine alkaloid in tea leaves, but theobromine and theophylline are also found, albeit in low quantities. Dry fresh tea shoots contain about 3–4% caffeine. After the shoots are plucked, the levels of caffeine increase slightly during withering. However, the levels do not change during fermentation and may decrease slightly during firing. A good ratio of caffeine and theaflavins in black tea imparts a brisk character to the liquors. High levels of caffeine in tea lead to the so-called 'creaming down' in the liquors, an indication of high quality.

Other Tea Components

Many aroma compounds have been identified in various teas. Their biogenetic pathways in green leaf have been worked out. However, here, only the chemistry of formation of volatile flavor compounds during tea processing shall be highlighted. The aroma compounds in tea can be classified broadly into primary or secondary products. The primary products are biosynthesized by the plant, whilst the secondary products are produced during tea manufacture via enzymatic, redox, or pyrolytic reactions of carotenes, amino acids, unsaturated fatty acids plus other lipids, and terpene glycosides.

Some aroma compounds constitute both primary and secondary products. The primary compounds that have been identified in fresh green teas include *Z*-2-penten-1-ol, *n*-hexanol, *Z*-3-hexen-1-ol, *E*-2-hexen-1-ol, linalool plus its oxides, nerol, geraniol, benzyl alcohol, 2-phenylethanol, and nerolidol. Their quantities change after plucking and during tea processing. In the course of manufacture, the concentrations of some of the alcohols increase, possibly due to hydrolysis of their glycosides, whereas for others, there is a decrease due to oxidative reactions and glycosidation.

Amino Acids

After a tea leaf has been plucked from the plant, the concentration of amino acids in the leaf increases as the proteins in the fresh green tea leaf break down in a process catalyzed by peptidase. The dominant amino acid in tea is theanine (5-*N*-ethylglutamine), accounting for 2% dry weight or 50% of total amino acids in tea. In green tea, theanine is associated with a 'brothy' taste. High levels improve the green tea quality. In black tea, however, high levels reduce the quality. This amino acid does not undergo the chemical transformations that the α-amino acids undergo to make volatile compounds. In black tea processing, the amino acid levels, decrease during fermentation, and this is accompanied by the production of aldehydes, as outlined in Figure 4. Valine, leucine, isoleucine, and phenylalanine are converted to 2-methylpropanal, 2-methylbutanal, pentanal, and phenyl acetaldehyde, respectively. These reactions

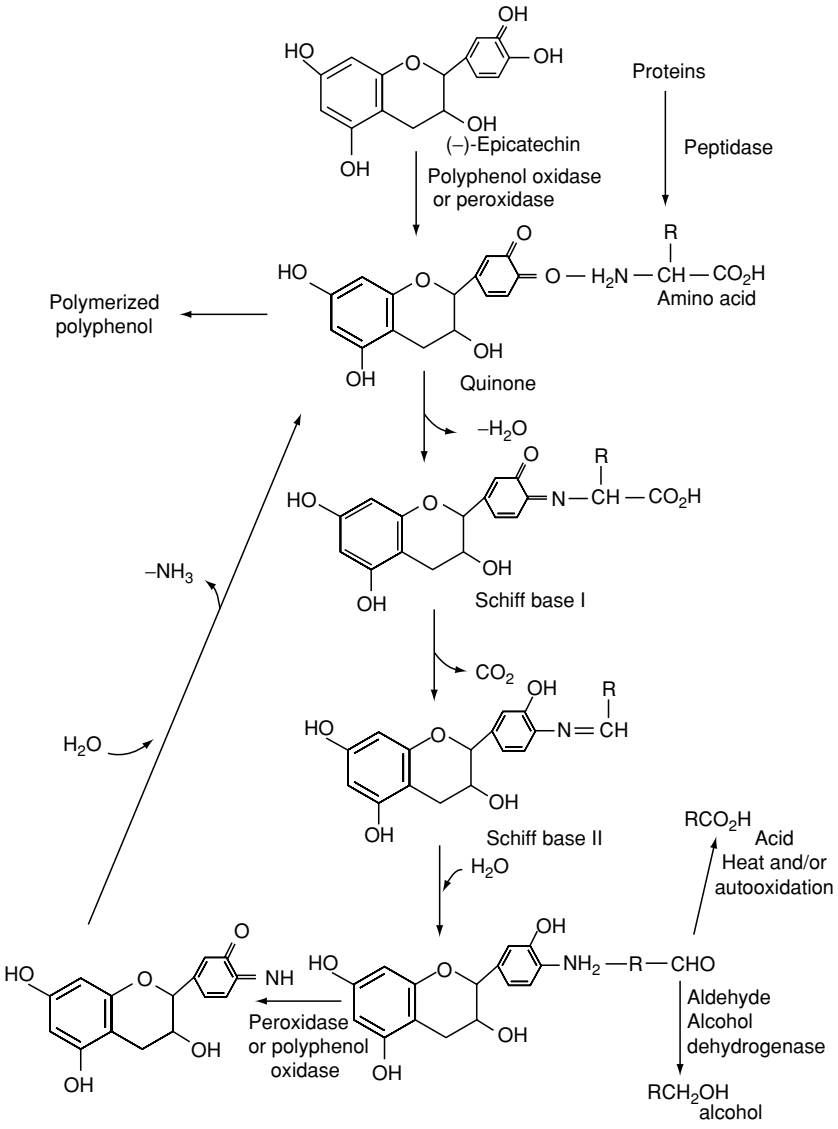

Figure 4 Formation of aldehydes, alcohols, and carboxylic acids from amino acids.

are catalyzed by polyphenol oxidase and/or peroxidase in the presence of oxygen and catechins. Some of the formed aldehydes are further oxidized to carboxylic acids during firing (as the concentration of acids is higher in fired teas) or storage, although some of the aldehydes are certainly reduced to their respective primary alcohols.

Lipids

Lipids make up between 4 and 9% dry weight of the fresh tea leaf and are composed mainly of free fatty acids and fatty acid esters. Linolenic acid is the major fatty acid in tea, but variations in this observation have been noted. The fatty acid profile changes with the geographical area of tea production, agronomic practices, and variety. The levels of fatty acids change throughout tea manufacture. During withering, the fatty acid esters are hydrolyzed to free fatty acids. The unsaturated free fatty acids degrade to form aroma compounds, but the fate of saturated fatty acids during tea processing is unknown.

The mechanism for the degradation of unsaturated fatty acids to aroma compounds is outlined in Figure 5.

Linoleic and linolenic acids produce hexanal and *E*-2-hexenal, respectively, when the acids are added to tea leaf extracts. *Z*-3-Hexenal formed from linolenic acid easily isomerizes to *E*-2-hexenal, and also is the precursor of *Z*-3-hexenol in macerated tea leaves. Alcohol dehydrogenase reduces the aldehydes to alcohols.

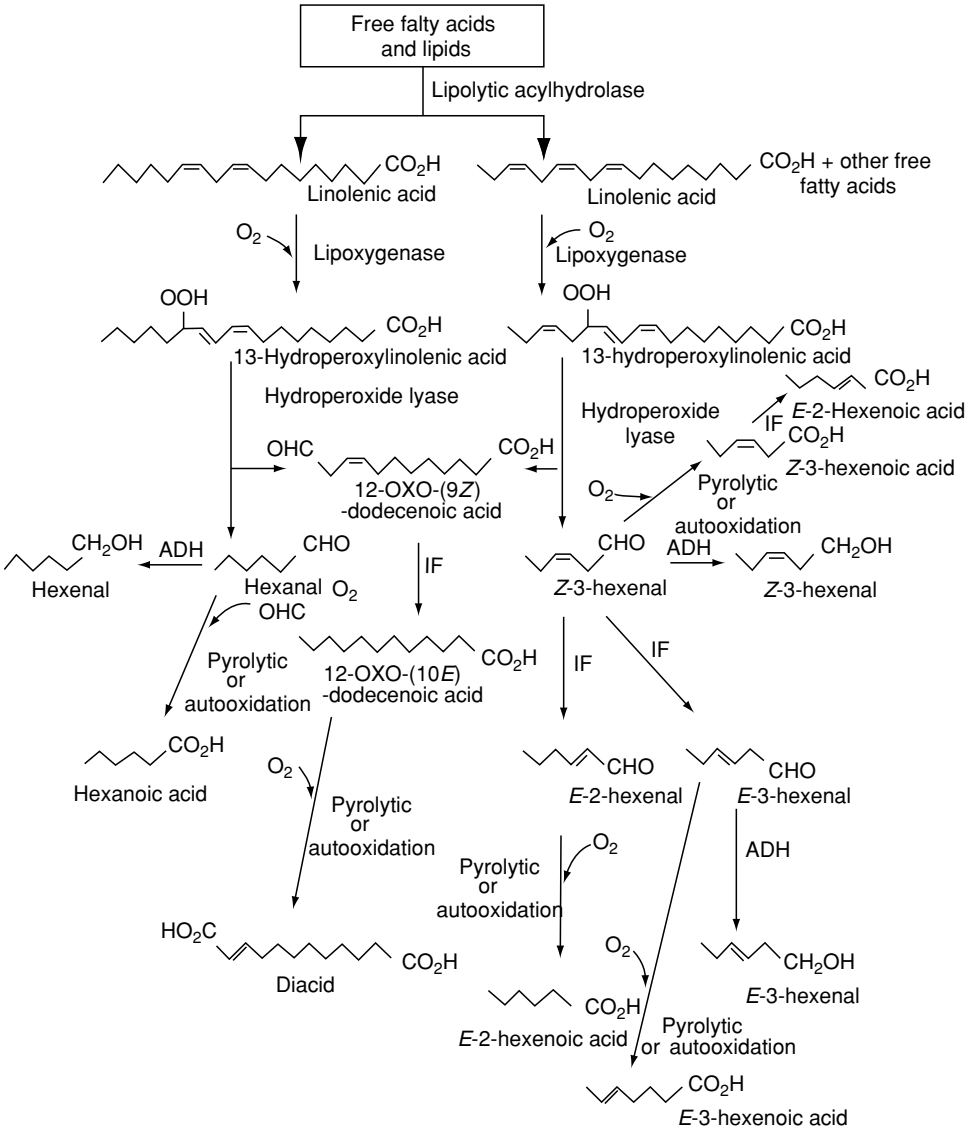

Figure 5 Production of volatile flavor compounds from linoleic and linolenic acids.

The linoleic acid forms 13-hydroperoxy acid, which is an intermediate in the production of C_6 aldehydes and alcohols in tea leaves. The hydroperoxidation of the acid occurs in the presence of lipoxygenase enzyme in a highly stereospecific manner forming only L-hydroperoxy acid. Hydroperoxide lyase breaks down the 13-hydroperoxide acid to C_6 aldehyde and 12-oxo-acid. The action of this enzyme is enentioselective, breaking down only the L-hydroperoxide acids.

The formation of 9-oxo-nonanoic acid from linolenic acid in tea chloroplasts, by cleavage at C-10, suggests that *Z*-3,*Z*-6-nonadienal, *Z*-3,*Z*-6-nonadienol, *E*-2,*Z*-6-nonadienal, and *E*-2,*Z*-6-nonadienol may also be derived from linolenic acid via a similar intermediate. Similarly, cleavage at the C-10 carbon of linoleic acid might be expected to produce *Z*-3-nonenal, *E*-2-nonenal and *E*-2-nonenol. However, only minor amounts of *E*-2,*Z*-6-nonadienal and *E*-2 nonenal have been detected in tea, implying that the hydroperoxidation of linoleic and linolenic acids occurs predominantly at the C-13 carbon to produce the C6 aldehydes and alcohols.

Low levels of palmitoleic and oleic acids have been detected in fresh tea leaves. These fatty acids break down to form heptanal and heptanol, nonanal, and nonanol, respectively, during tea processing. The relationship between precursor fatty acid in fresh leaf

and derived aroma compound in the processed product is rarely linear due to the various interactions that take place during processing. Linolenic acid and 13-hydroperoxylinolenic acid, for example, inhibit the formation of *n*-hexanal from linoleic acid during tea manufacture. In addition, the aroma compounds formed have different boiling points, and more of the lower boiling compounds are lost by volatilization during processing.

Terpene Glycosides

There has been considerable speculation on the mechanism of formation of monoterpene alcohols during tea manufacture. It was originally thought that linalool was a product of carotene degradation. Later, it was suggested that terpene alcohols were produced from oxygenated isoprenoid hydrocarbons. However, it has now been demonstrated that linalool and geraniol are hydrolytic breakdown products of β-D-terpene glycosides during tea manufacture. Indeed, many alcohols in the tea aroma are products of glycoside hydrolysis. In recent studies, several alcohol glycosides have been isolated from tea leaves. These include identified glycosides of 2-phenylethanol, all the four isomers of linalool, geraniol, benzyl alcohol, nerolidol, etc. These glycosides are hydrolyzed during tea manufacture to form their respective alcohols.

Pigments

Fresh tea leaves contain appreciable amounts of pigments, mainly chlorophyls and carotenes. Fresh tea leaves contain about $1.4\,mg\,g^{-1}$ dry weight chlorophyls a and b. During tea processing, the chlorophyls degrade to pheophytins and pheophorbides. These compounds play an important role in giving black tea its shade of color. A number of breakdown products from the phytol side-chain contribute to the aroma complex of tea.

More than 15 carotenoid pigments, dominated by neoxanthin, violaxanthin, lutein and β-carotene, have been identified in fresh tea leaf. These carotenoid compounds account for about 0.5% dry weight of tea leaves. The carotenes decrease during tea processing with the resultant production of various aroma compounds. β-Carotene degrades to β-ionone, whilst β-ionone, α-ionone, 3-hydroxy-β-ionone, 3-hydroxy-5,6-epoxyionone, 3,5-dihydroxy-4,5-dihydro-6,7-didehydro-α-ionone, and other terpenoid aldehydes and ketones are degradation products of other carotenes present in tea leaves. Dihydroactinidiolide, 2,2,6-trimethylcyclohexanone, 5,6-epoxyionone, 2,2,6-trimethyl-6-hydroxycylohexanone, and theaspirone and possibly formed form the primary oxidation products of carotenes, i.e., β-ionone. β-Damascenone, α-damascone, β-damascone, 3-oxo-β-ionone, 1,2-epoxy-1′,2′dihydro-β-ionone, loliolide, dehydrovomifoliol, and 3, 7-dimethyl-1,5-octadien-3,7-diol are speculated to be derived from carotenes via oxidative enzymatic reactions that take place during withering and fermentation, and pyrolytic reactions during firing. The mechanisms of these reactions have, however, not been fully worked out. The formation of these compounds is affected by the amounts of catechins present, oxidase activity, degree of mixing of the cell contents, and concentrations of the reactants. These factors change with degree of wither. Loss of carotenes has been demonstrated to increase with physical withering and fermentation process. Further pyrolytic and photo- and/or autooxidative reactions of carotenes occur during firing to produce more aroma compounds. The compounds produced from carotenes have a major effect on the aroma of tea. Flavory teas are normally produced from green leaf with high carotene contents.

As research on tea aroma continues, it is inevitable that more mechanisms and pathways for the formation of tea aroma compounds will be identified. These will likely involve nonvolatile precursors, which currently are largely ignored with respect to tea aroma and quality. For example, it is known that chlorophyl degrades to phytol and other products, but the contribution of chlorophyl degradation products to tea aroma is not known.

Considerable research has been directed into determining how the aroma complex changes with variations in agronomic, cultural, and manufacturing practices. Many studies have indicated the changes that occur in aroma composition by varying one parameter or the other without any attempts to quantify and classify the contribution of the aroma compounds to quality. Generally, the aroma compounds can be classified into two groups, i.e., those although important for the characteristic black tea smell, are deleterious to black tea quality when present at higher concentrations (group I compounds), and those that impart a sweet flowery aroma to tea, the presence of which is considered to be highly desirable (group II compounds). The classification of aroma compounds in group I and group II compounds has been based on either the odor characteristics or the retention time of the aroma compounds during gas chromatographic analysis. The ratio of group II to group I aroma compounds has been used to classify teas in order of flavor quality. In other studies, the ratio of terpenoid to nonterpenoid compounds has been used.

Although these ratios provide the basis of a semiquantitative method for classifying teas in order of their aroma quality, the ratios must be used with

caution as the olfactory perception limits of the aroma compounds differ widely. Some compounds may be present at very low levels yet have a large impact on aroma and vice versa. For example, methyl epijasmonate has an aroma that is 400 times stronger than that of methyl jasmonate at the same concentration. In addition, some of the compounds considered deleterious to black tea quality are important for green tea quality.

Chemistry of Tea Manufacture

Several tea beverages exist. These beverages include green teas, several semifermented teas, and black teas. The chemistry occurring during their processing varies depending on the desired final product. In green tea processing, oxidative reactions, discussed above, are completely discouraged. In black tea processing, there is more extensive oxidation of the catechins, other polyphenols, amino acids, and unsaturated fatty acids. Fewer oxidative reactions occur in the processing of the semifermented teas.

Black Tea Processing

Withering

Processing of tea beverages starts as soon as the leaf is detached (plucked or harvested) from the plant. The polyphenol oxidase activity decreases, while the catechins levels vary. (−)-Epicatechin, (−)-epigallocatechin gallate, and (−)-epicatechin gallate levels decline. This decline is associated with oxidative transformations. Caffeine levels rise, while protein levels decline. This decline is caused by an increase in the activity of proteolytic enzyme activity, which hydrolyzes the proteins to amino acids, with a concomitant increase in the level of free amino acids. Carotenoid compounds degrade due to photoisomerization to volatile flavor compounds. Fatty acid esters are hydrolyzed to free fatty acids that oxidize during fermentation through a lipoxygenase-initiated reaction to volatile flavor compounds associated with the green notes in tea. Terpene and other alcohol glycosides hydrolyze to simple alcohols that contribute to tea aroma. These transformations, which continue up to the point at which the leaf is macerated, are collectively called 'chemical wither.' Usually, the leaf is subjected to moisture loss to make it more flaccid, so that maceration is easy. Moisture loss, the most visible change in the leaf before maceration, is referred to as 'physical wither.' Chemical wither benefits mostly flavory black teas, as it improves the black tea aroma and to some extent benefits plain black tea as it reduces the level of green taste. Physical wither benefits both flavory and plain black tea quality. Hard physically withered leaves are easier to macerate and make more aromatic black teas. Withering therefore plays an important role in black tea processing.

Maceration

Maceration ruptures the leaf cell structure, exposing the chemical constituents of the cells, mainly polyphenols, oxidative and degradative enzymes, lipids, amino acids, etc., to oxygen. Most importantly, catechins come into contact with the polyphenol oxidase enzyme, initiating 'tea oxidation,' which is erroneously referred to as 'fermentation.' Several methods are used, but the most common are the orthodox rolling, crush, tear, and curl (CTC), and Laurie tea processor (LTP) methods. The method used has a significant effect on the resultant black tea. There is less cell matrix destruction with the use of orthodox rollers than the other two. The orthodox maceration therefore leads to fewer oxidative reactions, and fermentation is slow. Cell matrix destruction is greater in the CTC and LTP maceration methods, leading to more extensive oxidation, but these teas are less aromatic, with higher plain tea quality parameters. LTP manufacture requires a softer physical wither than CTC processing.

Fermentation

Most chemical transformations occur during the fermentation phase of black tea processing. These transformations are responsible for the characteristic taste and aroma products of black tea. As illustrated in Figures 2 and 3, the catechins and polyphenol oxidase form the theaflavins and thearubigins. The amino acids and fatty acids also oxidize to various volatile flavor components. For LTP and CTC manufacture, the process is complete after 60–120 min.

Firing (Drying)

Firing is necessary to terminate fermentation and to dry tea for storage and transport. As a result of the temperature rise, some reactions are accelerated until the rise is adequate to denature the enzymes or moisture has been adequately removed to prevent reactions occurring, but a lot of changes occur to give black tea its character.

As a result of firing, the color changes as a result of the transformation of chlorophyls to pheophytins and pheophorbides. Some caffeine is lost while the amount of volatile flavor compounds is reduced. The volatile flavor compounds that result from various pyrolytic reactions are formed during firing.

Sorting

The fired black tea is sorted first by removal of fiber then by separation into different particle sizes. The various particle sizes define the various grades. Generally, although the grades have different chemical compositions, quality is not solely dictated by grade.

Other Tea

Green and Semifermented Teas

There are fewer chemical transformations in the processing of the other teas compared with black teas. In green tea processing, attempts are made to insure that there is no oxidation, especially that of the catechins. The process therefore starts with steaming or roasting to deactivate polyphenol oxidase activity. The green teas are made from tea plant varieties with a lower catechin content than those for black tea, but this level is sufficient to create astringency. The volatile components of green tea are basically those of the primary products.

Partially fermented teas undergo incomplete fermentation. Several types exist. Some are processed by roasting, whereas others are subjected to high-temperature rolling.

Tea

Beverages produced from tea leaves include black tea, green tea, and various partially fermented teas such as oolong and pouchong. All of these products are cultivated and harvested using similar procedures, but variations in manufacturing methods determine the final product. This article deals with tea processing from cultivation through to packaging.

Cultivation

Tea was introduced into many countries of the world from South-east Asia and grows in climates ranging from the Mediterranean to the hot humid tropics. Commercially viable plantations have been established between as far north as Turkey and Georgia (24 °N), and as far south as Argentina (27 °S), at altitudes ranging from sea level to 2700 m.

Successful commercial cultivation of tea requires a minimum annual rainfall of about 1400 mm when irrigation is not carried out. Rainfall needs to be well distributed with at least 120 mm per month. Prolonged drought adversely affects tea growth, and in such conditions, irrigation is advocated. The interaction of soil texture and rainfall distribution is an important factor to be considered when assessing the suitability of an area for tea. Tea does not tolerate water-logged conditions.

Ambient temperatures of 12–30 °C are considered ideal for growing tea. Temperatures above 30 °C, accompanied by low humidity, have been shown to inhibit active growth. The optimum soil temperature for active growth within the feeder root depth is 20–25 °C. Using long-term average yield data from Kenyan tea estates, situated at altitudes between 1500 and 2250 m, it has been shown that annual tea production falls by 200 kg of black tea per hectare for every 100 m rise in altitude. This has been attributed to decreases in air and soil temperature. The tea plant cannot withstand frost conditions. Night

temperatures below 6 °C require that measures be put in place to mitigate frost, which could lead to the wilting of tea leaves.

Tea grows most successfully in acidic soils at pH values ranging from 4.0 to 5.8. A wide range of soil types are suitable for cultivation, including old sedimentary soils derived from gneiss or granite, soils formed from the wash of old sandstone, alluvial, peat, and soils derived from volcanic rock.

Propagation is carried out either from stumps generated from seeds or from cuttings. Propagation from seeds takes at least 3 years from seed planting to the production of viable plants capable of transplanting to the field, whereas plants generated vegetatively require a minimum of 6 months before they are ready for transplanting. However, when the plants are vegetatively produced under very cold conditions, the period needs to be lengthened. Vegetatively produced plants have the additional asset that they are usually of predictable yield and quality. Grafting plants with other desirable characteristics can further enhance these attributes.

After transplanting, the young plants are left to establish for at least 18 months in the field before commercial plucking (harvesting) can commence. During this time, the plant is manipulated through a process described as 'bringing into bearing' to form a plucking table. This is achieved by tipping and pegging. The tea is subsequently harvested regularly, with pruning every 3–5 years, thus maintaining a height at which the leaves and buds can be plucked easily. During this time, the tea is treated with regular applications of fertilizers, particularly nitrogen.

Harvesting

Harvesting (plucking) of tea involves manual or mechanical removal of the terminal young tender portions of peripheral shoots. In most countries, the recommended plucking standard is two leaves and a bud. However, under commercial production, it is difficult to select leaves of one plucking standard exclusively, and it is usual to find varying proportions of the more mature leaves in the harvested crop. The quality of the final product deteriorates with increase in mature leaf content.

After plucking, depending on climatic conditions, new shoots take between 40 and 100 days from bud break to develop into pluckable shoots. In general, the colder or drier the production area, the slower is the shoot growth. The intervals between plucking rounds vary accordingly. The appropriate plucking interval is determined by optimizing between the extent of new shoot development and the level of overgrowth of shoots that have been left after the previous plucking. Hand plucking is the preferred method of harvesting tea as it enables the selection of the quality requirements of two leaves and a bud. Compared with mechanical harvesting, however, hand plucking is slow. Mechanical harvesting is carried out in some countries where labor is either expensive or in short supply. This can be carried out using modified hedge trimmers, motorized machine pluckers operated by one or two people, or a self-propelled machine capable of negotiating the lines of tea bushes.

Black Tea Manufacture

Withering

The changes that occur in the green leaf from the time it is detached from the plant to the time of maceration or rolling are collectively known as 'withering.' These changes can be categorized into physical and chemical processes and are thought to be important in the manufacture of tea.

The main physical process that occurs during withering is moisture loss, leading to changes in cell membrane permeability. These changes are indispensable in orthodox black tea manufacture as they precondition the leaf for maceration or rolling. For teas made by alternate methods of maceration, such as those using the Legg-cut, the Laurie Tea Processor (LTP), or Crush Tear and Curl (CTC) (see section on Maceration), physical withering may not be obligatory. During physical withering, the stomata on the lower surface of the leaf begin to shut gradually, but continue to influence the rate at which water is lost. Air temperature, atmospheric vapor pressure, and air velocity and direction all affect the rate and degree of physical wither. The many biochemical changes occurring during withering are referred to as 'chemical wither.'

Several methods of withering have been developed. Traditionally, withering was carried out on banks of trays in thin layers so that the largest possible leaf surface would be exposed to air. Alternatively withering facilities consisted of open lofts built some distance from the factory, or on the upper, open storeys. These methods have largely become obsolete, as they were inefficient, time-consuming, and incapable of coping with increased crop production.

In most modern factories, withering is now carried out in troughs that can hold between 2000 and 3000 kg of green leaf, loaded to a depth of 25–40 cm. The troughs have dual-direction fans that either drive air into the withering troughs or draw air through them. Under low humidity, physical withering can be achieved using ambient air, even if the troughs are slightly overloaded. However, at high

humidity and/or when the troughs are overloaded because of a greater quantity of crop, stream-heated air is necessary to assist physical withering. Excessive use of heat during the withering process impairs black tea quality. Chemical withering is time-dependent. It requires a minimum of 6 h from the time the leaf is detached from the plant during plucking. Chemical withering beyond 20 h impairs plain black tea quality.

Despite these improvements, withering still takes up considerable factory space, and newer methods continue to be developed. One such method involves storing the leaf in a holding tank with minimal moisture loss for about 6 h to achieve chemical wither. The leaf is then spread on withering troughs, or a moving belt witherer, and the moisture is rapidly reduced by the use of warm air. This process is known as 'two-stage withering.' Other methods of withering used in black tea manufacture include the use of drum withering, tunnel withering, Tocklai continuous withering machines, Russian withering machines, and automatic continuous operating installations. Recent studies indicate that in the unorthodox methods of producing plain black tea, physical withering is not essential to produce high-quality black tea. Some factories are therefore now processing plain black tea after achieving chemical withering but without physical withering.

Factors that affect withering include the leaf type, leaf conditions, standard of plucking, thickness of spread, length of wither, drying capacity of air, and temperature of air used in drying.

Maceration and/or Rolling

Black teas are often referred to as 'orthodox' or 'unorthodox'. These descriptions are derived from the method of leaf distortion employed during manufacture.

In orthodox manufacture, leaves that have achieved physical withering are subjected to rolling. During conventional rolling, the leaf is damaged in such a way that it becomes twisted, and the semi-permeable membrane of the leaf is distorted, allowing the cell juices to be expelled to cover the leaf surface. This allows the juices to mix with the cellular enzymes in the presence of oxygen, and the chemical reactions necessary for fermentation will commence. The orthodox method of manufacture is particularly desirable in the processing of flavory black teas, but this method is slow and requires a large amount of factory space to process high volumes of leaves.

Although some factories still make tea using the orthodox (rolling) system, other methods of maceration have been developed and introduced into many factories. Such methods include Legg-cut, CTC, Rotorvane, LTP, Triturator, and other miscellaneous methods. These methods are particularly desirable for processing plain to medium-quality black teas. They are generally faster than the orthodox methods and can handle high volumes of leaves more easily.

The CTC method is widely employed and consists of two engraved metal rollers close together running in opposite directions. The machines work like a mangle, with one roller rotating approximately 70 rpm and the other 700 rpm. The leaf is cut, torn, and rolled in the small gap between the serrated surfaces of the rollers. Using this method, leaf distortion is much greater than with the most efficient orthodox rollers, fermentation is faster, and liquoring properties are improved.

Another popular method of maceration involves use of the Rotorvane. The rotor, consisting of segments, revolves in a cylinder of 15.20 or 37.5 cm diameter and is fitted with vanes propelling the leaf towards the discharge against resistors projecting from the casing. Maceration is achieved by rubbing and shearing inside the cylinder, and fermentation occurs simultaneously.

The LTP is another successful machine for maceration. This machine resembles a hammer mill and employs a centrifugal fan to induce and discharge leaves.

Most modern factories use a Rotorvane plus three CTC machines in series. However, there are factories that still carry out orthodox manufacture, and a few use the LTP. In general, orthodox teas have a superior aroma to CTC or LTP teas. However, CTC and LTP teas have higher levels of theaflavins and thearubigins and therefore have more color and are brighter and brisker than orthodox teas. (*See* **Phenolic Compounds**.)

Fermentation

In black tea processing, fermentation is defined as the chemical transformations occurring as a result of breakup of the cell membrane due to maceration.

Factories manufacturing tea by orthodox methods generally ferment on tables or trays. In factories that employ CTC, LTP, and Rotorvane systems, fermentation is carried out in batches using troughs or trolleys, or continuously on moving machines. In the case of batch fermentation, the troughs or trolleys are connected to an air supply by a duct, which can be humidified if necessary to reduce the temperature of the fermenting tea (dhool). A trolley can contain 110–130 kg of macerated leaf. The advantage of a trolley system is that the temperature of the dhool can be controlled more precisely than other systems. However, it has the disadvantage that the timing

of fermentation duration is manual and is subject to error.

A number of systems have now been developed, in which fermenting is carried out on a continuous fermenting machine. In most of these systems, the fermenting tea moves on a perforated belt through which air is passed. The speed of the belt determines the throughput and fermentation time. In other continuous methods, the dhool is fed into an open-topped, semicircular tank with two rows of rotating paddles that push the dhool forward in a mechanism similar to that of a screw. The speed of the rotation governs the rate of throughput and duration of fermentation. The temperature of the dhool is normally controlled by external fans. The paddles that continuously turn expose the dhool to air. Although, in most continuous fermenting systems, temperature control can be difficult, the timing of fermentation duration is usually very precise.

The liquor characteristics of the black tea can be determined by controlling the temperature and lime of fermentation. Generally, the lower the fermentation temperature, the better the black tea. Usually, the ambient air blown through fermenting dhool supplies adequate oxygen. Fermenting under enriched oxygen atmosphere therefore does not improve the liquor quality provided that the fermentation duration is timed correctly.

Firing (Drying)

Firing of tea is the process that reduces the moisture content of fermented tea from about 60% to below 4% and renders the product in a form suitable for storing. Firing terminates fermentation by deactivating the enzymes by subjecting the dhool to high temperatures. Inlet temperatures in the driers usually range from 140 to 98 °C with outlet temperatures ranging from 45 to 82 °C. During firing, considerable amounts of volatile aromatic compounds are lost.

Firing can be carried out using conventional driers in which the dhool is fed on to a perforated moving belt and is discharged off after the tea is dry. In most modern factories, fluidized bed driers are used. In these driers, hot air is blown into the drier, and this moves the dhool by the process of fluidization. Generally, fluidized bed driers have a higher throughput than conventional driers.

Grading and Sorting

Prior to grading, stalks are removed by the use of electrostatic separators. The process is effective because of the higher moisture content of stalks as compared with leaves after emergence from the drier.

Grading of leaves is generally carried out using mechanically oscillated sieves fitted with meshes of many different sizes. In some machines, the sieves are arranged in banks of diminishing mesh size, such that the outfall of the upper sieve falls on to the lower.

The products of the various siftings constitute the different grades (Table 1). The grade specification is entirely artificial. However, they are generally recognizable by their appearance; for instance, broken orange pekoe contains a high proportion of buds, orange pekoe is characterized by the abundance of twisted tender stalk, and pekoe and souchong grades tend to be more compact and dense. In recent years, the pattern of grading has been altering in the direction of smaller teas.

The sieve standards adopted for regulating grades differ in the various countries and even in different districts in the same country. However, there are efforts to standardize the sieve sizes.

Winnowing in one form or another is routinely employed and, according to the size and density of the particles, separates fannings and dust, carrying away the fibrous residue that is of no commercial value as a grade.

Packaging and Storage

Tea is hygroscopic, and if not adequately packed and stored, it can readily absorb considerable amounts of moisture, leading to a deterioration in quality.

Most tea is transported in bulk, and the common forms of packaging employed are either tea chests or multiwalled paper sacks. Tea chests are normally made out of plywood, lined on the inside with aluminum foil, which acts as a moisture barrier.

Table 1 Black tea grades

Leaf grades	
TGFOP	Tippy golden flowery orange pekoe
TFOP	Tippy flowery orange pekoe
FOP	Golden flowery orange pekoe
OP	Orange pekoe
FP	Flowery pekoe
Broken grades	
TGFBOP	Tippy golden flowery broken orange pekoe
TGBOP	Tippy golden broken orange pekoe
GFBOP	Golden flowery broken orange pekoe
TBOP	Tippy broken orange pekoe
GBOP	Golden orange
FBOP	Flowery orange pekoe
BOP	Broken orange pekoe
BP	Broken pekoe
BPS	Broken pekoe souchong
PS	Pekoe souchong
S	Souchong
BM	Broken mixed
BT	Broken tea

Multiwalled paper sacks have flat hexagonal ends to facilitate stacking and consist of a minimum of two plies of Kraft paper with an additional layer of aluminum foil on the inside of the sack to prevent moisture migration. Materials used for the construction of the sacks should be free from taint or odor. Both sacks and tea chests are designed to hold 40–60 kg of manufactured tea depending on grade.

Retail packaging of tea is wide and varied, but the common consideration is the requirement to keep out moisture. Tea should be stored in conditions that minimize the absorption of moisture, preferably at a low humidity. If teas are stored for long periods, however, moisture absorption and subsequent loss of quality are inevitable. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

Green Tea Manufacture

Green tea is manufactured from fresh leaves that have not been fermented. There are various methods of green tea manufacture, but they all depend on stopping enzyme activity in the green leaf. Withering is not mandatory in green tea manufacture.

In China, green tea manufacture begins by roasting the leaf in a hot iron pan for a few minutes, followed by hand rolling on a table. The leaf is then subjected to two or more further roastings and rollings.

In Japan, the leaf is steamed for 15–20 s in a revolving cylinder provided with an agitator. The steamed material is cooled by a fan or by air on a belt conveyor and then subjected to primary heating and rolling. The leaf may undergo further heating and drying before passing through secondary (final) rollers. The green tea is then dried to a moisture content of about 3–4%.

Partially Fermented Tea Manufacture

Oolong tea is manufactured in a similar manner to green tea, but with the following variations. The fresh leaf is withered at room temperature for approximately 16 h, or at 40 °C for 2 h followed by another 4 h at room temperature. In both cases, during the last 4 h, the leaf is rolled by hand for a period of 30 min every hour. This is followed by roasting (parching or pan frying) at about 160 °C for about 20 min. The tea is rolled further and then fired.

The manufacturing process for pouchong tea is slightly different than for oolong. The leaf is withered in the sun (solar withering) for 15 min, during which time it is turned over once. This is followed by indoor withering for 3 h, during which time the leaf is turned over three times. The leaf is then pan-fried at 160 °C for 20 min, rolled by hand for about 20 min, and dried at 80–85 °C for 40 min. Low-grade pouchong tea is often scented by blending with jasmine flowers to enhance the flavor (jasmine tea). Other partially fermented teas such as teekwang-yin and pan-fried longjing are also manufactured in a similar manner.

Other Tea Products

Earl Grey is flavored with the peel oil of bergamot, a citrus fruit, which is added by spraying on to black tea before final packaging. Jasmine flowers are sometimes added to manufactured black tea in the country of origin, and these impart a characteristic floral note. Lapsang souchong tea is a Chinese black tea flavored with natural smoke.

Instant teas are prepared in the producer countries by infusing the undried leaf and then evaporating the liquor by either freeze-drying, spray-drying, or vacuum-drying. All these drying procedures avoid using excessive heat and therefore reduce the loss of flavor components. Instant tea is also produced in the USA and UK, but details of the processes are secret or protected by patents.

In recent years, decaffeinated teas have appeared on the market. The tea is decaffeinated with methylene chloride or other chlorinated solvents and supercritical carbon dioxide. (*See* **Coffee**: Decaffeination.)

Analysis and Tasting

P O Owuor, Tea Research Foundation of Kenya, Kericho, Kenya

Tea Quality

The term 'quality,' as used in the tea trade is sometimes subjective and somewhat illusory. Largely, the tea tasters set the quality standards, and most scientific methodologies are based on what tea tasters consider as important. Tea tasters have set a large vocabulary of descriptive terms with which to assess the different parameters considered to contribute to tea quality. The most significant quality parameters are associated with smell, taste, and appearance. Considerable effort has been made to correlate various constituents of the fresh leaf, processed tea, or infusions with tea sensory evaluation. However, a particular characteristic that may be highly desirable in tea destined for a specific market could well be considered detrimental in a tea required by another market. Requirements also vary between the different processed products, e.g., the green, fresh aroma that is essential for green tea quality would be considered a defect in a black tea. Furthermore, a tea that may be described by a tea taster as an overall 'quality' tea may not satisfy the target market demands: therefore, quality does not necessarily equate with profit. Indeed, whereas producers tend to manufacture teas with desirable quality characteristics, in many instances, tea prices are determined by supply and demand. This does not, however, imply a lack of quality tea. Producers of teas with most desirable characteristics usually realize better values, especially when tea supply outstrips demand.

With the exception of a few specialty brands, most black tea is bought in bulk by tea buyers and then blended to suit target market demands. After blending, the tea loses its identity, and the producer has no control over the quality of the final product. A tea buyer is well aware of the quality of the teas required for blending for their own particular market, and the availability of teas of such quality will determine whether they buy and the prices they are prepared to pay. Occasionally, this can result in a high demand for lower-quality teas, whereas the premium-quality grades remain unsold or fetch relatively low prices. A producer might thus be tempted to concentrate on production of lower-quality teas, but the vagaries of the market are such that the emphasis may well have been reversed by the time their product reaches the market, and, more seriously, such a policy results in a general decline in quality, which damages the image of tea as a beverage. It is essential for producers to maximize the quality of all their grades, particularly as tea is invariably overproduced.

Tea Tasting

As with many products, tea requires constant quality evaluation during its processing, marketing, packaging and storage. Tea tasting has evolved, over centuries, as the most appropriate method to the needs of the trade. This is particularly so as instrumental methods of analysis tend to be slow and laborious, whereas tea tasting is fast and can evaluate a large number of samples within a short duration. The following method is specifically for black teas, but similar sensory and visual appraisals are also employed for other processed tea beverages.

The technique involves the description and evaluation of teas both before and after infusion in boiling water. A batch of tea samples is laid out in a row, and each sample is assigned an earthware or China bowl and a cup fitted with a lid, both of which are of a standard capacity. Tea equivalent to the weight of a silver sixpenny piece, i.e., 2.83 g (0.1 oz or 44 grains), is placed into each cup. Boiling water is added to the cups to produce a 2% brew, and the lid applied. After infusing for 5 or 6 min, the liquor is poured into the bowl, and the infused leaf is shaken from the cup, pressed free of excess moisture, and placed in the inverted lid, which is then placed on top of the cup.

The dry leaf is examined and evaluated for color grade or uniformity of particle size and form, degree

of manufacture and presence of leaf tip (for orthodox manufactured leaf) and/or undesirable stalk and fiber, feel, and aroma. Attention is then drawn to the infused leaf, which, disconcertingly, is often referred to as the 'infusion.' Ideally, this should be of a bright copper color and virtually free of the green tinge of chlorophyl. From the color and evenness of the infused leaf, the taster is able to make an assessment of the degree and quality of the fermentation.

On removing the lid, the aroma of the vapor present in the cup is evaluated. The liquor is then judged whilst it is still warm, first for appearance, which should be bright and clear with a distinct reddish tinge and a faint pink meniscus where the liquor touches the cup, then for taste. When cool, the better-quality liquors become opaque due to a process called 'creaming down,' which is essentially the precipitation of very finely divided colloidal material derived from caffeine, protein, and polyphenols, particularly the theaflavins.

The taste characteristics of the liquor are of particular importance. In nonscientific vocabulary, the terms 'taste' and 'flavor' are often considered synonymous, but in scientific nomenclature, these words are used to describe two different and distinct characteristics. The flavor of an aqueous solution comprises:

1. The basic taste sensations of sweet, sour, bitter, and salt, which are detected by the tongue and produced by nonvolatile substances present in appreciable amounts.
2. The odor, or aroma, detected by the nose and produced by vapors of volatile components, many of which are present only in minute amounts.

'Taste' refers only to those sensations produced by nonvolatile components. In tea tasting, the term 'taste' is used in its wider sense and therefore includes the aroma. The actual tasting (**Figure 1**) is carried out by sucking, rather than sipping, so that the liquor is drawn to the back of the mouth, on an inward breath, and up to the olfactory nerve in the nose. The liquor is then swished backwards and forwards and brought into contact with the tongue, palate, and other areas of the mouth where sensory receptors are located. Using this skillful, if somewhat noisy, technique, the taster is able to feel, taste, and smell the liquor virtually simultaneously and is thus able to determine its briskness, strength, body, and flavor. The liquor is either taken directly from the cup or from a special spoon. After tasting, the liquor is not swallowed, but discarded into a mobile spittoon.

The tea tasters' report concentrates on appearance, color, strength, pungency, and flavor. For each parameter or character, a large number of specialized descriptive terms are available for use by the tea taster. A tea taster can taste over 50 samples per session. The procedure is strictly standardized, and tea tasters require considerable individual training and experience in order to attain the necessary standards of competence.

Figure 1 (see color plate 133) Tea-tasting session (courtesy of the Tea Board of Kenya, Nairobi).

Although it is clearly a subjective method, prone to influence by variables such as supply and demand, the tasters' state of health, and personal preferences and prejudices, tea tasting is still considered to be the best method available for assessing tea quality as far as the tea trade is concerned. The success of the method lies in the fact that it is quick and inexpensive, and requires little equipment. From a scientific point of view, the method is less acceptable, and several chemical methods are currently being developed, and employed, as replacements or supplements to the tea tasters' evaluation of tea quality. Despite the advanced analytical equipment and procedures that are currently available, it is still not possible to replace tea tasting with a single, reliable, and objective scientific method.

Chemical Analysis of Black Tea

The International Organization for Standardization specification *Black Tea – Definition and Basic Requirements* (ISO 3720) specifies certain chemical requirements for black tea, which, when met, are considered to be indicative of a tea produced by recognized good production practice. These chemical requirements can be found in **Table 1** together with the individual ISO specification numbers for each parameter. ISO 3720 defines black tea as that tea derived solely from the leaves, buds and tender stems of varieties of the species *Camellia sinensis*. With the exception of ISO 6078 (*Black Tea*

Table 1 Chemical requirements for black tea

Characteristic	*Requirement (%)*	*Test method*
Water extract		
Minimum	32	ISO 1574
Total ash		
Maximum	8	ISO 1575
Minimum	4	
Water-soluble ash of total ash		
Minimum	45	ISO 1576
Alkalinity of water-soluble ash (as KOH)		
Maximum	1.0[a]	ISO 1578
Minimum	3.0[a]	
Acid-insoluble ash		
Maximum	1.0	ISO 1577
Maximum	16.5	ISO 5498

[a]When the alkalinity of water-soluble ash is expressed in terms of mm KOH per 100 g of ground sample, the limits shall be 178 (minimum) and 53 mm (maximum).

Vocabulary, a glossary of terms relating to black tea), the International Organization for Standardization has not dealt with a methodology for pricing black teas. More recently, the ISO has embarked on the development of chemical methods for classifying tea based on polyphenol content. However, efforts have not reached the standards stage. Tea prices, and quality, continue to be based on tea tasters' evaluations. In fact, it is generally accepted that expert tea tasters have the ability to assess whether a tea would be unlikely to comply with ISO 3720, and in practice, chemical analysis tends to be carried out only if the tea taster considers a tea to be 'suspect.'

Several chemical methods have been developed to determine specific quality parameters of tea. The volatile components of tea, often referred to as the 'aroma complex,' have been studied in depth by gas chromatography and mass spectrometry, and over 600 compounds have been identified. Routine methods for determining aroma have been developed. In one such method, the ratio of the gas chromatographic peak areas of the volatile compounds eluting before linalool to the sum of peak area of linalool plus all volatile compounds eluting after linalool was used as the aroma quantifying index. In another method, the ratio of the sum of the gas chromatographic peak areas of terpenoid compounds to nonterpenoid compounds was used as the aroma index. In yet another method, the ratio of the gas chromatographic peak area of linalool to that of 2-*E*-hexenal was used. For the last aroma index development, the major volatiles are divided into two distinct groups; substances that have a pleasant aroma and are highly desirable (group II) and substances that, although essential constituents of tea, are considered to have a deleterious effect on flavor when present in large amounts (group I). Lists of typical compounds in groups II and I are shown in Table 2. The ratio of the sum of the group II to group I volatile compounds gas chromatographic peak areas called the flavor index (FI) was used to quantify the black tea aroma quality. Using Kenya clonal black teas, the FI was recently shown to be a better measure for aroma quality compared with the other indices. The volatiles are usually extracted by simultaneous steam distillation/solvent extraction, separated by gas chromatography, and identified by mass spectrometry. The volatile FI is the ratio of group II to group I volatiles. Flavory teas have larger amounts of group II compounds in relation to group I.

Phenolic substances dominate the nonvolatile flavor components. In the case of black tea, most of the taste is believed to be due to the presence of the unique phenolic fermentation products theaflavins and thearubigins plus unoxidized catechins. The sensory qualities of the theaflavins, thearubigins and catechins are usually described in terms of mouth feel and color characteristics. The theaflavins are responsible for briskness and brightness, the thearubigins are considered responsible for body and color, and the catechins contribute to astringency. In general terms, teas with a high level of thearubigins relative to theaflavins and low catechin levels are considered to impart a soft mouth feel and dull color, and in the reverse situation, the teas are often described as lacking body and color.

The catechins, theaflavins, and thearubigins are determined by spectrophotometric methods, which gives a total value for each group. However, high-performance liquid chromatography (HPLC) is now

Table 2 Some volatile flavor compounds used to determine the flavor index of black teas

Group I volatiles	*Group II volatiles*
Isovaleraldehyde	Linalool oxide, (*Z*)-furanoid
2-Ethylfuran	Linalool oxide, (*E*)-furanoid
Hexanal	Benzaldehyde
1-Penten-3-ol	Linalool
Heptanal	β-Cyclocitral
(*Z*)-3-Hexenal	Ho-trienol
(*E*)-2-Hexenal	1-Ethylformylpyrrole
Penten-1-ol	Phenylacetaldehyde
(*Z*)-2-Penten-1-ol	α-Terpineol
Hexan-1-ol	Linalool oxide, (*Z*)-pyranoid
(*Z*)-3-Hexen-1-ol	Linalool oxide, (*E*)-pyranoid
Nonanal	Methylsalicylate
(*E*)-2-Hexen-1-ol	Nerol
(*E*)-2,4-Beptadienal	Geraniol
(*E,E*)-2,4-Heptadienal	Benzy alcohol
	Nerolidol
	Bovolide
	Dihydroactimdiolide

applied to these analyses as it allows the catechins and theaflavins to be determined individually. Black teas have four dominant theaflavins which have different astringencies and have variable contribution to tea taste. Their contribution to taste has been normalized to theaflavin digallate equivalent, which relates better to sensory evaluations. The chemical structures of thearubigins have not been determined.

Contaminants: Heavy Metals and Pesticide Residues

Several producer and consumer countries have passed legislation stipulating maximum permissible levels of heavy metal contaminants in tea. For example, in Kenya, according to the Food, Drugs and Chemical Substances Act (1978), limits were set for heavy metal and fluoride contaminants in black tea, based on the dry weight (Table 3). In the UK, statutory limits have been set for black tea, on a dry-weight basis, at 1 mg kg^{-1} for arsenic and 5 mg kg^{-1} for lead, and guideline limits have been set at 50 mg kg^{-1} for zinc and 150 mg kg^{-1} for copper.

High levels of lead have often been associated with tea, particularly in the past when lead linings were used in tea chests and lead-coated drier trays were used in tea factories. Lower concentrations were achieved by stopping such practices, but even so, levels of about 2 mg kg^{-1} are considered to be unavoidable. Evidence shows, however, that most of the lead remains in the tea leaves on brewing and is not consumed. Furthermore, tea leaves have been shown to absorb lead from water.

The Codex Alimentarius of the Food and Agriculture Organization of the United Nations World Health Organization has set down maximum permissible levels of various pesticide residues in black tea on a dry-weight basis (Table 4).

Most of the heavy metal and pesticide residue levels that have been set are based on the dry weight of processed tea. However, tea is drunk as an infusion using water of widely variable quality and at different temperatures. The solubility of the contaminants therefore varies. This has been largely ignored in the setting of the various limits.

Table 3 Maximum limits of heavy metals and fluoride contaminants permitted in black tea in Kenya

Contaminant	*Limit (mg kg^{-1})*
Arsenic	1.0
Lead	10.0
Copper	150.0
Zinc	50.0
Fluoride	100.0

Table 4 Maximum permissible levels of pesticide residues in tea

Pesticide	*Level (mg kg^{-1})*
Ethion	6.0
Fenitrothion	0.5
Methidathion	0.1
Methylparathion	0.2
Cyhexatin	2.0
Bromopropylate	5.0
Methylechlorpyrifos	0.1
Cartap	20.0
Permethrin	20.0
Deltamethrin	10.0

Off-flavors and Taints

Causes of Off-flavors and Taints

Off-flavor, or taint, may be defined as any taste or odor that is considered to be abnormal or foreign for tea. Off-flavors originate from a myriad of sources and can be attributed to either single or multiple chemical substances that are not normally present in tea or occasionally to unusually high concentrations of compounds that are generally found to be present only in trace amounts.

The chemicals responsible for taints are mostly volatile organic compounds with very low odor thresholds. Taint detection is an extremely time-consuming and difficult process as the compounds responsible are usually present at very low concentrations. Once tea is tainted, the condition is irreversible, and the subsequent loss in revenue is very often substantial. It is therefore imperative to take all possible measures to avoid the formation of such undesirable compounds in the first place.

Good factory hygiene is of paramount importance, and strict control of each stage of the manufacturing process is essential in order to insure an evenly processed product of the best possible quality. If hygiene standards or manufacturing controls are allowed to slip, an inferior product results, which is very often tainted or off-flavored. Additional common causes of taints in tea are described below.

Moisture Due to its hygroscopic nature, processed tea is particularly liable to generate or pick up taints; therefore, strict control of the moisture content is crucial. Moisture contents in excess of 6.5% are extremely detrimental as this encourages rapid fungal and bacterial growth. Volatile compounds produced

during the course of proliferation of fungi and bacteria are a major source of taints in tea. Taints from this source are variously described by tea tasters as 'musty,' 'fusty,' 'moldy,' 'gone-off,' 'sweaty,' and 'sour.' The presence of high levels of moisture in the tea at the time the taint is first perceived is indicative of the cause of such taints, and the identities of the individual compounds responsible are thus rarely pursued. However, such fungal and bacterial infections can also occur during the course of processing, particularly during the withering and fermentation stages, if the leaf is excessively damp or the conditions unclean. In such cases, the moisture content of the finished product would not necessarily be elevated, and the source of the contamination would be much more difficult to locate.

Conversely, teas that come out of the drier with moisture contents of 2.5%, or less, generally have a 'smoky' taint, if firing has been carried out using a conventional dryer. This renders them equally unacceptable.

Chlorophenols and chloroanisoles Chlorophenols impart disinfectant-like taints and are responsible for numerous incidences of tainting throughout the food industry. A major cause for concern is that many fungi and bacteria can readily convert chlorophenols to chloroanisoles by a simple process of methylation. Chloroanisoles possess intense musty/moldy odors, often described as 'old cellars' or 'damp sacks,' and have much lower odor thresholds than the parent chlorophenols. 2,4,6-Trichloroanisole and 2,3,4,6-tetrachloroanisole, both of which have been found in tainted teas, have odor thresholds in water of 2×10^{-5} and $4 \times 10^{-3}\,\mu g\,kg^{-1}$, respectively.

Due to the widespread usage of chlorophenols and their derivatives, considerable vigilance is required in order to minimize the chances of contamination. Chlorophenols have been detected in multiwalled paper sacks (and in the adhesives and printing inks used in their manufacture), wooden pallets, and containers used for the storage and transportation of tea. Chlorophenols from such sources have been deemed responsible for chloroanisole contamination in teas.

The use of certain chlorinated herbicides, fungicides, and pesticides in the field, and algaecides or disinfectants in the factory, may give rise to chlorophenol contamination. Storage of tea in the vicinity of such chemicals is also liable to cause tainting. In fact, tea must not be stored in close proximity to any commodity with a strong smell due to its remarkable ability to pick up odors. In addition, factory water supplies should not be chlorinated, as chlorophenols can also be formed by the reaction of chlorine with phenols in the tea or in the environment.

Detection and Analysis of Compounds Responsible for Taints

Tea tasters usually detect taints, in the first instance. This may take place at the factory, and in such cases, depending on the description of the taint, the source can be malfunctioning equipment or bad handling practices. Once the tea has been transported or stored, it can be extremely difficult to identify the source of the contamination, and it is only considered cost-effective to pursue the source of such taints in the events that they recur.

The techniques used for isolating and eradicating persistent, recurring taints are many and varied, as, indeed, are the agents responsible for such taints. Techniques employed are required to be meticulous and methodical, and involve two distinct processes. Firstly, the movements of the product from the time the taint was first perceived are traced back, even as far as the field, if necessary, in an attempt to pinpoint the association with any agent, or identify any deviation from normal practices, capable of causing the described taint. This requires the cooperation of all concerned and a knowledgable and skillful coordinator. Circumstantial evidence collected in this way can be most successful when confirmed by chemical analysis. Secondly, analysis of the tea is undertaken to identify the compounds responsible for the taint. The flavor analyst initially discusses the description of the taint with the tea tasters and then proceeds to search for specific compounds known to cause such taints. Analytical methods used include headspace gas chromatography, continuous steam distillation, and solvent extraction of the volatiles, followed by separation by gas chromatography (including splitting of the gaseous mixture exiting the gas chromatography column in order to enable 'sniffing' of the individual sample components), preparative gas chromatography to concentrate relevant fractions, specific detector gas chromatography, gas chromatography–mass spectrometry (including multiple ion monitoring) and HPLC.

THERMOGENESIS

P Trayhurn, University of Liverpool, Liverpool, UK

Background

The term 'thermogenesis' comes from the Greek word *thermos* for heat. All metabolic processes in animals (and plants) produce heat, as a reflection of thermodynamic inefficiency, and are therefore thermogenic. In general, however, thermogenesis is used to describe a facultative, or adaptive, process of heat generation, i.e., a process in which heat is the primary product of metabolism. It is also used to describe the heat produced in direct response to a meal.

The concept of facultative thermogenesis is well-established in relation to the generation of heat to maintain body temperature (thermoregulatory thermogenesis). It is also widely used in nutritional science to describe the adaptive production of heat in response to overfeeding (diet-induced thermogenesis), particularly as a component of the regulation of whole-body energy balance.

Thermogenesis and Thermoregulation

General

In homeotherms, heat is generated to maintain body temperature (at $\sim 37\,^{\circ}C$ in mammals) when an

animal is in a cold environment. In this context, 'cold' is defined as a temperature below the thermoneutral zone, i.e., below the range of temperatures at which metabolic rate is at a minimum. The thermoneutral zone varies widely between species, being for example, approximately 32–33 °C in mice, 26–28 °C in adult humans, and of the order of 0–25 °C in mature sheep (depending on factors such as the plane of nutrition and the length of the coat). At thermoneutrality body temperature is maintained above the ambient temperature by the heat generated by obligatory thermogenesis. This is the heat produced as a byproduct of all the basal metabolic processes of an animal, such as the pumping of the heart, the synthesis of proteins, and ion pumping across membranes.

The lowest point of the thermoneutral zone is referred to as the lower critical temperature. Once the environmental temperature has fallen below this point, then the rate of heat loss exceeds the rate of obligatory, or basal, heat production and body temperature will fall. Factors such as age, nutritional status, and the degree of thermal insulation all affect the thermoneutral zone and the lower critical temperature of an animal.

Two distinct mechanisms are available for thermoregulatory heat production – shivering and nonshivering thermogenesis. Shivering, which involves small contraction of the skeletal muscles, is a widely employed mechanism for the generation of heat in the cold. It is, however, behaviorally disadvantageous, in contrast to nonshivering thermogenesis where heat is produced without muscle contraction. The term 'thermogenesis' when applied to thermoregulation is often used with exclusive reference to nonshivering thermogenesis.

Adaptation of Adult Animals to Cold Environments

Exposure of mature homeotherms to a temperature below, or colder, than the lower critical temperature imposes an immediate requirement for thermoregulatory thermogenesis in order to maintain body temperature. The generation of heat by shivering is a major part of the initial response to cold. However, during long-term (days to weeks) cold exposure, heat generated by shivering is gradually replaced by nonshivering thermogenesis. In laboratory animals full adaptation to cold is considered to require a period of up to 3–4 weeks.

Newborn

The newborn of a species has a higher surface area to body mass ratio than the mature or adult animal, and insulation (hair, fur) is often absent or underdeveloped. These two factors result in a higher rate of heat loss at a given environmental temperature in the neonate than in the adult homeotherm. As a consequence, neonates are particularly vulnerable to cold and a high capacity for nonshivering thermogenesis is generally evident. The transition at birth from the intrauterine environment to the external world can present a major thermal challenge to the mammalian neonate, particularly in the case of precocial species. Lambs, for example, can experience a fall in ambient temperature in excess of 50 °C over a few minutes when being being born in cold northern climates in late winter. In some species, such as large ruminants (e.g., sheep, reindeer) the capacity for nonshivering thermogenesis falls rapidly over the first days or weeks of postnatal life.

Arousal from Hibernation

A limited number of mammalian species undergo hibernation during winter. Examples include hedgehogs, the European hamster (*Cricetus cricetus*) and various species of ground squirrel, e.g., Richardson's ground squirrel (*Spermophilus richardsonii*). Arousal from the deep torpor of hibernation, when body temperature may be as low as 4–6 °C, requires intense thermogenesis. Both shivering and nonshivering mechanisms are invoked in order rapidly (within a few hours) to raise the body temperature during arousal.

Thermogenic Effect of Food – Diet-Induced Thermogenesis

Nomenclature

Discussion of facultative thermogenesis in the context of nutrition is compounded by some terminological complexity and confusion. Feeding leads to a rapid increase in metabolic rate and different expressions have been used to describe this phenomenon. These include specific dynamic action (originally used in relation to the presumed particular effects of protein), thermic effect of food, postprandial thermogenesis, diet-induced thermogenesis, and the heat increment of feeding (Table 1). The term 'heat increment of feeding' is used primarily by those who work on farm animals, while the other expressions are employed in human nutrition and in connection with energy metabolism in laboratory animals.

In human and small-animal nutrition, diet-induced thermogenesis has become the customary expression. Even this, however, includes two distinct processes – obligatory and adaptive (or facultative) diet-induced thermogenesis – and involves both the short-term

Table 1 Synonyms for the thermogenic response to food

Name
Short-term
Specific dynamic action
Thermic effect of food
Postprandial thermogenesis
Heat increment of feeding
Diet-induced thermogenesis (obligatory and adaptive)
Chronic (overfeeding)
Luxoskonsumption
Diet-induced thermogenesis (adaptive)

response to a meal and the long-term response to overfeeding. It is emphasized that there are close parallels between adaptive diet-induced thermogenesis and nonshivering thermogenesis, particularly at a mechanistic level, and high levels of the former will reduce the need for the latter.

Short-Term Responses to Food

The consumption of food leads to a rapid increase in energy expenditure. Although this was originally considered to be a particular property of dietary protein, as noted above, it is now recognized that it occurs with the consumption of each of the macronutrients. The digestion, absorption, and initial metabolism of nutrients impose an energy cost on an organism, and include the cost of processes such as the synthesis of digestive enzymes.

The main component of obligatory diet-induced thermogenesis is the energy costs associated with the initial metabolic processing of substrates, once absorbed. Thus, glucose derived from dietary carbohydrate is initially stored as glycogen (in liver or muscle) or triacylglycerols (in liver or adipose tissue), following transport into tissues by either insulin-dependent or insulin-independent glucose transport. Obligatory diet-induced thermogenesis occurs in humans and in all other animals.

The energy costs associated with the storage of dietary carbohydrate as lipid amounts to approximately 25% of the energy potential of the substrate. In contrast, the deposition of dietary fat as triacylglycerol costs only some 5% of the energy associated with the substrate. Thus, calorie for calorie, the obligatory energy expenditure consequent upon the initial handling and storage of substrates as lipid will be lower with dietary fat than with carbohydrate (or protein).

The extent to which the acute response to food includes a facultative, energy-dissipative component is uncertain; there has, however, been much discussion of this possibility.

Responses to Chronic Overfeeding

In the early part of the twentieth century, German physiologists suggested that overfeeding leads to the stimulation of energy expenditure over and above obligatory diet-induced thermogenesis. The expression *Luxoskonsumption* was coined to describe the phenomenon, but adaptive diet-induced thermogenesis is now a more commonly used term. The basis of the concept is that overfeeding, particularly long-term, leads to the activation of mechanisms for the dissipation of the excess energy intake as heat. Thus, diet-induced thermogenesis is considered to represent a control mechanism in the regulation of energy balance.

Investigation of the metabolic responses to overfeeding in experimental animals has been greatly aided by the introduction of the cafeteria or supermarket diet. This diet, which provides a variety of human food items in addition to the standard laboratory animal chow, may induce up to twofold increases in voluntary food intake; the degree of hyperphagia depends, however, primarily on the variety and palatability of the foods. Energy balance measurements in rats and mice, in particular, have demonstrated that adaptive diet-induced thermogenesis is markedly activated in response to chronic overfeeding with a cafeteria diet. This reduces the extent to which fat is deposited in response to the overfeeding.

The phenomenon of adaptive diet-induced thermogenesis has at times been controversial. The controversy in part reflects the variability of the metabolic responses to overfeeding. In laboratory animals adaptive diet-induced thermogenesis appears to be strain-dependent, and to vary with other factors such as age, sex, and environmental temperature. Thus it is generally more substantial in young than in old animals, and in females than in males, and it is inhibited at thermoneutral temperatures. The process does not necessarily depend on the precise macronutrient content of the diet – it is the overfeeding rather than the nature of the macronutrients that is important. None the less, adaptive diet-induced thermogenesis has been widely noted in animals fed low-protein diets, and it is suggested that high-fat diets rich in polyunsaturated fatty acids are more thermogenic than those based on saturated and monounsaturated fatty acids.

The extent to which adaptive diet-induced thermogenesis is present, and a component of the regulation of energy balance, in humans is a matter of continuing debate. While some evidence in support of the concept is available, none is currently considered to be convincing.

Obesity

Obesity has been a major focus in studies on the regulation of energy balance, and some emphasis has been given to the hypothesis that obesity results, at least in part, from thermogenic abnormalities. Some animal models of obesity (e.g., the obese *ob/ob* mouse and the diabetic *db/db* mouse) exhibit a reduced capacity for nonshivering thermogenesis and under normal environmental conditions have a decreased energy expenditure on this process. Reduced adaptive diet-induced thermogenesis is a general characteristic of obesity in laboratory animals, and there is little doubt that this abnormality is significant in the energetics of the development of the obese condition, involving the recently discovered hormone leptin.

The situation is much more problematic in humans, and there is little convincing evidence to implicate reduced facultative thermogenesis (dietary or thermoregulatory) as an important factor in the development of human obesity. A reduction in diet-induced thermogenesis in response to nutrients is, however, frequently observed in the obese, and this appears to relate, at least in part, to insulin resistance.

Despite the absence of substantive evidence for major thermogenic abnormalities in human obesity, drugs which stimulate this component of energy expenditure have been the focus of continuing interest to the pharmaceutical industry as potential anti-obesity agents. Such drugs are primarily β-adrenoceptor agonists, selective for the β_3-adrenoceptor; however, none has yet progressed beyond the research and development phase.

Recently, the concept of nonexercise activity thermogenesis (NEAT) has been introduced and this proposes that small movements such as fidgeting and the maintenance of posture may contribute significantly to energy expenditure in humans. The absence of NEAT in response to overfeeding has been implicated as a factor in the etiology of obesity.

Biochemical Basis of Facultative Thermogenesis

A number of biochemical mechanisms have been proposed for the generation of heat by faculative thermogenesis – both nonshivering and adaptive diet-induced forms. These mechanisms are associated with a variety of tissues. Shivering is, of course, localized in skeletal muscle. Mechanisms for facultative thermogenesis can be divided into those in which there is a direct hydrolysis of adenosine triphosphate (ATP), and those in which the synthesis and hydrolysis of ATP are bypassed.

Thermogenic mechanisms where ATP is hydrolyzed include protein turnover, the pumping of Na^+ across the plasma membrane, and various substrate (or 'futile') cycles in specific metabolic pathways (Table 2). Examples of substrate cycles include the triacylglycerol/free fatty acid reesterification cycle which can occur both within and between tissues, and the fructose-6-phosphate/fructose-1,6-bisphosphate cycle in the glycolytic and gluconeogenic pathways (when both occur within the same tissue). Although there is good evidence that these mechanisms are thermogenic, individually their contribution to overall heat production is small – with the exception of highly specific situations such as in the warming of bumble bee flight muscle in cold environments. The simultaneous activation of a number of substrate cycles may, however, lead to the production of considerable amounts of heat.

Brown Adipose Tissue

The best documented and most widely recognized thermogenic mechanism is one in which the synthesis and hydrolysis of ATP are bypassed, namely the proton conductance pathway in brown adipose tissue. In this process the proton gradient that is normally established across the mitochondrial inner membrane during the oxidation of substrates is dissipated as heat rather than being coupled to the synthesis of ATP, in contrast to what generally occurs in mitochondria from other tissues.

The proton conductance pathway is regulated by a tissue-specific mitochondrial protein, termed uncoupling protein or now uncoupling protein-1 (it has also been called thermogenin), with a molecular weight of

Table 2 Putative biochemical mechanisms of facultative thermogenesis

Mechanism
Pumping of Na^+ across plasma membranes
Protein turnover
Mitochondrial Ca^+ cycle
α-Glycerophosphate shuttle

'Hot pipes' in the microvasculature[a]
Mitochondrial proton conductance pathway in brown adipose tissue[b]
Mitochondrial uncoupling through UCP2 and UCP3[c]

[a]The precise biochemical mechanism involved in this process is unclear.
[b]Exclusive to brown adipose tissue; the other mechanisms may occur in a number of tissues, particularly skeletal muscle.
[c]Whether uncoupling protein-2 (UCP2) and UCP3 'uncouple' is a matter of debate.

32 kDa. The amount of this protein, and its activity, varies according to the requirements for thermogenesis in an animal. Brown adipose tissue is particularly well-developed in small animals, in the newborn of a number of mammalian species (including humans and ruminants), and in hibernators. It is also prominent in small, cold-adapted animals and in rodents exhibiting adaptive diet-induced thermogenesis where a major activation takes place.

The proton conductance pathway through uncoupling protein-1 is unique to brown adipose tissue, and this mechanism, together with the tissue itself, has been the major focus of studies on thermogenic systems in recent years. A recent major development is the discovery that there are a family of mitochondrial uncoupling proteins, not just uncoupling protein-1. Uncoupling protein-2 exhibits a wide tissue distribution, being found even in the brain, but it is particularly evident in white adipose tissue. Uncoupling protein-3 is located primarily in skeletal muscle.

The initial view was that these new uncoupling proteins uncouple mitochondria in a manner generally similar to uncoupling protein-1. However, it is far from clear that this is the case and it is argued that their role is more concerned with fat oxidation than energy dissipation *per se*. This would be consistent with the fact that brown adipose tissue expresses the genes encoding uncoupling protein 1–3; a thermogenic role for 2 and 3 in the presence of uncoupling protein-1 would seem superfluous.

Neural and Hormonal Control of Thermogenesis

Catecholamines are the main stimulus for facultative thermogenesis, both the dietary and nonshivering forms. Heat production can be stimulated by norepinephrine (noradrenaline) or epinephrine (adrenaline). Brown adipose tissue is highly innervated by sympathetic nerves, and norepinephrine secreted by them plays a central role in both the acute and chronic regulation of the thermogenic process.

The thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), have long been recognized to play a permissive role in thermogenesis. They can themselves also lead to a direct stimulation of heat production, and have in the past been used for the treatment of obesity. In brown adipose tissue, T_3 is generated endogenously through the presence of a type II iodothyronine 5′-deiodinase enzyme, and is involved in the regulation of the expression of the gene coding for the mitochondrial uncoupling protein.

Insulin also plays a significant role in facultative heat production. Diabetic animals have an impaired capacity for both nonshivering thermogenesis and adaptive diet-induced thermogenesis. Insulin is considered to stimulate thermogenesis through a central activation of the sympathetic nervous system, and by a direct effect on peripheral tissues. The uncoupling protein content of brown adipose tissue is regulated by insulin, and this in part involves an interaction with the sympathetic nervous system. Insulin resistance impairs the thermogenic response to food in both animals and in humans. The acute activation of brown adipose tissue in response to cold is also inhibited by insulin resistance in the tissue.

Glossary

Brown Adipose Tissue Form of adipose tissue specialized for the generation of heat, heat being the primary product of its metabolism. Heat is generated in brown adipose tissue through the presence of the tissue-specific uncoupling protein-1.

Diet-Induced Thermogenesis Currently preferred term to describe the increase in heat production associated with feeding. Relates to both short-term responses to a meal, and to chronic overfeeding; divided into obligatory and adaptive components.

Nonshivering Thermogenesis Heat generated specifically for thermoregulatory purposes, by mechanisms that do not involve muscle contraction.

Thermogenesis Generic term generally used to describe facultative heat production.

Uncoupling Proteins Family of mitochondrial proteins of molecular weight 32 kDa; the first such protein, uncoupling protein-1, is responsible for the generation of heat in brown adipose tissue. Uncoupling protein-2 is expressed particularly in white adipose tissue while uncoupling protein-3 is found particularly in skeletal muscle.

Introduction

Thiamin (vitamin B_1), the antineuritic or antiberiberi factor, was first isolated from rice bran. Thiamin is distributed widely in natural materials in the forms of free thiamin and its mono- (TMP), di- (TDP), and triphosphate (TTP) esters. The ubiquitous distribution of thiamin in the plant and animal kingdoms is due to the presence of the coenzyme form, TDP, which plays an important role in carbohydrate metabolism throughout biological organisms. (*See* **Coenzymes**.)

This article concentrates on the physical and chemical properties of the vitamin, its occurrence in foods, its use as a food additive, and the problems associated with its analytical determination in biological and food samples.

The structures of thiamin and its phosphate esters found in living organisms are shown in **Figure 1**.

Physical and Chemical Properties

The physical properties of thiamin hydrochloride are given in **Table 1**. Thiamin hydrochloride crystallizes, usually as the hemihydrate. On exposure to air of average humidity, thiamin hydrochloride absorbs water in the ratio of 1 mol of water to 1 mol of thiamin. The water can be removed by heating at 100 °C or in a vacuum over sulfuric acid or phosphorus pentoxide. In the dry form the compound is stable at 100 °C.

Thiamin phosphoric acid esters have the following empirical formulae: TMP chloride, $C_{12}H_{18}N_4O_4PSC1$ (mol. wt 380.78); TDP chloride, $C_{12}H_{19}N_4\ O_7P_2SC1$ (mol. wt 460.76); and TTP, $C_{12}H_{19}N_4\ O_{10}P_3S$ (mol. wt 504.28). All these phosphate esters are freely soluble in water and are stable in the dry state for several months when stored at a low temperature in the dark.

Table 1 Physical properties of thiamin hydrochloride

Property	*Characteristics*
Formula	$C_{12}H_{17}N_4OSC1HC1$ Mol. wt 337.28
Appearance	White, slight thiazole order, crystalline solid
Crystal form	Monoclinic plates in rosette-like clusters
Melting point	248 °C
pH	3.58 (1 mg ml^{-1}); 3.13 (10 mg ml^{-1})
Ultraviolet maxima	247 nm (pH 3.0); 235 and 267 nm (pH 5.0)
Solubility	1 g in 1 ml water, 18 ml glycerol, 100 ml 95% alcohol, 315 ml absolute alcohol; more soluble in methanol; soluble in propylene glycol. Practically insoluble in ether, benzene, hexane, and chloroform

From Budavari S (ed.) (1996) *The Merck Index. An Encyclopedia of Chemicals, Drugs, and Biologicals*, 12th edn. Rahway, NJ: Merck.

Thiamin is readily split into the pyrimidine and thiazole moieties by sulfite treatment at pH 6.0 or above.

In strong alkaline solution thiamin is oxidized by oxidants (potassium ferricyanide, cyanogen bromide, mercuric chloride, and others) to thiochrome (Figure 1). Thiochrome is a highly fluorescent compound above pH 8, and thiamin phosphate esters are also quantitatively converted to thiochrome phosphate esters without affecting the phosphate bonds. All these compounds have identical excitation maxima, at 375 nm, and very similar fluorescence maxima, at 432–435 nm. This is the principle for the most common and sensitive assay procedures for thiamin as well as its phosphate esters.

Hydroxyethylthiamin (Figure 1) exists in living organisms in the form of hydroxyethyl-TDP. It is converted to the corresponding thiochrome derivative by alkaline ferricyanide oxidation but not by cyanogen bromide oxidation. This difference in the oxidation property is used for the assay of hydroxyethylthiamin.

In aqueous solution below pH 5, thiamin is quite stable to heat or even sterilization at 110 °C. At a pH of 5.5 or higher, it is rapidly destroyed by autoclaving, and at pH 7 or higher by boiling or even storing at room temperature.

In solution, TDP is unstable and partially decomposes to TMP and/or thiamin when stored for several months at pH 5 and 37 °C, but stable at pH 2–5 and 0 °C. TTP in aqueous solution is stable for at least 6 months when stored at − 80 °C. In 0.1 mol l^{-1} hydrochloric acid, TTP is decomposed quantitatively to TMP by boiling for 7 min at 100 °C, indicating

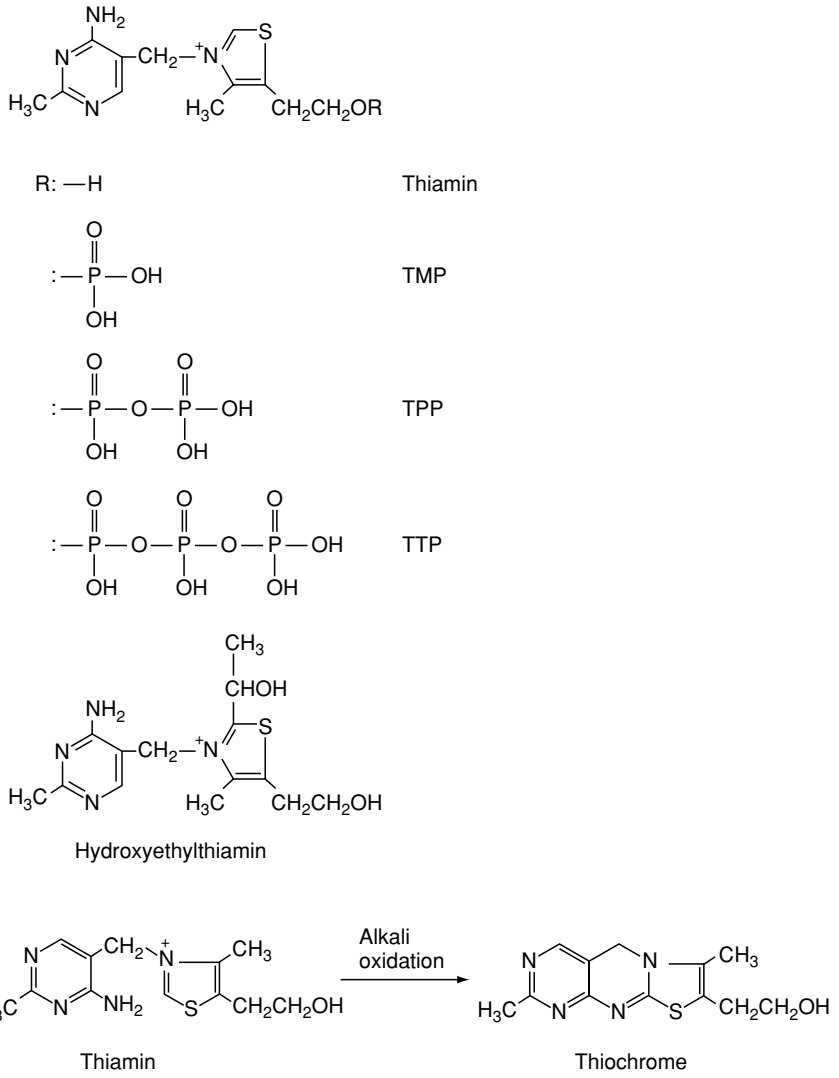

Figure 1 Structures of thiamin (vitamin B_1) and its related compounds.

the nature of the high-energy bond of its γ- and β-phosphates.

Thiamin-destroying or inactivating enzymes have been discovered in a variety of foods. Two thiaminases are involved. Thiaminase I catalyzes a base exchange between the thiazole moiety and another base and is found in fresh fish, shellfish, ferns, and some bacteria. Thiaminase II hydrolyzes thiamin to its pyrimidine and thiazole moieties and is found in certain bacteria.

In addition to thiaminases, certain plants have been shown to contain compounds which react with thiamin *in vitro* to produce thiochrome-negative products. One such product is thiamin disulfide. Such compounds in foods, which result in so-called thiamin inactivation, include caffeic acid, tannic acid, a variety of polyphenols, and some flavonoids (quercetin and rutin). The exact mechanisms of the inactivation reaction have not yet been elucidated. It appears that oxidative processes are involved, since the presence of oxygen increases the amount of thiamin inactivated.

It has been discovered that the treatment of thiamin with an extract of garlic containing allicin forms thiamin allyl disulfide, which is thiochrome-negative, but very active biologically. A variety of thiamin alkyl disulfides has since been synthesized and studied, and is now available commercially. These forms of thiamin are more fat-soluble and are therefore more rapidly absorbed than thiamin hydrochloride, and result in higher blood thiamin levels when therapeutically administered.

Occurrence in Foods

In most animal tissues, over 90% of the thiamin occurs in TMP, TDP, and TTP. The predominant form (80–85%) is TDP, the active coenzyme form. The exceptions are pig skeletal muscle and chicken skeletal white muscle, in which TTP exists in 70–80% of total thiamin (Figure 2). The most abundant form in plant tissues is free thiamin.

The content of thiamin in foods is relatively low. Practically no thiamin is contained in high-fat products (e.g., vegetable oil) and refined products (e.g., sugar). It is also relatively low in green vegetables, fruits, and seafoods. The thiamin content in a large variety of natural and processed foods has been listed in publications from the US Department of Agriculture (USA), Medical Research Council (UK) and Resources Council, Science and Technology Agency (Japan).

Table 2 lists the expected concentration in thiamin-rich foods. Refer to individual foods.

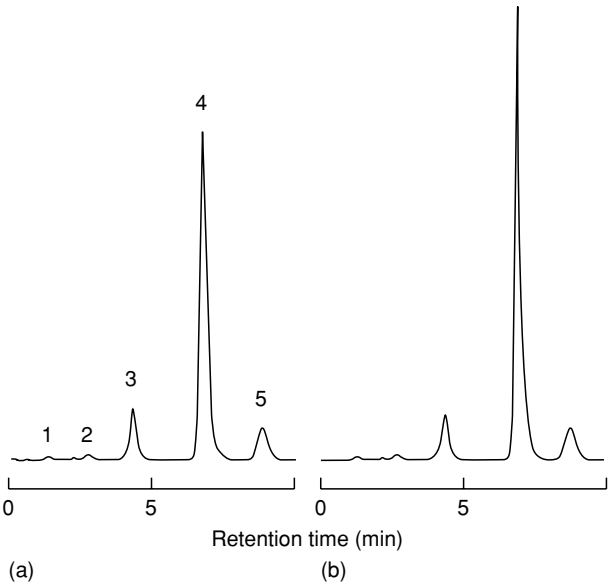

Figure 2 A typical chromatogram of fresh pig skeletal muscle extract by precolumn derivatization high-performance liquid chromatography (HPLC). (a) Skeletal muscle extract; (b) as (a), plus 1 pmol of authentic thiamin triphosphate (TTP) which was converted into thiochrome triphosphate and then added to the oxidized sample. The recovery rate of added TTP was 100%. 1, Thiamin; 2, thiamin monophosphate (TMP); 3, thiamin diphosphate (TDP); 4, TTP; 5, unknown, but possibly thiamin tetraphosphate.

In addition, average thiamin contents (μg per 100 g) in the following categorized groups of foods are as follows: dried beans, 680; nuts, 560; whole-grain cereals, 370; organ meats (liver, heart, kidney), 100; leaf and stem vegetables, 70; milk, 40; fruits, 30; pork muscle, 600–800; common white fish (cod, flounder, haddock, halibut), 50–90; hen's whole egg, 170; egg yolk, 500. Interesting foods of high thiamin content (μg per 100 g) are dried brewers' yeast (1800), wheat germ (2000), and tampala (a spinach-like vegetable) leaves (1600).

Losses During Food Processing and Storage

Factors affecting the survival of thiamin in the final food products after harvesting, handling, and processing the foods include pH, temperature, solubility, oxidation, and radiation. Among these factors, the effect of processing on the thiamin content has been extensively reviewed by several authors. A brief summary of the findings is given here.

Thiamin losses in dehydrated products, such as cereal grains, are very low if the materials are kept dry, and thiamin undergoes only limited destruction in the commercial refrigeration of meats and

Table 2 Top sources of thiamin

Top sources	*Thiamin (mg 100 g^{-1})*
Yeast, brewers', debittered	15.61
Yeast, torula	14.01
Yeast, brewers'	12.12
Sunflower seed, flour, partially defatted	3.60
Yeast, bakers', dry	2.33
Rice bran	2.26
Wheat–soy blend (WSB)/straight grade, wheat flour	2.02
Wheat germ	2.02
Sunflower seed kernels, dry, hulled	1.96
Rice polish	1.84
Wheat germ, toasted	1.65
Wheat–soy blend (WSB)/bulgur, flour	1.49
Pinenuts, piñon	1.28
Coriander leaf, dried	1.25
Cottonseed flour	1.21
Cornflakes, with added nutrients	1.20
Peanuts, raw with skins	1.14
Pork, fresh, loin, lean, boiled	1.13
Safflower seed, flour, partially defatted	1.12
Soybean flour, defatted	1.09
Alfalfa seeds	1.08
Sesame seed	0.98
Bacon, Canadian, broiled or fried, drained	0.92
Sausage, links or bulk, cooked	0.79

Beef liver	0.25
Luncheon meat, salami, cooked	0.25

From Ensminger AH (ed.) (1994) *Foods and Nutrition Encyclopedia*, 2nd edn, pp. 2102–2108. Boca Raton: CRC Press.

vegetables. Foods can be stored frozen for long periods without significant loss of thiamin, but losses are significant on thawing. Losses from frozen muscle meats are 20–40% during storage for 2–8 months.

On cooking and canning of meats, losses of thiamin (25–85%) strongly depend on the processing stresses encountered and type of meat product. Cooking by microwaves leads to much lower losses. Losses on cooking of vegetables vary from 0% to 60%. Vigorous boiling or other types of agitation result in greater losses of thiamin than simmering at the same temperature or pressure and steam cooking. Losses are caused by degradation and by leaching. (*See* **Canning**: Quality Changes During Canning; **Cooking**: Domestic Techniques.)

Roasting of beef and pork involves thiamin losses of 36–53%. Ionizing radiation used during sterilization destroys 53–88% of thiamin in meats, yet, in certain poultry, fish, and vegetables, losses are only 5–37%. Baking of bread leads to losses of 5–35%. In the processing of milk, losses of thiamin are 9–20% by pasteurization, 30–50% by sterilization, 10–15% by drying, and 40% by condensing and subsequent canning. (*See* **Irradiation of Foods**: Applications.)

The milling of cereal grains, wheat flour extraction of less than 85%, and the degerming of corn cause a marked drop in thiamin. Parboiling of rice and drying before milling conserve the majority of the thiamin. (*See* **Milling**: Characteristics of Milled Products.)

Uses in Food Fortification

Thiamin hydrochloride is the most common additive. (*See* **Food Fortification**.)

Thiamin (125 mg per 100 g) is added to polished rice and (1.5 mg per 100 g) to pressed barley in Japan, mostly in special cases, such as for use in school lunches.

The recommended daily allowance of thiamin is 0.5 mg per 1000 kcal. The continuing need for thiamin fortification of processed cereals has been proposed in the UK (1986), in order to meet the adult thiamin requirement, which has been determined biochemically.

Human thiamin deficiency, called beriberi, has been largely eliminated in those countries where fortification of staple foods (rice, cereal, dairy products) is practiced, but it is still prevalent in those countries where unfortified foods are used. However, even in western countries it is becoming evident that subclinical thiamin deficiency is more widespread than previously realized, especially among infants and the elderly, and other groups who consume snacks and highly refined, processed foods. Thiamin fortification of rice, dairy products and cereals is also recommended for these 'at-risk' groups and for athletes whose metabolic demands are greater.

Analytical Procedures

Alkaline oxidation of thiamin by either ferricyanide or cyanogen bromide gives thiochrome, an intense blue fluorescence compound. This principle is the basis for the official standard method of the Association of Official Analytical Chemists (AOAC). However, high-performance liquid chromatography (HPLC) is most frequently used at the present time for the assay of thiamin in foods. Microbiological

assays are still also widely used for both foods and animal feeds. (*See* **Chromatography**: High-performance Liquid Chromatography.)

An outline of the manual fluorimetric AOAC method follows. Thiamin in foods is protein-bound in both animal and plant tissues, although it occurs principally as the diphosphate in the former and as the free form in the latter. It is therefore necessary to extract thiamin and its phosphates from food proteins.

This is carried out by boiling the finely ground or homogenized sample in 0.1 mol l^{-1} hydrochloric acid or 0.1 mol l^{-1} sulfuric acid. The extract is then neutralized to pH 4–4.5 and treated with an enzyme preparation exhibiting phosphatase activity (Taka-diastase, Mylase P, or Clarase). After filtration or centrifugation, free thiamin thus obtained is purified through a column of cation exchange-type silica (Permutit T, Decalso F, or Zepolite S/E). After washing the column several times with almost boiling water, the thiamin is eluted with almost boiling acid potassium chloride solution.

An aliquot of the above eluate is oxidized by alkaline ferricyanide or alkaline cyanogen bromide solution and another aliquot is mixed with an alkali solution (blank). Thiochrome thus obtained is extracted into isobutanol. Thiochrome fluorescence intensity is measured spectrofluormetrically at an excitation wavelength of 375 nm and an emission wavelength of 435 nm. The amount of thiamin extracted is calculated from the standard curve obtained with thiamin standard solution treated in the same manner as above. Fortified foods and pharmaceuticals can be analysed for thiamine with reduced sample preparation.

Chromatographic Methods

Recent advances in HPLC techniques allow the determination of thiamin content in foods more rapidly, accurately, sensitively, and reproducibly than the standard AOAC method. The purification step of the extracts can usually be omitted in the HPLC procedure. In addition, thiamin and its phosphate esters can be determined separately by the HPLC method when the appropriate extraction procedure is employed. Furthermore, thiamin, riboflavin, pyridoxine, or niacin in foods can be simultaneously assayed when appropriate detection systems are used. This procedure has been successfully used for quantifying these vitamins in a wide range of foods, including cereal products, raw meat, processed meats, fruits, and vegetables.

Samples are treated, for example, by the AOAC method and then subjected to enzymatic hydrolysis. The filtrate or the supernatant after centrifugation can be directly analyzed by a reversed-phase column with ion-pairing chromatography. A wide range of mobile phases has been employed, but those based on octane sulfonate (as ion pair) in aqueous methanol or acetonitrile have proved to be generally successful. Detection is performed spectrophotometrically at 254 nm, which gives a detection limit on injection of 30 ng (90 pmol) of thiamin. This procedure is suitable for food containing a relatively large amount of thiamin, especially for fortified rice or cereals. (*See* **Spectroscopy**: Overview.)

An HPLC system equipped with fluorometric detection is suitable to quantify much smaller amounts of thiamin in foods with a detection limit of 5–50 fmol thiamin. Both precolumn derivatization and postcolumn derivatization procedures of thiamin into thiochrome are used.

When the extraction procedure is carried out with cold trichloroacetic acid or perchloric acid, thiamin and its phosphate esters are extracted intact and can be individually measured. Both straight-phase and reversed-phase columns are used in the HPLC method. In the former system, thiamin, TMP, TDP, and TTP are eluted and detected in that order, and in the latter system the elution order is reversed. Total thiamin is then calculated as a sum of thiamin and its phosphates. This procedure can avoid the enzymatic hydrolysis step. This HPLC method of determining thiamin and its phosphates has been successfully used to quantify the thiamin level not only in animal tissues, but also in human blood or serum to assess thiamin status in humans.

The chromatographic profile of thiamin and its phosphates in fresh pig skeletal muscle, obtained by the precolumn derivatization method, is shown in Figure 2. The analytical system consisted of LiChrosorb NH_2 (150 × 4.6 mm inner diameter (ID), 5 μm particle size) as the stationary phase, and acetonitrile–90 mmol l^{-1} potassium-phosphate buffer (pH 8.4) (60:40, v/v) as the mobile phase. Detection was carried out fluorometrically (excitation, 375 nm; emission, 430 nm) at room temperature.

Microbiological Methods

Microbiological methods are based on the nutritional requirement of a particular microorganism for the vitamin in question, in this case thiamin. A nutrient medium which is complete in all respects except for thiamin is prepared for the microorganism. The growth response for standard vitamin solutions is then compared with that achieved with extracts of the food sample, and hence the concentration of

thiamin in the sample is calculated. In most instances it is necessary to extract thiamin from foods under hydrolytic conditions and it may also be necessary to release bound forms with an enzymatic digestion, as in the standard thiochrome method.

Over the years, many microorganisms have been used in the assay of thiamin. Assays based on the use of *Lactobacillus fermentum* and *L. viridescens* are now widely employed as these microorganisms respond only to intact thiamin. Measurement of rate of growth is usually followed by nephelometry or measurement of turbidity, although production of acidity may also be monitored.

Microbiological methods are slowly being replaced by more rapid instrumental techniques, e.g., HPLC. However, they do provide simple, sensitive analyses, especially where a high degree of precision is not required.

Background

The discovery of thiamin or vitamin B_1 as an essential nutrient has opened a new area in the field of nutrition research in two respects. First, the nomenclature 'vitamin,' used for the whole class of the later on discovered essential micronutrients of organic origin, was derived from a functional group (NH_2 group) of the molecule. Second, thiamine was the first nutritional factor that could be identified as a curative agent against a deficiency disease in animals.

At the end of the nineteenth century, the Dutch medical officer Ch. Eijkman discovered the beneficial effect of rice bran or unpolished rice, respectively, for the treatment of polyneuritis in chickens resembling beriberi in man, which had been previously induced by feeding polished rice. In 1911, the German-Polish chemist C. Funk isolated a crystalline substance from rice bran and regarded the amino function as the essential principle of the molecule. The exact chemical structure of the thiamin molecule was elucidated by R. Williams and A. Windaus. Because of the sulfur content of the molecule or its thiazol moiety combined with the amine function, the compound was designated as thiamin instead of the former name aneurin. Nevertheless, the classical form of thiamin deficiency, beriberi, mainly affects human beings and has been well known in the rice-eating countries of East Asia for centuries. Even 25 years after the ingenious work of Eijkman, who clarified the cause of this deleterious disease, the mortality rate from beriberi in industrialized countries such as Japan was still more than 25 000 per year.

Physiological Function

Like other water-soluble B-vitamins, thiamin is in its primary function coenzymatically active. The thiamin-dependent enzymes are involved in carbohydrate and energy metabolism (**Figure 1**). Key enzymes in

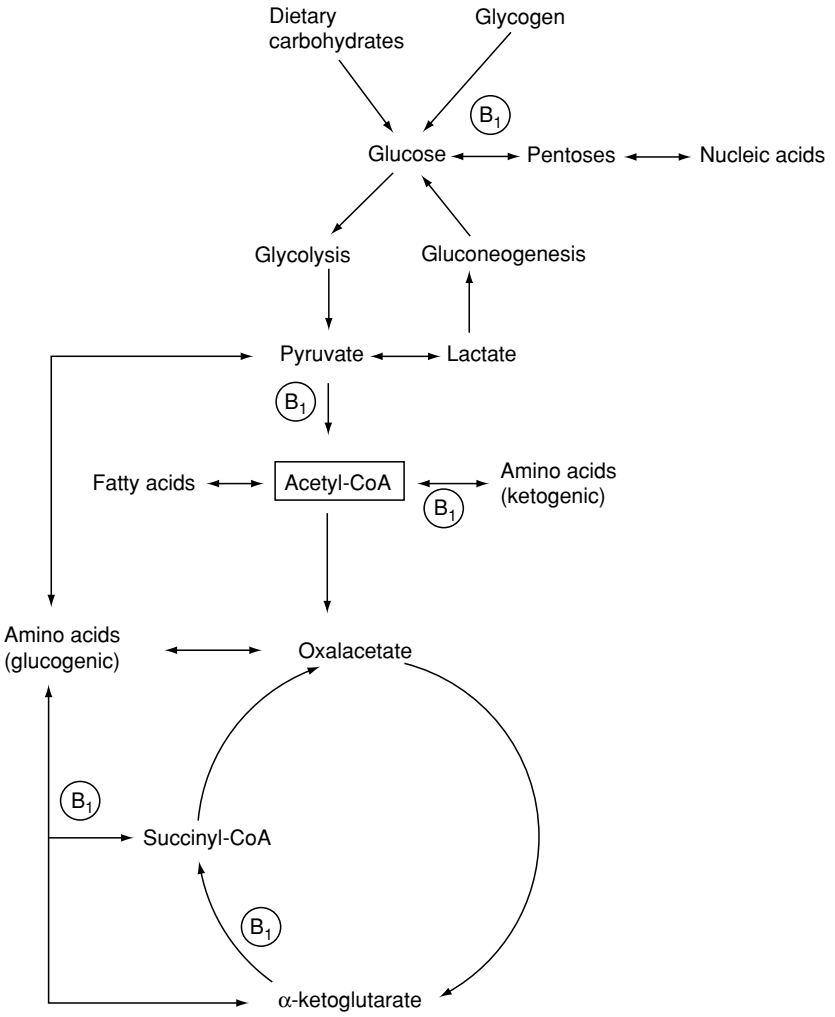

Figure 1 Metabolic pathways involving thiamin.

these metabolic pathways are mitochondrial pyruvate dehydrogenase (EC 1.2.4.1) linking glycolysis with the citric acid cycle, α-ketoglutarate dehydrogenase (KDH) (EC 1.2.4.2) within the citric acid cycle, and the cytosolic transketolase (EC 2.2.1.1) in the pentose phosphate shunt. Hence, it follows that the energy turnover of the organism is related to thiamin demand. As dietary carbohydrates are the predominant fuel for the rapid metabolizable energy of the organism, the thiamin requirement is often related merely to the carbohydrates ingested. KDH was identified as the rate-limiting enzyme of the cerebral glucose utilization. A low enzyme activity caused by a reduced intracellular TDP concentration results in lactacidosis, cerebral dysfunction of the energy metabolism, and neuronal cell degeneration. Additional thiamin-dependent enzymes are involved in the metabolism of branched-chain amino acids, e.g., leucin, isoleucin, and vallin. All enzyme reactions are characterized by transfer of an 'active aldehyde' from α-keto acids formed after previous decarboxylation to coenzyme A or an aldopentose.

The coenzymatically active form is thiamin diphosphate (TDP), also called thiamin pyrophosphate (TPP) or cocarboxylase, which is formed in the mucosal cell of the intestinal barrier with the aid of thiamin pyrophosphokinase (EC 2.7.6.2) in the presence of ATP. The latter enzyme is also found in mammalian liver and other tissues such as brain, nerves, and heart of mammals and birds. Further phosphorylated forms of thiamin, which are found in varying quantities in tissue, are thiamin monophosphate (TMP) and thiamin triphosphate (TTP). These derivatives are synthesized and metabolized according to the scheme in Figure 2.

Thiamin phosphorylation represents a partitioning process in a deeper compartment. Cell membranes are impermeable for the intracellularly active

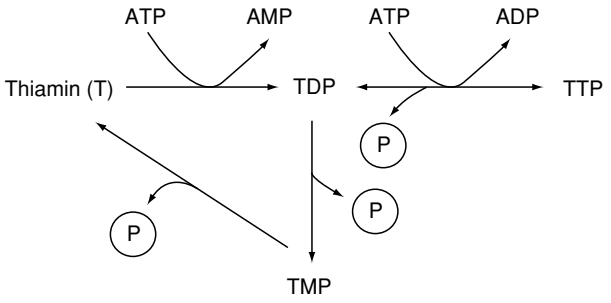

Figure 2 Interconversion of thiamin phosphates (according to Rindi, modified).

coenzyme TDP, which is released only after hydrolysis via TMP to thiamin. The total thiamin concentration of the blood cells as well as of the cerebrospinal fluid (CSF) has a nonlinear relation to the corresponding plasma concentrations. A linear increase in blood cells and CSF has been observed only with thiamin plasma levels above 10 nM ($3\,\mu g\,l^{-1}$). Otherwise, with extremely low plasma and CSF concentrations, a disproportionately high TDP content of erythrocytes and TMP content of the CSF is maintained for a longer period. Thus, the intracellular phosphorylation should be seen as a protecting mechanism, inhibiting rapid thiamin depletion by decreasing the membrane permeability.

After TDP, TTP is the next most phosphorylated metabolite, albeit the steady state concentrations in tissues are rather low. No coenzymatic function has been found for this metabolite. Several investigators have demonstrated in a variety of animals (rats, rabbits, cows, frogs, pigs) that TTP, together with a distinct part of TDP, is neurophysiologically active in the central and peripheral nervous system independent of the coenzyme function of the latter. After electrical stimulation of nerves or treatment with neuroactive drugs, e.g., acetylcholine, tetrodotoxin, or LSD, a release of the phosphorylated esters TDP and TTP concomitant with a shift to TMP and free thiamin has been observed. Furthermore, in patients with the deleterious 'subacute necrotizing encephalopathia,' or Leigh's disease, the TTP level in the brain was low and tended toward zero. It has been known for a long time that severe thiamin depletion of the mammalian central nervous system leads to encephalopathias, which are accompanied by regionally selective changes in neurotransmitter function. Though the exact function of TTP is not yet known, it plays an essential role in nerve excitation and transmission, possibly in gating the ion transport. From recent investigations, it has been argued that TDP might also be involved in the inhibition of nonenzymatic glycosylation processes. It is suggested that the emerging advanced glycosylation end products (AGE) are the reason for the segmental demyelinization observed in neurodegenerative diseases. Studies on cultivated cells have demonstrated that thiamin and TDP could prevent the AGE formation. In this regard, TDP is more effective than the standard inhibitor aminoguanidine that is normally used.

Absorption, Storage, and Excretion

Thiamin is absorbed from the gastrointestinal tract by a dual system, as has been shown for humans and rats. At low concentrations, it follows energy-dependent active transport with a saturation kinetics up to a maximal concentration of 2 μM. At higher concentrations, a simple diffusion process is predominant. However, the relative absorption decreases with increasing vitamin doses, so that with gram doses, only about 5% are incorporated.

A close association was assumed between thiamin transport and phosphorylation as well as Na^+ dependency. However, the coupling of thiamin transport with phosphorylation is now doubtful, and there is much evidence of a specific protein carrier being involved in the absorption, but the following intracellular phosphorylation seems to be a rate-limiting step in the active transport of thiamin across the epithelial cells of intestine. In contrast, in the guinea-pig intestine, thiamin seems to cross the brush-border membrane by simple diffusion throughout the concentration range from 0.06 to 10 μM.

The jejunum and ileum have been found to be the main sites of thiamin absorption in rats with a maximal rate in the proximal 22 cm of the small intestine. This specificity seems to resemble that of other animals as well as humans.

After uptake from the intestinal tract, thiamin is distributed rapidly into the organs and tissues according to the requirements. In humans and animals, the heart contains the highest thiamin concentration (3–8 $\mu g\,g^{-1}$ fresh weight), followed by the kidney (2.4–6 $\mu g\,g^{-1}$ fresh weight) and liver (2–7.5 $\mu g\ g^{-1}$ fresh weight), and the brain (1.4–4.4 $\mu g\,g^{-1}$ fresh weight). Lesser amounts are found in other tissues. Whole blood contains 0.05–0.12 μg of thiamin per milliliter, about 90% of this being found in the corpuscular constituents. The total storage capacity of man is estimated to be 25–30 mg of thiamin, 40% of this being in muscles. Interestingly, pig muscle has a relatively high thiamin content (8–12 $\mu g\,g^{-1}$) because of feeding conditions, higher than that in muscles of other mammals (1–2 $\mu g\,g^{-1}$) and pig liver (2–4 $\mu g\,g^{-1}$). The thiamin contents of several plant and animal foods are given in Table 1.

Table 1 Thiamin content of plant and animal foods (mg per 100 g fresh weight)[a]

Content	Foods	
1.0–2.0	Whole wheat and rye	Plant foods
0.9	Para nuts	
0.7–0.8	Soy flour	
0.6–0.7	White bran	
0.3–0.5	Whole cereal products, lentils, oats, unpolished rice, lima beans, whole corn meal, cashew nuts, pea nuts, hazel and walnuts, mung beans	
0.1–0.2	Parboiled rice, sorghum, beans and peas cooked, cauliflower, potatoes, fennel, broccoli cooked, asparagus, soy sprouts, mushroom	
< 0.1	Fruits, milk products, white flour products	
0.9	Loin pork	Animal foods
0.3–0.5	Liver, kidney (calves, beef, pork), duck	
0.1–0.2	Lean meat (calves, lamb, beef), eel, tuna, salmon, mackerel, plaice and flounder, oysters	

[a]Modified from Souci SW, Fachmann W and Kraut H (2000) *Food Composition and Nutrition Tables*, 6th revised edn. Boca Raton, FL: CRC Press/Medpharm Scientific.

As with other water-soluble vitamins, thiamin excretion is dependent on intake. Within the physiological range, most of it is excreted by urine. Besides free thiamin and small amounts of TMP, numerous metabolites can be detected as minor excretion products such as thiazol, pyramin, and methylthiazol acetic acid.

After ingestion of therapeutic dosages, the amount of thiamin excreted via bile increases proportionally, as does the unabsorbed part in feces.

Lipid-soluble Thiamin Derivatives

Under relatively mild conditions (e.g., in the gastrointestinal lumen) thiamin reacts with allicin, the active principle of garlic and onions, to form a lipid-soluble compound, called allithiamin, that is able to penetrate through membranes more easily than the water-soluble salts (Figure 3). Additional *S*-alkyl derivatives have been identified in cruciferous plants, and several lipid-soluble derivatives have been synthesized with a better stability than that of the spontaneously formed allithiamine (*S*-benzoyl-, *S*-tetrahydrofurfuryl analogs being the most important).

Oral administration of these lipid-soluble analogs results in higher thiamin blood levels than with equimolar thiamin doses, because the allithiamins from the gut lumen are preferentially absorbed by passive diffusion and rapidly converted to the active vitamin by reducing SH-compounds. These allithiamins are because of their improved bioavailability suitable transfer substances with which to establish high thiamin levels in target tissues comparable with drug targeting. The elevated blood level results in an improved vitamin status, as measured by enzymatic criteria.

Thiamin Antagonists

Synthetic Antivitamins

Like most of the B vitamins, thiamin has a rather high structural specificity, i.e., minor modifications of the molecule lead to a decrease or a total loss of

	R_1	R_2	R_3	X

physiological activity or even to antagonistic effects. Of the numerous analogs synthesized so far, only the 2-ethyl- and the 2-*n*-propyl homologs in the pyrimidine moiety of the molecule show any biological activity comparable with that of thiamin. For example, when the 4-amino group is replaced by a hydroxyl function, oxythiamin, one of the most potent thiamin antagonists, is obtained. Another prominent antivitamin is pyrithiamin, which contains an ethylene group instead of sulfur in the thiazolium ring. Some thiamin antagonists have been found to exhibit antiprotozoal activity, as in the case of amprolium, which is effective as a prophylactic agent for coccidiosis of fowl. Some of the modified thiamin derivatives are shown in Figure 3.

The use of antagonists results in rapid and severe deficiency symptoms in humans and animals. Amprolium is already known to affect the absorption process already, and this has been suggested as the mechanism for its anticoccidial action in fowls. Other antivitamins appear to function at the conzyme level, i.e., they bind to the apoenzyme, but inhibit the following enzymatic reaction. Nevertheless, there are several differences in the action on neurological symptoms. Only pyrithiamin (and not oxythiamin) can block the action potential of a single myelinated nerve fiber. It is also well known that only pyrithiamin produces polyneuritis. In addition, differences in neurophysiological action are caused by the different abilities of both antagonists to cross the blood–brain barrier, which has only been verified in the case of pyrithiamin. However, it can be shown that the amino group of the thiamin molecule is essential for the active transport of the vitamin from the rat small intestine and the formation of thiamin pyrophosphate.

Thiaminases and other Antithiamin Factors

Two thiamin-cleaving enzymes have been identified, called thiaminase I and thiaminase II.

Thiaminase I is found in shellfish, clams (but not oysters), some freshwater fish viscera, crustacea, and certain ferns, but very few higher plants. Also, certain species of *Bacillus* and *Clostridium*, which are components of the human and animal intestinal flora, have been found to produce this enzyme. The enzyme catalyzes an exchange reaction, in which the thiazol moiety of the molecule is displaced by another N-containing base or a SH-compound. The effect of this compound was first observed when silver foxes were fed raw fish waste, resulting in a deleterious thiamin deficiency disease called Chastek paralysis. Thiaminase I may also be produced by the rumen microflora of ruminants or by plants, and, in the presence of suitable cosubstrates, e.g., niacin, or pyridoxine, and certain antihelmintics, seems to be responsible for the ruminant CNS disorder, polioencephalomalacia.

Thiaminase II is of bacterial origin (predominantly *Bacillus, Candida*, and *Oospora*) and breaks down the free vitamin, but not the thiamin pyrophosphate, into pyrimidin and thiazol components. More prevalent are thermostable thiamin-inactivating factors of plant origin, e.g., polyphenolic substances such as flavonoids and catechol derivatives in fermented tea, ferns, sweet potatoes, and betel nuts, and, in small quantities, in other leaves, fruits, and roots. These can decompose the thiazol component of the vitamin, accelerate the oxidation to the disulfide form, or form unabsorbable adducts with thiamin. Rats fed on food high in polyphenolics have been shown to develop deficiency symptoms as a result of a marked decrease in levels of cerebral thiamin and thiamin-dependent enzymes. Likewise in man, high tea consumption leads to a deficient thiamin status, but ascorbic acid, if present, completely inhibits the thiamin-inactivating processes.

Status Assessment

In terms of biochemical status, urinary vitamin excretion and blood enzymes are suitable criteria. Urinary thiamin excretion is, as with most B vitamins, largely dependent on intake and therefore provides an indication of the recent dietary intake but does not adequately reflect the body stores. At intake levels below 0.5 mg of thiamin per 1000 kcal per day (0.1 mg MJ^{-1}) thiamin excretion varies only slightly, and the proportion of metabolites in the urine exceeds the vitamin content itself. Because urinary excretion follows a diurnal rhythm, 24 h urine or the creatinine excreted is taken as the basis for status assessment. Occasionally, the status can be interpreted more accurately by a thiamin load test. After administration of a 5-mg dose, vitamin excretion is measured for the following 4 h. A deficient status can be assumed if less than 20 μg is excreted during this period.

Erythrocytic transketolase activity (ETKA), the rate-limiting enzyme in the pentose phosphate pathway, and its activation coefficient, α_{ETK} are often used as an indication of functional status as they give a better idea of body stores than urinary excretion. According to the saturation deficit of the apoenzyme, the transketolase activity can be stimulated *in vitro* by the addition of TDP. The ratio of stimulated to basal activity, which increases with the degree of deficiency, indicated by the activation coefficient (AC) or α_{ETK}, is commonly taken as a prognostic status index. The AC is better as a comparison of status in groups, because

of the large interindividual variation in basal enzyme activity. Moreover, it can be assumed that apoenzyme levels are not affected by the vitamin deficiency. Nevertheless, in alcoholics, either the apoenzyme synthesis or the linkage to the coenzyme TDP seems to be impaired, and the transketolase assay may indicate misleading results about the true status. Furthermore, confounding factors in the enzymatic assay, irrespective of the thiamin status, may include certain cancers, uremic neuropathy, diabetes, and treatment with certain anticancer drugs (fluorouracil, acytoxin) or diuretics, such as furosemide.

Recently, in view of improved high-performance liquid chromatography techniques, the TDP content in erythrocytes has been suggested to be a better indicator of the body stores compared with ETKA and independent of confounding factors. The criteria of the thiamin status indices are listed in Table 2.

Thiamin Requirement

Regarding the essential role of thiamin-dependent enzymes in carbohydrate and energy metabolism, the requirement for this vitamin is usually related to energy intake. Irrespective of the catalytic function of enzymes emerging basically unchanged from a biochemical or metabolic reaction, controlled studies in man have demonstrated that static as well as functional status criteria (transketolase activity and urinary excretion) deteriorate with increasing energy uptake even when the thiamin supply remains unchanged, thus indicating an increased vitamin turnover. The dependence on energy metabolism seems to be particularly evident in a marginal vitamin status.

Previously dietary fat was postulated to have a 'sparing effect' on thiamin requirements. This effect is, however, comparatively small, even with major increases in fat in the diet. Furthermore, in a starvation or semistarvation status when the vitamin intake is zero and increasing amounts of fatty acids are metabolized to satisfy the body's energy needs, the tissue stores of thiamin are rapidly depleted.

International committees recommend safe levels of intake amounting to 100–130 μg of thiamin per megajoule, equivalent to 0.4–0.54 mg of B_1 per 1000 kcal. A critical intake point appears to be approximately 0.05 mg of B_1 per megajoule (0.2 mg per 1000 kcal), below which urinary excretion is low, and the first clinical signs of deficiency may appear. A minimum intake of 1 mg per day is recommended to provide an adequate margin, even for those consuming less than 8 MJ (2000 kcal) daily. The additional values for pregnancy and lactation mostly exceed the calculated additional requirement of pregnant and lactating women. These extra values insure optimal pre- and postnatal development. In the past, clinical deficiency symptoms of infants were sporadically observed in spite of an inconspicuous appearance of the mother (infantile beri beri; see Table 4).

Owing to the low storage capacity, regular thiamin intake is important. Although, within the margin of physiological requirements, the organism attempts to prevent considerable thiamin losses by partial tubular reabsorption and intracellular fixation as TDP, the biological half-life time of this vitamin is assumed to be 9–18 days. After this period, when thiamin uptake is restricted, early nonspecific deficiency symptoms occur.

The recommended daily allowances for several European countries together with the USA's dietary reference intakes are listed in Table 3.

Deficiency Diseases

In thiamin deficiency, primarily, organs and tissues, such as the central and peripheral nerve system and the heart are affected showing an increased energy turnover or close carbohydrate dependency. Clinical signs described in most animals refer to lesions in these tissues.

Since Eijkman's observations in fowls, the degeneration of the peripheral nerves was the first pathological symptom of thiamin deficiency noted in

Table 2 Reference values of thiamin status parameters[a]

Indicator	*Adequate*	*Deficiency*	
		Marginal	*Severe*
Thiamin excretion in urine (μg per gram of creatinine)	> 66	27–66	< 27

Italy, UK	0.8–1.2

animals, leading to spastic pareses and paralysis of legs. Later on, the role of thiamin in the central nervous system, especially in pyruvate metabolism of the brain, could be demonstrated, too.

Neurological signs are also characteristic of the deficiency state in human beings. The classical manifestation of deficiency can be seen in beriberi. This disease is endemic in several regions of East Asia. Depending on how far the disease has progressed and additional nutrients are involved (e.g., protein deficiency), it is characterized by either polyneuropathias and degenerative muscle wasting (dry or atrophic form) or cardiac arrhythmias and edema (wet or exudative form). The development of exudative beriberi predominates in cases of a high carbohydrate intake and increased physical activity. Protein deficiency is probably involved, too. The Wernicke–Korsakoff syndrome, the cerebral form of deficiency, is characterized by mental confusion, memory disturbances, ataxia, ophthalmoplegia, and nystagmus. This syndrome can be interpreted as neuropathia of the central nervous system and is most commonly observed in malnourished alcoholics. The thiamin-dependent PDH and KDH complexes are key enzymes in the metabolic pathways of glucose and other energy-delivery substrates. The activities of both enzymes were found to play a rate-limiting role in mammalian brain mitochondrial preparations. Thus, lactic acid accumulation, as a result of the impaired glucose oxidation and disruption of oxidative phosphorylation utilizing pyruvate, α-ketoglutarate, and succinate as substrates has been demonstrated in brain mitochondria from deficient rats. There is some evidence that localized lactic acid accumulation may contribute to the brain lesions in the Wernicke–Korsakoff disease. Futhermore, it is suggested that neurological symptoms may involve an impairment of the cholinergic neurotransmitter function. Acetylcholine and γ-aminobutyrate are primarily produced through the oxidative metabolism of glucose or via the citric acid cycle with acetyl-coenzyme A (acetyl-CoA) and α-ketoglutarate as precursors. Although no change in regional brain acetylcholine levels was found in thiamin-deficient rats, acetylcholine utilization and turnover were reduced, and the central cholinergic mechanisms appear to be depressed in a deficient state. These alterations may be due to a decreased PDH and thereby activity limited acetyl-CoA production.

Infantile beriberi occurring in breast-fed infants between 2 and 6 months has particularly devastating consequences. Symptoms include cyanosis, dyspnea,

Table 4 Symptoms of clinical thiamin deficiency[a]

Deficiency form	*Neurological signs*	*Cardiovascular signs*	*Other signs*	*Nutrient interactions*
Atrophic beriberi (dry or polyneuritic form)	Degenerative polyneuropathia of lower extremities, paresthesia, reflex disorders, dropfoot, muscle waste, convulsions			(Caloric restriction), anorexia
Exudative beriberi (edematous or cardiovascular form)		Sinus tachycardia, cardiac arrhythmias, heart dilatation (beriberi heart), pericardial effusion, cardiac insufficiency	Lung and peripheral edemas, ascites, dyspnea, rarely lactic acidosis without edemas	(High carbohydrate intake, protein deficiency), intense physical activity
Wernicke–Korsakoff Syndrome (cerebral form)	Nystagmus, ophthalmoplegia, cerebellar ataxia, paralysis of the sixth brain nerve, polyneuropathia (burning feet syndrome), reflex disorders		Psychoses, hallucinations, memory loss, irritability	Alcohol abuse
Infantile beriberi (2–6 month)	Convulsions (increased intracranial pressure)	Tachycardia, cardiac insufficiency	Vomiting, diarrhea, abdominal distension, anorexia, cyanosis, dyspnea

tachycardia, abdominal distension, and convulsions. Sudden death often occurs as a result of cardiac failure. Nursing mothers, however, often do not show any signs of clinical deficiency. The thiamin deficiency symptoms are summarized in Table 4.

Therapeutic Administration and Toxicity

The importance of thiamin for the metabolism of the central and peripheral nerve system, as is becoming clear from the deficiency symptoms, implicates its therapeutic application in all neurological system disorders. The recommended doses are 100–300 mg per day, often combined with pyridoxine and cobalamin. Because of the limited gastrointestinal absorption, the dose should be split up over the day. In progressive polyneuropathia and clinical beriberi, the same dosage may be initially administered i.m. or i.v., for a rapid tissue restoration, followed by oral therapy.

Lipid-soluble allithiamin derivatives can be given in smaller doses, because of the improved absorption. The passage of those derivatives across the blood–brain barrier is alleviated, too, as has been shown in animals. A significant improvement in the neuropathia score by oral application of the lipophilic benfotiamin has been observed in diabetic polyneuropathia patients as well.

As with other water-soluble vitamins, thiamin toxicity is very small when given orally, because of the limited absorption. In rare cases, with parenteral dosages above 100 mg, impaired sensations or even anaphylactic reactions have been observed, but it is not clear as to what extent additional components of the injection solution may interfere.

Thiamin-dependent Enzymopathies

Thiamin-dependent enzymes are involved in four rare hereditary enzymopathies: leucinosis, Leigh syndrome, congenital lactacidosis, and thiamin-dependent megaloblastic anemia.

In leucinosis or maple syrup disease, the degradation of branched chain amino acids is inhibited with following accumulation of ketoanalogs. In the alleviated or intermittent form, this disorder can be improved by an intake of 10–150 mg of B_1 per day under simultaneous protein restriction. If untreated, severe neurological complications, physical, and mental dysfunctions develop, followed by death.

Leigh syndrome is characterized by a necrotizing encephalomyelopathia and is also observed in ruminants. The exact biochemical defect is poorly understood but is thought to be a hereditary malfunction of thiamin triphosphate transferase, leading to impaired TTP formation, occasionally combined with a decrease in the amount of ketoacid dehydrogenase. Neurological symptoms develop, progressing from nystagmus and paralysis of the external eye muscles to convulsions, ataxias, and disorientation resembling the Wernicke disease. Thiamin therapy may be successful, particularly when lipophilic derivatives (fursultiamin) are ingested up to gram dosages. Lactacidosis (which occurs at the same time) can be alleviated by oral intake of hydrogencarbonate combined with a low-carbohydrate diet.

The clinical picture of congenital lactacidosis resembles Leigh syndrome, and it is often impossible to distinguish between the two. The primary cause is a defect of the PDH or of partial enzymes of this complex. Generally, the prognosis is deleterious. The lactacidosis and the concomitant neurological symptoms could only in rare cases be affected by therapeutic thiamin doses.

Thiamin-responsive megaloblastic anemia has until now been very rare. The characteristic symptoms are a very strange combination of anemia, labyrinthine deafness, and insulin-dependent diabetes. The anemia can be improved only by oral doses of

Table 5 Congenital thiamin-responsive enzymopathies

Metabolic disorder	*Biochemical defect*	*Clinical symptoms*	*Therapy*
Leucinosis (maple syrup disease)	Ketoacid dehydrogenase for metabolism of branched-chain amino acids	Acidosis, ketosis, cerebral degeneration	Leucin-, isoleucin-, and valin-poor diet, thiamin (orally) 10–150 mg daily
Leigh syndrome (necrotizing encephalomyelopathia)	TTP formation, keto acid dehydrogenase	Lactacidosis, nystagmus, ataxia, convulsions, mental and psychic abnormal development	Thiamin (orally) 2.0 g daily (lipid-soluble derivatives)
Congenital lactacidoses	PDH	Lactacidosis, neurological symptoms, mental retardation	Thiamin lipid-soluble (?)
Thiamin-responsive megaloblastic anemia	Thiamin transport in tissue compartments	Megaloblastic anemia, diabetes, labyrinthine deafness	Thiamin (orally) 20–100 mg daily (lipid-soluble derivatives)

20–100 mg of thiamin. Folate and vitamin B_{12} administration is ineffective. In one case, the diabetes was improved, and insulin therapy was no longer needed.

The primary metabolic defect is unclear. Thiamin-dependent enzymes remain unchanged, and there may be an impairment in thiamin transport in certain tissues. The enzymopathies are summarized in Table 5.

THIRST

D J Ramsay, University of Maryland at Baltimore, Baltimore, MD, USA

Introduction

Thirst is a term which evokes many meanings. In most nonhuman studies, it is equated with measurements of water intake. In human studies, analog rating scales are often used to evaluate answers to questions such as: 'How thirsty are you?' 'How dry is your mouth?' or 'How unpleasant does your throat feel?' Its use is not restricted to an appetite for water. Depending on culture, experience, and availability, a variety of fluids such as soft drinks and nonalcoholic beverages, in addition to water itself, may be consumed. It has been suggested that the definition is best left in general terms such as 'the disposition to drink' or 'the tendency to drink,' and those who wish to use the word in a more specific sense should define it.

Role of Thirst

Water loss from terrestrial animals is continuous. Ingestion of food results in the addition of osmotically active solutes to the body fluids either because they are contained in the foods (e.g., sodium chloride) or because the process of metabolism produces them (e.g., oxidation of sulfur-containing amino acids to sulfate). These solutes are usually excreted in the

urine accompanied by water in amounts determined by the concentrating capacity of the kidney. Thus, if the kidney can produce urine four times more concentrated than plasma – the situation in humans – 25% of the volume of water will be lost compared to the situation in which the kidneys could not concentrate urine over plasma. Nevertheless, even kidneys producing low volumes of urine at maximal concentrations result in loss of body fluid. Water is also lost from the skin by insensible perspiration and sweating. These amounts are highly variable, depending on the level of activity, body temperature, and ambient temperature and humidity. Breathing also results in fluid lost as expired air is fully saturated with water at body temperature, whereas inspired air is usually drier and at a temperature lower than that of the body. Small amounts of water are lost in the feces, although in diseases accompanied by severe diarrhea, such as cholera, large amounts of fluid can be lost by this route. All these mechanisms cause a continuous inevitable loss of fluid. Thirst resulting in the ingestion of an appropriate volume of an appropriate fluid is the only way to repair the fluid deficit. Without thirst, animals would die of dehydration. Human subjects who lose the sensation of thirst as a result of disease are very difficult to treat. Even the most stringently prescribed timetable of water intake regime can fail. Irreversible dehydration is the inevitable outcome of the lack of thirst. (*See* **Water**: Physiology.)

Regulation of Thirst

Water is the most abundant component of the body, making up approximately 65% of body weight. The transport of solutes throughout the body takes place in physical solution, as do most of the physicochemical processes which maintain life. The total osmotic concentration of body fluids, or osmolality, is maintained within very narrow limits. In humans, as in other animals, it rarely varies by more than 1% or 2%. This is important for two reasons. First, as water can move freely through cell membranes, the osmolality of intra- and extracellular compartments is equalized by the movement of water down concentration gradients or osmotic gradients. If plasma and extracellular fluid osmolality increase, water will be withdrawn from cells, resulting in cell shrinkage. Thus, in situations of increased plasma osmolality, extracellular fluid volume will expand and intracellular fluid volume will decrease. Acutely, cells behave as perfect osmometers. It is therefore not surprising that osmolality is maintained constant in order to maintain both blood volume and cell volume within normal limits. Second, many bio-chemical reactions and cell transport processes depend critically on the concentrations of solutes. Thus accurate control of water balance to insure constancy of the volume and composition of body fluids is found in all mammals.

Cellular Dehydration Drinking

The correlation between total plasma solute concentration or osmolality and drinking has been known since the work of Mayer in 1900. More recently, the relationship between plasma osmolality and drinking has been described by a number of workers in a number of species, including humans. The relationship is generally investigated by determining the effects of intravenous infusions of hypertonic sodium chloride on water intake or, in the case of humans, increased indications of thirst, as noted on analog rating scales. In general, there is a linear increase in thirst associated with increased plasma osmolality similar to that seen in plasma vasopressin levels, the major determinant of urinary concentration. Thus increasing plasma osmolality leads to renal water conservation and the stimulation of thirst, and hence water-seeking behavior (Figure 1).

Extracellular Dehydration Drinking

Reduction of blood or extracellular fluid volume without a change in its osmolality also stimulates thirst. A number of maneuvres have been used to investigate this phenomenon. Hemorrhage, restriction of venous return by occluding the thoracic part of the vena cava, or sequestration of fluid using subcutaneous or intraperitoneal injections of colloid all

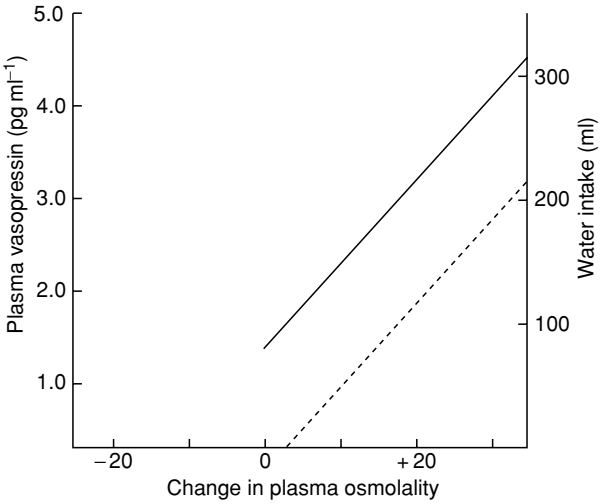

Figure 1 Increase in plasma osmolality stimulates vasopressin secretion (——) and water intake (- - -) in dogs. Reproduced from Thirst, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

result in stimulation of drinking. In general, drinking to extracellular fluid dehydration is less sensitive than that to cellular dehydration. The reduction of approximately 10% in blood volume is usually required to stimulate water intake, as is the case with stimulation of vasopressin secretion. With larger reductions in extracellular fluid volume, however, stimulation of thirst and vasopressin secretion is marked. Presumably, at the point where a reduction in extracellular fluid volumes severely compromises circulatory homeostasis, rapid restoration of blood volume becomes essential to insure survival.

Dehydration

During periods of water deprivation, plasma osmolality increases and extracellular fluid volume is reduced. It has already been emphasized that, under normal circumstances, water is lost continually, whereas drinking is a discontinuous process. Thus animals are always in a situation of potentially having to correct for dehydration by taking in fluids. In these situations, raised plasma osmolality, or cellular dehydration, is a more important input to the stimulation of thirst than is extracellular fluid dehydration. In primates, including humans, cellular dehydration may make up 90% of the stimulus.

Satiety

The stimuli responsible for the cessation of drinking are different from those which cause it. For example, dogs deprived of water for 24 h will make up fluid deficits accurately within 5 min of being allowed access to water. During this 5-min period, there is no correction of the raised plasma osmolality or decreased extracellular fluid volume as water would not have been absorbed from the gastrointestinal tract in sufficient quantities. Indeed, dehydrated dogs with an open gastric fistula will drink the same amount as intact dogs. In studies on water-deprived humans, subjects drank 65% of their total intake within 2.5 min. The remainder of the fluid deficit was consumed over a longer period of time. This satiety effect has been noted in a large variety of species; it is associated with a rapid inhibition of vasopressin secretion, and is based on oropharyngeal and gastric factors. However, it is only a temporary phenomenon and, unless drinking is followed by absorption of fluid and correction of the cellular and extracellular dehydration stimuli, drinking will be reinitiated. (*See* **Satiety and Appetite**: Food, Nutrition, and Appetite.)

Normal Drinking

Not all water intake depends on this simple deficit–satiety model. The water content of food, and that provided by its metabolism, can supply significant amounts of intake. The amount of water consumed on each occasion can depend heavily on learning and may be greatly influenced by other behaviors and by social factors. In humans the situation is even more complex and fluid may be taken in in association with caffeine or alcohol, and depend on specific tastes, such as sweetness, and on flavor. In spite of these factors, however, it should be noted than on average the kidney produces urine more concentrated than plasma. Thus renal-concentrating mechanisms are responding to a potentially dehydrating situation. In light of this information it might be asked why animals are not continually drinking. The answer is that drinking is only one of a large number of specific behaviors which may be expressed by an animal; if it were continually engaged in a search for water, to the exclusion of other behaviors such as feeding or reproduction, the animal would be incapacitated. Presumably, the inputs to thirst become more severe as dehydration proceeds, and water-seeking behavior moves to the top of the behavioral hierarchy and is expressed, resulting in water intake. In the long term, physiological control mechanisms must underpin drinking behavior. If inadequate quantities of fluid are taken in, particularly when urinary concentration becomes maximal, negative fluid balance and dehydration are the inevitable outcome.

Mechanisms of Thirst

Since the pioneering work of Verney on the location of osmoreceptors controlling vasopressin secretion, it has been realized that these are located in the hypothalamus. It now seems clear that receptors responding to physiological changes in extracellular fluid osmolality are located in circumventricular organs on the anterior wall of the third cerebral ventricle. In dogs, lesions of the organum vasculosum laminae terminalis result in the permanent loss of drinking behavior to increases in plasma osmolality of up to 15 mosmol kg^{-1}. In other species, another forebrain circumventricular organ, the subfornical organ may be involved. Circumventricular organs lack the normal blood–brain barrier, and thus can be more easily influenced by the composition of the blood that perfuses them. The connectivity between the circumventricular organs and other parts of the brain concerned with drinking behavior and secretion of vasopressin are shown in Figure 2. The nucleus medianus plays a central role in the integration of inputs which stimulate thirst. Lesions of this region result in the permanent cessation of drinking to any stimulus.

When extracellular fluid volume is reduced, information may reach the hypothalamus in two

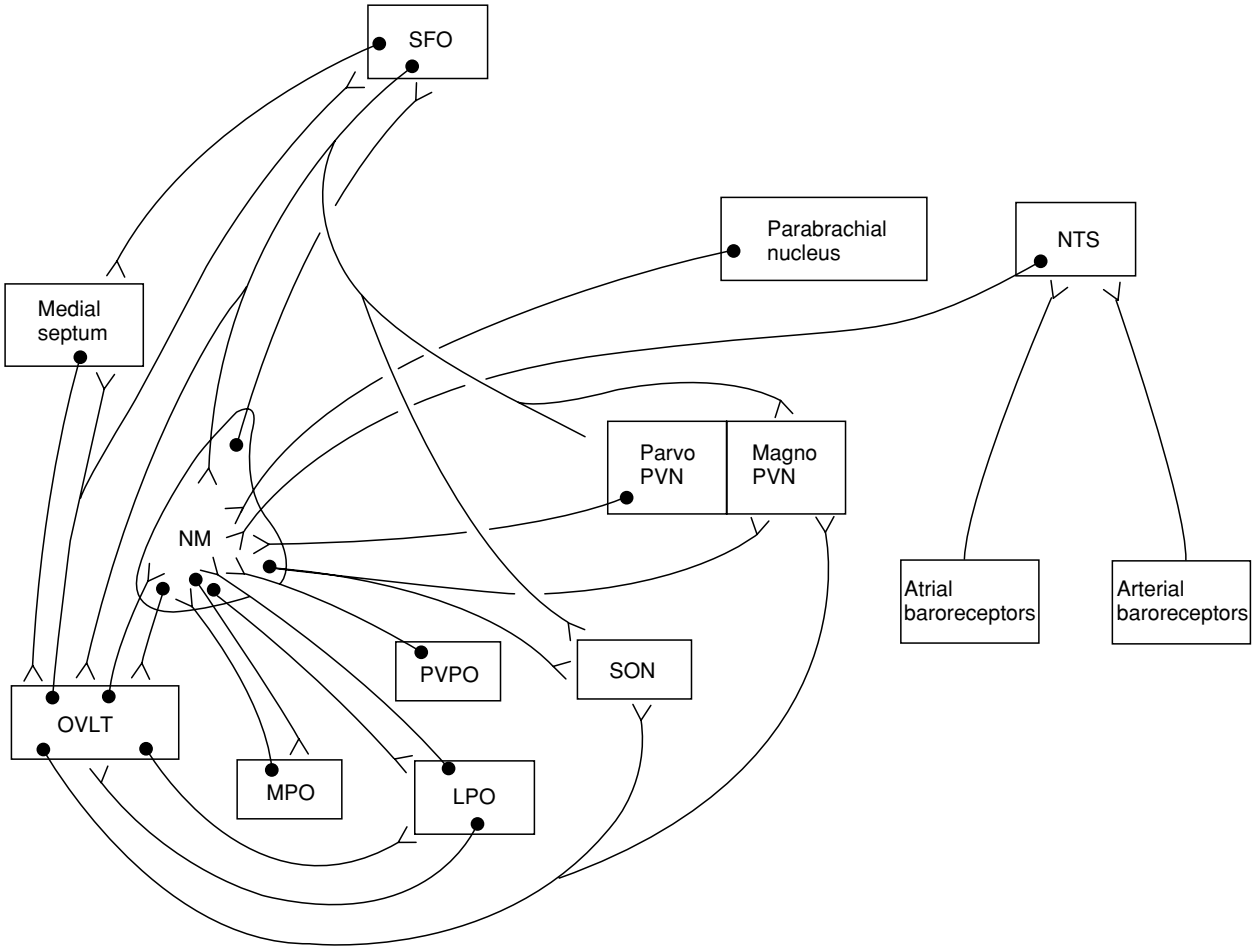

Figure 2 Neuroanatomical interconnections between forebrain circumventricular organs and the nucleus medianus in the control of water balance. main ways. Afferents from atrial and arterial baroreceptors enter the hindbrain via the ninth and tenth cranial nerves and synapse in the nucleus tractus solitarius. From this region, there are a number of inputs to the hypothalamus, including the nucleus medianus. Reduction in extracellular fluid volume also results in the stimulation of the secretion of renin from the kidneys. Through the renin–angiotensin cascade mechanism this results in raised plasma angiotensin II levels. Angiotensin II generated in the blood interacts with receptors in forebrain circumventricular organs, particularly the subfornical organ. Angiotensin II is a potent dipsogen, particularly when injected directly into the third cerebral ventricle. Thus extracellular fluid volume reduction can stimulate thirst directly through vagal afferents or more indirectly through the renin–angiotensin system.

The physiological inputs to thirst and the connectivity of the hypothalamic nuclei associated with these inputs are beginning to be understood. However, there is little information which links these with the complex neuro-physiological mechanisms associated with water-seeking and drinking behavior. The mechanisms which allow animals to choose drinking from the vast repertoire of behaviors available to them are also not clear. There is much to be learned of the higher-nervous-system functions involved in the link between a fluid deficit and the stimulation of thirst and fluid intake.

Requirements for Fluid

It is obvious from the foregoing that the requirement for fluid in humans must vary widely. In a temperate environment, the average loss of water

from the skin by evaporation is 900 ml day^{-1}, in feces 100 ml day^{-1} and in urine 1500 ml day^{-1}. The average figure for the amount of water contained in foods is 1000 ml day^{-1}; that produced by metabolism is 300 ml day^{-1}, leaving 1200 ml to be taken in in the form of fluid. However, these amounts may vary widely. For example, during moderate to severe exercise, particularly in a warm environment, many liters of fluid may be lost through sweating in order to maintain normal body temperatures. Under such circumstances, there is a marked stimulation of thirst with the resulting intake of large amounts of fluid. In the final analysis, in order to prevent dehydration the amount of fluids taken in must equal that which is lost.

The nature of the fluid ingested depends largely on cultural factors. For example, consumption of soft drinks appears to be the most characteristic feature of the USA. Beer, accompanied by milk (in the UK) and coffee (in Germany) are typical of middle Europe, and coffee and milk are the most popular beverages in northern Europe. Thus, as with food, culture is the major determinant of drink preference. It is important also to note the link between food intake and fluid intake. Under normal circumstances much of the daily intake of fluid is associated with eating.

A number of other factors will also influence fluid intake. During the luteal phase of the menstrual cycle, there is downward resetting of osmotic thresholds for both thirst and vasopressin secretion. These changes may be even more marked during pregnancy, when plasma osmolality may fall by about 10 mosmol kg^{-1} during the first few weeks of gestation. During this period the osmotic thresholds of both thirst and vasopressin are again reduced.

There is a reduction of thirst in the elderly. This is evidenced by the tendency for spontaneous dehydration to occur in the elderly, and their reduced sensitivity to infusions of hypertonic saline and water deprivation. The situation in the elderly is also complicated by their diminished ability to excrete water loads. For example, if an elderly individual with diminished thirst is encouraged to drink more fluid in warm weather, overcorrection can result in overhydration. Thus in the elderly, there may be problems of over- or underhydration. (*See* **Elderly**: Nutritionally Related Problems.)

TIN

T Y Toribara, University of Rochester, Rochester, NY, USA

Background

Tin does not occur freely in nature but occurs mostly in the form of the dioxide and sometimes as the sulfide. It is found combined in silicic rocks such as granite and in small amounts in feldspar. The chemistry of tin has been examined in great detail, and much of it has been published recently in a single book. It is the intention to cover only those topics that have some relevance to the occurrence and properties of tin in food.

Occurrence in Food

The presence of tin in food is primarily the result of man's use of the element. The greatest exposure is the result of the use in cans in which food is preserved. Rather strong acid solutions are necessary for dissolution of the metal, so usually, very little of the element found its way into food kept in metallic containers which were either lined with tin or sealed with solders, leaving tin as one of the ingredients. (*See* **Canning**: Principles.)

Its metallic form has been used from very early times as a foil and in alloys such as Babbitt (Sn, Cu, Sb), bronze (Sn, Cu), pewter (Sn, Pb), solder (Sn, Pb), and type metal (Sn, Pb, Sb). Contact with these alloys may allow tin to leach into foods.

Although not in food, exposure to tin chemicals may occur through their use in dentistry. Tin(II) fluoride is used as an aid in preventing tooth decay through its presence in toothpastes, topical solutions, and mouthwashes.

More recently, a number of organotin compounds have been used as a stabilizer for the plastic PVC, as a fungicide in paints, and for wood treatment. In most uses, there is no direct contact of the organotin compounds with food products, and whatever appears in the food chain is the result of extraction from the material containing the organotin compound. These compounds will be discussed in greater detail in separate sections.

Properties of Tin Compounds

The compounds of tin may be classified as inorganic or organic. The properties of the various forms and the reactions that would cause the element to appear in the food chain are considered.

Inorganic

Tin usually occurs as the metallic element in pure or alloyed state, or as compounds in the divalent stannous form or the tetravalent stannic form. The use of the metal to coat cans and other containers of food has been common for many years. The occurrence of compounds of inorganic tin most likely to be found in food result from dissolution of the metal.

Initially, tin would be dissolved by an acid and would be in the divalent form. To keep the metal in this form, the solution must be quite acidic, and the element forms complexes of the form $[SnX_3]^-$, where X may be a halide or one of several other anions. Also, to keep the tin in the divalent form, it must be kept under an inert atmosphere such as carbon dioxide. In dilute solution, the Sn(II) compounds undergo hydrolysis, giving hydrated tin(II) oxide, which is not very soluble. The extent of hydrolysis depends upon the pH of the solution. In the usual pH range naturally encountered in foods, rather extensive hydrolysis occurs. In concentrated solution in the presence of oxygen (air), the divalent form is oxidized to the tetravalent Sn(IV) state, the ease of oxidation increasing with pH. In very strong alkaline solutions, spontaneous disproportionation to the metal Sn and Sn(IV) can occur. The divalent stannous form is a strong reducing agent, and it functions as such in many reactions.

Most of the inorganic forms of tin found in solution or combined with some solid material are in the tetravalent form. Tin(IV) oxide, the form most abundant in nature, dissolves in aqueous solutions of both acids and alkalis. The predominant species present in acid solutions containing complexing anions is $[SnX_6]^{2-}$, where X may be a halide or one of several other anions. In strongly alkaline solutions, the main species is $[Sn(OH)_6]^{2-}$. In dilute solution in the absence of complexing agents, all aqucous solutions of Sn(IV) tend to hydrolyze to give a precipitate of hydrated tin(IV) oxide. The halide $SnCl_4$, is a liquid with a boiling point of 114 °C.

Organic

Organic derivatives of both divalent and tetravalent tin are produced by man in significant quantities for various purposes. The preparations and structures of many of these compounds have been studied extensively. The divalent compounds are mostly of

academic interest and would not be encountered ecologically. Tetra-, tri-, and disubstituted tin(IV) compounds have been used extensively for a number of purposes in recent years. Tetramethyltin is a very good alkylating agent for the transfer of a single methyl group. It has been used to convert inorganic mercury to the monomethylmercury chloride for measurement of small quantities by gas chromatography. (*See* **Mercury**: Properties and Determination.)

The property of most interest in the treatment of samples for speciation is solubility. The dimethyltin and trimethyltin chlorides and bromides are water-soluble. Similar ethyl compounds are somewhat less soluble in water. The tin compounds with larger alkyl and phenyl groups are very slightly soluble or insoluble in water. The tetra-substituted compounds are all insoluble in water.

When the various compounds enter the environment, their fate is of importance. At near neutral pH and normal environmental temperatures, alkyl and aryl tin compounds are stable in the dark, but breakdown occurs in ultraviolet light. This has been observed with compounds of trimethyltin, tributyltin, and triphenyltin, in which sequential removal of the alkyl groups occurs to yield finally inorganic Sn^{4+}. Other mechanisms of breakdown by soil microorganisms and fungi have been observed.

The only significant formation of tin–carbon bonds in the environment appears to be via methylation. Monomethyltin was produced by an inoculum of mixed microorganisms from Chesapeake Bay sediments with stannic chloride. An acrobic strain of *Pseudomonas* (Ps 244) produced a variety of methyltins from inorganic tin(IV) but very little from tin(II). Formation of methyltins by other organisms has also been reported.

Analytical Methods

Sample Preparation

In general, the analysis of the tin content of a sample measures the total amount of the element. Most methods used require a solution of the sample. To extract the tin from an insoluble substance such as a tin ore, an initial extraction with dilute nitric acid is followed by a fusion of the insoluble residue with sodium peroxide or an alkaline carbonate mixture. Wet ashing procedures for samples such as tissues or other biological material can be carried out using concentrated nitric acid together with sulfuric acid. Such a procedure will destroy the organic matter, so that only the total tin content can be measured.

For the successful analysis of an organotin compound, some knowledge of the chemistry of the compound is required. The solvent used for the first extraction depends upon the compound of interest. Aqueous combinations with tropolone with some organic solvent are the most common methods. The method of analysis may be GC (gas–liquid chromatography) or HPLC (high-performance liquid chromatography), again depending upon the compound of interest. These methods will be discussed in a later section. Sampling and the treatment of the sample are of utmost importance. Tissue samples are usually homogenized and then extracted. Complete extraction is difficult because of a relatively large emulsified solids layer between the aqueous and organic layers. One procedure to correct for this is to add a known quantity of an organotin compound such as a tripropyltin salt known not to be in the sample. The recovery of this compound in the subsequent analysis will give a correction factor for the compounds being determined. For a number of compounds, the addition of tropolone to the nonpolar solvent improves the recovery in the extraction.

Instrumental Methods

In most laboratories, emission or absorption atomic spectroscopy is usually used for measuring the tin content of a sample. Tin can be analyzed with a standard emission spectrometer. The newer high-temperature DC (direct current) arc or ICP (inductively coupled plasma) spectrometers are best.

Atomic absorption spectrometry is the most sensitive method available. For the analysis of tin, a nitrous oxide–acetylene flame must be used. Modern instruments with a graphite furnace are best. Here, only a small sample (*c.* 20 µl) is required. Using the programmed temperature facility, the sample is dried, then volatilized and decomposed.

The detection limits for the atomic spectroscopic methods are:

Emission spectroscopy	$30\ \mu g\ l^{-1}$
Flame atomic absorption (AA)	$100\ \mu g\ l^{-1}$
Hydride generation AA	$4\ \mu g\ l^{-1}$
Graphite furnace AA	$0.2\ \mu g\ l^{-1}$

Chemical Methods

The early methods for the analysis of tin were gravimetric and titrimetric, depending on the quantity to be measured. These techniques required the separation of the element prior to the final measurement. In the gravimetric method, tetravalent tin is precipitated as metastannic acid, as the sulfide, or with a reagent such as cupferron after first separating it from interfering ions. The insoluble tin compound is filtered off, ignited to SnO_2, and weighed.

Titrimetric methods involve reducing the tin to tin(II) and then oxidizing it to tin(IV) with an iodine or iodate solution. The stannous form is readily oxidized in the presence of air, and for accurate work, the reaction is carried out under an atmosphere of CO_2. A method using tin(IV) makes use of the oxalatostannate complex, which will incorporate one molecule of sulfide to form the oxalatothiometastannate complex. The amount of sulfide may be measured by titration with iodine.

Chromatographic Methods

The early analyses of organotin compounds were by GC, both conventional and, more recently, with capillary columns being used. The most common organotin compounds are those that are used as fungicides in paints or sprays. These include tetra-, tri-, and dimethyltin compounds, and the homologous ethyl compounds as well as some phenyl derivatives. GC, which would seem to be an obvious choice to distinguish among the various substituted organotin compounds, must be used with caution. The problem arises from the fact that elevated temperatures must be used to volatilize some of the compounds, and at elevated temperatures, some of the compounds will undergo transformation. There is a further complication if a mixture contains both tetramethyltin and a dimethyltin compound. Tetramethyltin is a good methylating agent, and the dimethyl compound will be methylated to a trimethyltin compound. (*See* **Chromatography**: Thin-layer Chromatography.)

In order to be able to operate at lower temperatures, some of the organotin compounds, such as certain halides, are converted to more volatile species. Among the more common methods used are the replacement of the halide by a methyl or ethyl group, or the formation of the organotin hydride.

HPLC has become the method of choice for many analyses, as decomposition of the compounds being analyzed does not occur in the liquid phase at the lower temperatures used. For the separation of methyltin compounds in HPLC, a mobile phase of 60 parts acetone and 40 parts *n*-pentane is used. For ethyltin compounds, a mixture of 70 parts acetone and 30 parts *n*-pentane is used. As elevated temperatures are not used, the redistribution of species that occurs during GC is not encountered. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Effects of Dietary Tin

Most of the tin ingested from canned food has been inorganic and has been considered low because of its poor absorption and retention in tissues. Many studies have been conducted at cellular levels using *Escherichia coli* and yeast cells to determine the effect of tin. It is not certain whether these studies may be applicable to humans.

By using controlled diets fed to weanling rats over prolonged periods of time, Rader and coworkers have made an extensive study of the effects of 100–1100 μg per gram of dietary tin on tissue and bone minerals of these weanling rats. The level of tin used in these studies was within the range of values reported for tin present in unlacquered cans. The total food consumption was restricted to the amount consumed by the rats fed 1100 μg of tin per gram. The amount of tin in the food of any rat was constant for a period of 4 weeks Food consumption by rats fed diets containing 0, 100, and 330 μg of tin per gram was measured weekly. After 4 weeks, the rats were sacrificed, and serum was prepared from the blood. Soft tissues were taken from liver, kidney, and duodenum. Femurs were also taken for examination. Serum ceruplasmin and cholesterol were then measured.

The results of these studies indicate that anemia and growth depression are common effects of chronic ingestion of inorganic tin. Low levels of dietary tin primarily affect copper and zinc status. Pronounced copper depletion in all tissues examined was observed at tin levels as low as $30\,\mu g\,g^{-1}$. Growth depression generally occurs when dietary tin levels exceed $500\,\mu g\,g^{-1}$. Diets high in copper and iron (50 and $250\,\mu g\,g^{-1}$) reduced the signs of anemia in rats fed tin at levels up to 1500 μg of tin per gram.

In normal animals, about 90% of copper in plasma is contained in ceruloplasmin. The finding of dietary decreased ceruloplasmin in tin-treated rats is consistent with the observation of decreased copper in plasma of rats fed diets containing more than 200 μg of tin per gram. Copper plays a major role in bone metabolism through its involvement in collagen cross-linking. The levels of copper and iron have been shown to affect anemia in rats.

Reduced growth is a common symptom of zinc deficiency. Low dietary tin adversely affects the growth of rats fed zinc-adequate diets. These studies on weanling rats indicate that many effects of inorganic tin have effects that are not directly attributed to tin, as in the case of reduced growth, even in zinc adequate diets.

The effects of continuous ingestion of small amounts of tin that reduce the quantity of essential elements to the levels that slow down growth and cause anemia have emphasized the importance of reducing the possible intake of tin. Since the principal source of tin is in containers used for food including cans, and items such as cans, trays, and other items

that may hold food, efforts are being made to reduce the possible contact to any tin that may be in the items. The primary target is the food can, and some efforts are included.

Food Cans

Early food cans were made of tin because of their permanent shiny appearance and the ease with which they could be manufactured. However, the lack of strength to maintain their shape led to the use of steel, which was much sturdier and less expensive. However, steel corrodes easily when exposed to air.

The findings that levels of tin that were at the levels of those originally eluted by contact with food in the tin cans has effects on the levels of copper, iron, and zinc, which can affect health, has made the coating of steel for food cans a very important issue. This led to various means to prevent corrosion, which occurred inside the cans with contents of juices of various foodstuffs. The early method used to prevent this corrosion (rusting) was to plate the surface with tin. However, any small deformations or pinholes would permit rusting of the steel. This led to the use of various plastics.

The literature is full of procedures for protecting steel, and most are coatings, for which patents describe in detail the ingredients and the procedure for preparing for them. An early simple procedure was to plate the outer coat with tin and apply an inner thermoplastic layer with particles of tin in them. The contents of the can would then be exposed to only a small amount of tin, and the outer surface of the can would be protected by the tin coating.

One Japanese patent describes a corrosion-resistant metal–polyester laminate formed by laminating a hot metal sheet with a polyester film coated with a thin aluminum layer. A number of layered coatings without plastic have also been patented. One such example describes a steel strip flash-electroplated with nickel, electroplated with tin, rinsed and dried, and then chromated.

Electric-resistance seam-welded cans are painted internally and have a tin coating with double chromate layers of chromium oxide layer. They then have a final coating of epoxy-phenolic paint and are baked at 205 °C. The patents all state that the resulting steel is suitable for food cans.

Summary

Long-term exposure of weanling rats to levels of tin expected in foods contained in tin cans has provided quantitative data on their effects. Copper and zinc levels were the primary targets of exposure through the diet. Since these elements are a vital part of many functions, tin has an indirect effect.

General exposure to tin is in the inorganic form in foods contained within cans containing tin. Originally, this exposure was through the use of tin cans, because tin seemed to be inert to general exposure and was an easy metal to mold into cans. However, the relative softness resulted in many dents in handling the cans, and many cans used to be rejected because of the dents. For this reason, the industry turned to the use of steel, a less expensive and much sturdier material.

However, the surface of steel is easily oxidized (rust), forming an unpleasant appearance. Initially, the steel was plated with tin to coat both the inside and outside surfaces. The tin coat did not provide complete protection, because small holes would allow exposure to the air, resulting in rust spots. What happened inside the can was not of general concern, because the amounts of soluble tin were not considered to be harmful. The first solution to maintain the external appearance was to coat the external surface with some type of plastic.

There have been many patents on the use of various plastics to coat the steel, and many elements including tin are included in the plastics. Many of the resultant steel sheets are satisfactorily electrowelded. The patents all state that the steel sheets are suitable for food cans. This interest is good evidence that the health of the consumers of canned goods is very important to showing the concern to produce safe materials for canning.

Properties and Determination

D C Woollard, AgriQuality NZ, Auckland 1, New Zealand
H E Indyk, Anchor Products, NZWP, Waitoa, New Zealand

Physical Properties

The generic term 'vitamin E' is used to describe a group of eight structurally related tocopherol and tocotrienol compounds (**Figure 1**). The parent form is commonly referred to as α-tocopherol and systematically named 2,5,7,8-tetramethyl-2-(4′,8′,12′-trimethyltridecyl)chroman-6-ol, as a derivative of the benzene-pyran ring structure.

The tocopherols are insoluble in water, freely soluble in fats and oils, and soluble in most organic solvents. They exist as pale yellow viscous oils in purified form but can be crystallized at subzero temperatures, the melting point of α-tocopherol being 2.5–3.5 °C. Each tocopherol contains three asymmetric carbon atoms, making possible a total of eight optical isomers, although the epimeric configuration at carbon-2 dominates biological activity. **Table 1** lists the major physical properties of the naturally occurring *RRR*-tocopherols, as well as the synthetic *all*-rac-α-tocopheryl acetate. Spectral properties and specific optical rotations are highly dependent on the solvent used during measurement.

All vitamin E congeners show weak UV absorption (290–300 nm) and unusually narrow bandwidths. However, they exhibit strong native fluorescence, emitting radiation at 324–330 nm, the practical use of which has increased with advances in detector design. The esters of vitamin E have

bathochromically modified spectral properties as a consequence of electronic interactions with the chromanol chromophore, and reduced extinction coefficients and quantum yields relative to the parent alcohols. The tocopherols and tocotrienols show a strong infrared band at 8.6 μm and O–H and C–H stretching frequencies at 2.8–3.0 and 3.4–3.5 μm, respectively.

Chemical Properties

The tocopherols and tocotrienols share a common chemical structure based upon tocol. Tocol consists of a chromanol nucleus with substitution at the 2- and 6-positions. A methyl group and a phytyl side-chain are bonded to C-2, while the hydroxy functionality on C-6 is available for esterification. Tocol itself is not

widely regarded as an E-vitamin but shares some of the properties of the group, particularly regarding its antioxidant role, and occurs naturally in low concentration.

The tocopherols are derived from tocol by the addition of methyl groups on the three available carbons (5,7,8) of the benzene ring. Trimethylation produces α-tocopherol, the most active E-vitamin as defined by rat fertility and other biological activity studies. In general, any structural modifications from α-tocopherol markedly reduces biological activity, including side-chain unsaturation, side-chain length, oxidation of the chromanol ring, and loss of any methyl group. While C-8 methylation is essential, β- and γ-tocopherol isomers (5,8- and 7,8-dimethyltocol, respectively) have reduced bioactivities of ~30% and ~12%, and δ-tocopherol (8-methyltocol) exhibits only 1% biopotency relative to α-tocopherol. Other mono- and dimethyltocols are also known to occur, as either minor natural components or synthetic byproducts, but are not classified as E-vitamins owing to their lack of any measurable physiological response.

Each of the four tocopherols has a related tocotrienol (abbreviated T3) through phytyl side-chain unsaturation at C-3′,7′ and 11′, resulting in reduced biopotency: α-T3 (25%), β-T3 (5%), γ-T3 (<1%) and δ-T3 (<1%) relative to α-tocopherol.

Optical asymmetry at C-2 yields stereoisomers, of which the D-form is biologically more active by a factor of 2.38 compared with the L-isomer. Thus, naturally occurring α-tocopherol, which exists exclusively as the D-isomer has a higher efficacy than the synthetic racemic equivalent.

The tocopherols have two additional chiral carbon atoms (4′ and 8′), and naturally occurring D-α-tocopherol is more correctly described as 2*R*,4′*R*,8′*R*-α-tocopherol (abbreviated *RRR*-α-tocopherol). The stereochemistry of the phytyl 'tail' is known to govern biological properties, believed to be a consequence of *in vivo* interaction with chiral biological membranes. Thus, the natural *RRR*-α-T isomer is approximately three times more effective than its stereochemically inverted relative *SRR*-α-T (referred to as 2-*epi*-α-tocopherol). While tocotrienols possess no side-chain asymmetric centers, geometrical isomerism becomes a possibility, although only the *trans*-isomers have been reported. The influence of *cis* geometry on biopotency is therefore unknown.

The tocopherols are vulnerable to aggressive forms of oxygen, leading to the formation of biologically inactive monomeric and dimeric quinones. These reactions are accelerated by UV light, heat, high pH, and certain transition elements, whereas in the absence of oxygen, the E-vitamins are relatively stable. Lability is decreased by esterification at the 6-hydroxy substituent, presumably through stabilization of the phenolic ring structure. Consequently, most nutritional uses of vitamin E involve α-tocopherol esters.

To account for the variation in biological activities of the isomers, the concentration of vitamin E is often defined in international units rather than by weight. The international unit (IU) is expressed relative to synthetic *all-rac*-α-tocopheryl acetate, where 1 IU is equivalent to 1 mg, based upon fetal resorption after oral administration to rats. The information agrees fairly well with rat hemolytic anemia studies. On this basis, 1 unit is provided by 0.91 mg of *all-rac*-α-tocopherol and 0.67 mg of *RRR*-α-tocopherol. The bioactivities of other tocopherols and tocotrienols are then calculated against these data by applying the appropriate conversion factors.

As a consequence of their phenolic structure, the tocopherols and tocotrienols are potent antioxidants, conferring protection to vulnerable lipids in biological tissues and foods. Such antioxidant behavior is presumed to depend on pyran ring cleavage to form the hydroquinone intermediate, followed by oxidation to tocopherol quinone. These and other oxidation products (tocopheroxides, epoxides, and polymers) are receiving increased attention.

Occurrence and Forms in Food

The dietary intake of vitamin E in the general population appears to be sufficient to meet the US Recommended Daily Allowances of 3 mg (infants) to 12 mg (adult males). Avitaminosis E is comparatively rare in well-nourished communities because of large physiological reserves in tissues and organs, although neuromuscular and other disorders have been associated with dietary deficiencies, particularly in children. (*See* **Cells; Dietary Requirements of Adults**.)

The tocopherols are well distributed in nature, the richest and most varied isomeric sources being vegetable oils and products derived from them, such as margarine. It has been common practice with these products to speciate the various vitamers during analysis (Table 2). Other valuable sources of vitamin E include nuts, cereals, green vegetables, fruits, and foods of animal origin such as eggs, dairy products, and meats (Table 3). In practice, the contribution of the non-α vitamers in most foods is sufficiently small after biopotency factors are applied that they are regularly excluded from estimations of total vitamin E status. Animal tissues contain vitamin E almost exclusively as α-tocopherol, with the exception of egg yolk, where γ-tocopherol is found in significant concentrations. There is a fairly wide disparity in literature data, probably as a consequence of genetic, geographical, seasonal, and processing factors as well

Table 2 Vitamin E content of selected vegetable oils

	Tocopherol (mg per 100 g)				*Tocotrienol (mg per 100 g)*				
Oil	*α-T*	*β-T*	*γ-T*	*δ-T*	*α-T3*	*β-T3*	*γ-T3*	*δ-T3*	*Total*
Coconut	0–2	0–1	0–1	0–1	0–1		0–4		1–5

[a]α-Tocopherol values are expressed as typical ranges, whereas representative values are reported for the less biologically active congeners. Blanks indicate a lack of data or the absence of traceable levels. Tocotrienol contributions are not reported as they are predominantly absent from these foods.
[b]To convert to IU per 100 g, multiply by 1.49 (as *RRR*-α-tocopherol).

as variations in analytical techniques. Refer to individual foods.

Tocopherols and tocotrienols are labile materials, and their stability during food processing and storage has been subject to intensive investigations. Storage of foods under anaerobic conditions and the incorporation of other synthetic or natural antioxidants are common strategies to optimize the preservation of their vitamin E status.

Role as Antioxidants

Oxidation of polyunsaturated lipids operates through a free-radical pathway that not only facilitates food spoilage but creates substances of potential toxicological significance that can have damaging consequences upon ingestion. The tocopherols and tocotrienols combat this process both *in vitro* and *in vivo* by trapping the hydroperoxide intermediates and preventing their propagation. The fate of the stable vitamin E phenoxy radicals so produced is variable, with formation of monomeric quinone, which can react further with a secondary radical forming a dimer. Under certain conditions, ascorbate is considered capable of synergistically repairing the phenoxy radical and regenerating the tocopherols. (*See* **Antioxidants**: Natural Antioxidants; **Oxidation of Food Components**.)

It has been confirmed that antioxidant activity of the tocopherols follows the same order as their biological potencies (α>β>γ>δ) and that this may be rationalized on a stereoelectronic basis. Thus, a higher resonance stabilization of the phenoxy radical is achieved in α-tocopherol where ring planarity is optimal relative to the other congeners.

Vegetable oils and margarines are particularly prone to oxidation, owing to their high content of polyunsaturated fatty acids but fortuitously also possess substantial native vitamin E, which functions protectively. However, additional stabilization is often considered necessary, particularly for refined oils where the tocopherols become depleted during the harsh manufacturing conditions. Although animal fats and foods rich in them are predominantly saturated and less sensitive to oxidative processes, the addition of tocopherols is usually of benefit since natural vitamin E contents are low. (*See* **Margarine**: Methods of Manufacture; **Vegetable Oils**: Types and Properties.)

The ratio of tocopherol to polyunsaturated fat is an important criterion in determining optimum oxidative protection offered by vitamin E and also the toxicological safety of the fat. Excessive concentrations of vitamin E are reported to accelerate lipid oxidation, although there is debate about the detail

and extent of this process. As expected, antioxidant and prooxidant properties differ between the various tocopherols and tocotrienols. Vitamin E acetate cannot be used as an antioxidant because this property is lost upon esterification.

Use in Food Fortification

As indicated previously, the tocopherols are among the most important fat-soluble antioxidants used in the prevention of food spoilage. However, vitamin E has other recognized biological functions and consequently is added to a variety of foods for the management of community health. This has particular relevance for infant nutrition and for sections of the population where inadequate nutrition is suspected. To maintain vitamin efficacy, the free phenols are not used during food fortification unless an antioxidant function is also required. (*See* **Food Fortification**.)

The most common nutritional additive is synthetic *all-rac*-α-tocopheryl acetate owing largely to its greatly enhanced oxidative stability. Technological problems during the fortification process can be overcome by utilizing the oily vitamin in a water-dispersible 'beadlet' form, contained within a gelatin coating. The vitamin can then be blended as an emulsion into liquid foods, usually prior to spray drying. Milk powders, dietetic, and infant formulae are often supplemented in this way, facilitating a uniform distribution of the additive. In other products, the ingredients may be mixed in the dry state, either because the nature of the food is not conducive to wet-blending procedures or because the vitamin E has a diminished stability owing to low fat content. Cereals and skim-milk powder products are regularly supplemented in this manner. The major disadvantage with this protocol is the potential for vitamin heterogeneity. Particle-size control and correct mixing, packaging, and storage conditions are therefore necessary to minimize uneven distribution of the vitamin beadlets.

Vitamin E succinate can be used if severe heterogeneity problems are encountered since this ester is a solid at room temperature and more easily dry-blended into foods and pharmaceuticals. A disadvantage with the use of the succinate ester is its lower bioavailability. The third commercially available vitamin E ester, tocopheryl nicotinate, is used in cosmetics rather than as a food additive.

Isolation and Analysis

Vitamin E poses analytical challenges because of its multiplicity of forms and its tendency to oxidize. Traditional bioassays (e.g., resorption gestation, encephalomalacia, myopathy, and erythrocyte hemolysis tests) do not discriminate between the various vitamers (vitamin isomers) in foods. They are tedious and relatively imprecise techniques, although they do exhibit true, host-specific, activity data. Lipid peroxidation tests for the accumulation of hydroperoxides or aldehydes in animals have also been used to indicate vitamin E status. (*See* **Vitamins**: Determination.)

Physicochemical tests have become more popular because of their ease of use, speed, and precision compared with bioassays. The traditional chemical test has been the Emmerie–Engel reaction, which detects the presence of fat-soluble reducing agents through conversion of trivalent iron to the red ferrous bipyridyl complex. The accuracy of this and related colorimetric procedures is, however, compromised by spectral interferences of other antioxidant materials such as biologically inactive tocols, retinoids, carotenoids, nonvitamin chromanol compounds, and synthetic food antioxidants. The success of the method is therefore dependent upon the degree of purity of the vitamin E analytes prior to colorimetry. The problem remains that the eight E-vitamins are not differentiated and will be quantified as a single analyte. These same difficulties remain, albeit to different degrees, whether detection is by UV absorption, fluorescence, or electrochemical techniques. In each case, a chromatographic step is required in the analytical scheme in order to remove interferences and, ideally, to separate the vitamers. Traditional column or thin-layer chromatographic (TLC) techniques have been used extensively for this purpose. (*See* **Chromatography**: Principles; Thin-layer Chromatography; **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Instrumental chromatographic techniques have now become the methods of choice, with separation and detection being performed concurrently. Gas–liquid chromatography (GLC) using various packed- or open-tubular capillary columns, coupled with flame ionization detection, allows a quantitative analysis of individual tocopherols and tocotrienols. A unique attribute of capillary GLC is its recent success in separating the diastereoisomers of *all-rac*-α-tocopherol and the potential of stereoactive chiral columns to resolve all eight stereoisomers. (*See* **Chromatography**: Gas Chromatography.)

The free phenols can be analyzed by GLC, where elution occurs in order of increasing methylation ($\delta < \gamma < \beta < \alpha$), although it is preferable to derivatize the analytes to their more volatile trimethylsilyl ethers or alkyl esters to improve the chromatographic quality. However, coelution of the β- and γ-isomers is often a problem unless very long capillary columns are used. In the analysis of foods, a more significant

problem exists from interferences by other lipid constituents, predominantly sterols. It is therefore usual to fractionate the crude extracts by TLC or column chromatography prior to the assay in order to facilitate resolution and interpretation.

High-performance liquid chromatography (HPLC) offers several advantages over GLC by avoiding the need for multistage clean-up or derivatization techniques. Either normal- or reversed-phase modes can be used to achieve a successful separation. Important advantages of normal-phase chromatography are its ability to separate the β- and γ-isomers and its solvent compatibility with oil-rich vitamin E extracts. Nevertheless, reversed-phase analysis is technically more robust and remains in common use, as illustrated in Figure 2 for an infant formula analysis. It is also amenable to gradient techniques, allowing concurrent determination of tocopherols and tocopheryl acetate as well as degradation products such as tocopherol quinone. Recently, variants of micellar capillary electrophoresis (CE) have been applied to fat-soluble vitamin separations. Although representing an alternative to HPLC techniques, the application of CE to the hydrophobic vitamins is currently in its infancy. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Direct UV detection is commonly employed for samples with reasonable vitamin E concentrations. The difficulty with this mode of detection is the potential for other materials to interfere and also the low extinction coefficients of the tocopherols and tocotrienols. There is consequently a regular need to increase the sophistication of sample preparation, which can cause problems with such labile analytes.

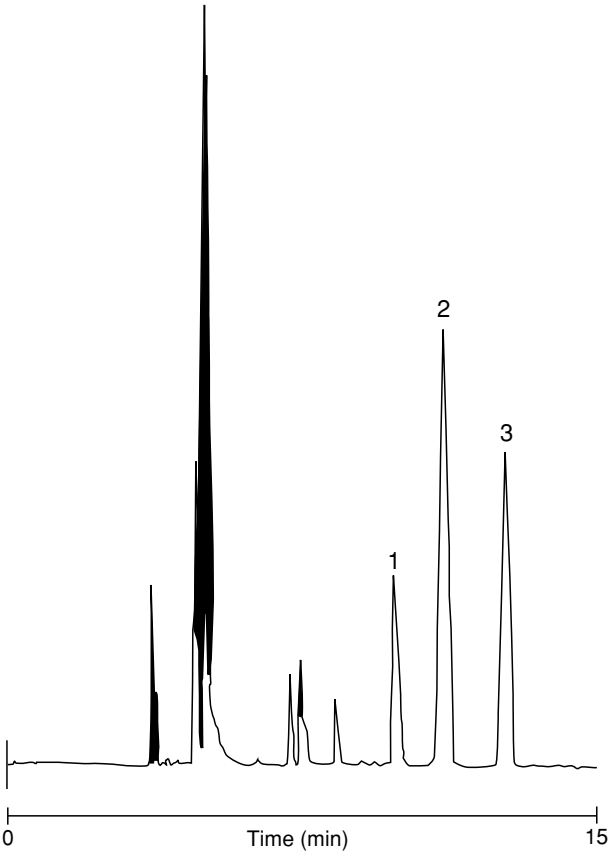

Figure 2 Reversed-phase HPLC chromatogram of a saponified fully oil-filled infant formulation. Waters Radial-PAK 5-μm C_{18} column with a mobile phase of methanol (100%). Flow rate, 1.0 ml min^{-1}. Detection by fluorescence at 295 nm (excitation) and 330 nm (emission). Peak identification: 1 = δ-tocopherol; 2 = β- and γ-tocopherol; 3 = α-tocopherol.

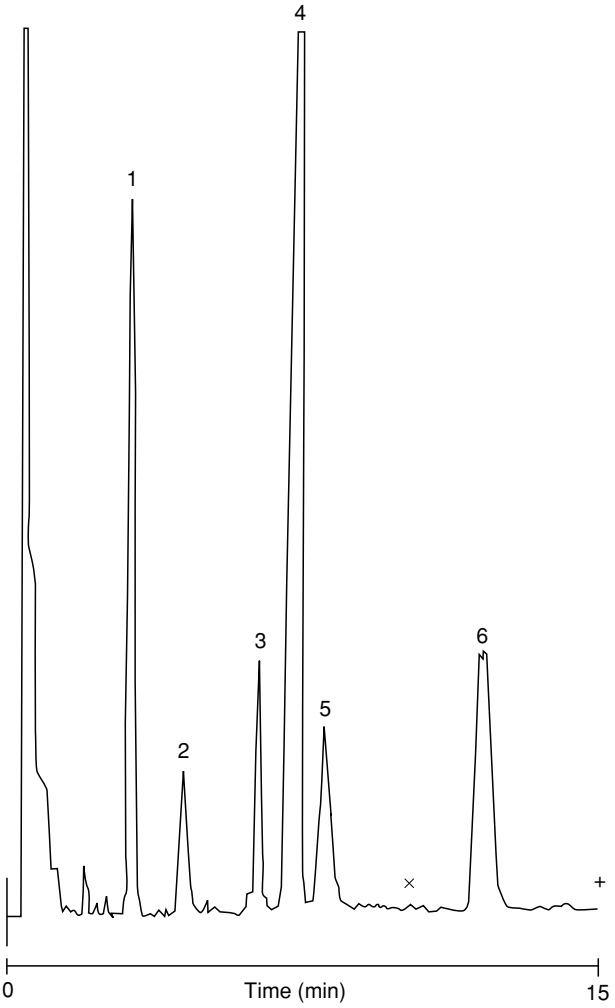

Figure 3 Normal-phase HPLC chromatogram of a saponified dietary formulation. Waters Radial-PAK 5-μm silica column with a mobile phase of 10% diisopropylether in hexane. Flow, 2.0 ml min^{-1}. Detection by fluorescence at 290 nm (excitation) and 325 nm (emission). Peak identification: 1 = α-tocopherol; 2 = α-tocotrienol; 3 = β-tocopherol; 4 = γ tocopherol; 5 = β-tocotrienol; 6 = δ-tocopherol; × = elution position of γ-tocotrienol; + = elution position of δ-tocotrienol.

Through the use of more specific detection modes, sample preparation can be further simplified together with substantial increases in sensitivity. Fluorescence detection at 292 nm (excitation) and 325 nm (emission) is a simple procedure with modern detectors, and encounters very few interference problems providing the separation is optimized. Excitation can be performed at 210 nm, but this is less common, except where spectral overlaps in the detector are unavoidable, as with filter-based instruments. Oxidative electrochemical detection (at 0.7–0.8 V) provides a further order of magnitude improvement in sensitivity compared with fluorescence but is less commonly used owing to operational difficulties and the need for a supporting electrolyte, incompatible with normal-phase separations. Similarly, recently reported LC-MS techniques have been restricted to research laboratories. (*See* **Spectroscopy**: Fluorescence.)

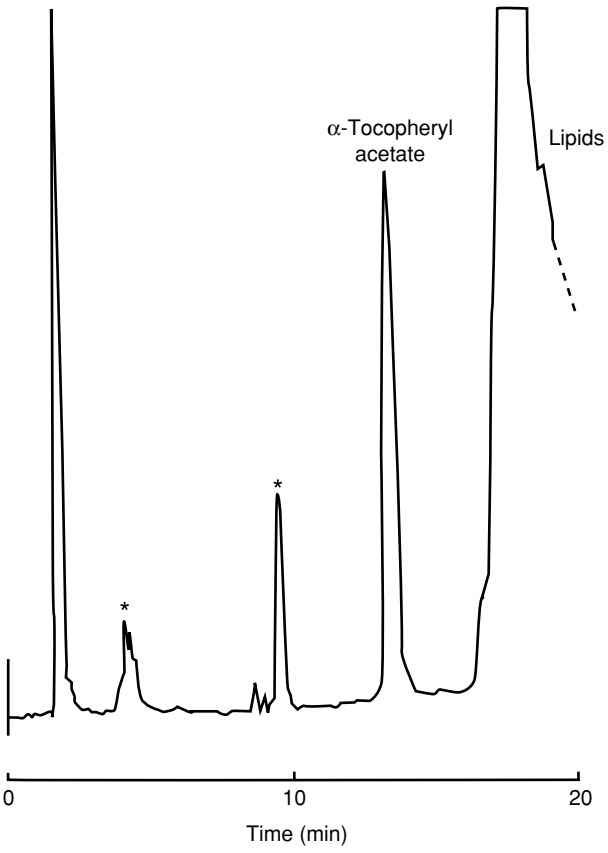

Figure 4 Normal-phase HPLC chromatogram of a fortified UHT milk without the use of saponification. Waters Radial-PAK 5-μm silica column with a mobile phase of 0.08% isopropanol in hexane. Flow rate of 2.0 ml min^{-1} is programed to 8 ml min^{-1} after 15 min to elute lipid components. Detection by UV at 280 nm at 0.01 aufs. The identification of α-tocopherol acetate is indicated. The retinyl esters (endogenous and supplemental) are also visible (*).

For most food products, it is generally necessary to precede any analysis, whether traditional or instrumental, with a clean-up stage aimed largely at removing bulk lipids, rupturing lipoprotein interactions and releasing supplemental vitamin E. Alkaline digestion (saponification), followed by solvent extraction of unsaponifiable material, is the usual technique employed where the free tocopherols are measured. If necessary, the vitamin-rich extract can then be concentrated by evaporation and subjected to further purification techniques. Figure 3 illustrates a complex food product analyzed under these conditions, using normal-phase HPLC. Six of the eight vitamin E congeners are visible, the elution order being α-T < α-T3 < β-T < γ-T < β-T3 < γ-T3 < δ-T < δ-T3.

Some simpler matrices, particularly oils, can alternatively be assayed by sample dilution, clarification and direct injection, whereas other high-fat products (e.g., dairy products) may lend themselves to simplified fat-extraction procedures without the need for a saponification step (Figure 4). This approach has the advantage of leaving any supplemental esters intact and eliminating most of the oxidative difficulties associated with the parent alcohols. Unfortunately, α-tocopheryl acetate has poorer UV absorption than α-tocopherol and greatly reduced fluorescence properties, whereas normal-phase chromatography is necessary in order to tolerate the high triglyceride loading that would quickly foul C_{18} columns. The alternative vitamin E additive, α-tocopheryl succinate, has no known fluorescence and is susceptible to peak distortion, both of which encumber chromatographic analysis, unless the sample is subjected to ion-suppression techniques or measured as α-tocopherol after saponification.

Physiology

W A Pryor, Louisiana State University, Baton Rouge, LA, USA

Background

Vitamin E is the most important fat-soluble antioxidant present in human tissues. It is found in the lipid-rich areas of cells, such as cell membranes and fat depots. Its role is thought to be the protection of polyunsaturated fatty acids (PUFAs) such as linoleic, linolenic, and arachidonic acids, which are present in lipids, against the types of oxidative damage to which these highly unsaturated fatty acids are so readily susceptible. (*See* **Antioxidants**: Natural Antioxidants; **Fatty Acids**: Properties.)

History

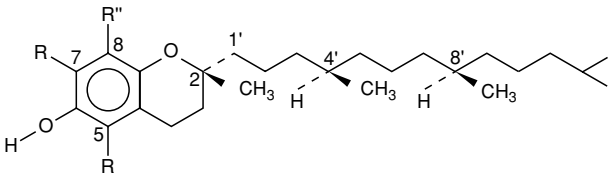
In 1923, Evans and Bishop reported that rats failed to reproduce if given a diet containing rancid lard, unless it was supplemented with a factor, called factor X, found in lettuce or whole wheat. Gradually, over the next 20 years, it became clear that factor X was associated with more than just reproductive failure in the rat. For example, a series of observations were reported linking this factor to encephalomalacia in the chick and nutritional muscular dystrophy in guinea-pigs and rabbits. In 1937, Olcott and Emerson reported that the tocopherols are antioxidants.

The first 15 years of the study of vitamin E were made difficult by the absence of a concentrated source of the vitamin or a knowledge of its structure and chemical make-up. However, in 1936, Evans and his group reported the isolation from wheatgerm of an 'alcohol' which had biological activity consistent with that of a tocopherol, and they suggested the correct chemical empirical formula for α-tocopherol $C_{29}H_{50}O_2$ (The free, unesterified tocopherols continue to be referred to as 'alcohols,' whereas they are actually phenols; in fact, alcohols are not, in general, antioxidants, whereas phenols are.) In 1938, the structure of α-tocopherol was deduced by Fernholz. The need for a pure, concentrated, and available source of the vitamin for nutritional studies was satisfied in 1939 when Karrer, of the Basel (Switzerland) laboratories of Hoffmann–La Roche, and then Smith and his group in America, reported the synthesis of the vitamin. (*See* **Phenolic Compounds**.)

The first international symposium on vitamin E was held in London in April 1939, and 15 papers were presented. In the current era, there have been major international symposia on the vitamin in various countries almost every year, each with 50 or 100 papers that appreciably add to our expanding knowledge of this fascinating vitamin.

Natural and Synthetic Forms of Tocopherol

The side-chain of the vitamin (see **Figure 1**) contains three carbons that are asymmetric; therefore, there are eight possible isomers of each of the tocopherols. Several forms of α-tocopherol are sold. One is a material that is derived from natural sources, called RRR-α-tocopherol, which has the stereochemical arrangement of methyl groups shown in **Figure 1**; another is the synthetic vitamin called all-*rac*-α-tocopherol, which is a mixture of all eight stereoisomers. Both the naturally derived material and all-*rac*-tocopherol are marketed as the free alcohol, the acetate ester, and the somewhat less bioavailable succinate ester. Some vegetable sources of tocopherols contain as much or more γ-tocopherol as α-tocopherol. The relative biopotencies of the various forms of tocopherol are shown in **Table 1**. Amounts of the tocopherols are expressed as either international units (IU) or equivalents of α-tocopherol (α-TE). The relationship between these terms is as follows: 1 mg of D-α-tocopherol (the naturally derived material) equals 1 α-TE; this is the unit used in *Recommended Dietary Allowances* (10^{th} edn.) by the Food and Nutrition Board of the National Research Council (National Academy Press, 1989). The IU is used in commerce for labeling



Tocopherol	Substitution pattern			Stereochemistry
	R	*R′*	*R″*	
α–	CH_3	CH_3	CH_3	2R,4′R,8′R
β–	CH_3	H	CH_3	2R,4′R,8′R
γ–	H	CH_3	CH_3	2R,4′R,8′R
δ–	H	H	CH_3	2R,4′R,8′R

vitamin preparations and food, and is defined as follows: 1 mg of D-α-tocopherol equals 1.46 IU. (*See* **Dietary Requirements of Adults.**)

Vitamin E Requirements

A recommended dietary allowance (RDA) for various food factors was first recognized in the USA with the publication of the first edition of the book on RDA requirements in 1946. A specific RDA for vitamin E was first recommended in the sixth edition (1964), in which the concept of the RDA was broadened and redefined from the 1946 idea – enough 'to insure good nutrition' – to an amount necessary 'to permit full realization of ... potential.' Thus, in the 1964 edition, the concept was expressed that vitamins might have a pharmacological use beyond that necessary merely to prevent vitamin deficiency diseases. The 1997 edition sets the need for vitamin E as 10 α-TE per day for males and 8 mg for females, which is equal to 10 mg of the natural RRR-α-tocopherol (see Table 1).

The vitamin E requirement for humans increases as their diet includes more PUFAs because of the susceptibility of PUFAs to undergo autoxidation. A value of 0.4 for the ratio of the intake of RRR-α-tocopherol (in mg) to the intake of PUFA (in g) in the diet has been suggested to be adequate for adult humans. Thus, if a person eating a 2000-cal per day diet consumed 35% of their calories as fat, of which 40% was unsaturated (typical of today's American diet), they would require a daily intake of about 13 mg of α-tocopherol.

The intake of vitamin E for Americans on typical diets has been estimated to vary between 5 and 20 α-TE. The requirement of 10 α-TE for men and 8 α-TE for women (who are generally smaller) was established as the RDA because it is believed that very few Americans have overt vitamin E deficiency symptoms, and the amount ingested in a 'normal' diet must therefore be sufficient. This rather unsatisfactory, backward and *ad hoc* reasoning is thought to be the only approach possible for establishing an RDA for vitamin E, for which deficiency symptoms are only obvious in humans who have severe malabsorption. There is an increasing body of evidence, however, that vitamin E may provide benefits (such as protection from chemically induced cancers, cataracts, and ischemic heart disease) that require higher daily intakes; scientific studies of the usefulness of vitamin E in these contexts generally use amounts of vitamin E up to about 800 mg per day, which is generally agreed to be safe for humans. (*See* **Cancer:** Diet in Cancer Prevention.)

Metabolism

As more tocopherol is ingested, a smaller fraction is absorbed, such that the uptake of tocopherol by tissues varies with the logarithm of the tocopherol intake. Thus, ingesting four times the amount of the vitamin will raise tissue levels by only twofold. Triglycerides enhance tocopherol absorption, and PUFAs inhibit it. If the acetate or succinate is ingested, it is hydrolyzed prior to absorption through the gut wall. Since the hydrogen atom of the alcohol group is intimately involved in the antioxidant properties of the vitamin, it is not unexpected that only the free alcohol is biologically active. For high doses, a higher blood level is achieved using the free alcohol than the acetate. Absorption of vitamin E is maximal in the median portion of the small intestine, and none is absorbed in the large intestine. Vitamin E is thought to be absorbed through the gut epithelial cells as a lipid–bile micelle, together with fatty acids,

monoglycerides, and other fat-soluble substances. The retention of α-tocopherol is much greater than that of γ-tocopherol.

The vitamin circulates in the lymph and blood bound to lipoproteins, but, unlike some fat-soluble substances such as vitamin A, no specific carrier protein for vitamin E has been discovered. There is a high correlation between the total fat and the tocopherol concentrations in blood serum. Thus, diseases associated with high serum lipids (hypothyroidism, diabetes, hypercholesterolaemia) produce high plasma vitamin E levels, whereas those with low serum lipids (abetalipoproteinemia, malnutrition, cystic fibrosis) produce low vitamin E levels. (*See* **Cystic Fibrosis**; **Hyperlipidemia (Hyperlipidaemia)**; **Malnutrition**: The Problem of Malnutrition; **Retinol**: Physiology.)

Different tissues have widely differing vitamin E contents, as shown in Table 2. The vitamin is most concentrated in cellular fractions that are rich in membrane lipids such as the mitochondria. The vitamin E content of red blood cells is about 20% of that in plasma, and there is a rapid exchange between these two pools.

Less than 1% of vitamin E is metabolized; however, there are reports of oxidation products of the vitamin, such as the quinone and hydroquinone, being found in tissues such as the liver and the lung. Tocopherol is mainly excreted unchanged in feces. Very little is excreted in the urine.

Biochemical Function

Unlike most vitamins, there is no specific, enzymatically controlled reaction for which vitamin E is known to be a required cofactor. Instead, it is generally agreed that vitamin E acts as an antioxidant, protecting tissue against the nonenzymatic process of air oxidation of PUFA, as suggested by Olcott in 1941 and extended and elaborated by Dam in 1957 and by Tappel in 1961. (*See* **Coenzymes**.)

Evidence for the antioxidant theory of the function of vitamin E can be found in the following observations. The more PUFA in the diet, the more vitamin E is required. Animals on vitamin-E-deficient diets and subjected to oxidative stress conditions (such as high ozone levels) develop indirect evidence of the presence of peroxidic products in their tissues. Animals exposed to stressful oxidizing conditions are protected by increased intakes of vitamin E; examples of oxidative stress include smog, cigarette smoke, and some types of chemical carcinogens. Synthetic antioxidants that are structurally unrelated to vitamin E (e.g., ethoxyquin and diphenyl-*p*-phenylene diamine) can be used to replace it in diets. Finally, there is some evidence that other dietary antioxidants (such as vitamin C and selenium) can partially ameliorate low intake levels of vitamin E. (*See* **Ascorbic Acid**: Physiology; **Selenium**: Physiology.)

Table 2 α-Tocopherol content of human tissues

Tissue	$\mu g\, g^{-1}$

Vitamin E Deficiency

Overt deficiency of vitamin E in the absence of nutritional deprivation is rare in humans, although animals can be made vitamin-E-deficient by feeding them synthetic diets that contain fats from which vitamin E has been removed. A number of diseases are known in various animals to result from a deficiency of vitamin E; perhaps the most notable feature of these deficiency states is the very great species specificity of the manifestations of vitamin E deficiency. Notable among the pathologies found are muscular degeneration, encephalomalacia, and, as discussed above, problems with gestation in some animals (e.g., rats but not mice).

Vitamin E deficiency in humans is generally measured by the time to observe hemolysis of red blood cells when the blood is exposed to hydrogen peroxide. In this test, the ability of vitamin E to protect red blood cell membrane lipids from undergoing destructive oxidation is measured. Normal levels of vitamin E in adult human blood serum average $1.05\ mg\ dl^{-1}$, but the range is very wide.

The first documented cases of vitamin E deficiency in humans were in patients with abetalipoproteinemia. These patients develop severe neurological abnormalities during their first two decades of life. Supplements of vitamin E (generally 100 mg per kg of body weight per day) can prevent the disease if started early enough in life. Children with cholestatic liver disease also develop neurological abnormalities due to inadequate delivery of vitamin E to the affected tissues. Studies in hyperlipidemic rats demonstrate that the transfer of vitamin E to tissues is impaired. (*See* **Liver**: Nutritional Management of Liver and Biliary Disorders.)

The ratio of maternal and fetal blood tocopherol levels is about 5, suggesting poor placental transport of vitamin E. For this reason, premature infants have

low vitamin E levels. Premature infants are often given elevated oxygen therapy, since their lungs are immature, and this places an added oxidative stress on their systems. Since modern medicine allows smaller premature infants to be saved than in the past, there has been an increase in diseases in these infants that may be ameliorated by vitamin E (such as intraventricular hemorrhage). Premature infants are now routinely given supplemental vitamin E.

PUFA Autoxidation and the Role of Vitamin E

Polyunsaturated fatty acids have methylene groups (—CH_2— groups) located between two double bonds, as shown in Figure 2. This type of chemical functionality makes these compounds particularly sensitive to the flameless oxidation in air that is called 'autoxidation.' Figure 2 shows the steps involved in

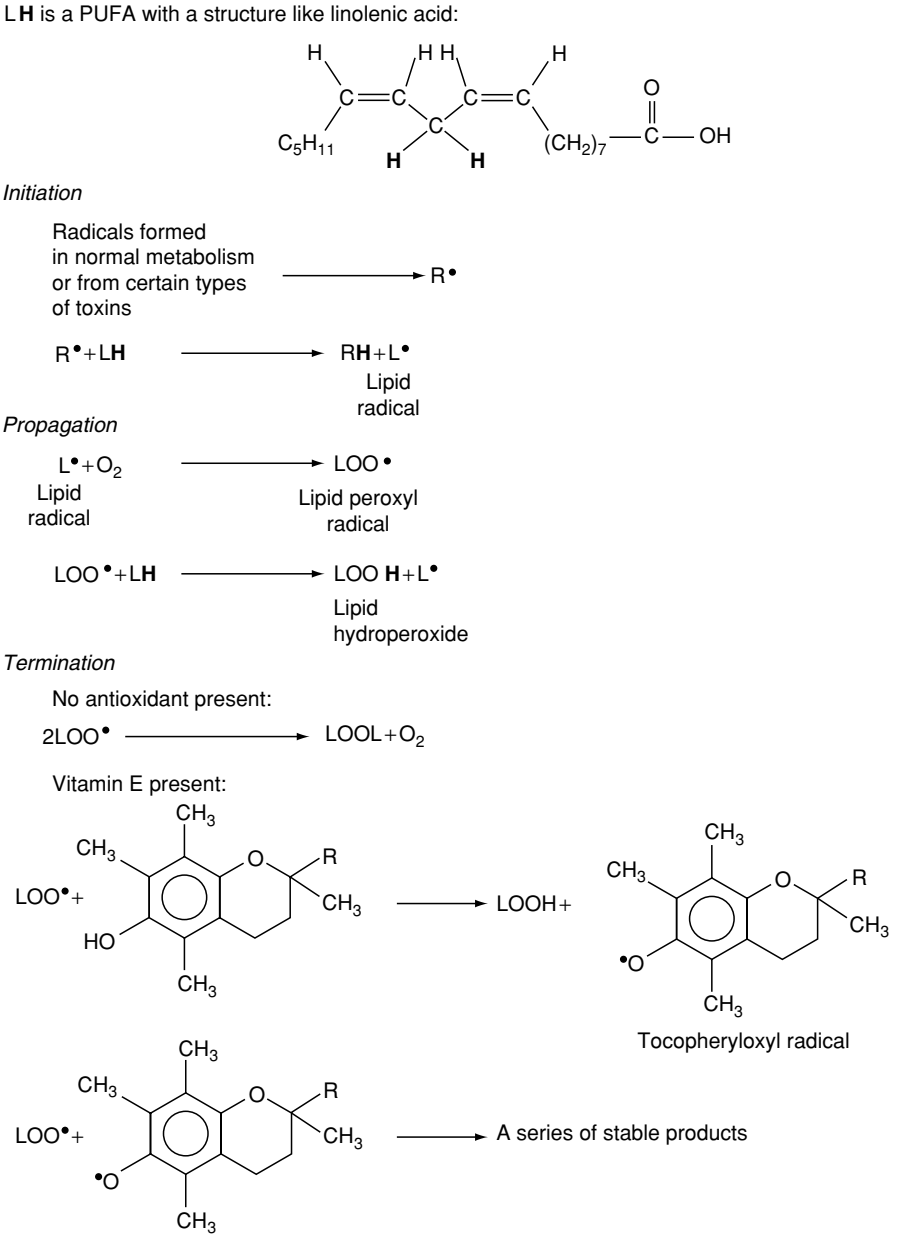

Figure 2 Chemical reactions involved in the autoxidation of a particular polyunsaturated fatty acid, linoleic acid. The autoxidation sequence involves three different types of reactions: initiation, propagation, and termination. Initiation is the process in which radicals are produced; propagation steps are those that occur over and over in the chain reaction and where products are formed; and termination steps are those in which radicals are destroyed. Reproduced from Tocopherols: Physiology, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

this process. Free radicals are produced both in normal metabolism and by the effects of toxins on tissue. These primordial free radicals can cause the formation of lipid-free radicals, as shown in the *initiation sequence*. The lipid radical, $L^{\cdot}$, then undergoes the *propagation sequence* shown, leading to the formation of lipid hydroperoxides, LOOH. These LOOH compounds also are formed in enzyme-catalyzed reactions; for example, the enzymes in the arachidonic acid cascade serve to convert arachidonic acid (the acid with 20 carbon atoms and four double bonds) to several types of hydroperoxides that have potent biological properties, such as 15-hydroperoxyeicosatetraenoic acid (15-HPETE). If vitamin E is not present, two of the peroxyl radicals ($LOO^{\cdot}$) involved in the propagation sequence must find each other and collide in order to convert radicals to stable, nonradical products. This reaction is shown in the *termination sequence*. If vitamin E is present, it reacts extremely rapidly with peroxyl radicals, converting them to nonradical products and stopping the autoxidation chain reaction. One tocopherol molecule can protect 100 or more PUFA molecules from autoxidative damage.

TOMATOES

B McGlasson, University of Western Sydney, Penrith South DC, New South Wales, Australia

Introduction

Tomatoes are an integral part of human diet worldwide and production in 1999 was estimated at 91.7×10^6 t. The tomato is a member of the Solanaceae – the potato family. Tomato fruit, often described as a vegetable fruit, is consumed fresh and in several processed forms, including dried, purée, paste, ketchup, sauce, soup, and canned whole-peeled. It is a watery fruit containing 5–7% dry matter. It contains relatively low concentrations of vitamin C, provitamin A and minerals, compared to other commercially important fruit species. However, because it is consumed in quite large quantities, it is a major source of these nutrients, especially in western societies. There is renewed interest in the dietary properties of tomato because it is the principal source of lycopene.

Lycopene is an antioxidant that is thought to be a factor in the prevention of several chronic diseases, including cancer and coronary heart disease. There is evidence that lycopene is absorbed more efficiently from processed tomato products compared to fresh fruit. Genetically, the tomato is probably the most highly defined and best mapped of all domesticated soft-fruited crop plants. An enormous range of commercial cultivars is available. There are cultivars bred specifically for the fresh market that produce fruit ranging in diameter from 15 mm to more than 90 mm, and processing types especially suited to machine harvesting. All modern cultivars incorporate multiple resistances to many pathogenic diseases and pests.

Genetic Origins

It is thought that the original domestication of the tomato took place in Mexico and probably resulted from selection over many generations from the ancestral form now known as *Lycopersicon esculentum* var. *cerasiforme*, the cherry tomato. The genetic center of origin of the tomato is believed to be the western coastal strip of South America which extends about 80 km inland and to altitudes of 3000 m. This coastal strip extends from Ecuador to Peru and Chile (latitude 0–25 °S). Geneticists, notably the late Professor Charles Rick of the University of California, Davis, USA, have collected, classified, and documented many wild species of *Lycopersicon* and other closely related genera. Some of these wild species have been sources of resistance against a wide range of diseases and pests, which have been incorporated into modern cultivars. The wild species include ecotypes that are adapted to low and high growth temperatures, arid and humid environments, and saline soils. However, some of these species cannot easily be crossed with the domesticated tomato (Table 1).

Genetic Mutants

Many natural and some induced mutants have been documented, and some of these have been shown to have commercial application. The tomato is typically diploid, comprising 12 pairs of chromosomes ($2n = 24$). Excellent gene linkage maps have been developed by classical plant breeding using defined genetic marker stocks and isozyme markers. Molecular genomic maps have been derived from restriction length polymorphism analysis. Extensive physiological and biochemical research, especially on the ripening-impaired mutants *rin*, *nor* and *Nr*, during the 1970s, provided the basis and the stimulus for the considerable advances in knowledge of the molecular biology of the genetic regulation of fruit ripening and cell wall softening that have been achieved during the last 20 years.

Since about 1980, the tomato has become a favorite model system for gene technologists. The tomato is an excellent experimental subject because it is easy to

Table 1 The species of *Lycopersicon*

Subgroup	*Characteristics*
esculentum complex	Hybridize readily
esculentum	Normal tomato
esculentum var. *cerasiforme* (cherry tomato)	Adapted to wet, tropical conditions
cheesemanii	Yellow to orange fruit, diameter 6–9 mm Source of jointless gene, aid to machine harvesting
hirsutum and its forms	Green fruit with purplish stripes, diameter 1.5–2.5 cm Source of cold tolerance, and resistance to several insect pests, root knot nematodes, some fungi and bacteria
parviflorum and *chmielewski*	Yellow-green fruit, diameter 1–1.4 cm *chmielewski* is a source of high solids
pennellii	Small, green fruit Initially classified in the genus *Solanum* Resistant to drought and some sucking insects
pimpinellifolium (currant tomato)	Resistant to *Fusarium* and bacterial speck
peruvianum complex	Do not hybridize readily with *esculentum* complex
chilense	Green fruit, diameter 1–2 cm Source of the $Tm2^a$ gene Resistance to the tobacco mosaic virus
peruvianum	Green fruit, diameter 1–3 cm Very diverse species which includes coastal and mountain races Potentially valuable source of genes for resistance to many fungal and viral diseases and insect pests

transform and regenerate in tissue culture. The plants can be grown easily under protected growing conditions year-round and fruit mature within about 3 months from sowing. Genetic transformation and gene technology have been used to reduce the amounts of cell wall-softening enzymes and ethylene production to slow ripening, and to introduce genes for resistance to glyphosate herbicide. (*See* **Pesticides and Herbicides**: Types, Uses, and Determination of Herbicides.)

Fruit Composition

Botanically, the tomato fruit is classified as a berry. The fruit can be divided into skin, pericarp, and locular contents. Jelly-like parenchyma cells which fill the locular cavities surround the relatively large number of hard, small seeds borne per fruit. Small-fruited cultivars, such as those grown for the fresh trade in cool climates or for machine harvesting for processing, generally contain few locules, whereas large-fruited cultivars tend to be multilocular. The locular juices contain higher concentrations of organic acids than the outer locular walls but the reverse is true for the reducing sugars. Blended tissue has a pH of 4.0–4.7.

Table 2 shows data for a fresh-market cultivar representative of modern determinate types grown outdoors in countries such as the USA and Australia. There is considerable variability in the concentration of nutrients, which are affected by genetic differences and especially by irradiance, growth temperatures, irrigation, and salinity. The fresh tomato fruit contains a comparatively low concentration of dry matter. The edible portion of the fruit comprises 99% of the fresh weight. The inedible portion includes the seeds and the skin which are removed during the production of the purée, paste, and soup.

Because of the relatively large amounts of fresh and processed products consumed, the tomato is an important source of vitamin C, β-carotene, and minerals such as potassium in the human diet. Standard commercial cultivars contain predominantly the reducing sugars glucose and fructose. Although sucrose is the main metabolite translocated in the tomato plant, acid invertase, present in the vacuoles of the fruit cells, insures that all but trace amounts of sucrose are hydrolyzed. However, some species other than *L. esculentum* are known to accumulate a significant proportion of sucrose. *L. chmielewski*, which lacks vacuolar acid invertase, has been crossed with *L. esculentum* to produce high-sugar lines. However, breeding of commercial cultivars with high soluble solids has proven difficult because sugar metabolism appears to be controlled by several quantitative traits. Green tomatoes store a small quantity of starch, which reaches a maximum when the fruit are about half-grown. Starch is hydrolyzed rapidly once ripening begins.

Table 2 Nutrient composition of tomato

Nutrient	*Content (per 100 g edible portion[a])*

Detailed information is available on the concentrations of (1) organic acids, in addition to citric and malic, that are involved in the tricarboxylic acid cycle of aerobic respiration, and (2) the enzymes which catalyze this cycle and related metabolic pathways. The principal phenolic compound found in tomato fruit is chlorogenic acid. Alkaloid glycosides are common throughout the Solanaceae. These compounds taste bitter. α-Tomatine is commonly found in the tomato. Quite low concentrations are found in unripe fruit and these decrease by about half during ripening. In contrast to solanine in potato, α-tomatine appears to pose a low risk of toxicity to people.

Detailed information on the free amino acid composition of fresh fruit is available. Glutamic acid is the major component. Glutamic, aspartic, and γ-aminobutyric acids, plus glutamine, comprise

about 80% of the total free amino-nitrogen-containing compounds in fruit. These compounds contribute to tomato taste.

Pigments

Traditionally, tomatoes are thought to be red, but pink, orange, yellow, white and even black strains occur naturally. The typical red color is caused by Lycopene, which is usually the predominant pigment. Lycopene is a carotenoid pigment, but it is not converted to vitamin A when consumed by people. Lycopene is more concentrated in the outer fruit wall (pericarp) than in the internal locular tissue. The distribution of β-carotene follows a reverse pattern.

During ripening, the chloroplasts are transformed into chromoplasts. Chlorophyll disappears completely within about 4 days at 20 °C, and lycopene reaches a maximum by about 6 days.

There are relatively small increases in the carotene pigments during ripening. Lycopene synthesis is optimum at 13–22 °C. Lycopene concentrations range from 2 to 7 mg per 100 g edible portion. At higher temperatures, synthesis is inhibited and is completely stopped above 30 °C. The fruit color is then yellow. There are many mutants that affect pigment synthesis, including some which retain chlorophyll when the fruit is ripe, e.g., Evergreen and Greenflesh. The crimson gene (og^c) increases lycopene concentrations at the expense of β-carotene, and the high-pigment gene (*hp*) increases total carotenoids, thus enhancing the color of ripe fruit. (*See* **Carotenoids**: Occurrence, Properties, and Determination.)

Production Systems

Domesticated cultivars display two kinds of growth habit – indeterminate and determinate. Indeterminate or vine types typically continue to grow, flower, and set fruit as long as the plants remain healthy, and growing conditions are suitable. These types require support. They may be trained on stakes or trellises, or suspended on twine from overhead wires. In general, a considerable amount of labor is required to prune and train the plants. Indeterminate cultivars for the fresh market are used in commercial glass or plastic houses, and yields of 250 t ha^{-1} have been reported in a full growing season in the UK. A high proportion of fresh market tomatoes produced in glass or plastic houses are grown hydroponically. Plants are either grown in a solid medium with the nutrients being allowed to run to waste or in a recirculating aqueous medium. This system enables the mineral composition and concentration of salts in the medium to be precisely controlled.

Most of the tomatoes commercially grown outdoors have a determinate habit. This habit is controlled by *sp*, the self-pruning gene. The plants have a compact bush habit and set fruit over a brief period of about 1 month. Determinate fresh-market tomatoes may be grown as a ground crop in dry climates or may be staked or trellised in regions with relatively high rainfall. Production on stakes or trellises facilitates spraying to control foliage diseases and pests. Little or no pruning or training is required. Recently some outdoor growers have replaced determinate cultivars with indeterminate or 'gourmet' cultivars. This has been made possible by the advent of improved cultivars incorporating the *rin* gene. Fruit of these cultivars remain firm when ripe and can be allowed to ripen to an advanced color stage (vine-ripe) before they are harvested. Gourmet tomatoes are expected to have better flavor because they are harvested when ripening is well underway and they may have higher sugar levels compared to determinate cultivars because they have higher leaf–fruit ratios. Tomatoes for processing are universally grown as a ground crop on raised beds. Irrigation by trickle is well suited to outdoor tomato production. Water and nutrients can be applied efficiently to the root zone according to the demands of the crop.

Most fresh-market tomatoes are harvested by hand. Fruit at early color stages is harvested at frequent intervals from trellised plants. Some harvest machines have been developed but they have not been widely adopted because of the risk of excessive fruit damage and limited cost savings. Mechanical harvest aids have been developed and are more widely used. These machines transport pickers along the rows and convey the harvested fruit into bulk bins carried on the machine. On-ground plantings are harvested up to four times, and a high proportion of the fruit is harvested green. Green fruit is usually held in controlled-temperature ripening rooms with the continuous addition of ethylene to reduce the time to the commencement of ripening.

In countries where labor costs are high, processing tomatoes are harvested by machine when most of the fruit is fully ripe. These machines cut the bushes at ground level, elevate the bushes into a shaker section to separate the fruit from the bushes, and then present the fruit either to an automatic color sorter, or to people riding on the machine who remove clods of soil and unripe or overripe fruit by hand. The sorted fruit is accumulated in large bins, traveling with the harvest machines, and then carried by road to the factory.

The development of the cultivars and the machine harvesters was a revolutionary step pioneered by the late GC Hanna of the University of California, Davis,

USA, in the 1950s. Cultivars with the following characteristics are required: plants are compact; fruit is set and ripened over a confined period; fruit stores well on the bush when ripe; fruit detaches easily and withstands the physical rigours of machine harvesting. Processors pay growers on the basis of total solids per tonne of fruit. The incorporation of the j^2 jointless gene in modern cultivars enables detachment of the fruit free from calyces and pedicels.

Fruit Growth and Ripening

Tomatoes take 6–7 weeks from flowering, depending on temperature, to reach full size. Cell division continues for about 2 weeks after flowering, but the bulk of the increase in fruit size is the result of cell expansion. In normal cultivars, the first appearance of red or pink color at the blossom end of the fruit signals the completion of growth and the beginning of ripening. Laboratory studies with fruit harvested at a mature green stage have shown that ripening actually begins about 2 days before the external color change. An early indication of ripening is a small increase in ethylene production, which can be measured with a sensitive gas chromatograph.

The tomato is a climacteric fruit in which ripening is accompanied by an increase in both respiration and ethylene production (Figure 1). A natural increase in endogenous ethylene production initiates ripening and regulates or integrates many of the biochemical events in ripening. The disappearance of starch, the destruction of chlorophyll, and the synthesis of lycopene, aroma, and polygalacturonase, a cell wall-hydrolyzing enzyme, are highly integrated with the changes in respiration and ethylene production. These events either do not occur or are diminished and protracted in the ripening-impaired mutants *rin, nor, Nr*, and *alcobaca*. Fruit produced by F_1 hybrids of mutant lines and normal cultivars has intermediate traits. The fruit ripens but may not develop acceptable color and flavor. The severity of these effects depends on the mutant gene and the genotypic background of the parent lines. However, many cultivars incorporating *rin* are being grown for the fresh market. The benefits include a slower rate of ripening and softening, so that the fruit has a longer shelf-life. Incorporation of ripening-impaired mutant genes in cultivars for processing appears to have no benefits.

Storage Temperatures

Tomatoes are chilling-sensitive. Storage of green fruit at less than 10 °C for more than a few days inhibits ripening. Severely chilled fruit will not ripen when returned to normal ripening temperatures. In less severely chilled fruit, ripening may be retarded but the fruit is much more susceptible to pathogenic decay. The recommended storage and transport temperature for tomatoes is 12 °C. Carefully handled fruit, harvested at an early color stage, may be stored for up to 3 weeks. Green and partly colored fruit should be ripened at 13–22 °C to the desired stage. Ripe fruit may be stored satisfactorily for about 4 days at about 5 °C. (*See* **Chilled Storage: Principles.**)

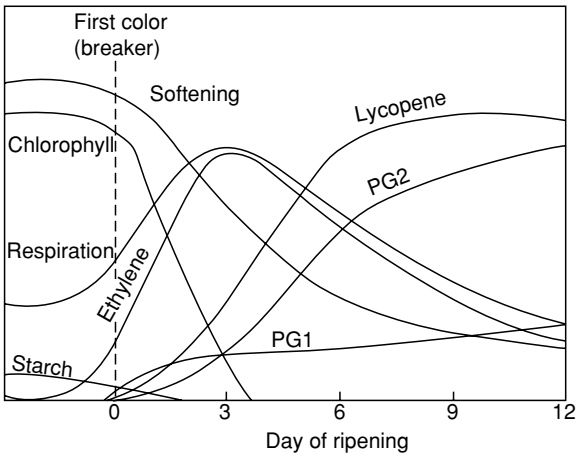

Figure 1 Changes in metabolism and composition during ripening. PG, endopolygalacturonase. Reproduced from Tomatoes, Encyclopaedia of Food Science, Food Technology and Nutrition, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Sensory Quality

Many countries have quality standards for fresh-market tomatoes. The criteria include size, color, and freedom from blemishes, decay, and insect pests. There are no dramatic changes in gross components, such as sugars and acidity, that enable the establishment of objective quality standards. The pressure of competition, on growers in countries such as the USA and Australia, to reduce production costs led to the adoption of large-scale production of determinate cultivars which soften slowly and have a long shelf-life (Figures 2–5). Fruit of the first introductions of these new cultivars sometimes retained a tough woody texture, even when fully colored. Even if tomatoes have optimum levels of sugars and acids, a tough texture greatly reduces their acceptability to consumers. The universal criticism of fresh tomatoes is tough texture and lack of flavor. This has led to an increased production of cherry and gourmet cultivars that are harvested at advanced color stages and generally sold at a premium price compared to standard cultivars. (*See* **Sensory Evaluation: Practical Considerations.**)

Figure 2 (see color plate 134) Harvest aid for fresh market tomatoes. Fruit are sorted and accumulated on a hopper on the machine. The fruit are periodically transferred to half-tonne bins for transport to the packing house.

Figure 3 (see color plate 135) Mechanical harvesting of processing tomatoes. Plants are cut at ground level, and elevated on to a shaker which separates the fruit from the plants.

Flavor of tomatoes is a product of the interaction of taste and aroma. Research has shown that taste is the more important factor. Taste principally involves an interaction between total sugars and titratable acidity. Most modern cultivars appear to have adequate acidity, but sugar levels are frequently too low. Other taste enhancers include the amino-nitrogen compounds, especially glutamate, and other unidentified compounds which contribute to 'tang.' Measurement of total soluble solids by refractometer gives a rough indication of the level of taste components because sugars comprise more than half of the soluble solids. However, refractometric values are often not well correlated with taste. Incorporating titratable acidity (mmol per 100 ml of juice) in a multiple regression equation improves the correlation, but it remains

Figure 4 In Australia fresh-market tomatoes are mostly volume-filled into 10-kg cartons for marketing.

Figure 5 (see color plate 136) Tray packs of glasshouse tomatoes, harvested once ripe.

unsatisfactory. Other components that contribute to taste remain to be identified. Improved analytical procedures allow direct measurements of the major taste components but are too expensive for routine use.

Despite these limitations, practical observations show that raising total soluble solids from the common level of 4.0–4.5% to over 6.0% gives a highly significant improvement in flavor scores. Cultivars with the genetic potential to accumulate high sugar concentrations and, consequently, higher total soluble solids are essential, but it is necessary to optimize growing conditions to enable full expression of this genetic potential. Research in several countries has examined the feasibility of raising the electrical conductivity of the irrigation solution, especially

during the fruit growth phase, either by the addition of salts, such as potassium chloride, in outdoor production, or by the addition of sodium chloride to hydroponic systems in glass or plastic houses. Ultimately the best way to increase sugar levels will be by plant breeding but this goal remains elusive because the regulation of sugar concentrations involves several quantitative genetic traits.

The volatile compounds that contribute to aroma have received much attention. Green tomato fruit produces low levels of volatile compounds, but more than 400 volatile compounds have been detected in ripe fruit. While a considerable number of these compounds contribute to tomato aroma, it is probable that only about 15 compounds have an influence on flavor quality. They include alcohols, aldehydes, carbonyls, and sulfur compounds. A few compounds may produce off-flavors but most evince a positive response. Tomatoes that have high levels of soluble solids tend to produce larger amounts of aroma.

The flavor of tomatoes is changed considerably by processing. An essential step in processing is denaturation of enzymes and sterilization by heating to about 100 °C. Although the major taste components remain, volatile aroma compounds associated with fresh fruit are lost. Additional flavor compounds are generated nonenzymatically during processing. A large proportion of processing tomatoes are concentrated in the form of paste which contains a minimum of 24% total solids. Paste can be stored for long periods before conversion to sauce, ketchup, and soup.

Cell-Wall Softening

Cell walls comprise α-cellulose, pectin, hemicellulose, and some protein. During ripening, the fruit softens, and softening is accompanied by changes in the pectin and hemicelluloses. Cellulose remains intact. Several hydrolases that attack cell walls are present in tomato fruit. Endopolygalacturonase (PG) has received particular attention and it is produced *de novo* during ripening (Figure 1). However, the extent of softening is not closely correlated with the amount of enzyme produced, although cultivars with firm fruit generally accumulate less enzyme than do cultivars with softer fruit. It appears that there are several factors that limit the action of PG *in vivo*. These factors may include the extent of methyl esterification of polygalacturonate, the amount of calcium bound to pectin, the distribution of PG in the cell walls, and the activity of other hydrolytic enzymes that act on cell wall components.

There are three closely related isozyme forms: PG1, PG2A and PG2B. PG1 comprises one subunit of PG2A or PG2B, plus a nonenzymatically active ancillary subunit. PG1 is the first form produced during ripening and may be the active form of the enzyme within the fruit. It has been suggested that the ancillary subunit plays a key role in binding the active PG2A or PG2B to its substrate. Normal cultivars continue to accumulate relatively large amounts of the small PG forms for several days after the fruit become fully ripe. Fruit of *rin* and *nor* produce little or no PG and soften very slowly. The amount of PG present in ripe fruit is especially important to processors. An important factor determining the yield of products such as ketchup, which is manufactured per tonne of raw fruit, is the viscosity (consistency) of the product, and the extent of depolymerization of pectin has a major influence on viscosity. When tomato tissue is comminuted, the vacuolar acids (principally citric acid) chelate calcium bound to pectin. The pH of the blended tissue is optimum for PG activity, and the protective calcium is removed from the pectins, which are rapidly solubilized unless the enzyme is denatured. A key step in paste manufacture is the 'hotbreak.' The tomato tissue is heated as rapidly as possible to 100 °C because PG remains highly active up to about 80 °C. Tomatoes transformed with DNA for PG in an antisense configuration have greatly reduced PG activity and yield products with higher viscosity.

Future Developments

Tomato breeders, in cooperation with plant physiologists, biochemists, and gene technologists, will continue to develop the commercial tomato. The tomato is an excellent model system for research on the genetic regulation of the biochemical events associated with ripening. Large catalogued international collections of wild tomato species are being maintained and researched. There is also enormous potential to improve resistance to pests and diseases, yield of solids for processing, and sensory quality. If further medical research confirms a role for lycopene in reducing chronic diseases in people, increased consumption of fresh and processed tomatoes selected for high levels of lycopene can be expected. A large amount of germplasm remains to be elucidated in species such as *L. peruvianum*, in which there are significant compatibility barriers with *L. esculentum*. Molecular biology provides the tools for overcoming these barriers.

TORTILLAS

S O Serna Saldivar, Instituto Tecnologico y de Estudios Superiores de Monterrey, Monterrey N.L., Mexico
L W Rooney, Texas A&M University, TX, USA

Introduction

A tortilla can be defined as a flat, round, unfermented bread produced from wheat (*Triticum aestivum* L.) flour or lime $Ca(OH)_2$ cooked maize (*Zea mays* L). Processes and characteristics of wheat flour and maize tortilla differ considerably. Both types of tortillas originated in Mexico, where they are considered the national bread and are generally consumed with others foods such as beans, meat, and vegetables. Tortillas are increasing in popularity throughout the world. Global sales were estimated at 6 billion dollars in 1998. Processing plants have been started in the UK, Spain, France, Australia, Brazil, India, China, Korea, and other countries around the world.

For wheat tortilla production, refined or wholemeal flour is mixed with shortening or lard, salt, baking powder, and other ingredients. The tortilla blend is mixed and kneaded with water to yield a gluten-developed dough that is divided into balls and hand-rolled or hot-pressed into a flat disk. The disk is baked on a hot griddle to yield the tortilla (**Figure 1**). Like bread dough, wheat flour tortilla dough is gluten-structured.

For maize tortillas, mature grain is cooked in water containing lime to produce nixtamal, which is ground

into a moist dough called masa. Masa is the base for the production of a wide array of indigenous foods, ranging from table tortillas and chips (Figure 1) to the popular tamales and breakfast gruels. Maize-based, lime-cooked snack foods are competing strongly with potato chips and other salty snack foods in North America.

Maize, lime, and water are three basic ingredients needed for the production of masa. Lime softens the pericarp and endosperm and protein hydration and a small amount of starch is gelatinized. Due to its high pH, the starch chains are charged, which helps to retard retrogradation and staling. Other ingredients, such as preservatives, acidulants, emulsifiers, and gums, are used to improve the shelf-life of table tortillas. Frying oil is the second major ingredient in fried snacks. Snacks are usually salted and flavored.

Wheat Tortillas

Historically, tortillas were homemade, prepared on a daily basis, and consumed fresh. The fastest-growing tortilla area in the USA is wheat flour tortillas. Flour tortillas represents about two-thirds of the approximately 3 billion dollars of tortillas sold in the USA in 1998. Most wheat tortillas are industrially manufactured by hot-press, die-cut, or hand-stretch procedures. Each operation requires different flour specifications, dough preparation, and baking conditions, which result in various tortilla characteristics.

Hot-press tortillas are slightly off-round, elastic, resistant to tearing, have a smooth surface texture, and resist moisture absorption from fillings. Hot-press tortillas are consumed as gourmet table tortillas, fajitas, and soft tacos. Die-cut tortillas have a lower moisture content, are circular, less resistant to cracking, and often have dusting flour on the surface. Die-cut tortillas are mainly used in burritos, frozen Mexican foods, and fried products, i.e., taco salad bowls, taco shells, chimichangas, and buñuelos. Hand-stretch tortillas are irregular in shape, elastic, moderately resistant to tearing, and have dusting flour on the surface. Hand-stretch tortillas are consumed as table tortillas, burritos, and some fried products.

All wheat tortillas contain flour, water, fat, and salt. However, in the USA, tortillas may contain several other ingredients to improve flavor, softness, rollability, and shelf-life (1–4 weeks). These ingredients include chemical leavening agents, emulsifiers, antimicrobial agents, acidulants, gums or hydrocolloids, reducing agents, sugar, and yeast.

Wheat flour, the most important ingredient, is usually enriched, bleached, hard wheat flour with a protein content ranging from 9.5 to 14%. Equipment limitations and processing conditions determine the functionality of the flour. Flours for hot-press and hand stretch tortillas generally require less protein and gluten strength than flours for die-cut tortillas. Dough mixing time and dough properties are modified by reducing agents (sulfite, cystine), emulsifiers (lecithin, mono- and diglycerides, sodium stearoyl-2-lactylate), salt, gums, fat, water content, and dough temperature. (*See* **Emulsifiers**: Organic Emulsifiers; **Gums**: Properties of Individual Gums.)

Water (45–55% of flour weight) is needed to form the gluten complex. Solid or liquid fats (5–15% of flour weight) are added to improve dough properties, retard staling, and produce a softer and more flexible tortilla. Salt (1–2%) is added for taste and to strengthen the gluten complex. Baking powder (1.0–2.5%) gives a whiter, less dense, spongy product. Various natural and modified cellulose gums are added at 0.1–0.5% levels to improve dough machinability and decrease the stickiness of baked tortillas. Antimicrobial agents (propionates, sorbates) and acidulants (citric, fumaric, and phosphoric acids) limit fungal growth and extend shelf-life. Optimum pH for propionate activity is 5.5, and for sorbate activity is 6.0 when used at 0.2% of flour weight; however, dough mixing is more difficult below pH 5.8.

Wheat tortilla dough is mixed to incorporate the dry ingredients, fat and water, and to form a pliable, viscous dough. Tortilla dough is optimally mixed to slightly overmixed and varies in temperature from 26 to 38 °C, depending upon subsequent operations.

The dough is divided and rounded into dough balls in the hot-press and hand-stretch procedures. The dough balls are rested in a warm, moist environment for 5–20 min to relax the gluten complex. Rested dough balls machine easier and form better tortillas. In die-cut operations, the dough is pumped and shaped into a sheet that is further thinned by a series of cross-rollers on a moving belt. The thin sheet of dough (about 0.5 mm) is cut by a circular die which forms the shape. The scrap dough is returned to the dough pump and processed. Regardless of the process, the formed tortilla are baked (190–260 °C for 30–50 s) in gas-fired ovens that generally have three tiers. Oven conditions vary depending upon tortilla thickness, type of conveyor (slat or wire), and forming operation. Puffing of tortilla occurs near the end of baking and is more common in hot-press and hand-stretch tortillas. Tortillas are cooled to < 32 °C on cooling conveyors before placing into plastic bags for distribution. Improper cooling causes the tortilla to stick together and increases microbiological problems. Wheat flour tortilla producers have recently developed low-fat and fat-free products. The USA market for fat-free tortillas is between 35 and 40 million dollars. Kosher tortillas are another market under development.

Lime-Cooked Maize Products

Three basic types of product are industrially produced from lime-cooked maize: table or soft tortillas, corn chips, and tortilla chips (Figure 2). Corn and tortilla chips are primarily produced and consumed in developed countries, where they have an important share within the salted snack-food market. In 1998, sales of US-made corn and tortilla chips totaled 3.57 and 0.74 billion dollars, respectively. In contrast with sales in 1989, the market of these salted snacks increased 70% and 15.6%, respectively.

Table Tortillas

The technology for maize tortilla production was developed by early Mesoamerican civilizations. Tortillas and masa products constitute the staple food for large groups of people in Mexico and Central America. In Mexico, annual per capita intake in some

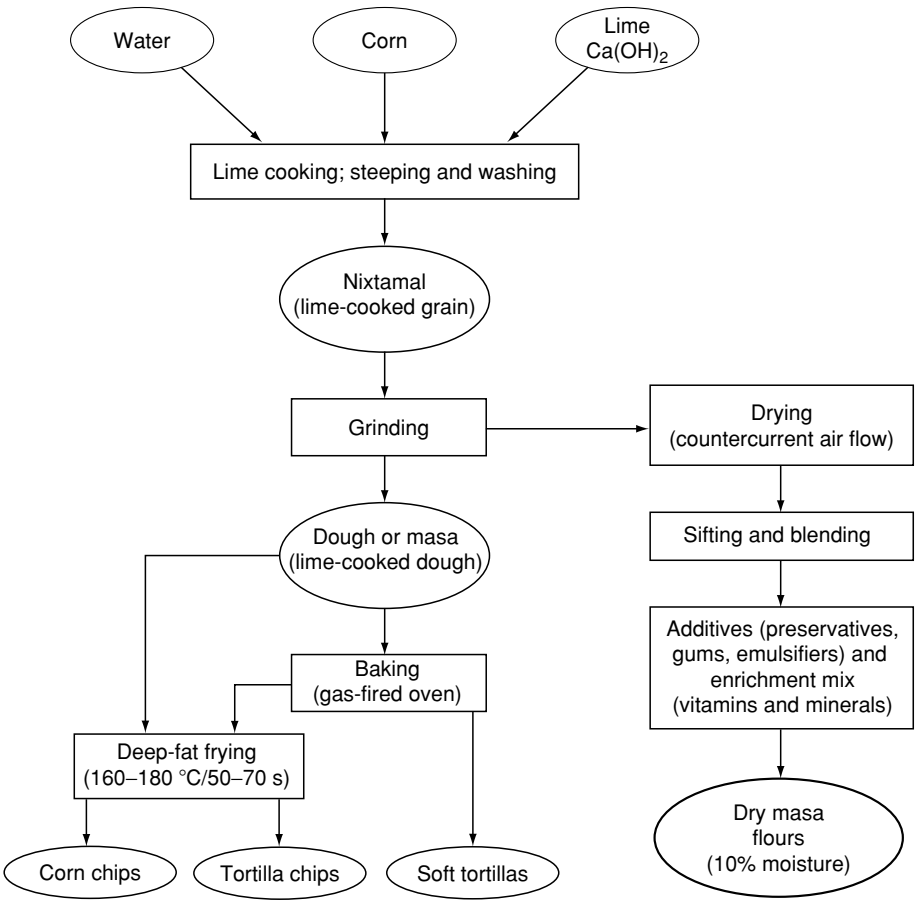

Figure 2 General scheme for the production of table tortillas, corn chips, tortilla chips, and dry masa flour.

groups of people is higher than 120 kg. In the USA, sales of table tortillas was estimated at 1 billion dollars in 1998. Tortillas are produced using traditional and industrial processes. In the traditional process maize is lime-cooked in clay pots over a fire, followed by steeping for 8–16 h (generally overnight). The cooking liquor, called nejayote, is discarded and then the nixtamal is hand-washed. Nixtamal is ground into a fine masa with a stone grinder called metate, or with hand-operated grinders. Masa is hand-molded or pressed into disks which are baked on a hot griddle or comal. Traditional tortillas are generally produced on a daily basis and are usually thicker and heavier than their industrially produced counterparts. Tortillas are the main source of energy, protein, calcium, and other important nutrients in Mexico and Central America. Lime-cooking considerably increases calcium and the bioavailability of niacin, and significantly decreases the amount of aflatoxins in contaminated maize. (*See* **Aflatoxins**; **Niacin**: Properties and Determination; **Pellagra**.)

The industrial production of maize tortillas is labor-intensive and requires considerable equipment. Quality of end products depends on the nature of raw material and manufacturing practices. The ideal grain should be sound, free of fissures, uniform, brightly colored, and with intermediate-to-hard endosperm. In addition, the kernels should have a rounded crown and a shallow, unwrinkled dent, and the pericarp should be easily removed after lime-cooking. Yellow and white maize, or mixtures therefrom, are commercially manufactured into alkaline products.

The industrial tortilla process starts when the maize is lime-cooked in agitated open baths, vertical cookers, or steam kettles. The grain is generally mixed with three parts water and 1% lime, based on grain weight, and cooked for 15–45 min at temperatures ranging from 85 to 100 °C. The nixtamal is then steeped for 8–16 h in the hot lime solution. After steeping, the maize is pumped with the steep liquor or dropped by gravity to washers. The cooking liquor is drained and the nixtamal washed with pressurized water. Most of the pericarp and excess lime is removed during this step. The cleaned nixtamal is discharged into a stone grinder, where masa is produced. The grinder consists of two volcanic or synthetic (aluminum oxide) stones carved radially, one stationary and the other rotating at 500–700 rpm. Masa particle size is directly related to the gap or pressure between the stones and the size and depth of the grooves. During grinding, the nixtamal is disrupted into a plastic and cohesive masa. Masa is then kneaded by mixers or extruders that feed the forming machine or sheeter rolls. During forming, the masa is rolled into a sheet which is cut by a rotating cutter positioned underneath the rolls. The formed pieces of masa are fed into a three-tier, gas-fired oven for baking. Tortillas are baked at temperatures ranging from 280 to 302 °C for 30–45 s, then cooled through a series of open tiers and packaged. Tortillas are generally treated with acidulants and antimold agents such as sorbates and propionates to improve their shelf-life. These additives are incorporated during grinding or masa kneading.

Dry Masa Flour

The use of dry masa flour is growing rapidly because of its convenience. More than 2 million metric tons of dry masa flour for table tortilla production are annually produced in Mexico. These flours are transformed into approximately 3.4 million tons of table tortillas. The dry masa flour industry supplies about 40% of the tortillas consumed in Mexico. Dry masa flour is produced by drying and grinding lime-cooked, coarsely ground masa (Figure 2). The masa is dried in large tunnels, or drying towers, in which warm air flows countercurrently to the masa. A wide array of products can be manufactured by selecting and blending streams with different particle size and color. In most cases, resulting flours are enriched with vitamins thiamin, riboflavin, niacin, and folic acid and minerals iron and zinc. Coarser flours with lighter colors are required for snacks. The flour with less than 10% moisture is shelf-stable and only requires water to form masa. Many manufacturers use dry masa flour because it does not require much labor, equipment, or space, and processors do not have to worry about effluent disposal and control of scheduling and manufacturing practices. Dry masa flours are generally mixed with 1.1 to 1.2 parts water for about 3–5 min to produce a suitable dough for further processing.

Fried/Snack Products

Frying has expanded the market for masa-based foods because the final product has excellent organoleptic properties and a long shelf-life. The two most popular snacks, tortilla and corn chips, are usually made from coarsely ground fresh masa or masa flours. Corn chips are produced directly from masa (Figure 2) and contain more oil than tortilla chips (Table 1). Tortilla chips are baked similarly to tortillas before frying. Tortilla chips absorb less oil, and have a firmer texture and a stronger corn flavor than corn chips. Nixtamal for these snack foods is generally cooked less than nixtamal for table tortillas, and it is ground into coarse masa which allows steam to escape through the many small pores during baking and frying. This prevents the formation of serious quality defects, such as oily appearance and pillowing or blistering. Masa for corn chips is extruded through a die, and cut by rotating knives before frying. Masa

[b]Salted corn chips.
[c]Unsalted tortilla chips. Salted tortilla chips contain approximately 774 mg of sodium per 100 g.

for tortilla chips is formed into triangles, strips, or circles before baking, equilibrating, and frying. Masa from yellow maize requires a lower frying temperature and longer residence time than masa from white maize. Frying temperatures and times range from 165 to 195 °C and 50 to 90 s.

Corn and tortilla chips are often salted and flavored immediately after frying. The hot chips are conveyed into an inclined rotating cylinder on to the product. Most popular flavorings include nacho cheese, hot/spicy, barbecue, lemon salt, and jalapeño. Corn and tortilla chips are packaged in moisture-proof or aluminized bags filled with an inert gas to protect the product physically and to prevent rancidity. Blue maize tortilla chips are often served in specialty restaurants and are available as organic and regular products. Blue maize has a pigmented aleurone that imparts an intense blue color. It has high levels of flavanoids and other phenolics that may have nutraceutical properties. The low-fat market of these products is increasing in the USA and other developed countries. Special processes to produce baked low-fat tortilla chips that combine air impingement, infrared, and microwaves have been developed. Olestra is currently being utilized to produce reduced-calorie chips. (*See* **Organically Farmed Food**.)

Nutritional Value

The nutrient composition of some lime-cooked maize foods is compared with white pan bread and wheat tortillas in Table 1. Tortillas, especially wheat flour tortillas, are commonly used as a substitute for pan bread by many people. Wheat flour tortillas have nutritional attributes similar to bread. Flour tortillas are higher in gross and digestible energy because their formula contains more shortening (5–15% based on flour weight). Wholemeal flour tortillas have higher amounts of fiber, protein, and ash than do white flour tortillas.

Lime-cooked maize products are an important source of energy, protein, dietary fiber, and calcium for people who depend on these items as their staple foods. Lime-cooking significantly improves the bioavailability of niacin. The caloric density of corn chips and tortilla chips is significantly higher than table tortillas. This is due to oil absorption during frying and their low moisture content. Tortillas and snacks produced from enriched dry masa flour contain higher levels of B vitamins and Fe and Zn than counterparts produced from fresh masa. In Mexico, dry masa flours are industrially enriched by a federal regulation and some of these flours are

optionally fortified with soybean protein. Human nutritional studies have demonstrated that fortified and enriched flours upgrade the nutritional status of low-income and marginal people, especially children. Toxicology *See* **Toxins in Food – Naturally Occurring**; **Mycotoxins**: Classifications; Occurrence and Determination; Toxicology

TOXINS IN FOODS – NATURALLY OCCURRING

S L Taylor, University of Nebraska, Lincoln, NE, USA

Background

The central axiom of toxicology is that all chemicals are toxic at some dose. Thus, all chemicals in foods, both synthetic and naturally occurring, are toxic. Though theoreticazlly correct, it is impractical to view all food constituents as toxicants. For the purposes of this review, naturally occurring toxicants are those chemicals of natural origin in foods that may present a hazard to consumers when eaten under some reasonable circumstances of exposure. Although toxicity is an intrinsic property of all chemicals, hazard is the capacity of a substance to produce

injury under the circumstances of exposure, taking into account the dose and frequency of exposure as well as the toxicity of the particular chemical. Illnesses caused by exposure to hazardous levels of chemical toxicants are called intoxications.

Definition of Natural

No legal definition exists for the word 'natural' in US food laws or the food laws of most other countries. Thus, there are no legal limitations on the use of the term. Webster's dictionary defines natural as "planted or growing by itself: not cultivated or introduced artificially (e.g., grass); existing in or produced by nature: consisting of objects so existing or produced: not artificial." Most consumers would likely define natural as being anything that is not artificial. Of course, artificial is another term that defies definition. Foods derived from animal or plant materials, whether processed or raw, are considered to be natural. The addition of additives to foods or the synthesis of a food from chemical sources would create a food that is perceived as not natural. To the food industry, additive-free or preservative-free foods are often described as natural. Naturally occurring chemicals from foods would be those chemicals that exist in foods in the raw, unprocessed state, although many of those chemicals would not be altered by processing or preparation practices.

Sources of Naturally Occurring Toxicants in Foods

Naturally occurring toxicants in foods can be either naturally occurring constituents of foods or contaminants that are produced in foods by various natural processes. Whereas naturally occurring constituents can be considered to be normal and unavoidable, naturally occurring contaminants are not always present and can be avoided, if contamination is prevented.

Naturally occurring toxicants are present in foods of animal, plant, or fungal origin. The majority of foods of animal origin, including meat, milk, cheese, eggs, fish, mollusks, and crustacea, are not hazardous. The most hazardous chemicals occurring in this category are found in poisonous seafoods. Foods of plant origin include vegetables, fruits, grains, seeds, nuts, and spices. Most plant-derived chemicals are also not especially hazardous, although some have the potential to be hazardous under some conditions of exposure. The major food of fungal origin is mushrooms, and many mushroom species are considered as poisonous and inedible.

Naturally occurring contaminants can be formed in foods as the result of contamination by bacteria, molds, algae, and insects. The chemicals produced from these biological sources can remain in the food even after the living organism has been removed or destroyed. Such contaminants represent the most important and potentially hazardous chemicals of natural origin existing in foods.

Additives Versus Natural

Consumers are often concerned about the chemicals added to their foods. These concerns likely arise from government regulatory actions against certain food additives or incidental contaminants such as pesticides. In contrast, natural products are widely viewed as beneficial to health.

Food laws are often predicated on the assumption that natural foods are safe, whereas most additives, especially all newly developed additives, must be proven to be safe. Although foods naturally contain many toxicants, including many chemicals that have been shown to be carcinogens in animal studies, government regulatory agencies have rarely taken any action to limit the availability of natural foods as a result of the presence of such toxicants. Meanwhile, the government has banned several food additives (cyclamate, FD&C Red No. 2 in the USA) and pesticides (DDT, ethylene dibromide in the USA) because of concerns about their safety, especially with respect to their possible carcinogenicity. Given this contrast, it is not surprising that consumers have developed a suspicious attitude regarding chemicals added to foods while remaining naïve about the potential hazards presented by naturally occurring chemicals in foods. (*See* **Food Additives**: Safety.)

Although unrecognized by many consumers, naturally occurring chemicals in foods present the greatest risk of any of the chemicals in foods. Thankfully, most of the potentially hazardous naturally occurring toxicants are ingested at doses that are unlikely to cause widespread illness, although the margin of safety is often lower for naturally occurring toxicants than it is for food additives. For example, the majority of the carcinogens in our diets are of natural origin. However, our diets also contain many naturally occurring compounds that have been shown to have anticarcinogenic activity in experimental animals and may also demonstrate similar activity in humans.

Hazards from Naturally Occurring Toxicants

Many naturally occurring, potentially hazardous chemicals exist in foods. These naturally occurring toxicants include acute toxicants (those capable of eliciting symptoms within a few minutes to hours after ingestion) and chronic toxicants (those that may

cause symptoms after life-long exposure or many years after exposure). Their ingestion does not invariably cause illness, because the dose and other circumstances of exposure are key factors. Chronic illnesses, such as cancer, are particularly difficult to correlate with foods or specific foodborne toxicants, since many confounding variables exist that affect the onset and course of such chronic diseases. Many naturally occurring carcinogens are known to exist in foods, but their relationship to cancer in humans remains unclear. A few of these carcinogens will be discussed. With acute toxicants, the relationship between ingestion of the toxicant and the development of symptoms is much stronger. Thus, many of the best examples of naturally occurring toxicants in foods involve acute illnesses.

The US Centers for Disease Control keep records on the incidence of foodborne disease. These statistics focus on acute illnesses, because the role of foods in chronic illnesses is uncertain. The most common foodborne illnesses are bacterial infections such as salmonellosis. Toxins produced by bacteria such as *Staphylococcus* enterotoxins and the botulinal toxins are important in the pathogenesis of some foodborne bacteriological illnesses. Illnesses of chemical etiology, other than bacterial toxins, account for 20–30% of all foodborne disease outbreaks in the USA. Fish and shellfish toxins account for the majority of these outbreaks, although other natural toxicants such as poisonous plants and mushrooms are also involved. The total number of foodborne disease outbreaks, including those of chemical etiology, is unknown because the reporting of such illnesses is very incomplete.

As noted earlier, the circumstances of exposure affect the likelihood of intoxication resulting from naturally occurring chemicals in foods. Table 1 describes some of the circumstances in which naturally occurring chemicals in foods can cause foodborne intoxications.

Table 1 Intoxications from consumption of naturally occurring foodborne toxicants

1. Abnormal though natural contaminants that adversely affect normal consumers eating normal amounts of the food
Algal toxins in seafood
Staphylococcal enterotoxins in various foods
Mycotoxins in various foods
2. Unusual 'foods' that adversely affect normal consumers eating normal amounts of this 'food'
Poisonous mushrooms
Poisonous plants
Poisonous fish such as pufferfish
3. Normal constituents of food that can cause illness if ingested by normal consumers in abnormally large amounts
Cyanogenic glycosides in lima beans, cassava, and fruit pits
Glycoalkaloids in potatoes and tomatoes
Estrogens in soybeans

Naturally Occurring Contaminants

As noted in Table 1, the sources of naturally occurring contaminants in foods can include algae, molds, bacteria, and insects.

Algal toxins in seafoods Seafoods, both fish and shellfish, can be occasionally contaminated with toxic substances that cause acute illnesses, and even death, within minutes after ingestion. These toxins are acquired by fish and shellfish through the food chain after being produced by certain species of microscopic, dinoflagellate algae. The fish and shellfish are hazardous only when feeding on toxin-producing algae. Seafood poisonings were once considered a public health problem only in coastal areas, but modern practices involving the shipment of fresh and frozen seafoods over long distances have made these a cosmopolitan concern.

Ciguatera poisoning is probably the most common cause of foodborne disease of chemical etiology on a world-wide basis. Ciguatera poisoning is common throughout the Caribbean and much of the Pacific. Fish that inhabit reef and shore areas in temperate regions, such as barracudas, groupers, sea basses, red snappers, and eels, are most commonly implicated in ciguatera poisoning. The identity of all the species of dinoflagellate algae associated with ciguatera poisoning remains unknown, although *Gambierdiscus toxicus* is one of them. Small reef fishes feed on the toxic dinoflagellate algae and are, in turn, consumed by the larger reef fishes. The toxins accumulate in the liver and viscera, but enough can enter the muscle tissues to result in ciguatera poisoning among humans ingesting these fish. Ciguatera poisoning is a neurologic illness initially characterized by tingling of the lips, tongue, and throat followed by numbness. Nausea, vomiting, a metallic taste, dryness of the mouth, abdominal pain, diarrhea, headache, and general muscular pain will ensue in many cases. Weakness may progress until the person is unable to walk. No antidotes are known, but many affected individuals recover within a few weeks, although deaths from cardiovascular collapse have occurred in a few instances.

Paralytic shellfish poisoning occurs in many coastal areas world-wide, including the Pacific and North Atlantic coasts of North America, Japan, and southern Chile. Many species of shellfish, such as clams and mussels, become poisonous through the consumption of toxic dinoflagellate algae. Two of the

most common algal species incriminated in paralytic shellfish poisoning are *Gonyaulax catenella* and *G. tamarensis*. The blooms of the toxic dinoflagellates are quite sporadic, so shellfish are hazardous only at certain times. Most shellfish clear the toxins from their system within a few weeks after the end of a dinoflagellate bloom, but some shellfish species, especially the Alaskan butter clam, appear to retain the toxins for long periods. The toxins involved in paralytic shellfish poisoning are known as saxitoxins. These are neurotoxins that act by blocking the passage of sodium ions into the nerve cells, an essential process in nerve transmission. The symptoms of paralytic shellfish poisoning include a tingling sensation and numbness of the lips, tongue, and fingertips, followed by numbness in the legs, arms, and neck with general muscular incoordination. Respiratory distress and muscular paralysis often occur. Death from respiratory failure can occur within 2–12 h depending on the dose. If the victim survives 24 h, the prognosis for a full recovery is good. No antidote exists for paralytic shellfish poisoning.

Pufferfish poisoning occurs more rarely because pufferfish are not frequently consumed except in Japan and China. About 30 species are found worldwide, but most are not poisonous. The most poisonous species occur along the coasts of Japan and China. The most choice, edible species belonging to the genus *Fugu* are the most poisonous and the most commonly consumed. The toxin in pufferfish accumulates in the ovaries, liver, intestine, skin, and roe (egg sac), so a carefully cleaned and eviscerated pufferfish may be safe to eat. Pufferfish likely become toxic through the ingestion of toxic dinoflagellate algae, although the food-chain relationships have not been completely elucidated. The toxin involved in pufferfish poisoning is a potent neurotoxin called tetrodotoxin, which also acts by blocking the sodium channel in nerve cells. The symptoms resemble those of paralytic shellfish poisoning. Death can result if a sufficient dose of tetrodotoxin is ingested.

Mycotoxins Mycotoxins are produced by a wide variety of molds that can grow on a wide variety of foods. The toxicity of many of the mycotoxins has been recognized by observing domestic animals fed moldy animal feeds. Their effects on humans are not so clearly established, although they are potentially hazardous to humans as well. (*See* **Mycotoxins**: Toxicology.)

Historically, ergotism was the first mycotoxin-associated illness recognized in humans. *Claviceps purpurea* is the responsible mold, which infects the heads of rye and sometimes wheat, barley, and oats. The shriveled, purplish grain kernel contains the mycotoxin. Ergotism is caused by a group of toxins known collectively as the ergot alkaloids and can be manifested in two forms: gangrenous ergotism and convulsive ergotism. In the former, also known as St. Anthony's fire, a burning sensation in the feet and hands is followed by a progressive restriction of blood flow to the hands and feet. This results in gangrene, which can lead to the loss of limbs. Convulsive ergotism involves hallucinations leading to convulsive seizures and sometimes death. No outbreaks of ergotism have been recorded since the early 1950s.

Aspergillus molds are known to produce several types of mycotoxins, most notably the aflatoxins and ochratoxin. The aflatoxins are produced primarily by *Aspergillus flavus* and *A. parasiticus* and often contaminate moldy peanuts and corn. Feeding of aflatoxin-contaminated grains or oilseeds to dairy cows can result in aflatoxin contamination of milk. The aflatoxins are potent carcinogens, especially affecting the liver. The role of aflatoxins in human carcinogenesis remains uncertain, but they are among the most potent animal carcinogens known. (*See* **Aflatoxins**.) Ochratoxin is produced primarily by *A. ochraceus*, which can contaminate cereals, peanuts, and tree nuts. Ochratoxin affects both the livers and kidneys of domestic animals, with the effects on the kidney being particularly damaging. The toxicity of ochratoxin to humans is unknown.

Fusarium molds produce a number of different mycotoxins, including the trichothecenes, fumonisins, and zearalenone. The trichothecenes are known to cause human illness and can be found as contaminants of grains primarily. Alimentary toxic aleukia (ATA) was observed in the former Soviet Union, owing to consumption of grains containing trichothecenes. ATA has four stages. In the first stage, a person experiences a burning sensation in the mouth and throat, which proceeds down the esophagus to the stomach. This is followed by diarrhea, nausea, and vomiting, occurring 1–3 days later and ceasing after about 9 days. The second stage occurs from about 2 weeks to 2 months and involves bone-marrow destruction, leukemia, agranulocytosis, anemia, and loss of platelets. At the end of this stage, small hemorrhages may occur on the skin. The third stage of ATA lasts from 5 to 20 days and involves total loss of bone marrow with necrotic angina, sepsis, total agranulocytosis, and moderate fever. The hemorrhages become larger, and necrotic lesions appear on the skin. Bronchial pneumonia appears, along with abscesses and hemorrhages in the lungs. The fourth stage is death, with the mortality rate approaching 80% and dependent on the dose and frequency of exposure to the trichothecenes.

Fumonisins are produced primarily by *Fusarium moniliforme*, which contaminates various grains and soybeans. The fumonisins have been implicated in equine leukoencephalomalacia, a fatal neurotoxic syndrome in horses characterized by extensive necrosis of the white matter in the brain. The fumonisins may also be carcinogenic, although this remains an active area of scientific scrutiny. Their effects on humans remain unknown, although low-level contamination of grains with fumonisins seems to be fairly common. Zearalenone is an estrogenic substance produced in grains by *F. graminearum*. It causes spontaneous abortions in pigs, but its effects on humans are unknown.

Penicillium molds produce a wide variety of mycotoxins, including rubratoxin, patulin, and citrinin. These mycotoxins cause various effects in domestic animals, but their effects, if any, on humans are quite uncertain. Many other mycotoxins have been identified, though most of these others have received little scientific study.

Bacterial toxins Most pathogenic bacteria exert their effects by the infectious route. They invade cells and tissues, multiply, and cause a variety of symptoms. A few bacteria produce exogenous toxins in foods before they are eaten. The ingestion of the toxins initiates the disease process even if the bacteria are destroyed in processing or preparation. The best examples of bacterial intoxications are the staphylococcal enterotoxins and botulinal toxins.

The staphylococcal enterotoxins can be produced in foods by certain strains of *Staphylococcus aureus*. When ingested, these protein enterotoxins cause nausea and vomiting within 1–6 h. Staphylococcal food poisoning is one of the most common forms of foodborne disease. (*See* ***Staphylococcus***: Food Poisoning.)

The botulinal toxins can be produced in foods under anaerobic conditions by *Clostridium botulinum*. Toxin formation often occurs in canned foods subjected to improper thermal processing. The commercial canning process is predicated on the destruction of this organism and its spores so that the spores will not germinate, grow, and produce toxin on storage of the canned product. Botulinal toxins are among the most potent toxins known to humans and frequently result in respiratory paralysis and death. (*See* ***Clostridium***: Botulism.)

Insect-produced toxins Insects can also produce and secrete toxic chemicals into foods, yet insect infestation of foods is often considered only in esthetic terms. Natural toxicants produced by insects in foods have received very little study. Flour beetles are known to secrete benzoquinones into flour, which are mutagenic and carcinogenic. The hazards posed by insect-produced toxicants in foods to humans remain unknown.

Naturally Occurring Constituents Eaten in Normal Amounts

Some plants and animals that should not be eaten are consumed intentionally or accidentally on occasion, resulting in foodborne chemical intoxications. Many plants and some animals contain levels of naturally occurring toxicants that are probably not hazardous to humans ingesting typical amounts of these foods.

Animals Very few animal species are poisonous. Several species of poisonous fish exist, the best example being the pufferfish, although recent evidence suggests that the toxin in pufferfish arises from an algal contaminant.

Plants Many plant species are decidedly poisonous. Plants such as hemlock and nightshade were used in ancient times to poison enemies. Consumers can easily avoid poisonous plants by purchasing foods from commercial sources. Intoxication from the ingestion of poisonous plants occurs primarily from misidentification of plants by individuals harvesting their own foods in the wild. The most frequent examples occur when harvesting herbs for herbal tea. For example, an elderly couple succumbed after mistaking foxglove for comfrey while harvesting herbs for tea.

Very rarely, intoxications from poisonous plants occur with products purchased from retail outlets. An example was the contamination of an herbal tea by *Senecio*, a well-known poisonous plant. The tea was fed to infants as an herbal remedy for viral infections. The infants suffered acute symptoms, involving impaired liver function, from the presence of pyrrolizidine alkaloids in the *Senecio* leaves. Several infants died in this unfortunate incident. (*See* **Alkaloids**: Toxicology.)

Occasionally, intoxications from poisonous plants occur from the intentional addition of such materials to foods. The most frequently encountered example would be the preparation of brownies laced with marijuana, a potent hallucinogenic plant.

In times of severe food shortages, humans may resort to eating large quantities of plants that contain hazardous components. Lathyrism is an unusual disease that has occurred on such occasions in India and Italy when seeds of *Lathyrus sativus* or chickling vetch are ingested as a principal part of the diet.

These seeds contain several lathyrogens, which cause both neurological and skeletal abnormalities when they are eaten in large amounts for an extended period.

Fungi Many species of poisonous mushrooms are known. Harvesting mushrooms in the wild can be a hazardous practice, even for those skilled in mushroom identification. Several different types of naturally occurring toxicants exist in poisonous mushrooms.

The most hazardous of the mushroom toxins are the Group I toxins. Amatoxin is the best example and is produced by *Amanita phalloides*, the so-called death cap mushroom. The symptoms of amatoxin poisoning begin 6–24 h after ingestion of the mushrooms. The first stage of the intoxication involves the gastrointestinal tract with abdominal pain, nausea, vomiting, diarrhea, and hyperglycemia. A short period of remission follows. The third and often fatal stage of the illness involves severe liver and kidney dysfunction with symptoms including abdominal pain, jaundice, renal failure, hypoglycemia, convulsions, coma, and death. Death from hypoglycemic shock occurs 4–7 days after the onset of symptoms. Recovery is possible but requires at least 2 weeks of intensive therapy.

The Group II toxins are hydrazines, with gyromitrin being the premier example, which is produced by *Gyromitra esculenta* mushrooms. Usually, the symptoms include a bloated feeling, nausea, vomiting, watery or bloody diarrhea, abdominal pain, muscle cramps, faintness, and a loss of motor coordination occurring 6–12 h after consumption.

The classic example of a Group III toxin is coprine, which causes symptoms only when ingested with alcoholic beverages. Symptoms begin about 30 min after consumption of alcohol along with mushrooms containing Group III toxins such as *Corpinus atramentarius*. Symptoms include flushing of the face and neck, distension of the veins in the neck, swelling and tingling of the hands, metallic taste, tachycardia, and hypotension, progressing to nausea and vomiting. Symptoms can last for up to 5 days.

The Group IV toxins, characterized by muscarine, affect the autonomic nervous system. Symptoms include perspiration, salivation, and lacrimation with blurred vision, abdominal cramps, watery diarrhea, constriction of the pupils, hypotension, and a slowed pulse. Death does not usually occur unless the Group III toxins are present in a mushroom such as fly agaric (*Amanita muscarina*), which also contains Group I toxins. With fly agaric, a fatal combination of symptoms can occur.

The Group V and VI toxins act primarily on the central nervous system to cause hallucinations. The Group V toxins include ibotenic acid and muscimol, which cause dizziness, incoordination, staggering, muscular jerking and spasms, hyperkinetic activity, a coma-like sleep, and hallucinations beginning 30 min to 2 h after ingestion. Fly agaric, in addition to its content of Group I and Group IV toxins, is also a good source of Group V toxins. The Group VI toxins include psilocybin and psilocin, whose symptoms include pleasant or aggressive mood, unmotivated laughter and hilarity, compulsive movements, muscle weakness, drowsiness, hallucinations, and sleep. Symptoms usually begin 30–60 min after ingestion of the mushrooms, and recovery is often spontaneous. *Psilocybe mexicana*, the so-called Mexican mushroom, is a well-known source of the Group VI toxins. Although Mexican mushrooms (also known as magic mushrooms or simply 'shrooms') have been used as recreational drugs for their hallucinogenic effects, it must be recognized that the dose of the Group VI toxins in these mushrooms varies widely (more than 100-fold). Exposure to high amounts of the Group VI toxins has led to prolonged and severe side-effects, even death. Often, patients experience persistent sequelae and are admitted to mental institutions. (*See* **Mushrooms and Truffles**: Classification and Morphology.)

Naturally Occurring Constituents Eaten in Abnormally Large Amounts

The dose of a toxic chemical is the major determinant of the degree of hazard that it poses in the diet. Many naturally occurring foodborne toxicants are present at levels that do not constitute a hazard to normal consumers eating a normal diet. However, if unusually large amounts of foods containing these toxicants are consumed, intoxication may occur. One classic example is the presence of cyanogenic glycosides in lima beans and cassava.

Many plants contain cyanogenic glycosides, which are sugars that can release cyanide on exposure to certain enzymes present in the plant tissues or by acid in the stomach of the consumer. Linamarin in lima beans is one example of a cyanogenic glycoside. Commercial varieties of lima beans contain very little linamarin, but wild lima bean varieties can have substantial amounts. Cyanide is a classic toxicant that binds to heme proteins in the mitochondria and hemoglobin in the blood. Cyanide prevents oxygen binding to hemoglobin, thus causing cyanosis, noticeable as a bluish discoloration of the skin and mucous membranes. It also inhibits cellular respiration by binding to the mitochondrial heme proteins. The

symptoms of cyanide poisoning include the rapid onset of peripheral numbness and dizziness, mental confusion, stupor, cyanosis, twitching, convulsions, coma, and death. Cyanide is rapidly absorbed, and the lethal dose is 0.5–3.5 mg of cyanide per kilogram of body weight. Commercial lima bean varieties release about 10 mg of cyanide per 100 g of beans. Assuming that the lethal dose is 0.5 mg kg^{-1}, a 70-kg adult would need to ingest 35 mg of cyanide or 350 g of lima beans. Though this is not impossible, it is certainly very unlikely.

Cassava can release as much as 50 mg of cyanide per 100 g of food. Cassava intake is substantial in Africa and South America in certain locales when other foods are scarce. The major source of cyanide intoxication remains the intentional ingestion of fruit pits that contain amygdalin, also known as laetrile, under the mistaken belief that laetrile counteracts cancer. The level of cyanogenic glycosides in fruit pits is considerable, and several deaths have occurred from their ingestion. (*See* **Cassava**: The Nature of the Tuber.)

In addition to the cyanogenic glycosides, plants contain an enormous variety of other potentially hazardous chemicals that are not typically evident unless large quantities of these foods are eaten. Examples include glycoalkaloids in potatoes and tomatoes, goitrogens in cruciferous vegetables, nitrate in spinach, celery, and lettuce, oxalates in rhubarb and spinach, estrogens and saponins in soybeans, and tannins and phytoalexins in many plant foods. Symptoms do not occur after ingestion of these foods in typical amounts.

Naturally Occurring Constituents Eaten by Consumers with Genetic Abnormalities

Some naturally occurring constituents of foods are hazardous only for consumers with allergies or intolerance to that food. Food allergies and intolerances are the subject of a separate review in this volume. (*See* **Food Intolerance**: Food Allergies; Milk Allergy.)

Naturally Occurring Constituents from Foods Processed or Prepared in an Unusual Manner

Many naturally occurring foodborne toxicants are removed or inactivated during processing or preparation. For example, raw soybeans contain trypsin inhibitors, lectins, allergens, amylase inhibitors, saponins, and antivitamins along with other potentially hazardous factors. However, humans never ingest raw soybeans. The trypsin inhibitors and lectins are inactivated by heating the soybeans. Fermentation in the preparation of tofu destroys certain toxic factors in soybeans. (*See* **Trypsin Inhibitors**.)

Intoxications have occurred from the ingestion of undercooked or raw kidney beans. Kidney beans, like soybeans, are legumes. They contain lectins, which can bind to sugar residues on the surfaces of cell membranes, causing hemolysis of red blood cells and intestinal damage. The lectins from kidney beans can be inactivated by thorough cooking. If not inactivated, the lectins will cause nausea, abdominal pain, vomiting, and bloody diarrhea. In England, intoxications have occurred among immigrants unfamiliar with proper cooking practices for this common item in the British diet. These consumers simply soaked the raw beans and ate them with little or no cooking, resulting in the prompt onset of gastrointestinal symptoms. (*See* **Hemagglutinins (Haemagglutinins)**.)

TRACE ELEMENTS

F H Nielsen, USDA, ARS, Grand Forks Human Nutrition Research Center, Grand Forks, ND, USA

Introduction

In the earlier part of the 20th century, scientists could qualitatively detect small amounts of several mineral elements in living organisms. In reports, these elements were described as being present in 'traces' or 'trace amounts.' Not surprisingly, these elements became known as trace elements. The trace elements found in living organisms may be essential, i.e., indispensable for performing functions necessary for life, or they may be nonessential, fortuitous reminders of our geochemical origins or indicators of environmental exposure. Some of the nonessential trace elements can be beneficial to health through pharmacological action. All the trace elements are toxic when intake is excessive.

Definition of Trace Elements

Presently, mineral elements considered to be trace elements are those that occur in the body in $mg\,kg^{-1}$ of body weight or less amounts. Essential trace elements are generally required by humans in $mg\,day^{-1}$ amounts. Since 1980, the term 'ultratrace element' has appeared in the nutritional literature. Ultratrace elements have been defined as those elements with estimated dietary requirements usually less than $1\,mg\,kg^{-1}$, and often less than $50\,\mu g\,kg^{-1}$ of diet for laboratory animals. For humans, the term is often used to indicate an element with an established, estimated, or suspected requirement of less than $1\,mg\,day^{-1}$, or generally indicated by $\mu g\,day^{-1}$.

Essential and Possibly Essential Trace and Ultratrace Elements

In the 1960s and 1970s, the standard to establish a nutrient as essential was liberalized for mineral elements that could not be fed in amounts low enough to cause death or interrupt the life cycle (interfere with growth, development, or maturation such that procreation is prevented). Thus, an essential element during this time period was defined as one whose dietary deficiency consistently and adversely changed a biological function from optimal, and this change was preventable or reversible by physiological amounts of the element. This definition of essentiality became less acceptable when a large number of elements was suggested to be essential based on small changes in physiological or biochemical variables. Many of these changes were questioned as to whether they were necessarily the result of a suboptimal function, and sometimes were suggested to be the consequence of a pharmacological or toxic action in the body, including an effect on intestinal microorganisms. As a result, if the lack of an element cannot be shown to cause death or to interrupt the life cycle, many scientists, perhaps a majority, now do not consider an element essential unless it has a defined biochemical function. However, there are still scientists who base essentiality on the older definition. Thus, there is no universally accepted list of essential trace and ultratrace elements.

Copper, iron, manganese, zinc, cobalt, iodine, molybdenum, and selenium are elements with evidence for essentiality that is substantial and noncontroversial. Specific biochemical functions have been defined for all of them. Boron and chromium also belong in the list of trace elements accepted as essential. Boron has recently been found to be required to complete the life cycle of fish and frogs. A defined biochemical function for chromium has recently been identified.

Circumstantial evidence is often used to contend that an element is essential. This evidence generally fits into four categories. These are:

1. A dietary deprivation in some animal model consistently results in changed biological function, body structure, or tissue composition that is preventable or reversible by an intake of an apparent physiological amount of the element in question.
2. The element fills the need at physiological concentrations for a known *in vivo* biochemical action to proceed *in vitro*.
3. The element is a component of known biologically important molecules in some life forms.
4. The element has an essential function in lower forms of life.

An element is considered to have strong circumstantial support for essentiality if all four types of evidence exist for it. There is strong circumstantial evidence for the essentiality of arsenic, nickel, silicon, and vanadium; thus, they are considered possibly essential elements.

If an element has only one or two types of circumstantial evidence to support essentiality, it generally does not receive widespread support for being a

possibly essential element. However, some of these elements have beneficial pharmacological actions (fluoride prevents caries; lithium is an antimanic agent), and some may eventually be found to be of some nutritional importance. Elements that fit in this category include aluminum, bromine, cadmium, fluorine, germanium, lead, lithium, rubidium, and tin.

Importance in the Diet

Trace and ultratrace elements have five known roles in living organisms:

1. In close association with enzymes, some elements are integral parts of catalytic centers at which the biochemical reactions necessary for life occur. Working in concert with a protein, and frequently with another organic coenzyme, an element attracts a substrate molecule and facilitates its conversion into a specific end product.
2. Some elements donate or accept electrons in reactions of reduction or oxidation. In addition to the generation and utilization of metabolic energy, redox reactions frequently involve the chemical transformation of molecules.
3. Some elements, particularly iron, bind, transport and release oxygen within living organisms.
4. Some elements have structural roles, imparting stability and three-dimensional structure to important biological molecules.
5. Some elements have regulatory roles. They control important biological processes through such actions as inhibiting enzymatic reactions, facilitating the binding of molecules to receptor sites on cell membranes, altering the structure or ionic nature of membranes to prevent or allow specific molecules or ions to enter a cell, and inducing genes to express themselves, resulting in the formation of proteins involved in life processes.

Although trace and ultratrace elements play key roles in a variety of processes necessary for life, except for iodine and iron, the occurrence of overt, simple, or uncomplicated deficiency of any trace element in humans is not common. The reasons for this are the powerful homeostatic mechanisms involved in absorption, storage, and excretion that work to maintain a rather constant amount of trace elements in the body despite varying intakes; and the consumption of diets with different types of foods from different sources which increases the opportunity to achieve adequate intakes. Nonetheless, reductions in health and well-being because of suboptimal status in some trace elements are probably not uncommon because of other factors. That is, most important in making trace and ultratrace elements of nutritional concern is that their metabolism or utilization can be impaired or their need can be increased by nutritional, metabolic, hormonal, or physiological stressors. This is exemplified by selenium, for which it is difficult to produce signs of pathology caused by a simple dietary deficiency in animals and humans. A stressor such as vitamin E deficiency or a viral infection is needed with selenium deficiency to obtain marked pathology such as that seen with Keshan disease, a cardiomyopathy that primarily affects children and women of child-bearing age in some areas of China.

Nutritional and Physiological Aspects of Specific Elements

Nutritional and physiological aspects of the essential elements copper, iron, zinc, iodine, selenium, and chromium are described in separate sections in this encyclopedia, and thus will not be described further here. For the other elements mentioned above, Table 1 and the following give a brief summary of findings that support their essentiality, possible physiological and biochemical functions, and conditions that might enhance susceptibility to pathological consequence because of low dietary intake.

Aluminum

The suggestion that aluminum might be essential is relatively new. It was recently reported that depriving goats of aluminum results in increased abortions, depressed growth, incoordination and weakness in hind legs and decreased life expectancy. Aluminum deficiency has also been reported to depress growth in chicks. *In vitro* biochemical actions which add circumstantial support to aluminum essentiality include the activation of the enzyme adenylate cyclase, enhancement of calmodulin activity, stimulation of DNA synthesis in cell cultures, and stimulation of osteoblasts to form bone. A concern about the evidence for essentiality is that the only deficiency sign found in more than one species is depressed growth. More of the other reported signs need to be confirmed by additional research groups or in other species. Moreover, in the deficiency studies to date, rather high amounts of aluminum were fed to supplemented controls; this gives the possibility that aluminum may have acted pharmacologically rather than nutritionally in these studies. The reported signs of deficiency do not give much insight into a possible biological function for aluminum. However, the *in vitro* findings suggest that it could possibly function as an enzyme activator.

Table 1 Human adult body content, adequate or typical daily dietary intake, and dietary sources of some trace and ultratrace elements

Element (symbol)	*Total adult body content*	*Adequate daily intake (ADI) or typical daily intake (TDI)*	*Dietary sources*
Aluminum (Al)	30–50 mg	2–10 mg (TDI)	Baked goods containing baking powder, grains, vegetables, tea
Arsenic (As)	1–2 mg	12–15 μg[a] (ADI)	Fish, shellfish, grains, cereal products
Boron (B)	10–20 mg	0.5–1.0 mg[b] (ADI)	Noncitrus fruits, nuts, leafy vegetables, pulses, legumes
Bromine (Br)	100–350 mg	2–8 mg (TDI)	Nuts, grains, fish
Cadmium (Cd)	5–20 mg	10–20 μg (TDI)	Shellfish, grains, leafy vegetables, organ meats
Cobalt (Co)	1.5 mg	2.4 μg as vitamin B_{12}[c] (ADI)	Green leafy vegetables, organ meats
Fluorine (F)	3 g[d]	3.0–4.0 mg[c] (ADI)	Seafood, fluoridated water, tea
Germanium (Ge)	3 mg	0.4–3.4 mg (TDI)	Wheat bran, vegetables, leguminous seeds
Lead (Pb)	120 mg	15–100 μg (TDI)	Shellfish, plant foodstuffs from high-lead soils
Lithium (Li)	350 μg	200–600 μg (TDI)	Eggs, meat, fish, milk products, potatoes, leafy vegetables
Manganese (Mn)	10–20 mg	1.8–2.3 mg[c] (ADI)	Whole grains, nuts, legumes
Molybdenum (Mo)	10 mg	45 μg[c] (ADI)	Milk products, vegetables, organ meats, pulses, grains, legumes
Nickel (Ni)	1–2 mg	100 μg[a] (ADI)	Nuts, chocolate, pulses, grains, legumes
Rubidium (Rb)	360 mg	1–5 mg (TDI)	Fruits, vegetables (especially asparagus), poultry, fish
Silicon (Si)	2–3 g	5–20 mg[a] (ADI)	Whole grains, cereal products, root vegetables
Tin (Sn)	7–14 mg	1–40 mg (TDI)	Nuts, canned foods
Vanadium (V)	100 μg	6–10 μg[a] (ADI)	Shellfish, mushrooms, condiments, prepared foods

[a]Estimated by author through extrapolation of data from animals.
[b]Estimated by author using data from both animals and humans.
[c]Recommended dietary intake (Co, Mo) and adequate intake (F, Mn) for adults 19 and older established by The Food and Nutrition Board, Institute of Medicine, National Academy of Sciences in *Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D and Fluoride* (1997); *Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B_6, Folate, Vitamin B_{12}, Pantothenic acid, Biotin and Choline (1998)*; and *Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium and Zinc* (2001). Washington, DC: National Academy Press. For Flourine and Manganese, the first value is for women, the second value for men.
[d]Mostly in bone; about 30 mg in soft tissue.

Arsenic

Signs of arsenic deprivation have been described for several animal species, including the chicken, goat, hamster, rat, and pig. In the goat, rat, and miniature pig, the most consistent signs of arsenic deficiency have been depressed growth and abnormal reproduction characterized by impaired fertility and elevated perinatal mortality. Other notable signs of deprivation described for goats include myocardial damage and death during lactation. Some biochemical changes that have been found in arsenic-deficient animals include depressed serum triglycerides in goats, depressed plasma taurine concentrations in hamsters, depressed hepatic *S*-adenosylmethionine and elevated hepatic *S*-adenosylhomocystine in hamsters and rats, and depressed hepatic putrescine, spermidine, and spermine concentrations and *S*-adenosylmethionine decarboxylase activity in rats. Factors enhancing the response to low dietary arsenic are stressors that affect sulfur amino acid or labile methyl group metabolism, including high dietary arginine and selenium, low dietary methionine, zinc, selenium and choline, and taurine and guanidoacetic acid supplementation.

In vitro findings that support arsenic essentiality include its ability to activate some enzymes, enhance DNA synthesis in unsensitized and stimulated human lymphocytes, and induce the isolated production of certain proteins known as heat shock or stress proteins. The control of production of stress proteins is apparently at the transcriptional level, and may involve changes in methylation of core histones. Arsenic can increase the methylation of the p53 promoter in human lung cells. Interestingly, although arsenic is thought to be carcinogenic by many, it has recently been found to be effective in the treatment of some forms of leukemia. Moreover, it has been suggested that arsenic can play an important role in human health because it was found that injuries of the central nervous system, vascular diseases, and cancer were correlated to markedly decreased serum arsenic concentrations.

A biochemical function for arsenic has not been identified in lower forms of life, although a bacterium, *Chrysiogenes arsenatis*, reduces As^{5+} to As^{3+} to gain energy for growth. However, there are enzymes in higher animals and humans that methylate arsenic with *S*-adenosylmethionine as the methyl donor. Arsenite methyltransferase methylates arsenite to monomethylarsenic acid, which is methylated by monomethylarsenic acid methyltransferase to yield dimethylarsinic acid, the major form of arsenic in urine. Findings to date indicate that arsenic might

have a function that affects the formation and utilization of labile methyl groups arising from methionine. Through this effect on methyl group metabolism, arsenic probably affects the methylation of important molecules such as DNA, which can affect the susceptibility to certain types of cancer.

Boron

Knowledge about the role and clinical aspects of boron in nutrition is just emerging. The biological function of boron has not been identified, but boron apparently has a role that influences the metabolism and utilization of several other nutrients. Thus, described deficiency signs and the pathological consequences of inadequate boron intake, because they can be affected by the intake of several other dietary substances, are numerous and variable. In humans, boron apparently affects calcium metabolism and hormone action. Among the various responses to low dietary boron are decreased serum 25-hydroxycholecalciferol, triglycerides, and ceruloplasmin; decreased erythrocyte superoxide dismutase; increased serum calcitonin, glucose, and creatinine; increased blood urea concentration; and decreased urinary hydroxyproline excretion. Boron deprivation also depresses the elevation in serum 17β-estradiol and plasma copper caused by estrogen ingestion; alters electroencephalograms such that they suggest impaired behavioral activation (e.g., more drowsiness) and mental alertness; and impairs psychomotor skills and the cognitive processes of attention and memory. A number of signs of deficiency have been found in animals that may eventually have some counterparts in humans. Signs of deficiency in the frog include increased necrotic eggs; high frequency of abnormal gastrulation in embryos; abnormal development of the gut, craniofacial region, and eye; visceral edema and kinking of the tail during organogenesis; and delayed tail absorption during metamorphosis. Signs of boron deficiency in the zebrafish include embryo death during the zygote and cleavage periods before the formation of a blastula during embryo development, and photophobia characterized by photoreceptor dystrophy in adults. Signs of boron deficiency in rats include the exacerbation of distortion of marrow sprouts and delay in the initiation of cartilage calcification in bones during marginal vitamin D deficiency, and decreased circulating concentrations of natural killer cells and $CD8a^{+}/CD4^{-}$ cells during antigen-induced arthritis. Factors enhancing the response to low dietary boron are stressors that affect calcium metabolism and utilization, especially low dietary intakes of vitamin D or calcium, and stressors that affect cell membrane function or signal transduction, including low dietary intakes of magnesium, potassium, or copper.

Over 70 years after being found essential for plants to complete their life cycle, a biochemical function apparently has been identified for boron in plants. Boron has a structural role in the cell wall, and also apparently a functional role in the cell membrane. These roles support the hypothesis that in humans and higher animals boron has a role in cell membrane function that influences the response to hormone action, transmembrane signaling, or transmembrane movement of regulatory cations or anions. It has also been hypothesized that boron is a metabolic regulator through its ability to complex with a variety of substrate or reactant compounds in which there are hydroxyl groups in favorable positions; the regulation is mainly negative.

Bromine

Evidence supporting bromine essentiality includes findings showing that bromide can substitute for part of the chloride requirement for chicks; bromide can alleviate growth retardation induced in chicks and mice fed iodinated casein; and insomnia exhibited by some hemodialysis patients has been associated with bromide deficit. The insomnia finding is tempered by the knowledge that, before barbiturates were used, doctors prescribed bromide for sleep. Recently it was reported that, when compared to goats fed 20 mg bromide kg^{-1} diet, goats fed 0.8 mg bromide kg^{-1} diet exhibited depressed growth, fertility, hemoglobin, hematocrit, and life expectancy, and increased spontaneous abortions. Although these latest findings give more credibility to the concept of bromine essentiality, the findings are still too limited. In other words, the deficiency signs of bromine need to be confirmed in additional species, preferably in another research setting. The evidence presented to support essentiality does not provide much insight into a possible biochemical role for bromine. Because it can partially substitute for chloride, bromide could possibly have a function similar to chloride.

Cadmium

Cadmium is best known for its intoxicating properties. However, in a study of goats, it was found that 9 kids from goats fed 15 μg cadmium kg^{-1} diet, when compared to kids from goats fed 300 μg cadmium kg^{-1} diet, exhibited muscular weakness; they were stiff and clumsy when they moved. Six of the 9 kids finally could not raise their heads and died; the other 3 were fed the 300 μg cadmium kg^{-1} diet which restored their mobility, feed intake, and growth. Muscle weakness that led to death also occurred in some

lactating goats fed the low-cadmium diet. It should be emphasized that the amounts of dietary cadmium in this study were much lower than those used in toxicological studies; these usually involve quantities measured in mg kg^{-1} diet and larger. Thus, the possibility that cadmium is an essential element in ultratrace quantities cannot be dismissed. Other findings supporting cadmium essentiality are that cadmium slightly stimulated the growth of suboptimally growing rats, and cadmium showed transforming growth factor activity or stimulated the growth of cells in soft agar. Because it is consistently associated with metallothionein, cadmium may have some biochemical effects via this biosubstance. Further study is needed before any substantial hypothesis about a biochemical function or physiological role, and conditions that might enhance the need for cadmium, can be presented.

Cobalt

Among the elements required for human health, cobalt is unique because its need cannot be satisfied by the mineral form. The only known function for cobalt is as the essential component at the center of the corrin ring of cyanocobalamin. Cyanocobalamin, also known as vitamin B_{12}, is a cofactor for three mammalian enzymes: methylmalonyl-coenzyme A mutase, methionine synthase and leucine 2,3-aminomutase. Biochemical signs of vitamin B_{12} deficiency include increased plasma homocysteine and urinary formiminoglutamate and methylmalonate; physiological signs include megaloblastic anemia, spinal cord demyelination, and peripheral neuropathy. Pathological consequences of vitamin B_{12} deficiency include pernicious anemia, memory loss, dementia, irreversible neurological disease, called subacute combined degeneration of the spinal cord, and death. It has been suggested that cardiovascular disease associated with elevated plasma homocysteine is another consequence of inadequate vitamin B_{12} intake. Factors enhancing the susceptibility to vitamin B_{12} deficiency include atrophic gastritis, *Helicobacter pylori* infection, gastrointestinal bacteria overgrowth caused by achlorhydria, celiac disease, drugs such as proton pump inhibitors and oral biguanides (used in the treatment of type II diabetes), vegetarian diets, and nitrous oxide anesthesia.

Cyanocobalamin is made in nature only by microorganisms; some of these are found in the rumen of ruminants. Thus, ruminants are the only animals that can have their vitamin B_{12} requirement fulfilled by the dietary intake of cobalt. Like other nonruminant animals, humans must get their requirement for cobalt by consuming foods rich in vitamin B_{12}.

Fluorine

It has been reported that goats fed less than 0.3 mg fluoride kg^{-1} diet, when compared to goats fed 1.5–2.5 mg fluoridekg^{-1} diet, exhibited decreased feed efficiency, depressed growth, histological changes in kidney and endocrine organs, and reduced life expectancy. These rather general effects have not been well accepted as evidence that fluorine is essential, because it is known that high or pharmacologic doses of fluoride have apparently beneficial effects such as the prevention of tooth caries; improvement of back pain and bone density in patients suffering from osteoporosis; improvement in iron absorption or utilization in mice and rats fed a diet marginally sufficient in iron; and slight improvement in the growth of suboptimally growing rats and chicks. High or pharmacologic amounts of fluoride also have been found to depress lipid absorption, alleviate nephrocalcinosis induced by high dietary phosphorus, and alter soft-tissue calcification caused by magnesium deprivation.

Although fluoride is not generally considered an essential in the classical sense for humans, it is still considered a beneficial element because of its ability to protect against pathological demineralization of calcified tissues (especially teeth). However, the possibility that fluoride is an essential nutrient should not be dismissed. It seems possible that fluoride could have a role in biological mineralization.

Germanium

Of all the elements discussed here, the evidence for essentiality is probably the weakest for germanium. Nonetheless, it is included here because of the attention germanium is receiving as an over-the-counter supplement. Germanium is touted as having anticancer properties because some organic complexes of this element have been found to inhibit tumor formation in animal models. It has been suggested that these compounds have such an effect because they influence immune function. A low germanium intake has also been found to alter bone and liver mineral composition and decrease tibial DNA in the rat. Additionally, germanium has been found to reverse changes in rats caused by silicon deficiency. However, more extensive and specific deprivation signs by at least one more research group are required before germanium can be considered a serious candidate for essentiality.

Lead

Lead is best known for its intoxicating properties. Nonetheless, some scientists strongly contend that lead is an essential element. One research group has reported that rats and/or pigs fed about 30 μg lead

kg^{-1} diet, when compared to those fed about 0.8 mg lead kg^{-1} diet, exhibited depressed growth; anemia; elevated serum cholesterol, phospholipids, and bile acids; disturbed iron metabolism; decreased liver glucose, triglycerides, low-density-lipoprotein cholesterol and phospholipids; increased liver cholesterol; and altered blood and liver enzymes. Another research group reported findings that indicated lead enhanced growth and improved hematocrits and hemoglobin concentrations of iron-deficient rat pups through a pharmacological action. Confirmation of the substantial animal deprivation findings by additional research groups is not likely to produce any widespread acceptance of lead having properties other than toxic. A defined biochemical function for lead will probably be required before this element is accepted as essential. Many of the reported apparent signs of lead deficiency are associated with iron metabolism; thus, lead possibly has a function that affects the absorption or utilization of iron. Furthermore, if lead is required, its need most likely would be enhanced by the stressor of suboptimal iron status.

Lithium

Like fluoride, lithium is another element with beneficial pharmacological properties; it has been used effectively in the treatment of manic-depressive psychosis. Lithium deficiency (<1.5 mg kg^{-1} diet) reportedly results in depressed fertility, birth weight, and life span, and altered activity in several liver and blood enzymes in goats. In rats, lithium deprivation (5–15 $\mu g\,kg^{-1}$ diet) results in depressed fertility, birth weight, litter size, and weaning weight. Additionally, these lithium-deficient rats had a decreased lithium content in testes, seminal vesicles, and epididymis, and relatively high concentrations of lithium in the pituitary and adrenal glands even after two generations on a low-lithium diet. These findings suggest that lithium may have a role in the regulation of some endocrine function. Other *in vitro* biochemical actions providing circumstantial support for lithium essentially include the stimulation of growth of some cultured cells and insulinomimetic action. Its ability to affect mental function perhaps explains the report that the incidence of violent crimes is less in areas with drinking water containing relatively high amounts of lithium.

Although two research groups using two animal species have reported similar signs of lithium deficiency (depressed growth and fertility), the signs were not very marked or specific; this has inhibited the widespread recognition that lithium is possibly essential. Additionally, the wide difference between apparent deficient intakes (based on rat experiments) and typical daily intakes inhibits the suggestion that lithium could be of practical nutritional importance. Thus, although more credence should probably be given to lithium essentiality, this most likely will not occur until a specific biochemical function is identified for this element.

Manganese

The essentiality of manganese for animals has been known for over 50 years. Deficiency causes testicular degeneration (rats), slipped tendons (chicks), osteodystrophy, severe glucose intolerance (guinea-pigs), ataxia (mice, mink), depigmentation of hair, and seizures. Manganese is a cofactor for enzymes involved in protein and energy metabolism, antioxidant action, and mucopolysaccharide synthesis. These enzymes include the metalloenzymes manganese-dependent superoxide dismutase, pyruvate carboxylase and arginase, and the manganese-activated enzymes phosphoenolpyruvate carboxykinase, glycosyl transferases, glutamine synthetase, and farnesyl pyrophosphate synthetase.

With such extensive knowledge about the essential nature of manganese, it is surprising that only a few descriptions of possible human manganese deficiency have come forth. The only description of an unequivocal case of human manganese deficiency was of a child with postoperative short bowel receiving over 90% of her nutrition parenterally, which was low in manganese; she developed short stature and brittle bones. In one attempt to induce manganese deficiency, men were fed a purified diet providing only 0.11 mg of manganese per day. They exhibited decreased serum cholesterol and a fleeting dermatitis. Calcium, phosphorus, and alkaline phosphatase activity increased in blood. However, short-term manganese supplementation (10 days) did not reverse these changes; perhaps a longer period of supplementation would have. Regardless of the lack of descriptions of human manganese deficiency, manganese is thought to be of nutritional importance by some scientists because low dietary manganese or low blood and tissue manganese has been associated with osteoporosis, epilepsy, atherosclerosis, impaired wound healing, and increased susceptibility to cancer. Thus conditions under which a low manganese status results in pathological consequences for humans needs to be determined. Perhaps exposure to a stressor that enhances the need for one of the manganese metalloenzymes, or high intakes of inhibitors of manganese absorption such as calcium, phosphorus, iron, fiber, phytate and polyphenolic compounds, will result in changes that demonstrate the nutritional importance of manganese for humans.

Molybdenum

Descriptions of human molybdenum deficiency are few. A patient receiving prolonged parenteral nutrition acquired a syndrome described as 'acquired molybdenum deficiency.' This syndrome, exacerbated by methionine administration, was characterized by high blood methionine, low blood uric acid, and low urinary uric acid and sulfate concentrations. The patient suffered mental disturbances that progressed to a coma. Pathological changes occurring in individuals with a genetic disease that results in a sulfite oxidase (a molybdoenzyme) deficiency include increased plasma and urine sulfite, sulfate, thiosulfate, *S*-sulfocysteine and taurine; seizures, brain atrophy/lesions, and mental retardation; dislocated lenses; and death at an early age.

Molybdenum functions as an enzyme cofactor. In humans, three molybdoenzymes have been identified; these are aldehyde oxidase, xanthine oxidase/dehydrogenase, and sulfite oxidase in which molybdenum exists as a small nonprotein factor containing a pterin nucleus. Molybdoenzymes oxidize and detoxify various pyrimidines, purines, and pteridines; catalyze the transformation of hypoxanthine to xanthine and xanthine to uric acid; and catalyze the conversion of sulfite to sulfate. A high sulfur amino acid intake could possibly be a stressor that would help induce signs of molybdenum deficiency in humans. In addition, because all of the molybdoenzymes can be involved in the detoxification of xenobiotic compounds, perhaps humans stressed by an exposure to certain xenobiotics have an enhanced need for molybdenum.

Nickel

The reported signs of nickel deprivation are extensive and are from several animal species. However, many of the described signs, especially those from early studies of nickel essentiality, may be of questionable validity because of the possibility that they were manifestations of pharmacological actions of nickel. More nutritionally designed subsequent studies indicate that signs of nickel deprivation include increased blood pressure, kidney damage, decreased sperm number and motility, and altered cyanocobalamin (vitamin B_{12}), glucose, triglyceride and sulfur amino acid metabolism. As with other ultratrace elements, the nature and severity of nickel deprivation signs are affected by diet composition or nutritional stressors; these include low dietary protein, inadequate dietary iron, high dietary simple sugars, and stressors that alter sulfur amino acid or labile methyl metabolism such as cyanocobalamin, folic acid or pyridoxine deficiency, or homocysteine supplementation.

Nickel has an essential function as an enzyme cofactor in lower forms of life. Nickel is a component of urease from bacteria, mycoplasma, fungi, yeast, algae, higher plants, and invertebrates. Nickel is present in hydrogenases from over 35 species of bacteria; it may be a common constituent of hydrogenases that function physiologically to oxidize rather than evolve H_2. Nickel is a component of carbon monoxide:(acceptor) oxidoreductase found in acetogenic, methanogenic, phototrophic, and sulfate-reducing anaerobic bacteria, and of a tetrapyrrole known as factor F_{430} found in methyl-*S*-coenzyme-M reductase that converts CO_2 to methane in methanogenic bacteria. Nickel is required for the hydrogenase gene to be expressed in *Bradyrhizobium japonicum*. These essential functions suggest that nickel may have a role in higher animals, including humans as a cofactor or structural component in an enzyme. It is also possible that nickel has a very basic function at the molecular level because *in vitro* studies show that nickel is a calcium channel blocker and can activate the Ca^{2+} 'receptor' on the osteoclast to elicit cytosolic Ca^{2+} signals.

The findings showing that nickel is so dynamic in lower forms of life, and that experimental animals are affected by nickel deprivation, provide almost overwhelming circumstantial evidence that nickel is essential for humans. Only the lack of a defined biochemical function in some higher form of life inhibits the general acceptance of nickel essentiality.

Rubidium

Rubidium is another recent addition to the list of possibly essential elements. Compared to goats fed 1 or 10 mg rubidium kg^{-1} diet, goats fed less than 0.28 mg rubidium kg^{-1} diet exhibited decreased food intake, growth, and life expectancy, and increased spontaneous abortions. These rather general deprivation signs need to be confirmed in additional species, preferably in another research setting, before strong consideration can be given to the possibility of rubidium essentiality. The reported signs of deficiency do not give insight into a possible biochemical function for rubidium. Because rubidium resembles potassium, it may have a role similar to potassium. Also, some findings have been obtained suggesting that rubidium possibly has a neurophysiological function. The rubidium content of brain differs significantly between defined functional regions, and rubidium can apparently enhance the turnover of brain norepinephrine (noradrenaline) and cause electroencephalogram activation in monkeys and rats.

Silicon

Most of the signs of silicon deficiency indicate an aberrant metabolism of connective tissue and bone. Silicon-deprived chicks exhibit structural abnormalities of the skull, depressed collagen content in bone, and decreased tibial articular cartilage, water, hexosamine, and collagen. Silicon-deprived rats exhibit skull structural changes, increased humerus hexose, decreased humerus hydroxyproline and alkaline and acid phosphatase activity, and decreased plasma ornithine aminotransferase activity (a key enzyme in collagen synthesis). The response to silicon deprivation can be modified by low dietary calcium and high dietary aluminum. For example, rats fed a diet low in silicon and calcium and high in aluminum accumulated high amounts of aluminum in the brain; silicon supplements prevented the accumulation.

Silicon essentiality in higher animals is supported by its essentiality for lower forms of life; it has a structural role in diatoms, radiolarians, and some sponges and affects gene expression in diatoms. It is required by some higher plants, including rice. Other findings supporting essentiality include findings that silicon is localized in the active growth area, or osteoid layer, and within the osteoblasts in young bone of mice and rats; silicon is chemically combined with the glycosaminoglycan fraction in several types of connective tissue; and silicon is required for maximal bone prolylhydroxylase activity in bone tissue culture.

The distribution of silicon in the body and the biochemical changes in bone caused by silicon deprivation indicate that silicon has an essential function that influences bone formation by affecting cartilage composition, and ultimately cartilage calcification. It is also likely that silicon has a function important for collagen formation; thus, it may be needed for proper wound healing.

Tin

The evidence for tin essentiality is quite weak. One research group has reported that tin deficiency results in impaired growth, decreased feed efficiency, alopecia, depressed response to sound, and changes in mineral concentrations in various organs. Other findings supporting tin essentiality include findings that it influences heme oxygenase activity, and has been associated with thymus immune and homeostatic functions. The oxidation reduction potential for $Sn^{2+} \Leftrightarrow Sn^{4+}$ is 0.13 V, which is near the potential of flavin enzymes. Thus, tin possibly has a role in some redox reaction.

Vanadium

The most substantive evidence for vanadium essentiality has come from deficiency studies with goats and rats. Compared to goats fed 500 μg vanadium kg^{-1} diet, goats fed 1–9 μg vanadium kg^{-1} diet exhibited an elevated abortion rate and depressed milk production. About 40% of kids from deficient goats died between days 7 and 91 of life, with some deaths preceded by convulsions; only 8% of kids from vanadium-supplemented goats died during the same time. Also, skeletal deformations were seen in the fore legs, and fore foot tarsal joints were thickened. Vanadium deprivation in the rat reportedly increases thyroid weight and decreases growth. The rat studies also showed that stressors that change thyroid status or iodine metabolism enhanced the response to vanadium deprivation. Factors that reduce vanadium absorption, including high dietary iron, aluminum hydroxide and chromium, may also enhance the response to a low dietary vanadium intake.

Vanadium has an essential function as an enzyme cofactor in lower forms of life. Vanadium is a component of some nitrogenases that reduce nitrogen gas to ammonia in bacteria, and for bromoperoxidase, iodoperoxidase, and chloroperoxidase in algae, lichens, and fungi, respectively. The haloperoxidases catalyze the oxidation of halide ions by hydrogen peroxide, thus facilitating the formation of a carbon–halogen bond. Other findings supporting vanadium essentiality have come from *in vitro* studies with cells and pharmacologic studies with animals. These studies show that vanadium has insulin-mimetic properties, stimulates cell proliferation and differentiation, affects cell phosphorylation–dephosphorylation, and affects oxidation reduction processes.

Because vanadium is so pharmacologically active, identification of a specific biochemical function for vanadium in higher animals and humans will be necessary to define the nutritional importance of this element. Based on the circumstantial evidence for essentiality, vanadium possibly has an essential function in some enzyme reaction, perhaps one that is involved in thyroid metabolism.

TRADITIONAL FOOD TECHNOLOGY

S Sefa-Dedeh, University of Ghana, Legon, Accra, Ghana

Introduction

The types of foods consumed by any population, methods of handling, marketing, distribution, processing, and utilization are deeply rooted in tradition and experience. In Africa, the conversion of the bulk of agricultural produce into forms readily utilizable by the population is achieved using simple indigenous methods. The technologies applied may be classified as traditional because they have strong links with the rural traditional environment. These technologies are also used in the towns and cities. The scientific principles behind the various unit operations may be the same as found in modern food technologies, but the mode of application may be different.

In general, traditional food technology may be conceived as encompassing the methods and tools used to transform agricultural commodities into intermediate or finished products. Many innovative techniques are applied to achieve various objectives and provide a wide variety of products which contribute to the curtailment of postharvest losses and national food delivery. Traditional food technology in many cases affects the economic and social life of the operators and may contribute to family nutritional status. Examples of these technologies found in Africa are described below.

Cereal Processing

The processing of cereals is very important with respect to the quantity, type, and quality of products. **Table 1** is a summary of processing methods for selected cereal foods. Important unit operations include soaking in water, size reduction, aflatization, aging or fermentation, cooking, and packaging. (*See* **Cereals**: Contribution to the Diet; Dietary Importance.)

Soaking allows imbibition of water into the grain and also facilitates size reduction. The soaking process may be prolonged for 2–3 days when dealing with very dry grains and this may initiate fermentation.

The production of cereal flour may be achieved by using manual methods (e.g., earthenware mashing bowl, stone grinding, or mortar and pestle), or mechanical size reduction. Traditional mashing bowls are made from clay and these have grooves on the mashing surface to facilitate size reduction. Many designs of mortar and pestles are available for different purposes. The disk attrition mill is very popular and can be found in many villages. (*See* **Flour**: Roller Milling Operations.)

In the processing of some cereal products, such as komi, maasa, and aboloo, approximately one-third of the flour is cooked into a stiff gelatinized paste. This paste is mixed with the remaining flour to form aflata. The process referred to as aflatization is critical for the development of texture in the finished product.

Three types of materials may be fermented in cereal processing: the grain (soaking of dry grain), dough or slurry (ogi, ga kenkey, fante kenkey), and wort extracts (alcoholic beverages, e.g., pito, burukutu, kaffir beer, amgba, busaa, and kibuku). In most cases, souring accompanies fermentation, and the process allows the material to develop desired flavor, texture, and processing qualities. Lactic acid fermentation is known to play a significant role. The fermentation of wort extracts in the production of alcoholic beverages is achieved through the activities of yeasts. In Ghana, some traditional processors apply an innovative technique to initiate fermentation in the wort extracts. A woven belt, about 3–4 cm wide and made from

strands of fiber, is used to trap yeast cells in the fermenting wort. The belt, which is usually covered with yeast cells, is dried in the sun after fermentation. It is used repeatedly for inoculating fresh wort. (*See* **Lactic Acid Bacteria**.)

Clarification of the wort is also achieved by adding an aqueous extract from the fresh stems of okra (*Hibiscus esculenta*). This allows the sedimentation of colloidal and suspended particles.

Food packaging is an important operation in traditional food processing. The packaging materials are derived from plant parts (Table 2). The material in some cases imparts color and flavor to the food (Figure 1). Methods of packaging vary.

Root Crop Processing

Root crops, such as cassava (*Manihot esculenta* Crantz), yam (*Dioscorea* spp.) and cocoyams (*Xanthosoma* spp. and *Colocassia* spp.), are important in the African diet. They form the bulk of the starchy staples utilized by the majority of the population. A variety of products are made from root crops. These may be classified into two groups: those processed exclusively from root crops, and those processed from root crops and other commodities (Table 3).

For most products, the processing technology may be at a rudimentary stage using simple techniques and implements; most are home-based operations. Table 4 is a summary of processing methods applied to root crops. Soaking, milling, or grating, fermentation, and drying are important. These processing steps may be applied to detoxify and modify in order to achieve a desired quality and preserve the commodity. (*See* **Cassava**: Uses as a Raw Material; **Vegetables of Tropical Climates**: Root Crops of Lowlands; Root Crops of Uplands.)

Soaking of root crops, especially cassava, is widely practiced. It serves as a means of detoxifying, softening, and initiating fermentation. In addition, soaking aids in manual size reduction. Size reduction achieved by either milling or grating is an important operation (Table 4), and is required in the processing of many root crop products. The operation initiates many biochemical (e.g., cyanide breakdown) and microbiological changes in the products.

Inoculants are added to grated cassava in the processing of agbelima in Ghana and attieke in the Ivory Coast. The inoculant for agbelima is called kudeme. It is made from cassava using different methods. The peeled cassava is blanched, toasted, or soaked in water. It is then wrapped in cloth and allowed to age for 2–3 days, during which it develops a disintegrated appearance. The inoculant is added as the raw cassava is grated, and this is known to affect the texture (smoothness) and promote fermentation.

Fermentation of root crops, especially cassava, is an important unit operation in processing (Table 4). The process contributes to flavor (souring) and texture development, as well as the detoxification (cyanide reduction) of the product. The detoxification is achieved through the activity of microorganisms or endogenous enzymes in the root crops.

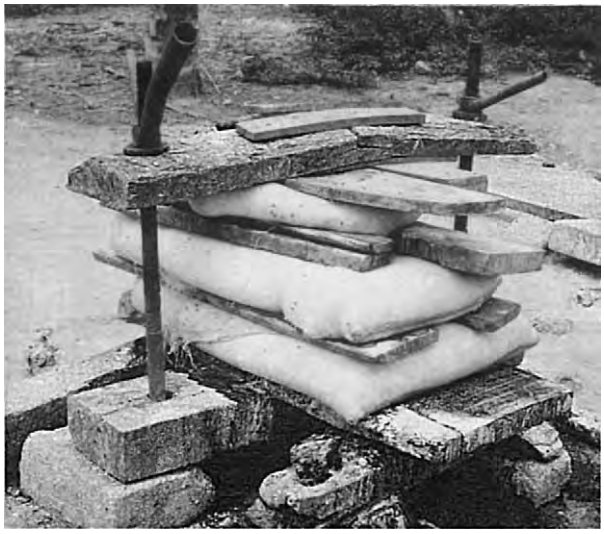

Figure 2 Dewatering of grated cassava for gari processing. Reproduced from Traditional Food Technology, *Encyclo-paedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Simple methods are used at the village level to dewater grated root crop products. These include the placing of heavy stones on the fermenting mash packed in a sack, or pressing the liquid with a manually operated press (Figure 2).

Drying of root crops is widely practiced in Africa. Peeled cassava chips are placed in the sun to dry for periods of 3–10 days. The conditions for drying vary and the product may develop characteristic color and flavor. (*See* **Drying**: Drying Using Natural Radiation.)

Fish Processing

Fish processing is carried out mainly by artisanal fish processors. The major products are dried, salted, fermented, and smoked fish. Table 5 is a summary of unit operations that may be applied in fish processing. (*See* **Fish**: Processing.)

The high perishability of fish demands that it is handled properly immediately after catching and until it is preserved for human consumption. The traditional technologies available for fish processing contribute to the reduction of postharvest losses.

The operations of importance in fish processing are washing, degutting, salting, fermentation, drying, and smoking. These operations contribute to the development of flavor, texture, color, and improved storage characteristics of the products. Different salting systems are used in traditional fish processing, e.g., dry salting and brine salting.

Salting serves to impart flavor and color to fish and has a profound effect on texture. Salted, fermented, or fresh fish may be dried in the sun to reduce the moisture content. In addition, fish may be dried without salting; examples are trigger fish (*Balistes forcipatus*), anchovy (*Engranlis encrasicholus*), and herring (*Sardinella aurita*). Drying of fish in the open sun (Figure 3) may introduce various contaminants into the product.

Smoking is an important operation used to give the combined effects of preservation, drying, and cooking to fish. Different smoking ovens are used. They are generally constructed with mud (Figure 4) and may be cylindrical or rectangular in shape. Recently, the Chorkor smoking oven has been introduced. This oven is reported to have a high fuel efficiency and give increased yield. (*See* **Smoked Foods**: Principles.)

Oil Seed Processing

Oil processing is an important activity in many rural areas in Africa. The major oils processed are palm oil (*Elaeis guineensis*), palm kernel oil (*Elaeis guineensis*),

coconut oil (*Cocos nucifera*), groundnut oil (*Arachis hypogaea*), and shea butter (*Butyrospermum parkii*). Although some large-scale modern mills have been set up in some areas, traditional technologies play a significant role in oil processing. (*See* **Ground Nut Oil; Palm Oil.**)

Table 6 is a summary of the unit operations associated with traditional oil processing. The general objective is to extract as much oil as possible from the tissues of the raw materials. Roasting is an important operation in coconut, palm kernel, groundnut oil, and shea butter processing. Simple systems are used for roasting the raw materials. Other operations of importance include aging, which is sometimes associated with fermentation. Boiling of extracts to release oil is a popular operation, normally performed after the extraction treatments, and salt may be added to aid extraction. The major problem in traditional oil extraction technology is the low yield of oil. (*See* **Vegetable Oils:** Oil Production and Processing.)

In addition to oil, the palm (*Elaeis guineensis*) yields a sap which is fermented to give palm wine. Fermentation is achieved as a result of the activity of

yeasts, bacteria, and other agents. Palm wine is drunk in a state of active fermentation. At the village level the product is tapped from the tree daily and is not preserved. The quality may deteriorate with time. In Ghana, palm wine is normally produced from palm trees after they have ceased to give economic yields of fresh fruits. The trees are felled before tapping. In Nigeria, palm wine production involves palm trees that are not felled.

Legume Processing

Grain legumes consumed in Africa are processed using traditional technologies. The products may be treated in the following ways: soaked in water and boiled; roasted; milled into flour; fermented; fried in oil; or steamed. (*See* **Legumes**: Dietary Importance.)

Dehulling of legumes is achieved using manual or mechanical methods. When performed manually it is very laborious, but the mechanical methods are not widespread. This limits the use of legumes in products requiring dehulled flour or meal.

Milling to produce flour is carried out for many products. At the village level this may be achieved by pounding using a mortar and pestle. Multipurpose mechanical grinders may be found in some communities and these are used for flour and paste production.

Fermentation of grain legumes is not widely practiced. In Ghana, two fermented legume products are dawadawa and koligo. Dawadawa is made from the seeds of the African locust bean (*Parkia biglobosa*). It is a food condiment which is popular in northern Ghana and Nigeria. Koligo is also made from the locust bean.

Legumes constitute an important source of protein in Africa. The processing of foods containing blends of legumes and cereals is practiced. These blends may be roasted, boiled, or milled together. Nutritionally, this is a good practice.

Meat Processing

Traditional technologies for meat processing are simple. They generally involve salting, spicing, aging, fermentation, drying, and smoking. Salting, drying, and smoking of meat are very popular among traditional hunters. Their products have a characteristic taste and flavor and may be stored for long periods. (*See* **Meat**: Preservation.)

The treatments applied to meat contribute to the development of color, flavor, and texture. Traditionally processed meats, usually game and wildlife, are highly priced and have wide acceptability. Examples of animals used for meat include giant African snail (*Achatina*), grasscutter (*Thryonomys swinderianus*), squirrel (*Atlantoxerus getulus*), and giant rat (*Cricetomys gambianus*).

Starchy Fruit Processing

Plaintains (*Musa paradisiaca*) and banana (*Musa sapientum*) are starchy fruits which may be processed in the ripe or unripe state. Ripe plantains, with their characteristic sweetness, find wide applications in the processing of various products. These may be boiled, steamed, baked, or roasted after pounding and mixing with other ingredients. Products such as ablongo, apiti, kakro, etc, ukpo gede, and mri jinoko are made from pounded ripe plantains. (*See* **Bananas and Plantains**.)

Dairy Processing

Traditional technology is applied in areas where animal husbandry is part of the social, economic, and agricultural activities. Milk products are processed for local consumption. (*See* **Milk**: Liquid Milk for the Consumer.)

Dairy products are generally consumed sour or curdled. In Kenya, for example, cows' milk is kept

in gourds for 2–3 days to allow fermentation, which leads to souring and the development of a coagulum. The fermented milk, called mala or 'milk that has slept,' has a sour taste and viscous consistency. (*See* **Fermented Milks:** Types of Fermented Milks.)

A product made from cows' milk in Ghana is referred to as wagashi. This is made by pasteurizing fresh milk. The stems of the Sodom apple, *Calotropis procera*, are cut and a milky exudate squeezed out. Salt is added to the plant extract and this is mixed with the pasteurized milk. The milk coagulates and the resulting curd is collected after squeezing the mixture in a cloth. A similar product, referred to as wara, is made in Nigeria.

General Characteristics

The major executors of traditional food technology are women. Most of them have a low educational level, operate from family houses, and have limited access to credit and improved technology. They need to be assisted to contribute better to the provision of healthy nutritious foods to the populations.

The equipment and implements used for traditional food technologies are simple. The labor input is high and efficiency is generally low. Progress has been made in upgrading some of the equipment to make them efficient. In a bid to increase efficiency, it is important that attempts are made to maintain the characteristic quality of traditional foods; otherwise, the improved technologies would not be readily accepted.

The products of traditional food technology are very important in Africa. They provide the nutrients required by the population. Some of the products, however, have very short shelf-lives and there is the need to improve shelf-life and build in convenience.

Other characteristics of traditional foods are the variability in the process and generally poor quality control. Some unit operations are inefficient, laborious, and time-consuming. Despite these disadvantages, the products will continue to play a critical role in Africa's search for solutions to the food problem. For this reason, the indigenous traditional technologies need to be studied and improved, and food scientists and technologists have an important role to play in this work.

TRANSPORT LOGISTICS OF FOOD

P van Beek, K Koelemeijer and D J van Zuilichem, Agricultural University, Wageningen, The Netherlands
M P Reinders, Agrotechnological Institute (ATO-DCO), Wageningen, The Netherlands
H F Th Meffert, Veluviaweg 3, Wageningen, The Netherlands

Introduction

Until the 1980s, logistics was synonymous with inventory control, production, and transport planning. In later years, the coordination between departments directly concerned with the flow of goods has attained more importance, covered by the term integral logistics.

The task of integral logistics is to develop control concepts for chain processes which avoid sub-optimization of links and result in win–win structures.

These chain logistics have to be based on knowledge of the processes involved, added value and cost per link, and a framework of obligatory and voluntary limitations. The flow of goods through the consecutive links is defined by:

- The composition of intermediate and/or final products.
- The production processes, and the protection required.
- The allocation of added value and cost throughout the links of the chain.
- The allocation of logistic processes in the chain with respect to the final quality of the product.
- The structure of the flow of information between the links.

The principal question is how to control the flow of goods to reach predetermined criteria of performance: flow time, cost, quality, level of service, flexibility, and added value.

The application of logistic principles in the agrofood industry has revealed specific characteristics of the chains of activities. This has resulted in the formulation of agro (food) logistics.

The specific characteristics relate to:

1. The variation of basic material in quality and composition, within lots of primary products, over the seasons. The final product must still comply with firm specifications.
2. The quality of intermediate and final products is strongly influenced by time and physical parameters (temperature, humidity, and atmospheric composition) in the chain between producer and consumer. Hence, there is a special need for protection.
3. Packaging technology plays an important role in the quality development of, as well as protection of, foods. It also influences the design of processes, size of units, and equipment for physical transformation and preservation by heating, chilling, or freezing.
4. The agrorhythm of the primary production must be obeyed for biological and technical reasons. Nevertheless, a constant flow of final products of constant quality must be achieved.
5. The production of linked products in the case of many intermediate and final products from one primary product.
6. The high expenditure on logistic efforts to bring the primary product in a suitable state to the consumer, which can amount to more than 300% of the value of the primary product.

Agrologistic Chains

While focusing on the agrofood industries, it should be recognized that other segments of agroindustrial activity form comparable logistic systems, including fisheries.

Based on these considerations, agrofood logistics can be defined as 'the integration of organization, planning, and control of acquisition, transport, storage, processing, and packaging related to the movement of foods from the origin of the primary product to the final destination at the point of consumption.'

Information technology, storage and transportation technology, and process technology must be considered to play a most important role in the flow of goods of agricultural origin.

Table 1 gives some idea of the mass flow in the food chain to consumers in Europe.

The following considerations are relevant for the control of chain processes for the distribution of food (and feed) products.

Perishability of Products

The quality loss of primary, intermediate, and final products requires the integration of quality models into the logistic concepts. The final product has to comply with requirements of warranted quality

Table 1 The food basket of European consumers, 1987/1988 (kg per capita per year)

and availability. These requirements have to be translated into actions within the links. Two main parameters can be recognized per link: residence or throughput time – a logistic parameter – and physical condition, e.g., temperature – a technical parameter. Generally, both fall within certain distribution boundaries.

The translation of requirements into conditions or actions in the chain is of crucial importance for the final result, in terms of cost and quality. Based on a fundamental knowledge of products and transformation processes, the cost-sensitivity of alternatives which comply with the given quality requirements of the market can be studied.

Autonomy of Actors

Agroindustrial chains consist, in most cases, of a large number of links, acting autonomously, and this hampers control and optimization. Concepts have to be developed which allow for effective control and avoid suboptimization; realization of such control concepts needs information technology. Effective and efficient systems and procedures for the exchange of information between the actors in the chain have to be developed.

Autonomy of actors and product perishability require special attention for the following items:

Modeling The impact of actions in the fields of process, storage, and transport technology can be evaluated with models that couple process parameters to product qualities. Technological models describe the development of quality (of a lot) of a product as result of flow time–environmental factor distributions along the chain. By adding economic information, such models are expanded to logistic models, which allow quality–cost optimization by comparison of various logistic channels. Such integrated models can take account of economic factors explicitly in terms of fixed and variable costs, for equipment, labor and energy.

Telematics Rationalizing the exchange and processing of communications by telematics allows improvement of the competitive edge of enterprises by increasing reach and/or flexibility. The investment in telematics has to be balanced against logistic advantages or savings in the total chain.

Logistic services In recent years logistic services to the customer have become an important part of the marketing strategy of companies. Many enterprises concentrate on core activities, thus creating new opportunities for service industries. Although not specific to the agroindustry, this development increases the number of links in the chain and therefore adds to the number of actors, and consequently can hamper control.

Audits, *ad hoc* or on a regular basis, of all actors in the chain, or commodity boards of a permanent character, are important instruments in accomplishing the necessary cooperation. Strong consumer preferences for high quality and freshness strengthen the need for effective control of logistic operations.

Operations research Agrologistics based on biological, physical, and economic sciences leads to complicated problem solutions. Operations research presents a common mathematical base whereby quantitative models are combined and developed, and algorithms are designed for planning logistic structures and procedures.

These models are integrated together in decision-support systems (DSS) for use in the development of logistic structures in enterprises and chain operations. Such models can be focused on the minimization of specific or general expenditure, with fixed values of performance criteria. The balance of fixed, location-dependent costs, and costs of transportation is one of the instruments of decision.

Logistic structures In comparison with general industry, the logistic structure of an agroindustrial enterprise depends more strongly on the primary product, its properties and availability, and the market for the final product.

Product design can be considered to be a most important variable for the logistic process. The composition of the product, based on primary and intermediate products, and production processes determines the location for production units for components, intermediates, and final products. In addition, telematics, technology and requirements for

production, processing, storage and transportation determine the logistic structure of an enterprise.

Models for the quantitative evaluation of the interdependency between these variables and their combined influence can be a powerful support for decisions on strategic, tactical, and operational levels for the structure and operation of agroindustrial systems and enterprises. The fresh market, in particular, presents examples of the distribution of effort, by translating the aim of a high quality level at the consumer into actions in the links of the logistic chain, e.g., to improve temperature management or to reduce throughput time, or both.

A Systems Approach

The characteristic of agrologistic chains appears to be the rapid quality degradation that results from suboptimal environmental factors and extended lead times. Logistical methods and techniques commonly being used in other industries, such as manufacturing resources planning (MRP) and optimized production technology (OPT) cannot be applied directly to distribution networks for perishable foodstuffs. Control of environmental factors and lead time in a complex system is essential for the success of the total operation. The complexity of the distribution of food products can be demonstrated by an aggregated picture of the logistic system (Figure 1).

Logistics in Organization

The management of an organization defines the goals with respect to product quality (e.g., minimum quality level at delivery, customer service level). In practice, it proves difficult to implement this policy at the operational level. The actors on the workfloor are specialists in their field: sales managers, technicians, operators, who all have different views of the target of the operation. With conflicting aims in the different echelons, the goals defined and agreed at management level cannot be implemented properly in the daily operation. In such cases, the creation of a Logistics Department between administration and operations departments can offer the necessary coordination and integration of effort.

The management must be able to communicate with, to coordinate, and to inspire the different areas of science and technology, contributing to agrofood logistics at the strategic, tactical, and operational levels (Figure 2).

Logistic Processes

A systematic approach to logistic chain operations reveals the basic tasks of conveyance of mass, energy, and information from origin to destination. Transformation and transport can be recognized as basic characteristic processes: product transformation to bring the material to be conveyed into a certain condition, goods transformation to bring it into a shape to comply with the requirements of the transport processes. For agrofood logistics in distribution networks, preservation processes and unitization processes are important links to food and transport technology. Packaging plays a role as well in both goods and product transformation, for unitization as well as conditioning (Figure 3).

Customer Service

Customer service links logistics to marketing. As the output of logistic operations is perceived by the customer in terms of products and services performance, a marketing approach is needed to determine the optimal level of logistic efforts throughout the supply chain.

A logistic system contributes to distribution channel profits by enhancing the efficiency of movement of goods, insuring quality maintenance, and providing time and place utility. In addition to a cost-oriented

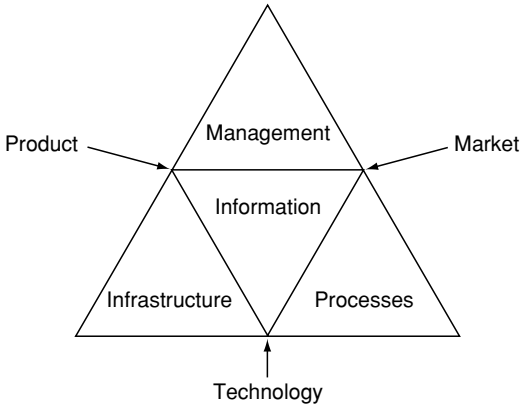

Figure 1 The agrologistic triangle. © ATO-DLO.

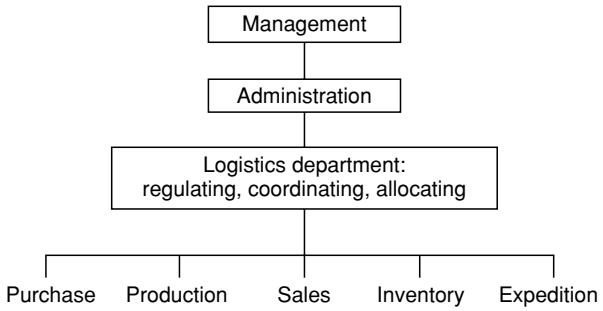

Figure 2 Logistics in the organization of an enterprise. © CIVO-TNO.

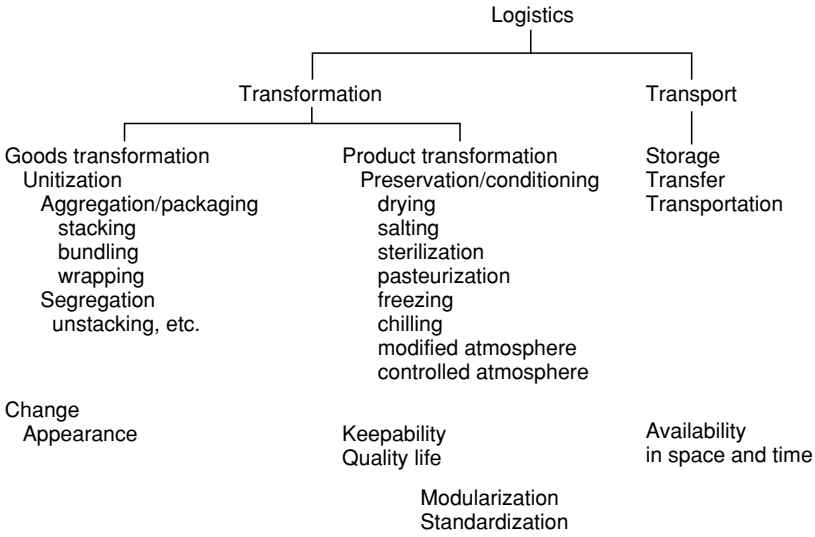

Figure 3 Physical processes relevant for agrofood logistics.

approach, the revenue-generating role of customer service and its use as a tool of competition have increasingly received attention. Logistics defines customer service as 'a process for providing significant value-added benefits to the supply chain in a cost-efficient way.'

In models of logistic operations, customer service is generally considered as a constraint which must be met while minimizing costs. More attention, however, should be given to the maximization of customer service within cost constraints. In this perspective, customer service becomes an instrument of competition.

Relevance of time and place utilities, and quality maintenance, which add value to the product, shifts along the consecutive links of logistic channels from mainly technological to mainly consumer-oriented aspects.

At the central storage and distribution center, mass and volume of units, protection against abuse (mechanical and thermal), and information are important.

On the retail level, reliability, speed, and punctuality of delivery and accurate compliance with the ordered quality and quantity are most important. Services of the preceding link in terms of continuity, communication, flexibility, and claims handling become more important.

Consumers do not explicitly consider technology and logistics, but instead focus on subjective attributes, like sensorial aspects, convenience, nutritive value, keepability, and waste disposal. Retailers translate consumer desires into their own demands.

Marketing activities are traditionally described in terms of the four 'big Ps' of product, place, price, and promotion:

- Product: the commodity that the market is looking for, including purchase of the raw material, processing and packaging, pollution, and politics.
- Place: availability of the product in space and time at consigned points of destination at the convenience of the consignee.
- Price ultimately expresses the monetary value of the product in the marketplace for the consumer, but determines at the same time the span between cost and revenue, the possible profit.
- Promotion is a means of dealing with nonuniform supply and demand. Customer service may be used as an argument in promotion. On the whole, promotion is strongly interrelated with the flexibility of the logistic system to respond to discontinuities in product flow.

Circumstantial factors can be designated the six 'small Ps':

- Purchase reaches forward to the raw material in order to meet the requirements for processing in the chain.
- Processes are necessary to bring the primary product into a state and shape to satisfy the different requirements of handling along the logistic chain, and of usage at the ultimate customer.
- Package indicates not only mass or number, volume, and shape in which the product satisfies the various requirements in the logistic chain, but also the protecting, preserving, and presenting function, especially in the downstream links of the chain.
- Pollution: environmental concern is becoming an important aspect concerning the use of resources, raw materials and energy, contributing to ozone

depletion and the greenhouse effect. Also, product losses and waste disposal (product and package material) must be considered. Product pollution by production, processing, and packaging has to be excluded for reasons of public health.

- Politics interfere on different levels in the distribution of perishable foodstuffs. Public health authorities have developed a strong interest in food processing and packaging, which has recently been paralleled in the field of pollution. Also, prices, conditions, and quality life (date marking) are under political control all along the chain. Regulations, guidelines, and standards for equipment, processes, and labor conditions can greatly affect the logic of logistic chains and, consequently, the cost/quality balance, which demonstrates the need for anticipating research and information.
- Public opinion: apart from political pressure, attitudes and opinions determine the actions of the consumer. Attentive retailers are aware of these marketing aspects, and try to follow trends of consumer preference.

Integration of Logistics and Marketing

The need for efficient distribution of perishable products, i.e., to meet quality requirements at minimum costs, has strengthened the need for integral planning of logistic activities. Customer service, considered as a goal variable and a constraint at the same time, must be analyzed from a total distribution channel perspective. This implies an integration of logistic and marketing theories.

Once the way is open to performing logistic operations in order to maximize customer service, the issue of allocation of channel cost–benefits emerges. This may give rise to alterations in distribution channel structures, resulting in forward or backward integration along the chain, and changes in distribution channel power.

Budgeting and Accounting

The growing need for the quantification of logistic efforts has induced new developments in budgeting and accounting, such as direct product costing (DPC) and direct product profitability (DPP). In view of stricter energy management and rising energy costs, energy accountancy has been used to compare different products with respect to their energy consumption, including processing, handling, and packaging. The same can be done for other cost elements, as long as they are accounted separately.

Integral Cost Accountancy The integral revenue-expenditure concept can be recognized in cost optimum production planning technique (COPPT), which requires an accurate integral cost-accounting system per unit of sales, including fixed and variable, labor, energy and maintenance costs of processes and equipment through all relevant links of the logistic system.

Total cost analysis The formulation of a total cost analysis is not without practical problems; the appreciation of quality development and its balance against capital costs represents a specific problem.

Modeling

Multiechelon models have been developed that integrate the links of the distribution channel. Although customer service is considered, in a narrow sense, as out-of-stock and/or delivery time, these models offer possibilities for modeling logistic operations, and enable users to consider customer service as goal, variable, and constraint.

The Physics of Physical Distribution

Logistics and Technological Processes

Two types of processes play important roles in logistic chains – transformation and transport. Transformation brings the products into a state and shape in which they can endure the rigors of the transport processes.

Goods transformation brings the products into a form convenient for handling in the links of the logistic chain.

Product transformation conditions the product into a state in which it can comply with the requirements of quality at the point of destination.

Transformation

Goods transformation Agricultural products become available in a given form, which is generally not the most convenient for handling in a transport chain. Small products have to be aggregated into larger units; large products have to be segregated into smaller units. Portioning, packing, and utilization are common physical processes in agrofood operations. For fluid products, the implementation of these processes is simple compared to those for solid products which cannot be fluidized. Mechanization of goods transformation is easy to accomplish for fluidizables. Solid products are more difficult to handle. Mechanization closely follows human actions. Sorting and grading are prerequisites for the formation of commercial units for the trade and, as such, are part of customer service.

Goods transformation processes affect the appearance of a product. Generally, an appearance has to

aggregate, to protect, and to present both the product and information about the product. It must also fit into the systems of transport, distribution, information and, most important for perishables, of conditioning.

These requirements can lead to contradictions with conventional solutions, and require special measures with respect to conditioning, design of appearances, and creation of the necessary external conditions. The importance of the functions of an appearance varies with the size of the unit. For the smaller units and articles, the presentation function often outweighs the protection, whereas the larger preparations mainly serve aggregation and protection purposes. With the larger size, the protective function includes facilitation of conditioning, which switches from outside to inside, e.g., pallet versus container (Table 2).

Unitization The formation of units by aggregation to larger appearances, or by segregation to smaller ones, is summarized as unitization. In more detail, stacking, bundling, wrapping, and their counterprocesses are concerned.

Unitization is a necessary step in rationalizing transport processes. Its interference with transformation and conditioning processes should be fully recognized. Methods and materials for unitization, such as glueing, bundling by straps, wrapping in foils or nets, by pallets, slip-sheets, slip-pallets, shipping cases, and ballet boxes, isolate the product from ambient conditions by the dimensions and properties of the material. Thus, more or less protection, e.g., resistance against external conditioning, is built up by insulation or permeability. Perforation of the separating covers and application of pressure differences across the units are means of controlling external conditioning.

Modularization It is obvious that a coordinated relationship between the dimensions of appearances greatly rationalizes handling, utilization of storage, and transportation space and use of equipment. An early example is the unicube concept, developed in The Netherlands, *c*. 1965. In later years, the National Materials Handling Bureau of Australia (*c*. 1980), the International Organization for Standardization (ISO) (in the early 1980s) and the US–Canadian Modularization-Unitization-Metrification Project pursued the same line.

A problem rises from the choice of the module. The early adoption of the manload as the module (1968) has led to diverging developments in unit loads, leading to the continuation of the problem in the domain of transport units. The result is a very unsatisfactory situation of competing unit loads and incompatible transport units.

Standardization Standardization of mass and dimensions is necessary for the operation of an efficient logistic system. Good examples are the Australian and the North American approach. Unfortunately, Europe cannot adopt a uniform, simple system as long as industries adhere to two standard unit loads. In spite of the recommendation of the ISO to prefer the 1200×1000 mm unit as maximum plan view size (MPVS) or gross unit load size (GULS) and central modular standard, some industries stick to 1200×800 mm units, which makes the manload (600×400 mm) the central module on a lower level of aggregation and means a loss of flexibility of configuration within the unit load.

Modeling Goods transformation process modeling has to start from the dimensions of the articles that have to be accommodated in the subsequent aggregated unit, taking account of the necessary tolerances for the design, stacking, deformation, and conditioning.

Design systems The design of modular packaging is greatly facilitated by the existence of transport package and loading pattern selection tables and palettizing charts, as well as graphical and graphical-plus-calculator design systems. Comprehensive computer programs are available to evaluate all factors influencing the basic package design. They are consulted to determine all three dimensions of the unit

Table 2 Thermophysical properties of appearances; results of goods transformation

Domain	*Mass (kg)*	*Diameter (m)*	*Cooling time (h)*[a]	*Overtemperature (°C)*[b]
Product	0.1	0.05	0.2	0.2
Article	0.5	0.1	2.0	1.0
Manload	15	0.3	18	6.0
Unit load	500	1.0	180	Thermal explosion
Transport unit	7500	2.5	900	Thermal explosion
Storage unit	30 000	5.0	3600	Thermal explosion

[a]With external conditioning.

load and the manloads which form it. Thus a means is provided to produce an extensive list of options and to evaluate the various compromises rated against the factors contained in the input data. Computer programs also allow for the use of average industry allowances for many factors involved, which reduces the preparation work. With regard to conditioning, the thermophysical properties of product and package have to be considered, as well as penetration by the conditioning medium, which is generally air.

Product transformation By various processes, agrofood products can be transformed into a state in which they can meet the requirements of a given transport process within given limits of quality. The choice is between chilling, freezing, pasteurization, sterilization, salting, and drying, in order of increasing keeping times and decreasing approximation to the fresh product. Food preservation technology is thus linked directly to agrofood logistics. Irradiation, modified-atmosphere (MA) and controlled-atmosphere (CA) treatments also transform the product with respect to its keepability. Generally, these techniques require close temperature control as well. There is also a link to packaging with respect to heat and mass transfer. Refer to individual processes.

Quality life Keeping time or quality life, as dependent on the environmental conditions around the product, limits the throughput time of products in the logistic chain. Parts of the total quality life are often considered separately, as storage life (the first part) or as shelf-life (the last part) of the total economic quality life.

The quality life of a product is limited by the rate of quality loss or deterioration and the imposed limitations. A difference can be made between high-quality life and practical quality life; these differ in the degree of change of characteristic properties of the product. Development of quality with time can be attributed to different principal processes of a physical, chemical, or biological nature, the rates of which are dependent on environmental factors such as temperature, water vapor concentration or pressure deficit, and atmosphere composition. (*See* **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability; Shelf-life Testing.)

These quality-affecting processes act in different ways on two main groups of foodstuffs:

1. Dead products: subject to (bio)chemical and microbiological processes.
2. Living produce: in addition exhibiting biological processes, dissimilation with O_2-CO_2 conversion and heat production.

N.B: fermentation and microbiological growth can also cause CO_2 and heat production. Both groups can be divided into two subgroups:

A. Those in need of a process of maturation to reach maximum consumer quality: red meats, cheeses, fresh fruits (banana, peach, pear, plum).
B. Those which start commercial life at maximum consumer quality: sterilized, pasteurized, and frozen products, white meats, fish, fresh vegetables, mushrooms, bakery products, prepared meals.

Group A products, represented by *c.* 16% of the food basket, need controlled holding times and conditions to reach maximum quality. From then onwards, they require limited throughflow times in the logistic chains, adjusted to the environmental conditions for tolerable quality loss, as do group B products.

Quality models The necessity for quality models to be incorporated into logistic models results from the great number of alternative logistic processes which have to be evaluated in the design of distribution chains. Quality loss of food is largely determined by the cumulative effect of the environmental conditions throughout the handling history of the product. The simple rules of additivity and exchangeability are obeyed better the less the product is processed.

It is impractical and expensive to conduct product spoilage tests for all possible scenarios. Mathematical models can be chosen after verification by simple experiments on the basis of statistical tests on the lack of fit against experimental error. By measuring and modeling deterioration reactions, quantitative data are collected, and models as well as model parameters can be generated. For integration into process or logistic models, quality models for the influence of environmental factors should comply with the following, in the order presented:

1. The broadest possible application on the processes considered.
2. Appropriate consideration of the mechanism of the reaction.
3. Simplicity of determination of parameters, and application.
4. The smallest deviations from experimental values.
5. No discontinuities.

These models may be based on the time-course of specific components or properties from physical, chemical, or sensorial analysis or, in the absence of objective information, on expert judgment, always keeping in mind the possibility of adjustment of the quality scale of the chosen model.

Zero or first-order reaction mechanisms can cover practically all deterioration processes regardless of their nature. Arrhenius-type relationships satisfactorily describe the influences of temperature; linear, hyperbolic, or squareroot relationships require the same type of parameters. For other environmental factors, more direct relationships to the driving force exist. For the combined influence of temperature and gas concentration, special models have to be derived from specific experimental research.

Combined models For temperature-dependent deterioration processes, combined heat-transfer models are most useful. They allow prediction of the effects of management decisions on quality life of conditioned products, especially on the shelf-life. Better protection during transport processes, by reducing the time–temperature load, can be balanced against lower temperature levels or shorter flow-times in one or more links of the chain.

It is obvious that the performance of deterioration tests for all possible scenarios is highly impractical and expensive. Mathematical modeling, computerized on the basis of experimentally established parameters, and a few validation experiments can perform the necessary sensitivity analyses and assist in finding the optimal operational conditions.

Chain reactions A product passing through a logistic chain generally encounters a sequence of environmental conditions. The final state when leaving the *n*th link of the chain is decisive. If the prerequisites of additivity and exchangeability are fulfilled, the result of the chain reaction can be described on the basis of average time and temperature conditions by a sequence of ideal reactors.

Temperature and time distributions Average time and temperature provide only a crude way of describing the flow of goods and the influence of environmental conditions in the chain. Statistical mathematics offers a way of dealing with the time and temperature distributions encountered in practice. The Weibull distribution appears to yield the most general model for time and temperature distributions in the links of logistic chains. The background for the ready modeling of logistic distributions by the Weibull function is given by the fact that the minimum value is given by a solid physical condition, whereas the maximum is open to stochastic influences. Two parameters for scale and shape allow for the modeling of a wide range of practical situations, from plug flow to ideal mixing, with all possible intermediate situations.

Arbitrary distributions A more direct approach can be based on the fractional distribution of time and conditions in the links of the chain. The stepwise calculation of the final quality distribution after a number of links, from the distributions of time and temperature in the links, and the initial quality distribution, can easily be computerized. This approach presents a means of balancing profits of quality retention against expenditure for throughflow time and improvement of conditions, if the cost–revenue analysis is done in appropriate figures.

Standardization As in goods transformation, product transformation also presents reasons for standardization in terms of quality life, temperature sensitivity and, as a consequence, keeping equipment, storage facilities, as well as transport vehicles and transfer processes. Products can be categorized according to keeping temperatures and quality life at

Table 3 Categories of refrigerated foodstuffs[a]

Code	*Reference temperature T_{ref} (°C)*	*Temperature increment B (1/K)*	*Examples*
DF	−18	Positive/negative	Regulations
F	−12		Deep-frozen, frozen products
C04	+4	Negative	Small meat portions, ready-to-eat vegetables, pasteurized meals, salads, large meat portions, sterilized meals, dairy products
C07	+7		
F00	0	Positive	Leafy vegetables, berries, pears
F04	+4		Apples, oranges, potatoes
F07	+7		Green beans, subtropical fruits
F10	+10		Avocado, mango, subtropical, and tropical produce
F13	+13		Bananas, pineapple, tropical produce

Quality life at temperature T: $t = t_{ref} \exp[B(T - T_{ref})]$.

[a]Temperatures and commodities quoted are arbitrary examples. They can vary by national regulation or specific product requirements. From Meffert HFTh (1990b) Chilled foods in the market place. In: *Processing and Quality of Foods*, vol. 3. London: Elsevier Applied Science, with permission.

Table 4 Time–temperature matrix of keepability characteristics[a]

Denomination	*Time, t_{ref} (days)*	*Temperature increment, B(1/K)*			
		< 0.05 Low	*0.05–0.15 Medium*	*0.15–0.25 High*	*> 0.25 Extra sensitive*
Chilled product (category CO4)					
Extra short	< 3	Kitchen-ready vegetables			
		Leeks	Cabbage	Carrots	
Very short	3–7		Minced beef	Poultry	Pork
Short	7–14		Beef slices	Pasteurized milk	
Medium	14–30		Beef joints (CO_2-packed)		
Long	> 30		Lamb carcass (cryo-vac)		
Frozen product (category DF)					
Extra short	< 30				
Very short	30–100	Cooked meals	Cured pork		
Short	100–200		Seafood		
Medium	200–400	Cream	Carcass meat	Vegetables	
Long	> 400	Butter, lamb	Raw dough, poultry	Green peas, fruit	

[a]Examples are given for two categories from **Table 2**.

From Meffert HFTh (1990c) Quality development of foodstuffs under time–temperature conditions in cold chains. In: *Progress in the Science and Technology of Refrigeration in Food Engineering*. Paris: International Institute of Refrigeration, with permission.

a reference temperature and temperature sensitivity, as shown in Tables 3 and 4.

Standardization in such a way facilitates the design of distribution processes in existing chains and of new operations, especially if paralleled by a standardization of storage and transport equipment, and transfer processes, in terms of operational performance, e.g., temperature maintenance by a degree of thermal protection derived from the nonaccomplished temperature fraction. Existing classification and standardization of these types of equipment and processes do not attempt to enter this problem area. ISO, ATP, and Lloyd's classification are based on technical rather than technological performance characteristics.

Recent European Community and national legislation concerning the temperature of frozen and chilled products may create a need for a more operational approach to product, equipment, and process classification, or even standardization, as explained above.

Transport = Storage–Transfer–Transportation

The second, more genuine logistic process is that of transport. Generally, the transport in a logistic chain involves mass, energy, and information (M–E–I). Mass flow downstream and information flow up- and downstream are easily recognized. Less obvious is the transport of energy. For refrigerated products, this aspect is closely related to product transformation and conditioning. Attention is required for reasons of economy in quality protection.

Mass The most apparent transport process is that of mass. However, as agrofood products are mostly in the category of high-volume goods (load density lower than $500\,kg\,m^{-3}$), it is more appropriate to treat transport in agrofood logistics in terms of volume. Figure 4 depicts a scheme of the mass flow in distribution chains for refrigerated foodstuffs.

All activities of moving goods between origin and destination can be understood as transport, storage being transportation with zero speed. Generally, the goods pass a number of storage and transportation links on their way through the chain. All links are interfaced by transfer or transshipment processes.

As a rule, a reduction of the links in the logistic chain reduces cost and losses; in addition, it saves time. This pleads for careful consideration of the necessity of the links, which can lead to integration of processes, such as product transformation by chilling or freezing, into the transportation link. In-transit treatments, thermal or by gas injection, are also practiced for disinfection or disinfestation.

The second important rule is the rationalization, for time and cost reasons, of the transfer process, which links transport closely to goods transformation.

The maintenance of the established condition of the product is a specific task in the transport chain of agrofood products, in addition to the general task of conveyance.

Interrelationships with transformation and conditioning Modular coordination, i.e., dimensional capability of appearances and equipment as elements of a system, is a prerequisite for rationalization of transport processes, and as such subject to standardization. Elements of a covering system for modular coordination are represented by ISO standards on manloads, unit loads, and transport units in ISO 668–1968, 3676–1983, 6780–1988, 3394–1984,

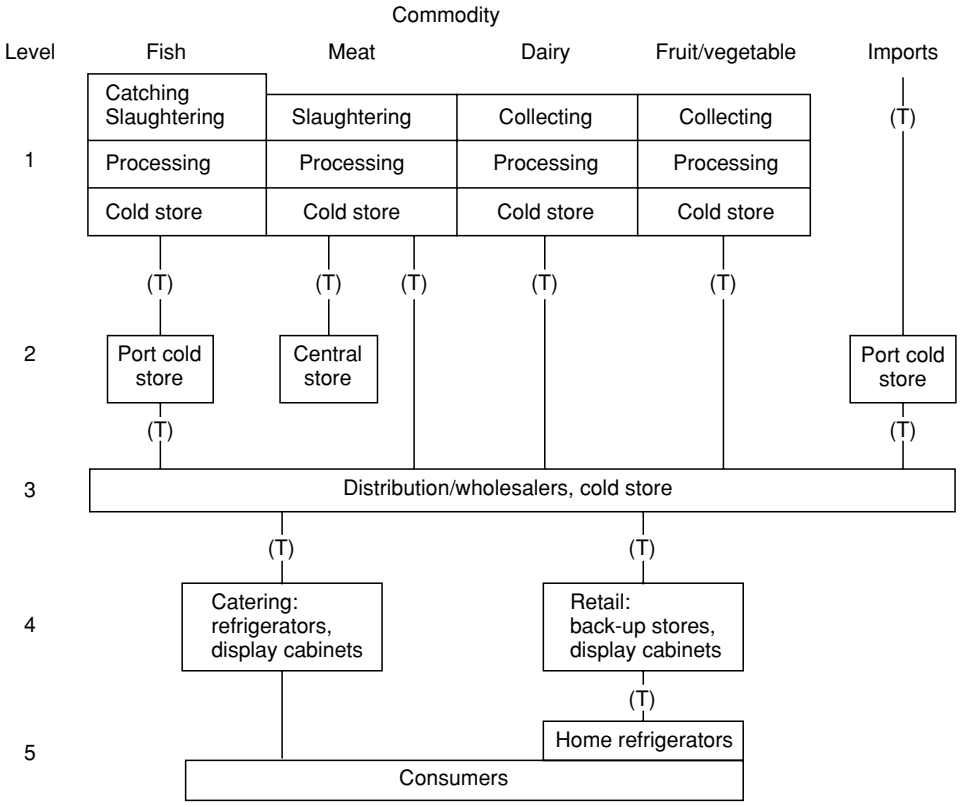

Figure 4 Principal structure of distribution chains for refrigerated foodstuffs (T), transportation and transfers. Note that for products with extremely or very short quality life, the distribution link is cut short by direct links between processing and retail/catering. Adapted from Nowotny S (1988) Computer-modeling of cold chain systems. In: *Cold Chains in Economic Perspective*, Paris: International Institute of Refrigeration.

1496/2–1988. Unfortunately, the system is not practical for conditioned units, because of the space requirements for insulation, air circulation, and the necessary equipment for conditioning. The Australian Standards represent a more logical coordination. Revision of the dimensions of the transport unit for better compatibility with unit loads has so far met much opposition. Elements for a better-fitting system appear in European and US traffic regulations, and in the standards of the European Normalization Centre (CEN) for removable vehicle bodies (swap-bodies), allowing extra width for conditioned road vehicles.

For perishable products, conditioning is necessary to keep the quality loss in logistic chains within a preset span. Distribution of time and conditions, the most important being the temperature, are the governing process variables.

Methods of unitization generally interfere with conditioning processes. Pallets, slip-sheets, slip-pallet, etc., and wrappings influence the distribution of conditioning air. Perforations and build-up of pressure differences around the unit promote air penetration. This must be considered in the choice of tolerances which make the modular system work. The larger the unit handled, the shorter are the transfer times per mass between the links of the transport chain. Shorter times of exposure, together with a small surface-to-volume ratio, improve the thermal protection.

Storage

Facilities for storage in logistic chains are destined to buffer discontinuities of the product flow between supply and demand. They can be subdivided into types differing in task, size, and operational conditions:

1. Primary or production stores. Storage space at the production site serves as a buffer volume between the discontinuities of the inflow from the production process and the outflow of products to secondary stores. Residence times are short. The band of conditions cannot be kept small because of the high turnover. For unitized products, row storage on pallets is preferred.
2. Secondary or central stores. In the case of seasonal production, central stores are loaded within a

short period, but emptied slowly. Volume-saving block storage of unit loads or transport units, if necessary with supporting frames, minimizes investment in conditioned space. The principle of first-in–first-out (FIFO) cannot be fully realized because of the limited accessibility of the units.

Nonseasonal products are supposed to pass central stores rapidly to keep investment in space and product low. Owing to the high turnover rate, the FIFO principle cannot be strictly observed, but through-flow racks, gravity or mechanically driven, can help.

Storage conditions are optimized within a narrow band of environmental factors. Residence times vary according to the type of product, but tend to be a substantial part of quality life.

3. Tertiary or distribution stores. Distribution stores are mere turnover facilities designed for rapid handling of flows of various products. Again the FIFO principle cannot be applied; mixing of products of different age is usual. Incomplete unit loads remain longer in store than complete ones.

   Rack storage, manually or automatically operated for separate accessibility of units, is frequently used, in spite of the large loss of space. Arrival and departure areas are separated, and commissioning areas are provided, mostly with only partial protection against external conditions. Environmental conditions are not optimal, but residence times are comparably short. In partially protected areas, a high flow rate of products must keep the ambient load low.

4. Quarternary stores, retail cabinets. At the retailers, display cabinets of fractions of a cubic meter shelf volume per meter present the product to the consumer. Because of the great influence of the ambient conditions in the shop, and the fact that the product is handled in articles rather than manloads, conditioning is possible only within a broad band. This restriction must be compensated for by extremely short, carefully watched residence times, which also keep at bay the comparatively high costs per volume per time in this link.

   For the reception of a discontinuous flow of goods at the retailer, a conditioned back-up store can form a buffer. This is kept as small as possible. Row storage is used. Conditioning is problematic, owing to the high turnover rate; thus residence times have to be kept at a minimum, depending on consumers' buying attitudes.

Standardization Generally, storage facilities up to tertiary level are built to customer specifications, including layout for unit loads and, in some cases, even whole transport units. Standards apply for technical equipment. Exceptions are the standard cold stores in East Europe, which are classified for layout, size, and storage conditions.

The usage of space by different stacking methods can be given approximately as:

- Block storage 100%
- Movable racks 80–90%
- Row storage 60–80%
- Rack storage 50–60%

depending on the height. Additional space has to be provided, according to the equipment, for the conveyance of goods.

Heat load from ambient and air circulation performance, which determine the quality of conditioning, are chosen for economic considerations, including losses of mass and quality. Small storage and retail cabinets are built serially. Detailed general standards exist only for refrigerated display cabinets (ISO 1992/1–8; ISO 5160/1–2).

Transfer

Processes of cargo transfer or transshipment are characterized by transfer times and degree of protection against ambient conditions. Cargoes are handled in units from manloads to transport units, with various types of equipment from manhandling to large forklift trucks or cranes for whole transport units. Fortunately, the rate of cargo transfer and the degree of protection increase with the size of the unit, and costs decrease per unit of volume (Table 5).

Table 5 Cargo transfer in large and small units: time, protection, cost

Operation	*Transfer time (min)*	*Relative cost (%)*
Long-haul truck,		
18 pallets of 720 kg, with lift truck	Load/unload, 15	100
560 manloads of 28 kg, belt conveyor	Load/unload, 84	140
Delivery truck, 16 deliveries of 20 manloads of 15 kg		
On pallet	Load, 13; unload, 16×5	100
Per manload	37 16×18	250

Flow times in the transfer links are determined by the rate of transfer and the volume to be transferred. The need to condition the transfer area depends on the external climate. The degree of protection in this case is a function of time.

Standardization The standardization of appearances in transport chains has led to a standardization of transfer equipment in terms of speed, volume, and mass that can be handled (conveyors, trucks, cranes).

Transportation

Means of transportation exist for the land, road and rail, sea and air modes. The intermodal container has united these and closed the protected-chain operation. On a regional scale, the removable body or swap-body serves the same purpose.

Road vehicles account for the largest part of the transportation of agrofood products. On a national basis in the EC, up to 90% of the flow of foodstuffs is by road transport that must conform to traffic regulations; this has resulted, practically, in standardization according to size and mass. Containers and removable bodies (swap-bodies) comply with stringent ISO standards for external and internal dimensions. Conditioned road vehicles and swap-bodies can comply better with ISO unit loads than do ISO containers. For both types of vehicle, performance is regulated. Residence times are close to transit times, and almost uniform, except for delivery runs, which are mostly short.

Railcars are larger and comply with standards of the railroad administrations, not necessarily with unit load standards. Ships are built to customers' or builders' standards, and aircraft largely to builders' standards, which include compliance with unit load, pallet, and/or container regulations. Unfortunately, air cargo unit load devices other than air/surface containers are not part of the ISO modular system.

Conditioning depends on the specifications of the customer and the performance of the builder. In sea carriage, narrow bands of conditions are normally realized, much less in air transportation, which leans on the advantage of short transit times.

Residence times under transit conditions are mostly close to transit times, because waiting times are under pressure in all links of the chain. On short distances by rail, waterways, and air, waiting times can be considerable, depending on schedules. The speeds of land and sea transportation are practically the same, between 30 and 60 km h^{-1} (considerably less on inland waterways), but transit times are in fact restricted by the frequency of departures for intermodal combined transportation, and by regulations concerning the active time of drivers for the road leg.

Standardization Standardization of means of transportation is traditionally concerned with external aspects. Only recently has the principle of vehicle design around the cargo been introduced by allowing double-pallet-wide, conditioned road vehicles in the EC and the USA. ISO is also paying attention to this aspect by standardizing the minimum internal dimensions of thermal containers (ISO 1496/2–1988). Modular coordination with unit loads has not been attained yet.

Standards for containers (ISO) and regulations for road vehicles and railcars (Economic Commission for Europe) exist for thermal insulation and refrigeration power, but not for operational characteristics, such as the temperature band.

Standardization of road vehicles, railcars, ships, and aircrafts as carriers is linked to the external dimensions of unit loads or transport units to be accommodated within the limits given by the traffic system, by law or by convention.

Degree of protection For all conditioning processes in the transport chain, the degree of protection against temperature rise can be defined by means of the nonaccomplished temperature rise of the product as the fraction of the difference from the target or reference temperature to ambient.

For refrigerated spaces, the quotient-heat load factor over air circulation is a specific operational criterion of performance. For the evaluation of the conditioning process, the influence of air distribution and product heat load can be introduced by an empirical coefficient.

For transient processes, such as the temperature rise during cargo transfer, transient heat transfer theory offers suitable models for the estimation of the degree of thermal protection, which now depends on time.

Energy If the accumulated energy per conveyed unit of mass by the processes in the chain is recognized as transported energy, the concept of energy transport in distribution chains becomes meaningful, especially if the energy input is accounted for. Particularly for perishable products which have been subjected to a product transformation, the energy accumulated by the transformation process and by the subsequent conditioning for protection against quality loss makes the quality of energy management visible. A very basic approach considers the total energy input for primary production, processing, and handling, as well as for auxiliary materials. More chain-relevant information takes account of chain processes only (Tables 6 and 7).

Low degrees of protection in the links of a chain mean great deviations from the target temperature

Table 6 Energy consumption in distribution chains of refrigerated foodstuffs

Link	Frozen			Chilled		
	Energy rate ($W\,t^{-1}$)	Time (days)	Energy accumulated ($kJ\,kg^{-1}$)	Energy rate ($W\,t^{-1}$)	Time (days)	Energy accumulated ($kJ\,kg^{-1}$)

From IIF/IIR (1980).

and bad energy management, leading to additional costs of energy to restore conditions and quality loss.

Finally, the economic consequences of distribution processes boil down to cost accounts (Table 8).

Information Transport processes are controlled by the demands of the market. In order to realize just-in-time (JIT) delivery, the signal for replenishment has to be sent in due time, allowing for the necessary time for the order cycle. A scheme of the information flow in a cold-chain system with computer-assisted guidance, management, and supervision is shown in Figure 5.

Data acquisition and processing Upstream communication along logistic chains mostly concerns the order procedure, which has to be initiated by reliable information from the outlets. Because the signal has to be given in advance of stock depletion, a model is needed to predict the necessary JIT delivery. Further information upstream can be required to redirect the goods flow in case of unforeseen developments of the market. Downstream communication should contain information on the product and its peculiarities, quality life and reference conditions (date marking). More relevant are remaining quality life, required conditions, and handling recommendations. These should be communicated in advance of the goods. They must be matched by information on equipment and conditions in the links. Standardization of information is helpful to reduce variations and mistakes, and to speed up the information flow. Bar-coding and scanning at the interfaces backed by a computerized inventory management system is a powerful means of quality management of an agrologistical chain of operations. Its introduction again requires standardization of information and procedures, and must be the subject of a careful cost–benefit analysis.

Processing of these data for operational purposes is only possible by powerful computer systems with specific software. In the preparatory phase, for the establishment of the necessary tools, even more computing capacity is needed to evaluate possible alternative chains and networks by modeling calculations and simulation in a reasonable time. It is in this application that large computer capacities and high calculation speeds are required.

Inventory management In many cases, the conventional FIFO concept is not able to satisfy the justified quality requirements of the customer. Limitation of throughflow time deals with one aspect of quality management, limitation of temperature with another, whereas only the combination of the two can yield the appropriate measures. Inventory management, therefore, should be based on information about the time–temperature load on the product rather than on time-based information alone (shortest remaining shelf-life instead of FIFO as a management criterion).

Table 8 Average production and distribution costs for three main food chains (Netherlands, Fl kg^{-1})

	Meat and meat products	*Milk and dairy products*	*Fruit and vegetables*

From Meffert HFTh (1990a) Economic developments pertinent to chilling foods. In: *Chilled Foods, the State of the Art*. London: Elsevier Applied Science, with permission.

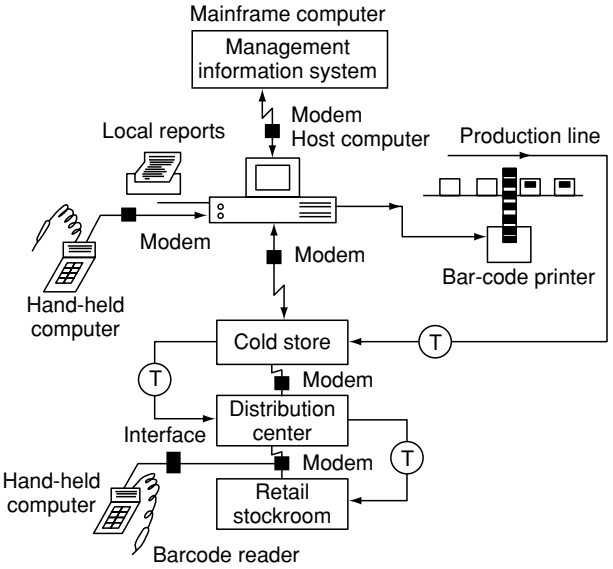

Figure 5 Schematic presentation of a system for a computer-assisted guidance, management, and supervision system of a cold-chain system. From Nowotny S (1988) Computer-modeling of cold chain systems. In: *Cold Chains in Economic Perspective*. Paris: International Institute of Refrigeration.

This requires a new system of control which, in its simplest form, is represented by cheap, physicochemical, time–temperature integrators for each lot of product. A more suitable approach can be expected from the application of microelectronic sensors backed by a computer-assisted inventory management system.

Modern miniaturized, self-contained, time–temperature data-logging sensors, with readable and/or barcode readout, and computer-assisted processing of the information, allow a system to control the flow-time down the chain according to the remaining quality life of the product.

Monitoring product conditions During recent years, a great number of devices for temperature monitoring in conditioned distribution chains have been developed, on mechanical, physicochemical, microbiological, or electronic bases and with indicating or integrating functions, or both.

As it is impossible to keep track of the quality development of every product by time–temperature integration with one or even a handful of built-in deterioration models, solutions can be found in the classification of products and corresponding sensors with direct indication, or sensors readable by a computer-based system which compares the monitored time–temperature load with stored keepability data, and converts the result into information on the remaining quality life expectation of the product.

For a wider use of such instruments, standardization of sensors and information processing equipment is necessary.

Simple time–temperature integrating devices can monitor distribution chain operations for the general purposes of quality management. But even highly sophisticated monitoring systems remain in need of expert supervision, because of the general rule that the sensor is not identical with the product.

Effects of Scale

Costs per unit of storage and transport rise approximately with the square root of volume. Therefore, large stores and vehicles are greatly favored by logistic enterprises. Whereas production stores can afford uniformly conditioned facilities of maximum size, distribution storage is in need of compartmentation and separate conditioning to meet the requirements of different product groups. Towards the end of logistic chains, at the retail outlets, storage facilities and deliveries become necessarily smaller, dictated by high surface charges and problems of accessibility in cities. At the same time, compartmentation and separate conditioning becomes more problematic.

The same reason, low cost linked to a high degree of protection, favors large appearances for transfer operations. Warehouses exist which handle whole transport units, i.e., containers, porthole or integral reefers, but also flats with superstructures to be covered by an insulated hood when in transit. Mostly,

however, unit loads (on pool-pallets) are the normal appearances for transshipment. Smaller units, carts with supporting superstructures, are favored at the retail level for closed-circuit operations.

As the transportation link tries to maximize deliveries, a trend emerges leading to maximum size, multicompartment, multitemperature, expensive vehicles. This tendency towards large vehicles is counteracted by traffic situations and regulations, which restrict the accessibility of cities and, because of the need for supplementary deliveries JIT, add to the logistic costs.

Also, the degree of protection is generally greater at large facilities and operations, owing to their more sophisticated technical equipment and better supervision of operations. For this reason, large-scale operations in logistic chains for conditioned products serve two purposes – low cost and good protection of quality. Costs per unit per time increase remarkably towards the end of the chain, where smaller facilities are in use, together with decreasing protection. Longer lead-times for storage at large facilities lead to cost and quality savings. Shorter lead-times at small facilities are favored for the same reason, and reduce inventory costs. An effective information system is necessary to guarantee the continuity of the product flow to the customer.

Location of Facilities along the Logistic Chain

The general model of a logistic chain for agrofood products is the tree of Pythagoras, showing the collecting and the distributing function on both sides of the trunk. Small facilities are located at the beginning and at the end of the logistic system, implying high flow speeds for cost and quality reasons. Large facilities mark the middle of the trunk, the center of the logistic system.

For production with a quality life longer than the minimum lead-time through all the links of the chain, a buffer station can most economically, in terms of both cost and quality, be situated at the point of maximal aggregation.

If quality life and lead-time are of the same magnitude, the buffer function tends to move towards the end of the chain. The storage function of all the preceding links is minimized for a maximization of quality at the retail outlets. The retailers, however, favor daily shopping, which generates greater sales, and reduces quality problems that result from long residence times at suboptimal conditions at the retail end of the chain. The buffer function is thus located at the wholesalers and distribution centers, which often have to take care of the delivery service as well, governed by effective order processing.

Combination of Product Flows

A powerful means of reducing logistic costs is given by the combination of goods in consecutive links of the distribution chain; Table 9 gives an example.

The possibilities for combination depend on the required conditions and lead-times, but can also be enlarged by multicompartment, multicondition facilities for storage and transportation. In this field, protective packaging for specific products has its special merits, allowing for combinations which are otherwise impossible.

Considerable reductions of transportation costs are reported through savings on labor, equipment, and energy costs. The total savings percentages are much less spectactular, but interesting enough with respect to price competition. In storage links, the advantages of combination are more indirectly realized by simplified, uniform inventory administration and order processing.

Table 9 Integration of product flows for delivery at retail level; developments in Europe (Netherlands) and USA, 1984–1990

Product group	*Conditioning*	*Average volume flow (%)*					
		Europe (NL)	*USA*[a]				
			1	*2.1*	*2.2*	*2.3*	*2.4*

Logistical Policy

In agrofood logistic systems, storage and transportation – the main activities in all logistic systems – are, in addition, characterized by critical design considerations originating from product quality development in time, and conditioning. The two activities compete for minimum costs, by aiming for the largest possible facilities in the relevant links of the transport chain, but under the limiting influences of differentiated product requirements and restrictions imposed by high housing costs and traffic regulations in cities.

Total cost analysis provides a methodology for the integrated design of activities along the whole chain of operation. For a complete analysis in the planning phase, a wide variation of design alternatives has to be considered: alternative location of primary (production), secondary (distribution), and tertiary (retail) storage facilities, type of transportation, shipment size, appearances, equipment for processing, conditioning, and handling.

As decision criteria, maximum service, maximum profit, maximum competitive advantage or minimum investment (hired services) may be used. Regardless of the chosen strategy, the desired level of customer service should be accomplished at minimum total cost. The number of possible alternatives to reach this aim can only be tested by the use of mathematical models. The formulation of a total cost analysis is not without practical problems, especially the appreciation of quality degradation.

Limitations of throughflow time deal only with the general logistic aspect of product flow. The limitation of conditions, the most important of which is temperature, is considered the second most important aspect for perishable products, whereas only the combination of the two can yield the appropriate criteria in terms of quality maintenance in the chain.

Supervision of chain processes, therefore, should be based on information on time–temperature load on the product rather than only time-based information (shortest remaining shelf-life instead of FIFO as the management criterion). This requires a new system of control, which in its simplest form is presented by cheap physicochemical, directly readable, time–temperature integrators for each lot of product. A more suitable approach can be expected from the application of microelectronic sensors backed up by a computer-assisted inventory management.

TRICARBOXYLIC ACID CYCLE

D A Bender, University College London, London, UK

Background

The tricarboxylic acid cycle is the major energy-yielding metabolic pathway in cells, providing the greater part of the reduced coenzymes that will be oxidized by the electron transport chain to yield adenosine triphosphate (ATP). The pathway is sometimes known as the citric acid cycle, or the Krebs' cycle, after its discoverer, Sir Hans Krebs. In addition to its role in energy-yielding metabolism, and the oxidation of 2-carbon units, the cycle is also the major pathway for interconversion of 4- and 5-carbon compounds in the cell, many of which arise from, or are intermediates in the synthesis of, amino acids. Oxaloacetate, a key intermediate in the cycle, is the main precursor for gluconeogenesis in the fasting state.

Reactions of the Tricarboxylic Acid Cycle

As shown in **Figure 1**, the tricarboxylic acid cycle provides a pathway for the oxidation to carbon dioxide and water of the acetate moiety of acetyl coenzyme A (CoA) arising from the oxidative decarboxylation of pyruvate (the end product of glycolysis), the β-oxidation of fatty acids, the metabolism of ethanol, ketone bodies, and a number of amino acids. For each mole of acetyl CoA oxidized in this pathway, there is a yield of 12 × ATP equivalents, arising from:

- 3 × nicotinamide adenine dinucleotide (NAD^+) reduced to NADH, equivalent to 9 × ATP when reoxidized in the electron transport chain;
- 1 × flavoprotein reduced, leading to reduction of ubiquinone, equivalent to 2 × adenosine diphosphate (ADP) when reoxidized in the electron transport chain;
- 1 × guanosine diphosphate (GDP) phosphorylated to guanosine triphosphate (GTP), equivalent to 1 × ATP.

The four-carbon intermediate, oxaloacetate, reacts with acetyl CoA to form a six-carbon compound, citric acid. The cycle is then a series of steps in which two carbon atoms are lost as carbon dioxide, followed by a series of oxidation and other reactions, eventually reforming oxaloacetate. The CoA of acetyl CoA is released, and is available for further formation of acetyl CoA from pyruvate, fatty acids, or ketone bodies.

Although oxaloacetate is the precursor for gluconeogenesis, fatty acids and other compounds that give rise to acetyl CoA or acetoacetate cannot be used for net synthesis of glucose. As can be seen from **Figure 1**,

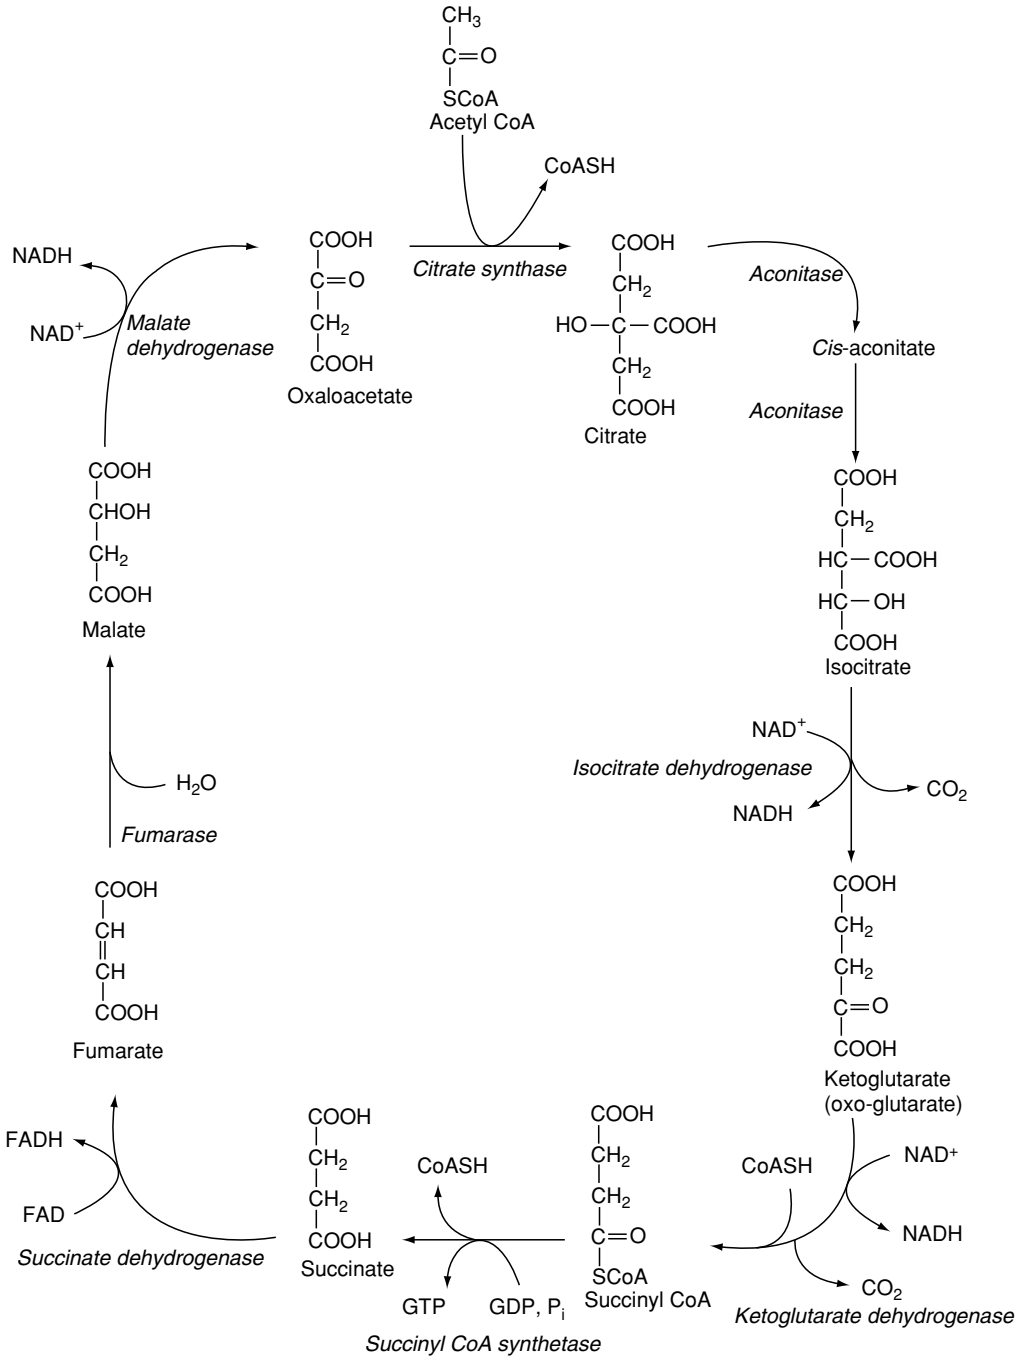

Figure 1 Tricarboxylic acid cycle. Citrate synthase EC 4.1.3.7, aconitase EC 4.2.1.3, isocitrate dehydrogenase EC 1.1.1.41, ketoglutarate dehydrogenase EC 1.2.4.2, succinyl CoA synthase EC 6.2.1.4, succinate dehydrogenase EC 1.3.5.1, fumarase EC 4.2.1.2, malate dehydrogenase EC 1.1.1.37.

although two carbons are added to the cycle by acetyl CoA, two carbons are lost as carbon dioxide in each turn of the cycle. Therefore, when acetyl CoA is the substrate, there is no increase in the pool of tricarboxylic acid cycle intermediates, and therefore oxaloacetate cannot be withdrawn for gluconeogenesis when acetyl CoA is being metabolized.

Although citrate is a symmetrical molecule (carbons 1 and 2 are equivalent to carbons 5 and 6), it behaves asymmetrically in the cycle. When tissue is incubated with [^{14}C]acetyl CoA in the presence of malonate, an inhibitor of succinate dehydrogenase, there is no release of $^{14}CO_2$, despite the fact that 2 mol of CO_2 are released in the sequence of reactions between citrate

synthetase and succinate dehydrogenase. The two carbon atoms that are lost in the first turn of the cycle are not the same two atoms added from acetyl CoA. This is because citrate does not diffuse from the active site of citrate synthetase into free solution, but is channeled directly from the active site of citrate synthetase to that of aconitase.

The main regulation of the rate of tricarboxylic acid cycle activity is by control of the activity of isocitrate dehydrogenase, which is regulated by both phosphorylation/dephosphorylation, and also by the intramitochondrial ratio of NADH:NAD^+, it is also inhibited by NADH, and activated by ADP. When the rate of entry of acetyl CoA into the cycle, and hence the rate of formation of citrate, is greater than the rate at which isocitrate undergoes dehydrogenation, aconitase is inhibited by its product. The result of this is that citrate can no longer be channeled from the active site of citrate synthetase to aconitase, and now leaves the active site of citrate synthetase into free solution in the mitochondrial matrix. In most tissues, free citrate can be transported out of the mitochondria into the cytosol. Here, it can act both to inhibit phosphofructokinase, so reducing the rate of glycolysis and formation of acetyl CoA, and the cytosolic as the source of acetyl CoA for fatty acid synthesis (see below).

α-Ketoglutarate dehydrogenase catalyzes a reaction similar to that of pyruvate dehydrogenase – oxidative decarboxylation and formation of an acyl CoA derivative. Like pyruvate dehydrogenase, it is a thiamin diphosphate-dependent enzyme. However, thiamin deficiency does not have a significant effect on the tricarboxylic acid cycle, because α-ketoglutarate can undergo transamination to yield glutamate, which is decarboxylated to γ-aminobutyric acid (GABA). In turn, GABA can undergo further metabolism to yield succinate. This pathway, shown in Figure 2, is sometimes called the GABA shunt; it provides an alternative to α-ketoglutarate dehydrogenase in thiamin deficiency, so that oxidation of acetyl CoA and formation of ATP can continue.

The reaction of succinyl CoA synthetase, the formation of free succinate and CoA from succinyl CoA, is linked to a substrate-level phosphorylation of GDP to GTP, which is energetically equivalent to the formation of ATP.

In tissues that synthesize glucose in the fasting state (liver, kidney, and intestinal mucosa), this reaction also provides an important link between the rate of tricarboxylic acid cycle activity and the withdrawal of oxaloacetate for gluconeogenesis. The formation of phospho-enolpyruvate from oxaloacetate, catalyzed by phospho-enolpyruvate carboxykinase (see Figure 4) requires GTP as the phosphate donor; the

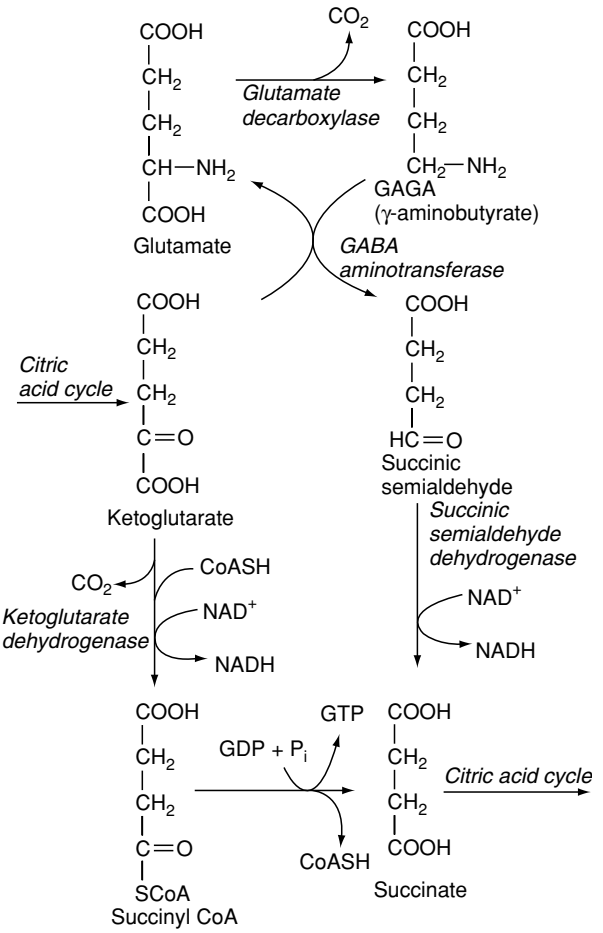

Figure 2 GABA shunt. Glutamate decarboxylase EC 4.1.1.15, GABA aminotransferase EC 2.6.1.19, succinic semialdehyde dehydrogenase EC 1.2.1.24, ketoglutarate dehydrogenase EC 1.2.4.2.

major, if not only, intramitochondrial source of GTP is the reaction of succinyl CoA synthetase. This means that it is not possible to withdraw oxaloacetate from the cycle for gluconeogenesis if this would result in a slowing of the rate of cycle activity, and hence the rate of formation of GTP.

Under conditions where ketone bodies are being metabolized (especially in muscle and brain in the fasting state), there is an alternative reaction that bypasses succinyl CoA synthetase – direct transfer of CoA from succinyl CoA on to acetoacetate to form acetoacetyl CoA. This provides a link between the rate of tricarboxylic acid cycle activity and the ability to take up and utilize acetoacetate; if there is little succinyl CoA available, little acetoacetate can be utilized.

The sequence of reactions between succinate and oxaloacetate is chemically the same as that involved in the β-oxidation of fatty acids:

- Oxidation to yield a carbon–carbon double bond. Although this reaction is shown in Figure 1 as being linked to reduction of FAD, the coenzyme is tightly enzyme bound, and succinate dehydrogenase reacts directly with ubiquinone in the electron transport chain.
- Addition of water across the carbon–carbon double bond, to yield a hydroxyl group.
- Oxidation of the hydroxyl group, linked to reduction of NAD^+, to yield an oxo-group, so reforming oxaloacetate to undergo reaction with a further molecule of acetyl CoA.

Citrate as the Source of Acetyl CoA for Lipogenesis

The substrate for fatty acid synthesis is acetyl CoA. However, the only source of acetyl CoA is intramitochondrial, whereas fatty acid synthesis is a cytosolic process. Under conditions where fatty acids are

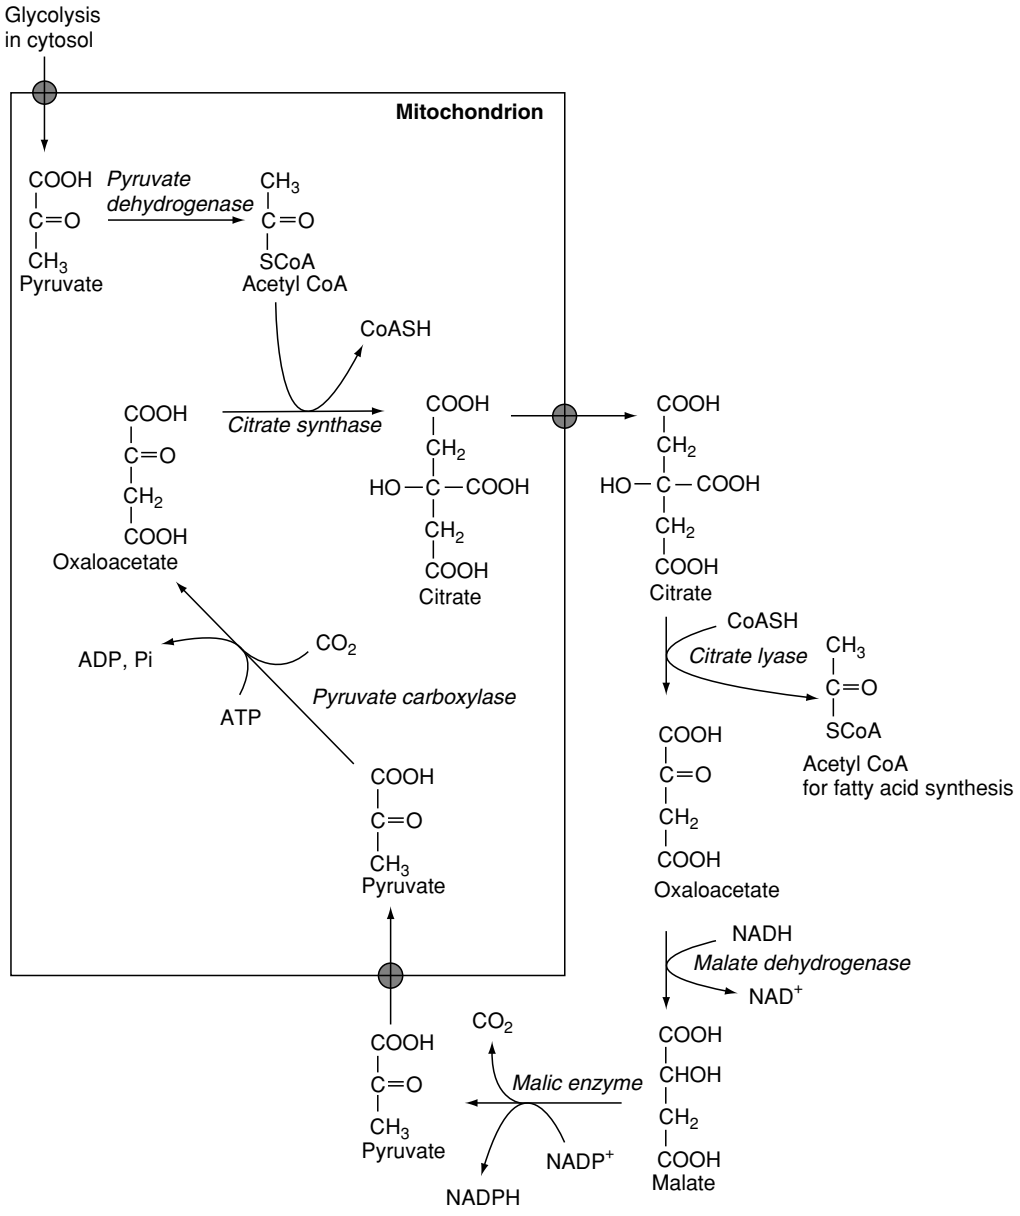

Figure 3 Citrate as the source of acetyl CoA for fatty acid synthesis. Pyruvate dehydrogenase EC 1.2.4.1, citrate synthase EC 4.1.3.7, citrate lyase EC 4.1.3.6, malate dehydrogenase EC 1.1.1.37, malic enzyme EC 1.1.1.38, pyruvate carboxylase EC 6.4.1.1, phosphoenolpyruvate carboxykinase EC 4.1.1.32.

to be synthesized, and the rate of entry of acetyl CoA into the cycle is greater than that required for maintenance of ATP formation, free citrate is transported from the mitochondrial matrix into the cytosol. Here, it undergoes cleavage to acetyl CoA and oxaloacetate.

Oxaloacetate cannot reenter the mitochondrion, but undergoes the sequence of reactions shown in Figure 3: reduction to malate, followed by oxidative decarboxylation to pyruvate, which enters the mitochondrion, and is carboxylated to oxaloacetate. The oxidative decarboxylation of malate to pyruvate, catalyzed by the malic enzyme, is linked to the reduction of $NADP^+$ to NADPH. This reaction provides half the NADPH required for fatty acid synthesis; the remainder comes from the pentose phosphate pathway of glucose metabolism.

Anaplerotic Reactions – Replenishing the Supply of Tricarboxylic Acid Cycle Intermediates

If oxaloacetate is removed from the cycle for glucose synthesis, it must be replaced, since if there is not enough oxaloacetate available to form citrate, the rate of acetyl CoA metabolism, and hence the rate of formation of ATP, will slow down. Similarly, under conditions of hyperammonemia, the reaction of glutamate dehydrogenase leads to withdrawal of a considerable amount of α-ketoglutarate, to the extent that ATP formation is impaired, leading to coma and convulsions.

As shown in Figure 4, a variety of amino acids give rise to tricarboxylic cycle intermediates, so permitting removal of oxaloacetate for gluconeogenesis. In addition, the reaction of pyruvate carboxylase is a major source of oxaloacetate to maintain tricarboxylic acid cycle activity.

The metabolic fate of pyruvate, oxidative decarboxylation to yield acetyl CoA or carboxylation to yield oxaloacetate, is determined by the relative availability of acetyl CoA (which also arises from β-oxidation of fatty acids and metabolism of ketone bodies) and the need for oxaloacetate to maintain tricarboxylic acid cycle activity. Pyruvate dehydrogenase is inhibited by both NADH and acetyl CoA, whereas pyruvate carboxylase has an absolute requirement for acetyl CoA for activity. Thus, at times when there is an abundance of acetyl CoA, pyruvate will not undergo decarboxylation and oxidation in the tricarboxylic acid cycle, but rather will be carboxylated to oxaloacetate. Once the pool of tricarboxylic acid cycle intermediates is adequate, further oxaloacetate formed by carboxylation of pyruvate can be used for gluconeogenesis.

Metabolism of Amino Acid Carbon Skeletons – Gluconeogenesis From Amino Acids

Acetyl CoA and acetoacetate arising from the carbon skeletons of amino acids may be used for fatty acid synthesis or can be oxidized as metabolic fuel, but cannot be utilized for the synthesis of glucose (gluconeogenesis, see glucose metabolism). Amino acids that yield acetyl CoA or acetoacetate are termed ketogenic. Only two amino acids, leucine and lysine, are solely ketogenic; isoleucine, phenylalanine, and tryptophan yield both ketogenic and glucogenic fragments. All the other amino acids yield carbon skeletons that can be used for gluconeogenesis.

The principal substrate for gluconeogenesis is oxaloacetate, which undergoes the reaction catalyzed by phospho-enolpyruvate carboxykinase to yield phospho-enolpyruvate, as shown in Figure 4. The points of entry of amino acid carbon skeletons into central metabolic pathways are shown in Figure 4. Those that give rise to ketoglutarate, succinyl CoA, fumarate, or oxaloacetate can be regarded as directly increasing the tissue pool of tricarboxylic acid cycle intermediates, and hence permitting the withdrawal of oxaloacetate for gluconeogenesis.

Those amino acids that give rise to pyruvate also increase the tissue pool of oxaloacetate, since pyruvate is carboxylated to oxaloacetate in the reaction catalyzed by pyruvate carboxylase.

Gluconeogenesis is an important fate of amino acid carbon skeletons in the fasting state, when the metabolic imperative is to maintain a supply of glucose for the central nervous system and red blood cells. However, in the fed state, the carbon skeletons of amino acids in excess of requirements for protein synthesis will be used mainly for formation of acetyl CoA for fatty acid synthesis, and storage as adipose tissue triacylglycerol.

Complete Oxidation of 4- and 5-carbon Compounds

Although the tricarboxylic acid cycle is generally regarded as a pathway for the oxidation of 4- and 5-carbon compounds such as fumarate, oxaloacetate, α-ketoglutarate and succinate arising from amino acids, it does not, alone, permit complete oxidation of these compounds. Four-carbon intermediates are not overall consumed in the cycle, since oxaloacetate is reformed. Addition of 4- and 5-carbon intermediates may increase the rate of cycle activity (subject to control by the requirement for ATP), but once the pool of intermediates is saturated, no more can enter.

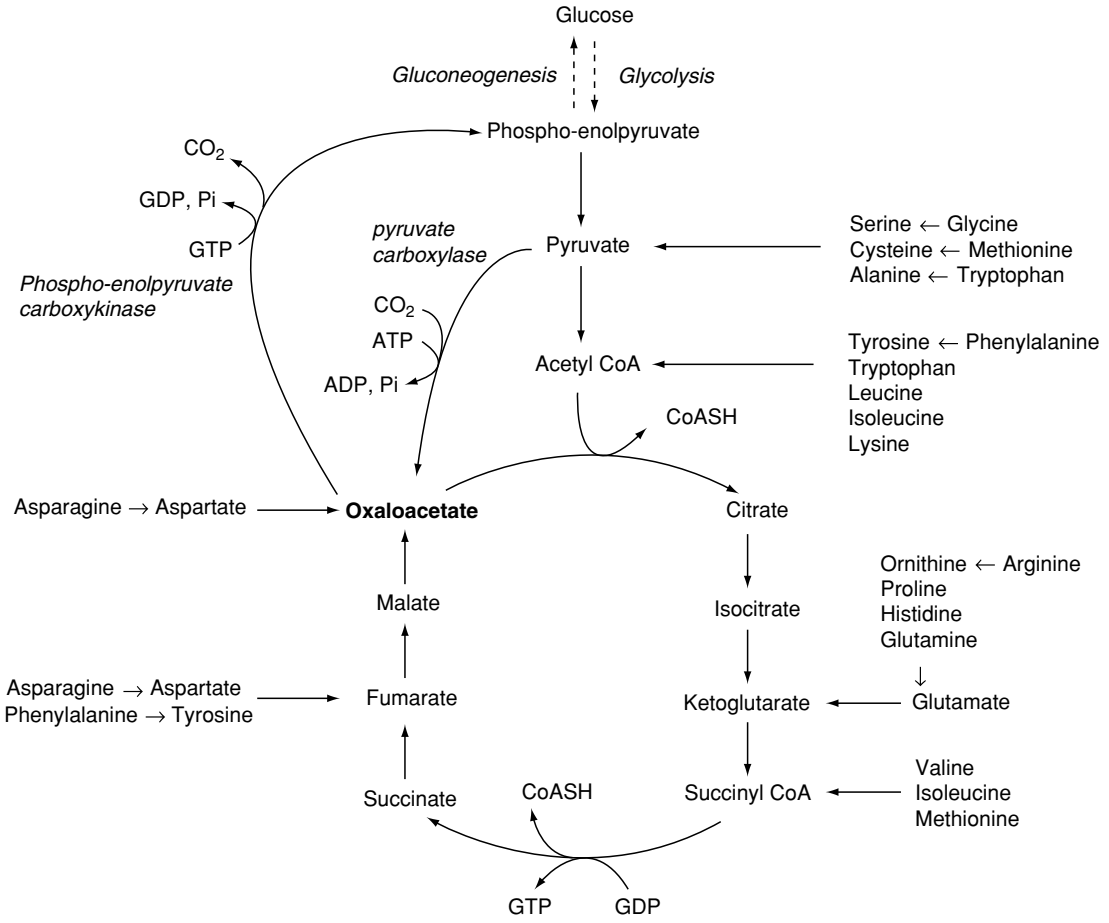

Figure 4 Entry of amino acid carbon skeletons into the tricarboxylic acid cycle.

Complete oxidation of 4- and 5-carbon intermediates requires removal of oxaloacetate from the cycle, and conversion to pyruvate, as shown in Figure 4. This pyruvate may undergo decarboxylation to acetyl CoA, which may be oxidized in the cycle, or can be used for fatty acid synthesis or as a substrate for gluconeogenesis.

Isomerism and Structure

Triglycerides are the most abundant lipid class of fats and oils, in which glycerol is esterified with three fatty acids. The glycerol molecule is prochiral. If the primary hydroxyls of glycerol are esterified with different fatty acids, the molecule is chiral and thus may have two enantiomers. Instead of the *R*/*S* convention or D/L convention, the triacylglycerol (and other glycerolipids) enantiomers are designated using 'stereospecific numbering' (*sn*) according to the recommendations of the International Union of Pure and Applied Chemistry – International Union of Biochemistry (1967) commission on the nomenclature of glycerolipids. When a Fischer projection formula is drawn for a glycerol derivative so that oxygen is shown to the left of secondary carbon 2, which is designated *sn*-2 (Figure 1). The carbon above it is *sn*-1, and the carbon below it is *sn*-3. Owing to regio-(positional) and stereoisomerism, a great number of different triacylglycerols exist. Three different fatty acids can form 10 different molecular species, i.e., triacylglycerols having different fatty acid compositions: three monoacid triacylglycerols (AAA, BBB, CCC), six diacid triacylglycerols, each composed of a pair of enantiomers and a symmetric isomer (AAB/BAA; ABA, ABB/BBA; BAB, AAC/CAA; ACA, ACC/CCA; CAC, BBC/CBB; BCB, BCC/CCB, CBC), and three pairs of enantiomers of three-acid triacylglycerols (ABC/CBA, ACB/BCA, BAC/CAB), altogether $n^3 = 27$ different triacylglycerol molecules. In natural fats such as milk fat, in which more than 400 different fatty acids have been identified, a large number of different triacylglycerol molecules may theoretically exist. In addition to positional and stereoisomers, natural fats include acyl chain isomers, which have the same molecular formula, but are composed of different fatty acids.

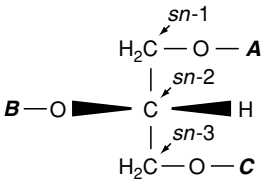

Figure 1 Fischer projection formula of a triacyl-*sn*-glycerol. ***A***, ***B***, and ***C*** are acyl groups.

Although, in recent years, positional isomers of some molecular species have been chromatographically determined, the information on triacylglycerol structure is based on studies, in which the distribution of fatty acids between the *sn*-1, *sn*-2, and *sn*-3 positions (stereospecific analysis) or between the *sn*-1(3) and *sn*-2 positions (regiospecific analysis) is determined in an isolated triacylglycerol fraction of fat or oil. A variety of methods have been developed. In these, pancreatic lipase (Methods A and B shown in Figure 2) and Grignard degradation (Methods A–E) has been used to produce partial acylglycerols. The former hydrolyzes fatty acids from the *sn*-1 and *sn*-3 position producing free fatty acids and 2-monoacyl-*sn*-glycerols and 1,2- and 2,3-diacyl-*sn*-glycerols. Owing to the fatty acid specificity of lipase, representative diacylglycerols are not formed: long-chain polyunsaturated fatty acids are hydrolyzed more slowly, and small triacylglycerol molecules containing short-chain fatty acids are hydrolyzed more rapidly than large triacylglycerol molecules. Grignard reagent degrades primary and secondary ester bonds equally and has no fatty acid specificity. The products are 1,2-, 2,3-, and 1,3-diacyl-*sn*-glycerols, 1-, 2-, and 3-monoacyl-*sn*-glycerols, and tertiary alcohols. Special attention has to be paid to the spontaneous acyl migration in both hydrolysis and Grignard degradation products. Methods A and B (Figure 2) are based on the specificity of phospholipase A_2 (EC 3.1.1.4) to hydrolyze the *sn*-2 ester bond of *sn*-1,2-diacylglycerol phosphatidylcholine and selectivity of diacylglycerol kinase (EC 2.7.1.107) to phosphorylate 1,2-diacyl-*sn*-glycerols, respectively. Methods C and E (Figure 2) are based in the chiral high-performanc liquid chromatography (HPLC) separation of

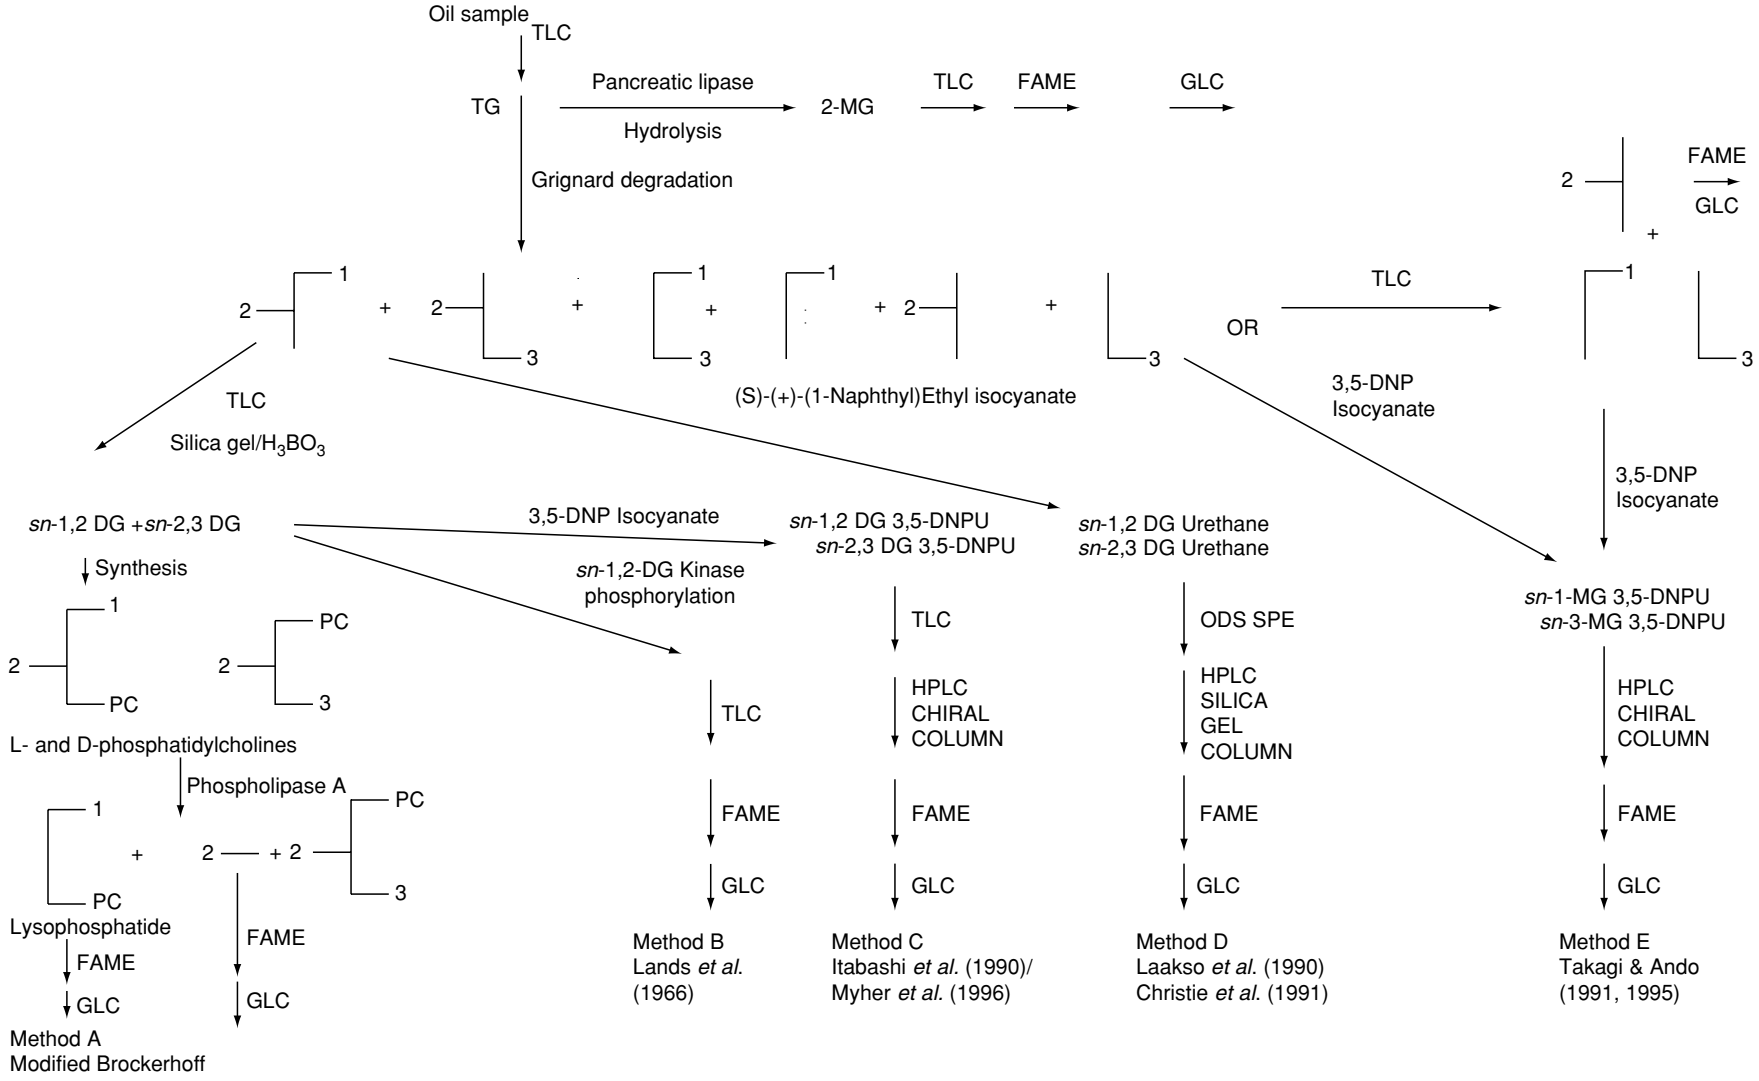

Figure 2 Basic features of the methods used in the determination of the fatty acid distribution between the *sn*-1, *sn*-2, and *sn*-3 positions in triacyl-*sn*-glycerols. 3,5-dinitrophenyl urethanes of 1,2- and 2,3-diacyl-*sn*-glycerols and 1- and 3-monoacyl-*sn*-glycerols, respectively. The method D (Figure 2) is based on the separation of diastereomeric derivatives of 1,2- and 2,3-diacyl-*sn*-glycerols on a silica-gel HPLC column.

Triacylglycerol Structure of Food Fats and Oils

Fruit Pulp Oils

In olive oil, the saturated fatty acids are esterified mainly in the *sn*-1 and *sn*-3 positions (Table 1). A little more than one-third of oleic acid is esterified in the *sn*-2 position and a little less in the *sn*-1 and *sn*-3 positions. The ratio of both primary positions is close to 1. Nearly half of linoleic acid is esterified in the *sn*-2 position and approximately one-third in the *sn*-1 position. Table 1 shows a high degree of similarity between the distributions determined by two enzymatic methods. A study by Damiani *et al*. did not reveal any statistical difference between the methods B and D (Figure 2) by Student's *t*-test. Also, in palm oil, saturated fatty acids are preferentially esterified in the *sn*-1 or *sn*-3 positions. Unsaturated fatty acids are esterified to a great extent in the *sn*-2 position.

High Lauric and Myristic Acid Seed Oils

Regiospecific analysis has shown that in coconut oil, lauric and linoleic acids are esterified mainly in the *sn*-2 position and oleic acid and saturated acids in the *sn*-1(3) positions (Table 2). A similar trend is in the distribution of lauric and oleic acids in palm kernel oil. Also, linoleic acid shows a slight preference

for the *sn*-2 position. Myristic acid is distributed equally between the *sn*-2 and *sn*-1(3) positions, whereas the rest of saturated fatty acids are esterified principally in the primary positions.

High Palmitic Acid Seed Oils

In cocoa butter, palmitic and stearic acids are esterified to a great extent in the *sn*-1 and *sn*-3 positions, distributing nearly equally between them (Table 3). Arachidic acid is esterified totally in the *sn*-1 and *sn*-3 positions, the *sn*-3 position being more favored. Oleic and linoleic acids are esterified mainly in the *sn*-2 position, and palmito-oleic acid in all three positions. The distributions determined by enzymatic stereospecific analysis and by chiral phase HPLC separation of enantiomers of monoacylglycerol derivatives (method E, Figure 2) were very similar. In maize oil, palmitic and stearic acids are principally in the *sn*-1 and *sn*-3 positions (Table 3). Oleic acid is distributed quite evenly between the three positions with a slight excess in the *sn*-3 position. Linoleic acid is esterified predominantly in the *sn*-2 position.

High Oleic and Linoleic Acid Seed Oils

In soy bean oil, high-erucic acid rape seed oil, sunflower oil, and peanut oil, palmitic, and stearic acids are esterified preferentially in the primary positions (Table 4). Also arachidic, behenic, and lingnoceric acids are esterified mainly in the primary positions, the *sn*-3 position clearly being preferred in peanut oil. Oleic acid (18:1*n*-9) is relatively evenly distributed between the three positions in soy bean oil, sunflower oil, and peanut oil, but is predominantly at the *sn*-2 position in high-erucic rape seed oil. Vaccenic acid (18:1*n*-7) is esterified preferentially in the primary positions in soy bean oil and high-erucic rape seed oil. Eicosenoic and docosenoic acids are in the primary positions in high-erucic rape seed oil and peanut oil. In sunflower oil, linoleic acid is esterified in all positions, with a slight excess in the *sn*-2 position. In soy bean oil, high-erucic rape seed oil, and peanut oil, linoleic acid is preferentially in the *sn*-2 position. Linolenic acid is esterified preferentially in the *sn*-2 position in high-erucic rape seed oil and relatively evenly in all positions in soy bean oil. The distributions of soy bean oil fatty acids, determined by enzymatic stereospecific analysis and by HPLC separation of monoacylglycerol derivatives on a chiral column (method E, Figure 2), show a high degree of accordance. Harp and Hammond applied the method of Takagi and Ando in the stereospecific analysis of soy bean mutants representing a wide distribution of fatty acid compositions. In low-erucic-acid rape seed oil, the *sn*-2 position has reported to be occupied by unsaturated C18 fatty acids in the order of linoleic > linolenic > oleic acids.

Milk Fat

Even-numbered triacylglycerols with 26–54 acyl carbons dominate the triacylglycerol composition of bovine milk fat, but odd-numbered triacylglycerols are also present. Only very few triacylglycerols with more than 54 or fewer than 26 acyl carbons exist, indicating a scarcity of the molecular species with very-long-chain fatty acids (> 20) or those with two short-chain fatty acids, respectively. A high number of mono-butyryl triacylglycerols is unique among food fats.

[a]Enzymatic stereospecific analysis. Adapted from Brockerhoff and Yurkowski (1966).
[b]Method based on separation of enantiomers of monoacylglycerol derivatives by chiral-phase HPLC. Adapted from Takagi and Ando (1995).

The asymmetric distribution of fatty acids in bovine milk fat between the three *sn*-positions has already been demonstrated in the late 1960s by Pitas *et al*. and by Breckenridge and Kuksis. Short-chain fatty acids (4:0, 6:0) in mono-butyryl and mono-caproyl triacylglycerols are almost exclusively in the *sn*-3 position (Table 5). However, a small amount of triacylglycerols with two short-chain acyl groups has been detected, and thus traces of butyric and caproic acids have to be esterified in the *sn*-1 and/or *sn*-2 positions. Medium-chain fatty acids (8:0, 10:0) are also most prominently in the *sn*-3 position. More than 50% of lauric and myristic acids is esterified in the secondary position in triacylglycerols. Fatty acids

with 16–18 carbons are more evenly distributed between the *sn*-1 and *sn*-2 positions. According to Gresti *et al*. the most common individual triacylglycerol species in bovine milk fat are 4:0–16:0–18:1 (4.2 mol%), 4:0–16:0–16:0 (3.2 mol%), and 4:0–14:0–16:0 (3.1 mol%), all of which are representatives of the triacylglycerol class consisting of one butyryl group at the *sn*-3 position and two long-chain acyl groups at the *sn*-1 and *sn*-2 positions.

The triacylglycerol composition of other ruminants' (e.g., goat and sheep) milk fat resembles that of cows' milk. A high proportion of even-numbered saturated short-chain fatty acids and fatty acids with 14–18 carbons, as well as the dominating amount 18:1 fatty acids among unsaturated fatty acids of triacylglycerols, is obvious (Table 5). Distribution of fatty acids between the *sn*-positions is also similar to bovine milk fat. However, unsaturated fatty acids (18:1–18:3) and saturated 16:0 and 18:0 fatty acids are more evidently esterified in the *sn*-3 and *sn*-1 positions, respectively, than in bovine milk fat.

One of the main differences between monogastric mammals (e.g., human, pig, horse) and ruminants' milk fats is the absence or scarcity of short- and medium-chain fatty acids in the milk fat of monogastric mammals (Table 5). Also, the amount of diene and polyene fatty acids is much higher in their milk fat. Palmitic and oleic acids are the most prominent saturated and unsaturated fatty acid, respectively, in monogastric mammals' milk fat as they are also in ruminants' milk fat. High concentration (70%) of palmitic acid at the secondary position is typical for human milk fat, as is the esterification of stearic acid in the *sn*-1 position. Unsaturated fatty acids are preferentially acylated in the primary positions of triacylglycerol molecules.

Depot Fats

Triacyglycerol compositions of animal depot fats are much simpler than those of milk fats, and almost all fatty acids are very unevenly distributed between the three *sn*-positions. In triacylglycerols of lard, *c*. 85% of palmitic acid and almost 80% of stearic acid are in the *sn*-2 and *sn*-1 position, respectively. However, all unsaturated fatty acids are mainly esterified in the *sn*-3 position (Table 6).

The most characteristic feature of tallow is the high content (> 25 mol%) of stearic acid, which is equally distributed between the two primary positions (Table 6). Palmitic and myristic acids are also most prominent in the *sn*-1 and *sn*-3 position, respectively. In contrast, the main proportion of unsaturated fatty acids is in the secondary position, *c*. 90% of linoleic acid and over 50% of oleic acid.

Egg Yolk

Oleic acid, palmitic acid, and linoleic acid, in that order, consist of nearly 90 mol% of all fatty acids in triacylglycerols of egg yolk (Table 6). According to Gornall and Kuksis, the most common triacylglycerol

species of egg yolk are 16:0–18:1–18:1 (29 mol%), 16:0–18:2–18:1 (15 mol%), 18:1–18:2–18:1 (7 mol%), and 16:0–18:1–18:0 (7 mol%). Palmitic and linoleic acids are very unevenly distributed between the *sn*-positions: over 70% of 16:0 and 18:2 is in the *sn*-1 and *sn*-2 position, respectively. Stearic acid is evenly distributed between the primary positions and oleic acid between the *sn*-2 and *sn*-3 positions.

Fish Oils

In fish oils, myristic and palmitic acids are esterified preferentially in the *sn*-2 position or in the *sn*-1 position (Table 7). Stearic and palmito-oleic acid are esterified to a great extent in the *sn*-1 position or distributed evenly between the three positions with a slight preference for *sn*-1 position. Oleic and

eicosenoic acids are esterified predominantly in the primary positions with a higher proportion in the *sn*-1 position. Also, docosenoic acid is esterified abundantly in the primary position, but with a higher proportion in the *sn*-3 position in most fish species. Linoleic acid is esterified preferentially in the *sn*-2 or *sn*-3 positions. Eicosapentaenoic acid is preferably in the *sn*-2 or *sn*-3 positions, docosapentaenoic acid in the *sn*-2 position, and docosahexaenoic acid in one of the three positions.

Triacylglycerol Structure of Modified Fats and Structured Lipids

Modification of fats and oils has been studied extensively in order to improve their physical, chemical, and nutritional properties, and to make them more suitable for manufacture of fat products with desired properties. Generally used methods of modification that change the fatty acid composition of fat or oil, are hydrogenation, fractionation, and blending. In the last two decades, interest has focused on the lipase-catalyzed interesterification reactions. The change in the distribution of fatty acids between the three positions of glycerol backbone depends on the regiospecificity of the lipase catalyst. When a nonspecific lipase is used, the specific distribution of fatty acids of a natural fat changes to a random distribution. A similar product is obtained to that in chemical randomization. The change in triacylglycerol composition depends on the type of interesterification reaction. Ester–ester exchange is a reaction between two or more esters, for example triacylglycerols of plain fat or oil (intramolecular interesterification). The acidolysis reaction is a reaction between triacylglycerol and free fatty acid, in which an exchange of acyl groups takes place. In alcoholysis reaction, an acyl group is changed between an acylglycerol and an alcohol. Lipase-catalyzed modification of milk fat has been reviewed, including industrial applications for the manufacture of lipolyzed milk and cheese flavor products and the research efforts with the aim to improve nutritional and technological properties based on ester–ester exchange, acidolysis, and alcoholysis reactions.

The following definitions have been used for structured lipids: Structured lipids are modified or synthetic oils and fats containing both long-chain (mainly essential) fatty acids and medium- or short-chain fatty acids. Specific structured lipids are modified or synthetic oils and fats containing long-chain (mainly essential fatty acids) and medium- or short-chain fatty acids, in which each group is located specifically at the *sn*-2 position or *sn*-1,3 positions of the glycerol backbone. Specific structured lipids can be produced only by interesterification reactions catalyzed by regiospecific lipases.

As examples of industrial applications of lipase-catalyzed reactions, the manufacture of cocoa butter equivalent and human milk substitute are briefly described here. In cocoa butter, 87% of oleic acid is esterified in the *sn*-2 position, and 97% of palmitic and 98% of stearic acid is esterified in the primary positions (Table 3), and the three major molecular species are 16:0–18:1–16:0, 18:0–18:1–18:0, and 16:0–18:1–18:0. This specific distribution of fatty acids is reflected in the unique melting characteristics with a narrow melting range. Using 1,3-specific lipase to catalyze the reaction between oils, in which oleic acid is in the *sn*-2 position, and saturated acyl donors, a cocoa butter substitute, can be produced, with triacylglycerol composition and melting properties very similar to those of cocoa butter. In human milk, 70% of palmitic acid and in cows' milk 45% of palmitic acid is esterified in the *sn*-2 position (Table 5). The unique fatty acid distribution plays an important role in the nutrition of newborn. During ingestion, lipases hydrolyze the fatty acids esterified in the *sn*-1 and *sn*-3 position, and 2-monoacylglycerols and free fatty acids are absorbed. However, a part of the long-chain fatty acids is precipitated in the gut as calcium salts, leading to the loss of long-chain fatty acids and calcium. To overcome the problems of palmitic acid absorption, a human milk fat substitute, which closely resembles the specific structure of human milk fat, is produced from

Properties of Triacylglycerols

Physicochemical Properties

The melting and crystallization properties of triacylglycerols of food fats and oils are of paramount interest in the food industry in manufacturing fatty foods. They are influenced by fatty acid composition, acyl distribution, molecular size, and polymorphism of triacylglycerols. Most triacylglycerols of natural fats and oils consist of straight-chain fatty acids with an even number of carbon atoms, 18:1, 18:2, and 16:0 being the most abundant. Double bonds are almost exclusively in *cis*-configuration, but ruminants' milk fats with a significant amount of *trans*-fatty acids are a rare exception. In polyene fatty acids, methylene-interrupted double bonds are most common, but conjugated double bonds are found in significant amounts in milk fat and other fats of animal origin. Substituted fatty acids are uncommon among natural fats and oils.

The crystallization properties of triacylglycerol mixtures at ambient temperatures are strongly associated with the amount of trisaturated triacylglycerols, but also, triacylglycerol species consisting of two saturated, long-chain fatty acids and one *trans*-monoene fatty acid influence the solidification properties. A strong positive correlation between softening point and content of trisaturated triacylglycerols has been detected in relatively simple fats and oils, but the situation is more complicated with more complex triacylglycerol mixtures. For example, no significant correlation between the softening point and the amount of trisaturated triacylglycerol in milk fat was observed, indicating the importance of the composition of the trisaturated fraction. In milk fat, a decrease in softening point is associated with an increase in the proportion of short-chain trisaturated triacylglycerols (TG 26–32) and a decrease in the proportion of long-chain trisaturated triacylglycerols (TG 44–54). In the 1960s, deMan and colleagues demonstrated the effect of the distribution of fatty acids between the *sn*-positions on the melting and solidification properties of triacylglycerols by randomizing the highly specific fatty acid distribution of milk fat using chemical interesterification. Although the treatment did not affect the fatty acid composition or the proportion of trisaturated triacylglycerols of milk fat, it resulted in an increased softening point, hardness, and content of high-melting-point triacylglycerols in milk fat.

Polymorphism is a common phenomenon for organic compounds consisting of long aliphatic carbon chains resulting in various packing of molecules in the crystal lattices, hence the multiple melting points of polymorphic forms of both pure triacylglycerols crystals and compound crystals of various triacylglycerols in natural fats and oils. The main polymorphic forms of triacylglycerols are named α, β′, and β. Generally, the α polymorph is the least stable, and the β polymorph is the most stable, but all of them can be found in crystallized food fats in appropriate conditions. Some of their properties and examples of differences between melting points of polymorphs of pure medium-chain and long-chain triacylglycerols are presented in Table 8. A schematic presentation of possible phase transitions from liquid to solid, and from solid to solid is shown in Figure 3.

Technological Properties

The importance of fatty acid composition of triacylglycerols is clearly demonstrated in oxidative and hydrolytic deterioration (lipolysis). Oxidative stability increases in the order polyunsaturated > monounsaturated < saturated fatty acids. The methylene-group ($-CH_2-$) between double bonds in polyunsaturated fatty acids is especially sensitive for radical formation, and thus initiation of autooxidation of fats and oils.

In addition to fatty acid composition, the distribution of fatty acids in triacylglycerols together with molecular size is important in hydrolytic deterioration catalyzed by lipases (EC 3.1.1.3). Several technologically meaningful lipases hydrolyze fatty acids exclusively from the primary positions and attack more rapidly at small triacylglycerols. Because of the specific fatty acid distribution in most food fats and oils, the composition of free fatty acids differs markedly from that of intact fat. This is most pronounced in lipolysis of bovine milk fat. Most triacylglycerols in bovine milk fat (over 30 mol%) are relatively small molecules containing at least one short-chain

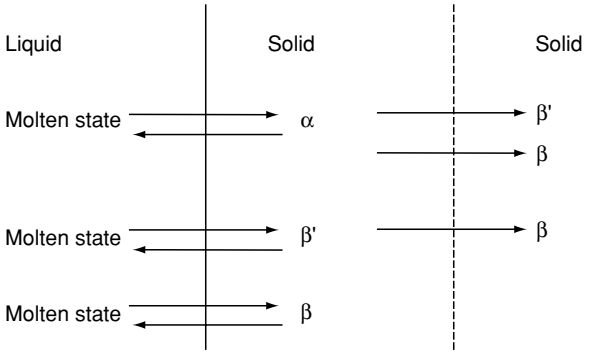

Figure 3 Possible transitions between liquid and solid, and between different polymorphic forms.

fatty acid esterified in the *sn*-3 position, resulting in rapid liberation of highly unpleasant-tasting and technologically problematic butyric and caproic acids into the media.

Rheological properties of spreads are greatly affected by the composition of raw materials, crystallization of emulsion (initial and final temperature, cooling rate, duration of crystallization), mechanical treatments, and configuration of manufacturing equipment. However, the polymorphism of triacylglycerols also has a substantial effect on the consistency and organoleptic acceptability of spreads. A rapid cooling rate of fats with complex fatty acid and triacylglycerol composition, e.g., milk fat, results in the formation of α polymorphs with rather fragile small crystals. Because of a larger mobility of molecules within the crystal lattice of the α polymorph, triacylglycerol molecules, even with a large difference between the chain length of acyl groups, are able to fit into the crystal lattice, and so a large amount of fat will crystallize initially. α crystals are very unstable and will usually transform into more stable polymorphs very rapidly. A slower cooling rate of fats with a simpler and more coherent triacylglycerol composition, e.g, cocoa butter, favor the formation of more stable β′ and β polymorphs. Small and needlelike crystals of β′ polymorph are desirable in spreads, because they increase plasticity of the products. In baked products, they aid creaming by incorporating large amounts of air in the form of small air bubbles into the structure. A decrease in the chain length variety enables the formation of a highly ordered crystal structure, increasing the probabiblity of crystallization of triacylglycerols straight into the most stable β polymorph. β crystals are larger than those of β′ and may lead to undesirable sandiness in spreads. The influence of technological modification of food fats on polymorphism has been demonstrated. For example, an increase in the proportion of liquid canola oil in butterfat decreased the amount of β′ polymorph in the mixture. Further, interesterification of butter resulted in crystallization of butterfat in the β′ polymorphic form.

Marangoni and Rousseau emphasized that, although the triacylglycerol structure, solid–liquid ratio, and polymorphism greatly affect the rheological properties of spreads, the microstructure of the fat crystals network, *i.e*, aggregates of fat crystals and their interaction, is of paramount importance in the viscoelastic properties of spreads. The elastic properties of crystal network and of individual aggregates influence the overall rheology of spreads. The formation of large crystals and further aggregation of the crystals in the form of spherulites (Ostwald ripening) are energetically favorable. The differences in aggregate formation could not be explained sufficiently by changes in polymorphism. Rousseau *et al*. suggested that the viscosity of the liquid phase, composition, and tempering have a more pronounced effect on the aggregation of spherulites than polymorphism.

The addition of milk fat or its fractions in chocolates or in imitation chocolates (compound coatings) is another important application in which modification of the composition of triacylglycerol mixture, and hence polymorphism of triacylglycerols, has an important role. Cocoa butter, the main component of chocolate, with three major triacylglycerol species, i.e., 16:0–18:1–16:0, 18:0–18:1–18:0, and 16:0–18:1–18:0, crystallizes mainly in the β polymorphic form and has six subforms named I–VI. The V polymorph is a very stable and desirable form, giving an excellent appearance (gloss) in chocolates. Polymorphic transitions during storage are known to result in bloom development, i.e., loss of the bright glossy appearance of chocolates. Milk fat is added to chocolate in order to prevent blooming, soften the chocolate, and improve the flavor. The addition of anhydrous milk fat or high-melting-point fractions of milk fat in dark chocolate inhibits both the rate of bloom development and the time for the onset of visible blooming, which is most likely related to changes in the phase behavior and crystallization kinetics. The softening effect of milk-fat addition is due to the increase in the amount of stable β′ polymorph resulting from the more complex triacylglycerol structure and the increase in the proportion of low-melting-point triacylglycerols. Up to 30% of milk fat can be added to cocoa butter without resulting in extreme softening.

Triacylglycerol Structure and Fat Metabolism

When a chiral triacylglycerol with three different esterified fatty acids enters the upper intestinal tract, lingual and gastric lipases catalyze the hydrolysis of some of the fatty acids in the *sn*-3 position, producing 1,2-diacyl-*sn*-glycerol and free fatty acid. The short-chain acyls at the *sn*-3 position are easily hydrolyzed by gastric lipases. A mixture of triacylglycerol proceeds to the small intestine. Pancreatic lipase and its colipase hydrolyze the fatty acid from the *sn*-1 position of the 1,2-diacyl-*sn*-glycerol, and 2-monoacylglycerol and free fatty acid are formed. Pancreatic lipase also hydrolyzes the triacylglycerol that was not hydrolyzed by the gastric lipase, slightly preferentially in the *sn*-1 position producing 2,3-diacyl-*sn*-glycerol and free fatty acid. The 2,3-diacyl-*sn*-glycerol is hydrolyzed further by carboxyl ester hydrolase or pancreatic lipase, and 2-monoacylglycerol and free fatty acid

are formed. A very small fraction of the 1,2- or 2,3-diacylglycerols is expected to undergo acyl migration to the 1,3-diacylglycerol, which is probably hydrolyzed by lipases. Polyunsaturated fatty acids are poor substrates for pancreatic lipase, but carboxyl ester hydrolase hydrolyzes them effectively. When the fatty acids and 2-monoacylglycerol are absorbed into the enterocyte, the 2-monoacylglycerol is reacylated by monoacylglycerol transferase to 1,2-diacyl-*sn*-glycerol and 2,3-diacyl-*sn*-glycerol. The fatty acyl-CoAs are similar for acylation of the position 1 or the position 3. The activated fatty acids used in the acylation come from newly synthesized fatty acids in the cell and the fatty acids absorbed from lumen after bile phospholipid and fat digestion. The formed 1,2-diacyl-*sn*-glycerol and 2,3-diacyl-*sn*-glycerol are acylated by diacylgycerol acyl transferase to triacylglycerols. Since the acyl migration is expected be slow at 37 °C, the synthesized triacylglycerols retain the original fatty acid at the *sn*-2 position. The reacylation of absorbed 2-monoacylglycerols is the predominant pathway during active fat absorption. When the absorption 2-monoacylglycerols from the gut is minimal, the acylation of free glycerol through the 3-glycerophosphate by activated fatty acids proceeds to form 1,2 diacyl-*sn*-glycerol phosphate. The unsaturated fatty acids acylate mainly the *sn*-2 position and saturate the *sn*-1 position. Triacylglycerol is formed through dephosphorylation and acylation at the *sn*-3 position. Triacylglycerols formed by the 3-glycerophosphate pathway do not maintain the original fatty acid of the diet at the *sn*-2 position. However, during fat absorption, the 2-monoacylglycerol pathway dominates.

The synthesized mucosal triacylglycerols are packaged to chylomicrons and intestinal very-low-density lipoproteins, and secreted into the lymph. They are hydrolyzed in the capillary bed. Finally, the fatty acids and partial acylglycerols are reesterified in adipose or muscle cells. If the monoacylglycerol pathway is active in the tissue, where the triacylglycerols are stored, the original composition of 2-monoacylglycerol is retained. However, it is more likely that a different distribution of fatty acids occurs in adipose tissue triacylglycerols.

Characterization and Determination

E W Hammond, Greenisle-Consulting, Kettering, UK

Fatty Acid Composition

The fatty acid (FA) composition of triacylglycerides (TAG) is dependent upon the origin of the TAGs, but the FAs will normally be of even carbon number for vegetable fats and oils. Exceptions are TAG containing FA originating from bacterial (and some other microflora) origins. Thus, the TAG from ruminants such as cattle and sheep contain odd-chain and branched-chain fatty acids in small amounts. Typical fatty acid chain lengths for all TAGs are generally between C14 and C22, with the major fatty acids being of the C16 and C18 types. There are exceptions

here also. Some plants major in other chain lengths such as palm kernel and coconut fats (C8–C14), as well as cuphea, which has mostly C8 and C10, and wild-type rapeseed, which has half its FAs as a C22 chain length. Fish and marine animals have longer-chain FAs in the C18–C22 range. Amongst these FAs are the unsaturated series. These have one to six double bonds at specific positions in the chain because of their biochemical origin and species origin. There is also a range of FAs which have other chemically functional groups such as hydroxyl (e.g., ricinoleic acid from castor bean), epoxide (e.g., epoxyoleic acid from *Vernonia anthelmintica*) and cyclopropene (e.g., sterculic acid from *Sterculia foetida*).

The reason for mentioning the wide range of FAs is to point out that confident and accurate analysis of a sample of TAGs requires some knowledge of its origin. However, for most purposes, the analysis of the FA composition of TAGs from food is relatively simple, since the fats used have fairly uncomplicated fatty acid compositions. (*See* **Fats**: Classification; **Fatty Acids**: Properties.)

FA analysis of TAGs is done by gas chromatography after derivatization to methyl esters. (*See* **Fatty Acids**: Analysis.)

Positional Analysis

The FA composition of the three positions of the glycerol in TAGs is not entirely random: there is positional order. Lipase enzymes associated with TAG synthesis and hydrolysis are positionally specific in their action. This specificity is partly responsible for the differences in TAG composition between the many natural vegetable and animal fats and also for the consistency of fat structure within a fat species. The specific TAG structure of some fats is very important to their use in foods. For instance, cocoa butter has a high proportion of symmetrical TAGs, where position 2 is occupied by oleic acid, while positions 1 and 3 are occupied by a saturated fatty acid, typically palmitic and stearic acids. This structure produces a fat with very specific melting and crystallisation properties that are responsible for the particular physical qualities of chocolate products.

During research on such fats, it can be necessary to determine the positional composition of the FAs in the TAGs. This is achieved very conveniently using the specificity of some lipases. Usually, pig pancreatic lipase is used, which, in its purified form, is 1:3-specific. It hydrolyzes the esters on the 1 and 3 positions of TAGs, leaving the 2 position unchanged. The 2-monoacylglyceride obtained yields the composition of position 2. By examining the diacylglycerides (DAGs), product information on positions 1 and 3 can be obtained. If the DAG is chemically phosphorylated and then reacted with phospholipase A, information that is more specific is obtained about the *sn*-1 and *sn*-3 positions. (*See* **Cocoa**: Production, Products, and Use; **Enzymes**: Uses in Analysis; **Vegetable Oils**: Composition and Analysis.)

Recent significant advances in the interpretation of ^{13}C nuclear magnetic resonance spectra of pure TAGs show a more powerful way forward in determining TAG structure. However, at this time, the interpretation of spectra from natural vegetable oils is complex, because these oils are complex mixtures of different TAGs. In addition, the equipment used is not generally available to all laboratories that might be doing such an analysis. Alternative approaches using enzymes combined with different stereospecific derivatives and other column chromatographic techniques have been used with some success. These new approaches increase the possibility that such stereospecific positional analysis of natural TAG mixtures can become routine.

Methods

Isolation of TAGs

The sample must be greater than 99% TAGs for these methods to produce accurate results. If it is not, seven drops (100–120 mg) of melted and well-mixed fat are added to 2 ml of diethyl ether. This solution is applied to a small column of basic alumina (2.0 g, Brockmann Grade 1 basic alumina) in a glass filter tube, the column is washed with 2×5 ml diethyl ether, and the eluate is then collected in a screw-cap vial. The sample in the vial is then evaporated with a stream of nitrogen. This procedure normally provides 80–100 mg of pure TAGs. The method can be scaled up, but it is better to do multiple preparations in parallel.

Lipolysis – 2 Position Only

Approximately 100 mg of melted and well-mixed TAG is weighed into a screw cap vial (10 ml size). Two milliliters of tris(hydroxymethyl)aminomethane (Tris) buffer (1.0 M, pH 8.0) is added to the vial together with 0.2 ml of 22% aqueous calcium chloride (made up from the hexahydrate) and 10 drops of 10% aqueous Biosolve detergent/emulsifier (Beckmann solubilizer for scintillation counting). (Note: 0.5 ml of 0.1% sodium cholate may be substituted for the Beckmann biosolve, but emulsification will be less efficient, and yields are variable in our experience.) Other emulsifiers may be substituted, but require testing. The vial is placed in a water bath (set at 40 °C) for 15 min, and a solution of pure

monoheptadecanoin internal standard in diethyl ether (5 mg ml^{-1}) is prepared and stored in a closed vessel. The sample is sonicated for 1 min using an MSE ultrasonic sample preparator (MSE Soniprep 150) and then replaced in the water bath. This step needs to be done efficiently with a probe-type sonicator, particularly when the sample has a high melting point. The sample temperature is stabilized in the water bath for 2 min. An amount of the pancreatic lipase enzyme (Sigma catalogue number L3126), approximately equal to the weight of TAGs used, is added to the sample (the amount of enzyme is important). The vial is immediately capped and shaken vigorously in a wrist-action shaker for exactly 3.5 min (or the time determined for each batch of enzyme using standard TAG). Without delay, approximately 1.5 ml of cold, 2 M hydrochloric acid is added, and the vial transferred to an ice bath and shaken. Exactly 2.0 ml of the monoheptadecanoin solution and a further 2.5 ml diethyl ether are added and the sample quickly inverted a few times but without vigorous shaking. The vial is replaced in the ice bath, and the separated upper ether layer is transferred to another vial in the ice bath. The reaction mixture is extracted with a further 5 ml of ether and combined with the first on the ice bath. The combined ether extracts are washed twice with 5-ml portions of water, and then the ether extract is transferred to a vial containing approximately 3.0 g of anhydrous sodium sulfate. This is then capped and shaken to dehydrate the extract.

Isolation of monoacylglyceride (MAG) for FA analysis is carried out using the following procedure. Using either a pipette or a thin-layer chromatography (TLC) sample applicator, the ether solution is applied as a continuous streak 1 cm above the bottom of a TLC plate. The plate should be 20 cm × 20 cm glass coated with a 0.5-mm-thick layer of kieselgel 'G' (plates supplied by Anachem). This streak is focused by developing the plate twice to 3 cm above the base in 100% diethyl ether and air-drying the plate between developments. The plate is fully developed in a solvent of hexane/diethyl ether/formic acid (60:40:1, by v/v/v). The plate is air-dried and lightly oversprayed with 0.05% methanolic dichlorofluorescein. When the plate is dry, it is examined under ultraviolet light (350 nm), and the MAG, which will be at or just above the focused origin, is marked. (*See* **Chromatography**: Thin-layer Chromatography.)

The marked MAG band is scraped off and placed in a 20 ml Q/Q tube, to which 7 ml of acid methanolysis reagent is added. After thorough mixing, this is heated to 60 °C for 1 h with occasional mixing. Refluxing temperatures are discouraged here as vapor locks can form in the silica bulk, causing localized hot spots and possible decomposition of the fatty acid methyl esters (FAMEs). Water (7 ml) and diethyl ether (5 ml) are added, and the mixture is shaken after cooling. The top layer is transferred to a vial containing anhydrous sodium sulfate. The sample is then analyzed by gas chromatography. The MAG yield can then be estimated from the internal standard peak. The yield should be between 20 and 30% for reliable results that will reflect the true composition of FA on the 2 position of the TAG. (*See* **Chromatography**: Gas Chromatography.)

Lipolysis – 1:2 and 2:3 Positions

The DAG is required for this procedure. It is rare for good results for both MAG and DAG to be achieved from a single lipolysis. This is because the technique has to be optimized for the best yield of either MAG or DAG with zero or the least possible amount of acyl migration. Therefore, the lipolysis technique reported above for 2-MAG is repeated with the following changes:

1. The weight of lipase enzyme is reduced to one-quarter the weight of sample TAG (e.g., 25 mg of enzyme to 100 mg of TAG).
2. The reaction time is increased to 6 min or that time found for each batch of enzyme using standard TAG.
3. The MAG internal standard is not used.
4. After reaction, the sample is cooled on ice and carefully acidified to pH 2.0, then rapidly extracted into diethyl ether. The extract is washed twice with 5-ml aliquots of cold water, keeping it on ice as much as possible. The ether extract is then transferred to a vial containing anhydrous sodium sulfate, prior to TLC.
5. TLC is done as above, except that the formic acid is replaced by 2% ammonia. The 1,2/2,3 DAG will be found as a single band about 3 cm above the MAG. If lipolysis has been too protracted, acyl migration may have taken place, and two bands will be apparent (1,2/2,3 (lower) and 1,3 (upper) DAG). If the 1,3 DAG level is seen to be major component, the sample lipolysis must be repeated. The 1,2(2,3) DAG is recovered by elution from the silica with diethyl ether and concentrated with a stream of nitrogen.

The pure DAGs have to be chemically phosphorylated prior to reaction with phospholipase A, this is done according to the Lands *et al*. procedure using DAG kinase.

Twenty-five milligrams of the *sn*-1,2(2,3) DAG is weighted into a tube; the following are then added in sequence: 100 µl of bile salts solution (200 mg ml^{-1} in

water); 600 µl of 0.05 M adenosine triphosphate; 250 µl of 1.0 M magnesium chloride; 500 µl of 0.05 M sodium phosphate buffer, pH 7.95; 5.0 mg of DAG kinase in 500 µl of cysteine phosphate buffer.

After mixing and incubating at 37 °C with continuous shaking for 60 min, 1 ml of 1 M hydrochloric acid is then added.

The lipids are extracted from the reaction mixture with 15 ml of chloroform/methanol (2:1, v/v), shaking carefully, and then adding 3 ml of 1% sodium chloride solution. The lower chloroform layer is then transferred to another tube, and a second extraction is made with a further 6 ml of chloroform. Two drops of triethylamine are added to the combined chloroform layers, and the solvents are then evaporated. The phosphatidate products may be purified by TLC in a developing solvent of chloroform/methanol/water (65:36:8, v/v/v).

Stereospecific hydrolysis of the phosphorylated DAG is the final stage and is achieved with phospholipase A (*Crotalus adamanteus* venom – Sigma catalogue No. P0790). This enzyme is specific for the 2 position FA in an *sn*-1,2-diacyl 3-phosphatide but does not attack the *sn*-2,3-diacyl 1-phosphatide.

Ten milligrams of the phosphatidate is dissolved in 3 ml diethyl ether, to which 0.1 ml of 0.5 M Tris buffer (pH 8.5) containing 0.002 M calcium chloride and 0.5 mg of *Ophiophagus hannah* venom is added. This mixture is shaken gently for 16–20 h (overnight). Then, 5 ml of isobutanol and 20 µl of acetic acid are added and the whole reduced to dryness. The lipid in the residue is dissolved in a small amount of chloroform/methanol (2:1, v/v) and applied as a streak to a TLC plate and the application area thoroughly dried. The plate is first developed in hexane/diethyl ether/formic acid (50:50:1, v/v/v) to the top. The top third is sprayed with dichlorofluorescein (0.1%) in methanol. The free FA band is located under ultraviolet light (320 nm) and recovered. The TLC plate is then redeveloped in chloroform/methanol/14 M ammonium hydroxide (90:8:2, v/v/v), dried, and sprayed with rhodamine 6 G (0.1%) in toluene. The lysophosphatide and unhydrolyzed phosphatidate are located as above and recovered. All three of the recovered materials are prepared for analysis of their component FA by gas–liquid chromatography (GLC).

Results

The initial pancreatic lipase technique gives a reliable composition of the FAs present at the 2 position of a TAG. The phosphorylation and phospholipase A techniques produce a free FA fraction, a lysophosphatide, and unreacted phosphatidate. The FA fraction is typical of the *sn*-2 position and should confirm the result from the 2-position lipolysis, although there are often discrepancies in this comparison, and the primary (pancreatic lipase) result should be regarded as more reliable. The lysophosphatide gives the FA composition of the *sn*-1 position of the TAG. The unreacted phosphatidate gives the FA composition of the *sn*-2 and *sn*-3 positions, combined, of the TAG. The difference provides a complete TAG positional composition.

Cis/trans Ratios

The analysis of the total *trans* content by infrared (IR) techniques is covered in detail elsewhere in this Encyclopedia, which includes a full IR method. A *cis/trans* ratio is obtained in this case by the ratio of the percentage total unsaturates (determined by GLC) minus the percentage *trans* value (determined by IR analysis). (*See* **Fatty Acids**: Analysis; **Spectroscopy**: Infared and Raman.)

Trans unsaturated fats have been a part of the human diet at least since meat and fat derived from ruminant animals began to be consumed. However, the amount of such *trans* unsaturated FAs consumed was relatively small. The advent of chemically hardened fats for the manufacture of margarine and shortenings dramatically changed the level of *trans* unsaturated FAs consumed. The hardening process involves catalytic addition of hydrogen across the unsaturated centers. However, during the process, a proportion of the double bonds isomerize to the *trans* geometry, typically 30–70% depending on the type of catalyst and the conditions of the hardening process. The *trans* isomerization process is accompanied by double bond movement along the FA chain, so that a complex mixture is formed. This mixture is very difficult to analyze with which to obtain accurate *cis/trans* ratios. GLC of FAMEs derived from the fat has proved the best technique, but even here, there are considerable problems. (*See* **Margarine**: Methods of Manufacture.)

For GLC of FAMEs, the official AOCS method prescribes the cyanopropylpolysiloxane phase SP2340. The column should be 60 m × 0.25 mm fused silica with a 1-m retention gap of silanized fused silica with a film thickness of 0.2 µm. Such columns provide adequate separation of *cis* and *trans* FAME for most situations involving food fats (except fats containing hydrogenated fish oils). However, there will be peak overlap, and for exacting analyses, where information is required on the isomeric nature of the *trans* FAME, even these columns are not adequate. For separation that is more complete, a column of SP2560, 0.2-µm film on 100 m × 0.25 mm fused silica should be used. In both column cases, the

carrier gas can be helium (linear velocity 20 cm s^{-1}) or hydrogen (40 cm s^{-1}). The column temperature should be optimized, using standards, between 175 and 200 °C isothermal. Otherwise, faster results can be obtained by programming the temperature between 100 and 225 °C with some sacrifice to optimum resolution. The samples should be injected using the on-column technique in preference to split injection.

Cis/trans ratios calculated from this type of chromatography are generally more accurate than those obtained via IR techniques. However, this is true only below 10% *trans* content. Above 10% *trans* content, the IR technique gives more accurate results.

TAG Analysis in Foods

TAG is readily analyzed by chromatography after extraction from the food matrix. The extraction may be the most difficult part of the whole method and should be given careful attention. Many foods lend themselves to Soxhlet extraction with petroleum or chloroform solvents. Other foods containing spray-dried, or encapsulated fats have to be hydrated first, or fat yields will be low. Cereal flours require extraction with water-saturated *n*-butanol followed by a mixture of chloroform/methanol in order to obtain all their lipids. Once a total lipid extract is obtained, it can be analyzed complete for class composition.

If the TAG is less than 95% of the total lipid, it should be 'cleaned up' as above. This TAG can be analyzed via three routes; high-temperature gas chromatography (HTGC), nonaqueous reversed-phase high-performance liquid chromatography, or argentation high-performance liquid chromatography. (*See* **Chromatography**: High-performance Liquid Chromatography.)

HTGC can be applied in two forms: nonpolar-phase- and polar-phase gas chromatography (GC). Nonpolar phase GC is the choice for accurate basic information about composition, which, when considered together with FAME analysis, will normally confirm the type of fat. The data provided are a separation based upon 'carbon number' (essentially molecular weight), but it does not discriminate between saturated and unsaturated species of TAGs. A 7–10 m × 0.53 mm fused-silica column with a bonded phase of SP2100, OV1, or equivalent at a thickness of 0.1 μm gives excellent results (a 1-m silanized retention gap must be fitted). The injection technique should be on-column (Carlo Erba) with helium or hydrogen as the carrier gas. The carrier gas flow is high at 10 ml min^{-1}. For nonlauric fats, the initial column temperature is set at 100 °C, held for 2 min, and then programmed at 25 °C min^{-1} to 310 °C. For lauric fats or fats containing butter, the initial temperature is set to 50 °C with a hold of 4 min, and then programmed at 25 °C min^{-1} to 310 °C. The TAG sample is dissolved in iso-octane (or, if solubility is a problem, chloroform) to a concentration of about 5 mg ml^{-1} (5 μg in 5 μl). The sample volume loaded is 0.5 μl, equivalent to about 2 μg of TAGs. Figure 1 shows typical data.

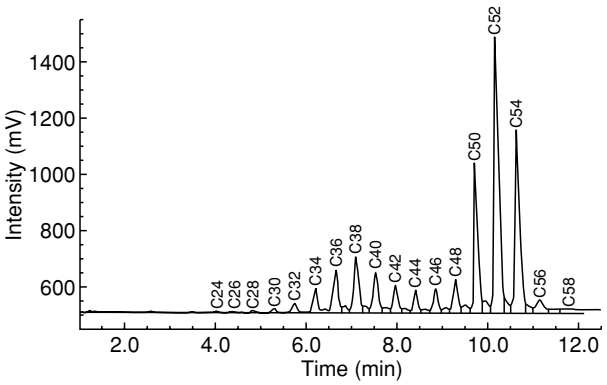

Figure 1 Triacylglyceride carbon number analysis by HTGC using cold on-column injection and a Carlo Erba gas chromatograph. See text for further details. The sample is a mixture of cocoa butter and butter fat. The peak names are the sum of the carbons in the FA chains and exclude those in glycerol (e.g., C54 might equal 3 × C18 or C16 + C18 + C20).

The polar-phase GC technique provides more information on the isomeric composition of TAGs and discriminates between the saturated and unsaturated TAGs. However, there are quantitative problems in the application of this method, requiring trained analysts with good interpretive skills.

TRITICALE

K Lorenz, Colorado State University, Fort Collins, CO, USA

Introduction

Triticale, the first synthetic cereal, is the product of a cross between wheat (*Triticum* spp.) and rye (*Secale cereale* L.) and has been of both practical and theoretical interest. This cross is an attempt to combine in one strain the high yield and good bread-baking quality of wheat and the winter hardiness, high lysine and protein, drought tolerance, and disease resistance of rye. In all soils presently unsatisfactory for wheat but acceptable for rye, it would be desirable to be able to grow a cereal which is equal to wheat in both yielding capacity and in nutritional, and bread-baking quality.

While it was simple to outline this task, many difficulties had to be overcome before successful crosses and fertile hybrids could actually be produced. From the 1930s to the 1950s, research on triticale never really progressed past the botanical curiosity stage, despite considerable efforts. Many of the goals that had been set eluded the plant breeders. Recent research efforts, however, have resulted in triticales of acceptable quality and characteristics which are grown commercially in many countries around the world.

Breeding

Triticales are produced by crossing either tetraploid wheat (*Triticum durum* L.: genomes AABB) or hexaploid wheat (*Triticum aestivum* L.: genomes AABBDD) with diploid rye (*Secale cereale* L.: genomes RR) and doubling the resulting haploid by treatment with colchicine, which produces a fertile amphidiploid. These crosses produce primary hexaploid (genomes AABBRR) and octoploid (genomes AABBDDRR) triticales, respectively. The production of triticales is outlined in **Table 1**. Intercrossing primary triticales within their own ploidy levels was practised from the 1930s until the 1950s and resulted in improvements in plant type, but yields and stabilities of the best lines remained significantly below those of wheat. In the mid-1960s, hexaploid triticales and hexaploid wheat were intercrossed, producing significant improvement. Dwarfing and disease resistance genes from hexaploid wheat were added to the hexaploid triticale gene pool. In the 1980s, crossing of octoploid triticales with hexaploid triticales, which allows substitution of D-genome chromosomes and chromosome segments from wheat for those of the A and B genomes, became the main approach to triticale germ plasm expansion. Perhaps the most important aspect of triticale breeding for the future, especially for hybrid production, is the use of doubled-haploid technology.

World Production and Yields

Triticale production figures, given in **Table 2**, are obtained from communications with plant breeders. Areas of production have been increasing annually for several years: the increase is occurring mainly on marginal soils, such as the sandy soils of Poland and Russia. In many countries, triticale offers farmers an alternative crop which is not controlled by any

Table 1 Development of primary and secondary triticales and examples of substitutional triticales

Primary triticale		
Common wheat	×Rye	[a]→Octoploid triticale
Triticum aestivum L.	*Secale cereale* L.

All Africa Crop Science Congress, Pretoria, South Africa, pp. 10–15.

marketing board nor required to meet quality standards of other grain crops. Recent cultivars also have a dual purpose by providing green feed for animals before developing into a grain crop.

The yield potential of triticales under optimum crop production environments has reached nearly the same level as that of wheat while outperforming wheat under marginal environments. Yield capacity has improved because of the addition of genes for tillering, additional dwarfing, and better grain test weight. Yields will vary, however, depending on the triticale variety, location at which it is grown, the date of seeding, and the amount of available water during the growing season.

Machinery designed for the harvest of wheat can be used for triticale. No special harvest equipment is needed.

Agronomic Factors

The influence of agronomic variables on yield, composition, and other triticale characteristics has been described in many scientific publications. In general, the ability to adapt still seems to be limited for some varieties of triticale. Their performance is influenced by such factors as latitude, day length, elevation, temperature, availability of moisture, and nutrients in the soil. Some triticales still have the tendency to produce few tillers which limits yield. Triticale still lacks the benefits of many generations of natural selection which wheat and rye have gone through in order to perform well under many different agronomic conditions.

Any disease that attacks wheat and rye also attacks triticale. The cross does not exhibit improved

resistance to many wheat diseases, as was hoped. Some genes for resistance in either parental species are not fully expressed in triticale, which resulted in susceptibility to disease for which wheat or rye show resistance. There are no explanations. Obviously, complex reactions between genes of wheat and rye take place.

Kernel Development and Sprouting

Kernels of some triticales have a tendency to be shriveled. Triticales developed from the late 1960s up to the mid-1970s almost always showed shriveled grain. The causes still need to be elucidated today. Many potential causes for grain shriveling have been examined and rejected. There seems to be a genetic component influencing this condition. Shriveled kernels have a higher production of aberrant nuclei in the coenocytic endosperm and higher levels of acid phosphatase. Application of selection pressure for plump grain between 1977 and 1992 produced triticale advanced lines with high test weights and high flour yield. These lines have plump to only slightly shriveled grain.

Preharvest sprouting associated with late maturity has been a major problem, inhibiting the commercialization of triticale in several countries. Development of early-maturing varieties, capable of escaping the high-moisture period during harvest, has decreased chances of preharvest sprouting. New sources of genetic resistance to this condition in wheat parents are being utilized in present breeding efforts.

Composition

Average percentage composition of triticales is shown in Table 3. Slightly higher protein values compared to wheat are frequently cited as an advantage of triticale over wheat. However, high protein values are often misleading. Nitrogen values for shrivelled kernels, in which ratios of endosperm to bran plus germ are low compared to normal kernels, are higher than those for plump grains. Germ, scutellum, and aleurone are proportionately higher in nitrogen than the endosperm. Furthermore, triticale proteins are often calculated using a conversion factor of $N \times 6.25$, expressed on a dry-weight basis, which gives 30% higher values than $N \times 5.7$ at 14% moisture. Decreased protein values have accompanied the improvement of triticale's agronomic qualities. This is not surprising, since improvements in grain size result in a decrease in the percentage of protein in cereals owing to a disproportionate increase in starch content. (*See* **Cereals**: Contribution to the Diet.)

Lysine, which is the first limiting amino acid in wheat, is often, but not always, present in larger amounts in triticale than in wheat. Lysine is still the first limiting amino acid in triticale. Essential amino acid content of triticale compared to wheat and rye is shown in Table 4. Expressed as yield per hectare, the differences in lysine between wheat and triticale do not seem significant since lysine depends on the productivity of the variety. (*See* **Amino Acids**: Properties and Occurrence.)

The starch and fat (ether extract) contents of triticale are not significantly different from those of the parental species.

Except for lower amounts of nicotinic acid in triticales compared to wheat, the vitamin composition of triticales is comparable to that of wheat and better that that of rye, as illustrated in Figure 1. Average mineral composition of triticales compared to that of wheat shows no major differences, with the possible exception of iron, which appears to be present in higher amounts in triticales than in wheats, as shown in Table 5.

Toxic substances and nutritional inhibitors in triticale, which may interfere with the digestibility and availability of certain nutrients to humans and/or animals, include ergot, resorcinols, phytates, and enzyme inhibitors.

Ergot results from an infection of cereal grains by the fungus *Claviceps purpurea* which produces

Table 3 Average percentage composition of triticales

	Average composition (%) (ranges in parentheses)
Dry matter	87.0 (86.7–90.0)
Moisture	12.0 (10.0–13.3)
Crude protein (N × 6.25)	13.2 (11.3–18.5)
Ether extract	1.8 (1.3–2.7)
Crude fibre	2.4 (1.4–3.8)
N-free extract	67.8 (65.0–80.0)
Ash	1.8 (1.4–2.4)
Starch	50.7 (46.5–54.4)

alkaloid-containing sclerotia. Relatively high levels of infections of ergot on triticales have occurred in some years. However, no statistics are available about the extent of infections in the various triticale-growing areas of the world.

Resorcinols seem to be partially responsible for reduced food intake and rate of weight increase of cattle, sheep, pigs, poultry, and horses. Triticales contain higher amounts of resorcinols than wheat. Milling of triticales will channel most of these resorcinols into the feed fractions. Phytic acid forms insoluble compounds with minerals, making these elements unavailable. Phytic acid, trypsin, and chymotrypsin inhibitors have been extracted from triticale in amounts intermediate between wheat and rye. (*See* **Phytic Acid**: Nutritional Impact.)

Food Uses

The prediction of the 1970s of a rapid expansion of the acceptance of triticale by millers and bakers for cereal-based products has not been realized. It appears that the success of triticale today depends on its ability to substitute to a greater or lesser extent for traditional wheat products.

Triticale grain can be milled into flour by the same milling process as used for wheat or rye. Because of the wide variation in kernel hardness and the degree of kernel shriveling, there is no standard procedure for triticale. Research has shown that breads can be baked from triticale flours provided that adjustments in formulation, mixing, and fermentation are made from those used in the production of white bread. Yeast level is increased, the fermentation temperature is lowered, and fermentation and proofing times are shortened. The high α-amylase activity of most triticale flours requires fermentation adjustments. Dough mixing is critical, since triticale flours do not have the same quality of gluten as wheat flour. The production of breads of low specific volume from triticale flours, as they are produced in many developing countries, creates less of a problem than production of the high-volume white bread.

The overall bread-making quality of newer triticale cultivars is considerably better than that of earlier ones, but it is still somewhat inferior to that of bread wheat of the same protein content due to a deficiency in protein quality, as reflected by a lower percentage of gluten compared to bread wheat.

Triticale flour can be used to some extent in the production of cakes, biscuits, tortillas, and other soft wheat products since triticale basically performs like a soft wheat. Layer cakes of acceptable quality can be produced from 100% triticale flour after proper chlorine treatment of the flour. Formulations of layer cakes from blends of triticale–wheat flour, ranging from 20% to 50% triticale, and additional emulsifier in the formulation produced cakes equal to or significantly larger than the soft wheat control cakes without additional emulsifier.

Triticale flours gave significantly smaller biscuit diameters and top-grain scores than biscuits baked with soft wheat flours. The biscuit-baking performance of flours from certain triticale cultivars may be improved, however, by increasing emulsification in the dough system, to equal or exceed soft wheat standards without additives.

Triticale pancake and waffle mixes have appeared on supermarket shelves. They are indistinguishable in appearance from those made with wheat flour, but differ in flavor and taste. Protein concentrates and starch have been prepared from triticale. Whole-grain triticale has been used to make bulgur.

Malting and Brewing

Compared to barley, triticales show relatively large malting losses, but yields of malt extracts are generally higher with triticales than with barley. Triticale malts are high in nitrogenous material, diastatic power, and α- and β-amylase. (*See* **Malt**: Malt Types and Products; Chemistry of Malting.)

Beers from triticale worts are darker in color and have a higher pH than beers from barley. Most triticales produced beers with satisfactory clarity–stability and gas stability. Triticale beers generally contain less alcohol and more nitrogenous compounds than barley beers. (*See* **Beers**: Wort Production.)

Feed Grain

Most triticale grown in the world today is used as feed grain. Triticale feeding trials in general have been encouraging. The overall conclusion from tests on weaned piglets, growing-finishing pigs, and broiler chicken was that triticale rated equal to wheat and corn. Protein digestibility was significantly higher with triticale than with sorghum in rations for cattle and sheep. Triticale was found to be comparable to durum wheat fed to turkeys. There are, however, also triticale feeding studies which reported poor feeding efficiency and reduction in weight gain. Reasons for such inconsistencies are as varied as the triticale varieties themselves. Variations in protein content, amino acid composition, nutritional availability, and antinutritional factors can all have an effect upon triticale's performance as a feed grain.

It appears, however, that ergot-free triticale is at least equal to wheat when used as a partial replacement in animal rations.

Forage

Triticale has been used as a forage from Palouse silt loam of the US Pacific Northwest, to loam soils of Guelph, Ontario, Canada, to the fine sandy loam of Texas; although not originally intended for its use, it has gained acceptance in most areas as an alternative forage. Both winter and spring varieties may be utilized as a nutritious food supply for livestock. Forage yields have been reported from as low as 4.98 tons ha^{-1} to 12.55 tons ha^{-1} with different varieties.

In southern New South Wales, Australia, dual-purpose triticales have almost completely replaced oats as a forage crop. In China, triticale has been identified as a promising silage crop compared to barley. In many parts of the world triticale is being used successfully as a forage or in mixtures with legumes for grazing, cut forage, hay, or as whole crop silage.

TRYPSIN INHIBITORS

G P Savage and S C Morrison, Lincoln University, Canterbury, New Zealand

Introduction

Trypsin inhibitors occur in a wide range of foods. They have been studied extensively in plants belonging to the Leguminoseae, Solanaceae, and Gramineae families, as the majority of species in these families are considered as important food sources; the most important species are the grain legumes such as chickpeas, mung beans, and soy beans. Grain legumes are a major source of protein in the diets of many people throughout the world and are thought to provide about 10% of the world's dietary protein. They are used extensively as a protein source for animal feeds. The existence of a number of antinutritive factors in legume plants, especially a group of protease inhibitors, has limited the use of legume seed protein. Several different types of protease inhibitors may be present in the same tissue.

Structure and Mechanism of Action

The most common inhibitors in legumes act on serine proteases, a group of proteolytic enzymes, including trypsin and chymotrypsin. Serine protease inhibitors are proteins that form very stable complexes with these digestive enzymes, reducing their activity to very low levels. Some nonprotein inhibitors have also been identified.

Protease Inhibitors

Protease inhibitors have been classified into families based on the homologous sequences of amino acids at the reactive inhibitory sites. The molecular structure of the inhibitor affects both strength and specificity of the inhibitor. The two main groups of protease inhibitors found in legumes are the Kunitz soy bean trypsin inhibitor and the Bowman–Birk soy bean protease inhibitor.

Protease inhibitors exist in several different isoforms, each with differing isoelectric points and stability towards heat. In New Zealand peas, for instance, between six and 10 isoinhibitors in each cultivar have been observed, with isoelectric points ranging from 4.6 to 7.6.

Kunitz Soy Bean Trypsin Inhibitor (KSTI)

The first protease inhibitor to be isolated and characterized was KSTI. Molecular weights (mol wt) ranging from 18 to 24 kDa and isoelectric points of 3.5–4.4 have been reported. This wide variation may be attributed in part to isoforms of the inhibitor. Taking into account all the variations, it appears that the mol wt of most KSTIs is approximately 21 kDa. KSTI consists of 181 amino acid residues linked by two disulfide bonds; the reactive site is located at residues 63 and 64, as shown in Figure 1.

A competitive inhibitor, KSTI binds to the reactive site of trypsin, in a similar manner as it does to the substrate protein, causing hydrolysis of the peptide bonds between reactive site residues of the inhibitor or substrate. Inhibitors differ from substrate proteins in that the reactive site residues are held between disulfide bonds. After hydrolysis, the modified inhibitor is held together with the same conformation, because of the disulfide bond. This forms a stable enzyme–inhibitor complex.

Bowman–Birk Soy Bean Proteinase Inhibitor (BBI)

The second proteinase inhibitor to be isolated and characterized, BBI, differs from KSTI in four ways. It is a relatively small molecule of molecular weight 7–9 kDa, and is a 'double-headed' inhibitor with independent binding sites for chymotrypsin and trypsin. As it contains seven disulfide bonds, BBI is rich in cysteine (20%). There have been conflicting reports about the stability of this inhibitor. Bowman and Birk commented that BBI displayed marked stability towards heat, acid, alkali, and proteolytic enzymes such as pepsin. It was initially thought that increased heat stability was attributed to the stabilizing effect of the disulfide bonds on the whole structure (Figure 2), thus BBI would be more stable than KSTI. However, some chymotrypsin inhibitors from potato and barley, which display thermostability, contain no or only one disulfide bridge. Other reports found BBI to be more heat-labile than the Kunitz inhibitor. This might be attributed to the many disulfide bonds, which do not give BBI stability but rather make the inhibitor susceptible to bind with other sulfhydryl (-SH) groups other than those of the inhibitor. The heat stability of BBI, however, has been shown to be dependent on concentration.

Limited proteolysis results in separation of the inhibitor into two active fragments, one with trypsin inhibitor activity and the other with chymotrypsin inhibitor activity. Further study of protease inhibitors

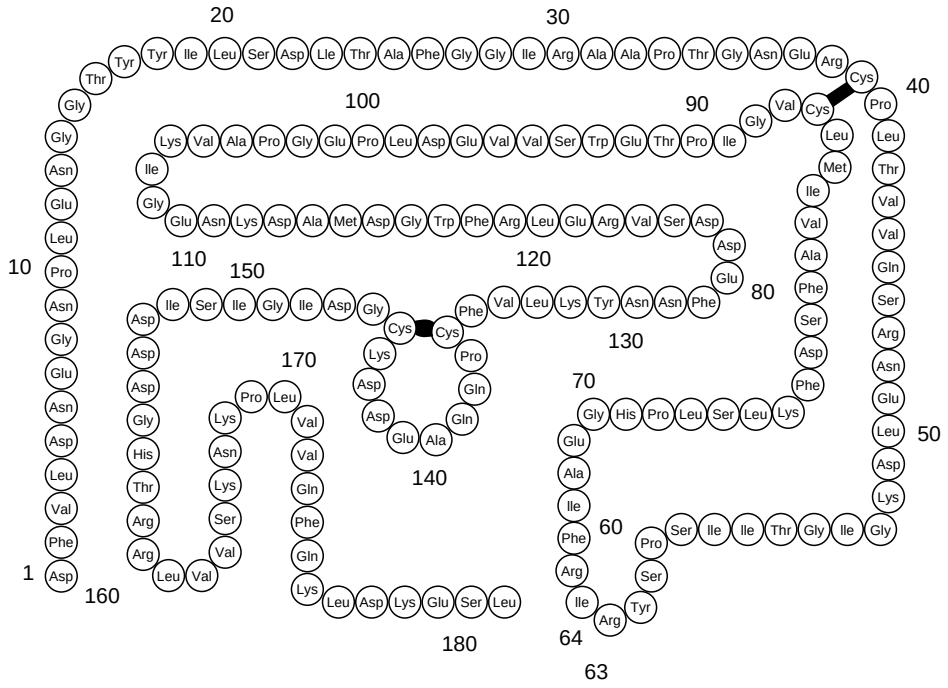

Figure 1 Structure of the Kunitz soy bean trypsin inhibitor. From Koide T and Ikenaka T (1973) Studies on soybean trypsin inhibitors: 3. Amino acid sequence of the carboxyl-terminal region and the complete amino-acid sequence of soybean trypsin inhibitor (Kunitz). *European Journal of Biochemistry* 32: 417–431, with permission.

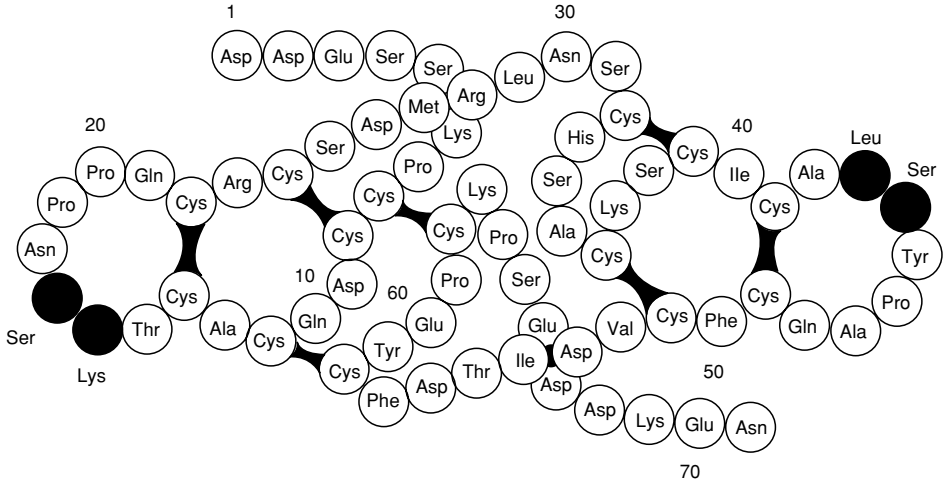

Figure 2 Structure of the Bowman–Birk inhibitor. From Odani S and Ikenaka T (1973) Studies on soybean trypsin inhibitors: VIII. Disulfide bridges in soybean. Bowman–Birk protease inhibitors. *Journal of Biochemistry* 74: 697–715 with permission.

has revealed that the BBI is a prototype for a whole family of homologous inhibitors found in grain legumes and in some other plant families. The sequences of amino acids surrounding the two reactive sites of the BBI are remarkably similar, not only to each other but also to homologous active sites of legume inhibitors isolated from other common grain legumes. Comparison of the BBI with inhibitors isolated from pea, groundnut, and chickpea show that these are double-headed inhibitors, although the mechanism by which they inhibit trypsin may differ slightly owing to the spatial arrangement of

the reactive sites. As many as five protease inhibitors that have properties similar to the BBI may be present in soy beans.

Determination of Activity

The basic method of quantifying trypsin inhibitors has been improved to increase its accuracy and sensitivity and has been further simplified and miniaturized. Many modifications to the basic method have been made: the most common are the use of different substrates, e.g., casein instead of the synthetic substrate benzoyl-DL-arginine-*p*-nitroanilide, or the use of other types of trypsin, e.g., porcine rather than bovine. These modifications make it difficult to compare the results published by different authors. Assessing the variations in inhibitor activity between legumes is made very difficult by the fact that trypsin inhibitor activity (TIA) is not determined using a standard procedure.

The trypsin inhibitor affinity assay only determines protein-type inhibitors forming complexes with trypsin, but is highly sensitive at low concentrations.

Immunological methods developed for the detection and characterization of specific types of protease inhibitors involve the use of specific protease antibodies. Recently, a specific immuno-(chymo)trypsin inhibitor assay has been developed, which discriminates between the two main protease inhibitors in soybeans, KSTI and BBI, unlike the Kakade enzymic assay which does not.

Several different units have been used when measuring TIA, which also make comparisons between data difficult. TIA is most commonly expressed as trypsin inhibitor units (TIU) per milligram of sample ($TIU\,mg^{-1}$ DM) where one TIU is defined as a decrease of 0.01 absorbance units at 410 nm per 10 ml assay solution under specified assay conditions. These units make it possible to measure protease inhibitors of any material without having to find a suitable trypsin inhibitor standard.

Interfering Substances

With samples which are low in TIA, the accuracy of the values obtained can be distorted by nonspecific interference from other proteins and compounds in the reaction mixture. Interfering substances include tannins in colored legume seed coats; free fatty acids released in fermented products such as miso and tempeh and indigestible polysaccharides can complex with trypsin and contribute to the total TIA under assay conditions.

However, the presence of tannins and TIA in field peas was found to be significantly negatively correlated, indicating that tannins were unlikely to be responsible for the additional inhibition of trypsin in the Kakade assay. Maple and wrinkled peas have high tannin levels but low TIA, irrespective of testa or flower color. It would seem that those cultivars exhibiting high tannin content have low levels of TIA or vice versa, possibly to compensate for the other compound, as both of these antinutritional factors have been linked with disease resistance in plants.

Distribution within Plants

Trypsin inhibitors are found most often in the seed but their location is not necessarily restricted to this part of the plant. In some legumes, such as the mung bean and the field bean, high levels of TIA are found in the leaves as well. They are present in many legumes in varying amounts. They are also found in the leaves and tubers of tuberous plants, such as potatoes (*Solanum tuberosum*) and sweet potatoes (*Ipomoea batatas*).

A higher level of TIA has been found in the outer part of the cotyledon of soy beans, kidney beans, and chickpeas, and in five different cultivars of peas four times as much TIA was found in the cotyledon than in the seed coat. Similar findings have been reported for soy beans. In contrast, *Vicia faba* (faba bean) seeds were found to have twice as much TIA in the hull than the cotyledon.

Levels in Grain Legumes

Trypsin inhibitors are widely distributed across many genera and species in the Leguminoseae family and many other plant families; TIA has also been found in a range of legumes, including red gram, kidney beans, navy beans, black-eyed peas, peanuts, field beans, French beans, and sweet peas, and in all varieties tested of cowpeas, mung beans, lima beans, winged beans, chickpeas, and rice beans. In addition, TIA was found in lentils, but there was almost no TIA in lupins.

Although trypsin inhibitors are found in most legumes, the levels present tend to vary considerably. Most legume species contain less than 50% of the TIA of soy beans. Particularly low levels are present in broad beans, peas, mung beans, lupins, and a few varieties of kidney beans. Those species with at least 75% of the TIA in soy beans include cowpeas, pinto beans, pigeon peas, kidney beans, moth beans, and navy beans. Common legumes that contain levels higher than those of soy bean include lima beans, winged beans, and black beans.

Differences in TIA between cultivars have been observed, suggesting the possibility of breeding for low TIA. For example, it was found that winter cultivars of peas were twice as active as summer cultivars and that wrinkled cultivars were more active than smooth cultivars. Considerable variability has also been reported amongst different strains of cowpeas.

Stage of maturity has also been shown to influence TIA. As soy beans mature, the amount of TIA increases, although the magnitude of increase differs between varieties. The germination of a number of grain legumes appears to increase their nutritive value, although the effect on TIA seems to be quite variable. There have been no reports of a significant decrease in TIA on germination of lentils, chickpeas, and navy beans but there was a decrease in TIA when field peas were germinated. Other studies have found that after germination of *Vicia faba* for 5 days TIA decreased by 63%; TIA decreased by 50% in red kidney beans after 10 days' germination, and TIA in three soy bean varieties decreased by an average of 13% over 3 days' germination. The loss of TIA in some cases may be accounted for by leaching during soaking and washing procedures.

Effect of Processing

Processing can generally be divided into methods that are commonly used to prepare legumes for human consumption, and those that are used in the production of animal meals. The popularity of grain legumes in human diets is no doubt attributable to the relative ease with which TIA can be destroyed by many of these methods. However, destruction of TIA inevitably results in loss of some of the nutritive value of the legume.

Boiling

Cooking presoaked (24-h) winged beans in boiling water for 30 min was found to destroy most TIA. It was also reported that mature soy beans required a presoak of 24 h and cooking for at least 20 min to eliminate TIA completely. Immature seeds do not require presoaking to eliminate TIA. This, and the fact that oven heating has very little effect on TIA, suggests that the moisture content of the seed plays an important role in the destruction of trypsin inhibitors. Soaking chickpeas, broad beans, and mung beans alone reduced TIA levels by 58–92%. Combined soaking (18 h) and boiling (20 min) led to a 9.9–56.7% reduction in peas, depending on cultivar.

It has been suggested that the extent to which TIA is destroyed by heating is a function of the temperature, duration of heating, particle size, and moisture content – variables that are closely controlled in the industrial processing of soy bean meals in order to obtain a product maximum nutritional value. The nonprotein TIA content would also determine the reduction in TIA achieved by the heating process. Researchers have also found that the percentage of TIA remaining in the cooked peas was found to be negatively correlated to increased TIA levels in the raw form, therefore it appears that the effect of cooking is more effective in destroying TIA when the original inhibitory activity (raw seed) was higher than when it was low. A summary of the effects of various heat treatments on TIA is given in Table 1.

Table 1 Effect (percentages of original activity) of various types of heat treatment on the trypsin inhibitor activity (TIA) of legumes

TI, trypsin inhibitor.

From Rackis JJ, Wolf WJ and Baker EC (1986) Protease inhibitors in plant foods: content and inactivation. In: Friedman M (ed.) *Advances in Experimental Medicine and Biology: Nutritional and Toxicological Significance of Enzyme Inhibitors in Foods*, pp. 299–337. New York: Plenum Press, with permission.

Other Cooking Methods

Heating at temperatures below 75 °C appears to have no effect on winged beans. Increasing the temperature to 100 °C resulted in a 5% decrease in TIA of winged beans. By increasing the temperature to 80 °C, it was found that TIA in white winged beans decreased by 25%, in 5 min and 45% after 30 min. Dry heating (177 °C for 20 min) peanuts and soy beans decreased TIA by 7% and 20% respectively.

Autoclaving has been shown to decrease TIA significantly. In peanuts and soy beans autoclaved at 121 °C for 20 min TIA decreased by 80% and 86% respectively Autoclaving whole winged beans and winged bean meal decreased TIA by 80%.

Infrared treatment for 30 s on winged beans was reported to have destroyed most TIA in the seeds.

Microwave radiation of broad beans for 30 min was found to destroy 90% of their TIA. It was found that microwave treatment (time not known) had no effect on TIA in winged beans. Microwave treatment for 1.5–3.0 min of presoaked soy beans destroyed 85–90% of the TIA.

Physiological Effects

The majority of experiments which have considered the physiological effects of grain legume TIA have been carried out on animals and inferences made about the effects on humans. The effects of TIA found in soy beans have been predominantly studied as the availability of pure forms of KSTI and BBI have made the task of elucidating the inhibitor actions much easier. The efficient digestion of proteins in the digestive system requires the action of a number of proteolytic enzymes, each hydrolyzing peptide chains at specific points. These enzymes are produced and stored in the pancreas in a precursor form known as zymogens. The efficient digestion of proteins requires simultaneous activation of all the zymogens. Trypsin is thought to act as the common activator of pancreatic zymogens.

Proteolytic Activity and Growth

Because trypsin activates proteolytic enzymes, an overall decrease in proteolytic activity would be expected from the action of trypsin inhibitors. *In vitro* studies have shown that KSTI, BBI, and lima bean inhibitor completely inhibited trypsin and chymotrypsin activity of human and rat pancreatic juice. The TIA caused up to 50–60% reductions in total proteolytic activity, and the residual activity observed was attributed to carboxypeptidase activity.

Reduction in growth owing to loss of proteolytic activity appears to vary between species fed raw soy bean diets. Growth was reduced in the rat, mouse, chick, and young guinea pig, whereas the adult guinea pig, dog, pig, calf, monkey and, probably, the human appeared to grow normally when fed these diets.

There are a number of factors that might contribute to the differences in proteolytic activity and growth between different species. One is that gastric juices can inactivate protease inhibitors. In one study human gastric juice almost eliminated the protease inhibitor activity of KSTI when incubated for 24 h. It was found that lima bean inhibitor activity was only slightly affected by incubation in gastric juice, suggesting that inhibitors homologous to lima bean inhibitor are nutritionally more important than inhibitors from the KSTI family.

Another reason for the varying activity of protease inhibitors between species may be differences in the specific activity of species-specific trypsin. In humans, proteolytic enzymes hydrolyze casein at a lower rate than in many animals, and the effect of inhibitors may therefore be weaker in humans. Soy bean trypsin inhibitor was shown to have a much greater effect on trout trypsin than bovine trypsin, probably owing to a higher specific activity of trout trypsin.

Human trypsin is known to exist in two forms. The cationic form constitutes two-thirds of the total trypsin secreted and is only very weakly inhibited, whereas the anionic form is inhibited stoichiometrically. Infusion of raw soy bean extract into the duodenum of rats and humans caused the secretion of a modified inhibitor-resistant trypsin, which was resistant to typical serine protease inhibitors. The BBI was more potent than KSTI in producing TIA-resistant enzymes. Whether or not this was just the cationic form of trypsin is unclear. The ability of the pancreas to adapt to trypsin inhibitors may determine the effects that they have on different species.

Toxicological Effects

The main toxicological effect observed from the ingestion of trypsin inhibitors is a marked hypertrophy of the pancreas. Pancreatic hypertrophy is thought to be caused by TIA stimulating excess enzyme secretion, which draws essential amino acids away from other body functions; in some cases this results in death of the animal.

Negative feedback control of pancreatic secretion is mediated by cholecystokinin (CCK). CCK is released from the intestinal mucosa when levels of trypsin or chymotrypsin are lowered, such as in the formation of the trypsin–trypsin inhibitor complex. The action of this complex is mediated by a

trypsin-sensitive CCK-releasing peptide, which interacts with the luminal surface of the small intestine to stimulate the release of CCK into the circulation. CCK stimulates the secretion of the pancreozymins, trypsinogen and chymotrypsinogen, the precursors to trypsin and chymotrypsin respectively. Recently, complexed as well as free inhibitors have been found to stimulate the discharge of CCK in rats and as a result have significantly increased the trypsinogen and chymotrypsinogen secretion rates. In normal circumstances, when trypsin levels are adequate, trypsin exerts a negative effect on this monitor peptide in the gastrointestinal tract suppressing its pancreatic secretion rate.

The pancreas may therefore function abnormally when these inhibitors are present as it produces more enzymes to compensate for the loss of the enzyme via the enzyme–inhibitor complex. Dietary amino acids may be directed from other protein synthesis sites in the body tissues for the synthesis of these additional pancreatic enzymes. As pancreatic enzymes are rich in the essential sulfur-containing amino acids, removal of these amino acids from other sites of protein synthesis involved in growth and maintenance is critical. Continued ingestion of legumes would compound these effects and, in small animals such as rats, have been found to result in pancreatic hypertrophy, growth depression, and failure to thrive.

This negative-feedback control is known to occur in the rat, pig, and calf, as well as in humans, suggesting that other factors are also involved in pancreatic hypertrophy.

ULTRAVIOLET LIGHT

F Thompson, Halma PLC, London, UK

Introduction

Since the turn of the century, when its existence was proved experimentally, ultraviolet (UV) light has been used to reduce microbiological contamination in drinking water, process water, fluids, effluent, and air, and on surfaces. The first municipal UV water disinfection system was built in 1910 in Marseilles, and since then, the technology has been refined and developed, providing today's reliable, computer-controlled systems.

This article reviews the technology of UV disinfection and outlines its industrial applications, especially in food and drink manufacturing.

The Nature of UV Light

What is UV?

The term 'UV' is applied to wavelengths of radiation found in the electromagnetic spectrum between visible light and X-rays (see Figure 1), from 100 to 400 nm. The region between 190 and 400 nm is divided into three sections:

1. U1V-A, 320–400 nm. The longer wavelength limit corresponds roughly to the start of visible light, whereas the lower limit corresponds to the point at which proteins and genetic material begin to absorb significant amounts of UV energy.
2. UV-B, 290–320 nm. Ultraviolet light of these wavelengths begins to damage biological molecules and is the region of the spectrum responsible for sunburn and skin cancers.
3. UV-C, 200–290 nm. Far UV wavelengths are highly destructive to biological molecules. In nature, these wavelengths in sunlight are almost totally absorbed by the ozone layer. UV-C wavelengths are mainly responsible for the germicidal properties of UV light.

Commercial UV disinfection systems generate a high proportion of UV-C, particularly at 254 nm, which is very close to the most biologically damaging wavelength of 260 nm (see Figure 2).

How UV Works

In sufficient doses, UV light of the wavelengths mentioned is lethal to all microorganisms, including bacteria, viruses, protozoa, molds, yeasts, fungal spores, and algae.

The effectiveness of UV results from its ability to cause molecular rearrangements in the genetic

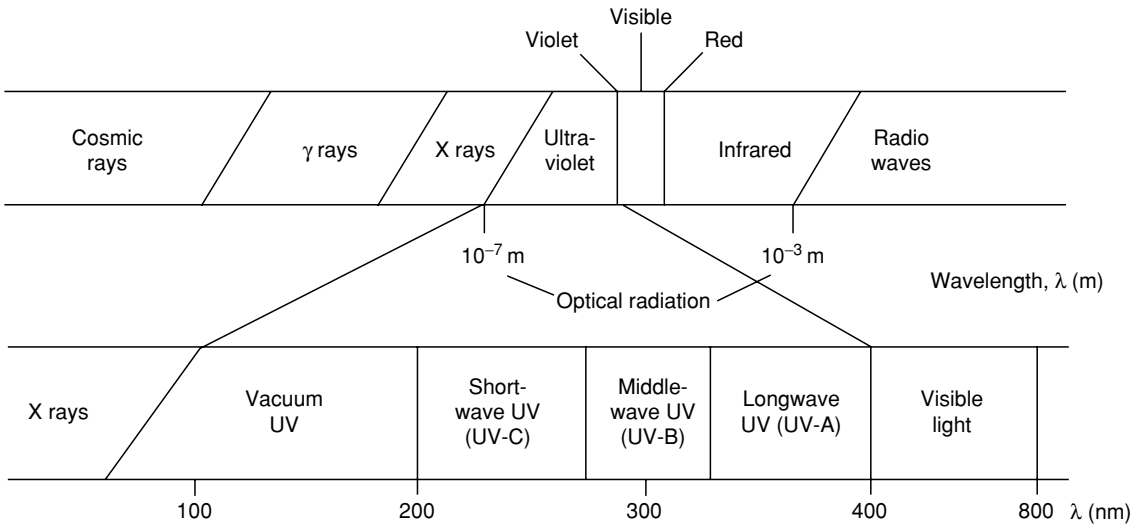

Figure 1 Electromagnetic spectrum with expanded scale of UV radiation. Reproduced from Ultraviolet Light, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

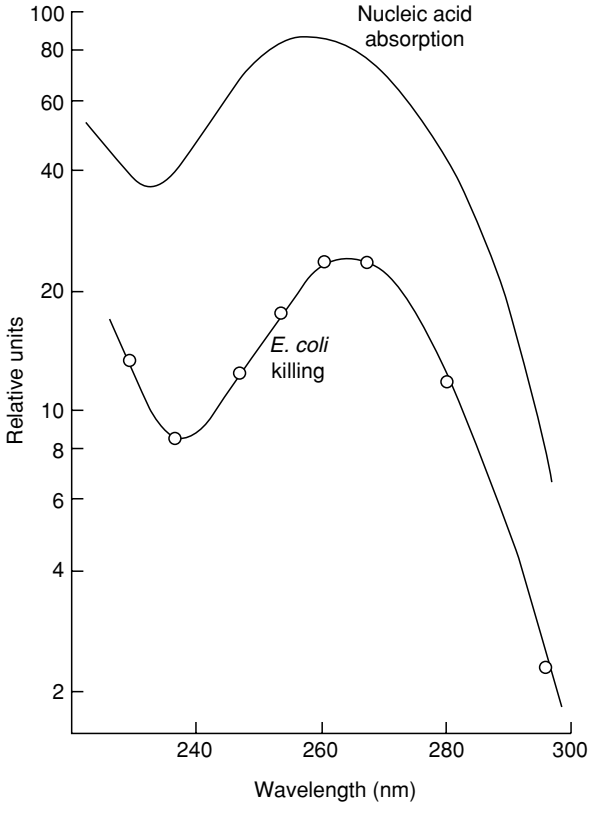

Figure 2 Similarity of the action spectrum for inactivation of *Escherichia coli* cells, determined by FL Gates, to the absorption spectrum of nucleic acids. Redrawn from Rupert CS (1960) In: Burton M, Kirby-Smith JS and Magee JL (eds) *Comparative Effects of Radiation*, pp. 49–61. New York: John Wiley with permission.

material of microorganisms. This cripples the organism's normal metabolism and prevents it from reproducing. If a microorganism cannot reproduce, it is considered dead.

The detailed mechanisms by which UV deactivates microorganisms have only been fully understood recently through advances in microbiological techniques.

Deoxyribonucleic acid (DNA) is a helical macromolecule responsible for the storage, expression and replication of a cell's genetic information. (In some cases, especially viruses, ribonucleic acid (RNA) is the main carrier of genetic information, but as the principle of UV damage is the same, we will limit the description to DNA). Molecules of DNA are particularly susceptible to damage by UV-C energy, and are the primary site of absorption of UV photons.

Deoxyribonucleic acid is composed of four types of deoxyribonucleotides, which differ only in their base components. These are adenine, guanine, cytosine, and thymine (which is replaced by uracil in RNA). The main photochemical change to occur when DNA is exposed to UV light is the dimerization of thymine (and, less often, cytosine), where two of these molecules lie adjacent on a DNA strand. The effect of this dimerization is to block the normal replication of DNA, causing an irreversible breakdown in the cell's metabolism and replication.

Quantifying the Effectiveness of UV

The germicidal effectiveness of UV is expressed as the number of organisms that survive after exposure.

Table 1 Dose–effect relationship for *Escherichia coli* (D_{10} = 5.4 mJ cm^{-2} in water)

Dose (mJ cm^{-2})	*Percentage of organisms remaining*	*Log reduction*
5.4	10	Log 1
10.8	1	Log 2
16.2	0.1	Log 3
21.6	0.01	Log 4

This depends on the intensity of UV (measured in mW cm^{-2}), the number of microorganisms present before disinfection, and the duration of exposure to the UV source. These parameters are combined to give the UV dose, the standard indicator of UV effectiveness. In its simplest terms, UV dose is a function of intensity and time and can be illustrated as follows:

$$\text{UV dose} = \text{UV intensity} \times \text{time}$$
$$(\text{mJ cm}^{-2}) = (\text{mW cm}^{-2}) \times (\text{s})$$
$$1\,\text{J} = 1\,\text{W s}.$$

For water disinfection systems, the presence of molecules or suspended solids in the water, which may absorb UV energy, must also be taken into account in any calculations.

The required UV dose differs for each type of microorganism and is measured as a D_{10} value, i.e., the UV dose necessary for 1 log reduction in concentration of any given microorganism. For example, the D_{10} value for *Escherichia coli* in water is 5.4 mJ cm^{-2}. This means that a UV dose of 5.4 mJ cm^{-2} will reduce the population of *E. coli* to 10% of the original number, i.e., a 1 log reduction. A dose of 10.8 mJ cm^{-2} (twice the D_{10}) will give a 2 log reduction, and so on (see Table 1).

Types of UV Systems

Lamp Type

Ultraviolet energy for disinfection is produced using mercury vapor lamps. These are similar in operation and appearance to a fluorescent lamp. Ultraviolet light is emitted as a current flows through vaporized mercury. A protective quartz sleeve, which is transparent to UV light, surrounds the lamp. Two types of UV lamp are available – low-pressure lamps and medium-pressure lamps.

Low-pressure Lamps For low flow rates and surface disinfection applications, low-pressure lamps are most often used. These are highly efficient at producing UV energy but are limited to a relatively low UV output.

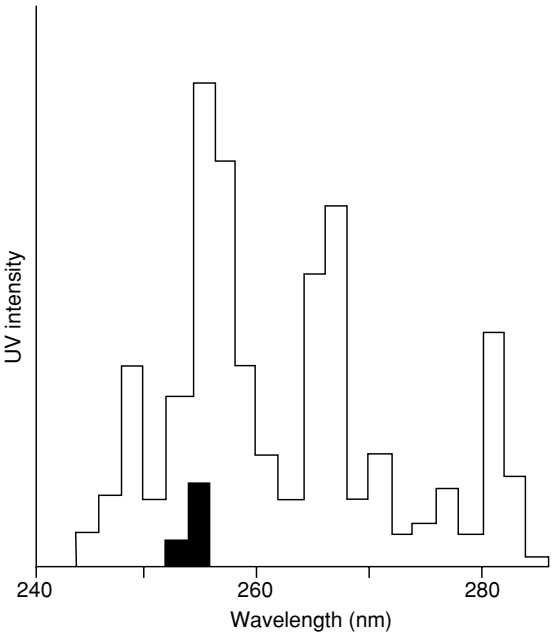

Figure 3 Energy distribution of medium- (□) and low-pressure (■) UV lamps. Reproduced from Ultraviolet Light, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Medium-pressure Lamps Medium-pressure lamps draw a much greater current than low-pressure lamps, leading to a rapid rise in the mercury vapor pressure. This gives a typical diffuse medium-pressure UV spectrum (see Figure 3). Per unit area, the effective germicidal output of a medium-pressure lamp is much greater (up to 30 times) than a low-pressure lamp, allowing high flow rates to be treated using fewer lamps. Medium-pressure lamps are used for most industrial water and fluid disinfection systems owing to their greater compactness and disinfection capability. Unlike low-pressure lamps, which only function efficiently within a limited temperature range, medium-pressure systems are temperature-independent, and therefore suitable for low-temperature and chilled-water applications.

System Design

The following parameters must be considered when specifying a UV disinfection system:

1. The energy output of the UV source.
2. The flow rate of the fluid or air through the treatment chamber, i.e., the time period of exposure to UV.
3. The transmission value, i.e., the ability to transmit UV light, of the fluid or air being treated.
4. The geometry of the irradiation chamber.

By optimizing these criteria, a UV system can be tailored to treat virtually any water- or airflow, or

transport fluid containing high levels of dissolved solids, starch or sugar compounds.

The ideal geometry of a fluid disinfection system for maximum utilization of the UV energy is a single lamp running along the axis of a cylindrical treatment chamber.

Practical Applications of UV

Microbiological contamination can occur at any stage of a production process from the incoming process water to the surfaces of packaging. In many cases, UV disinfection can offer a safe and effective method of providing microbe-free process water, fluids and air. It is effective against food pathogens, including viruses and fungal spores (see Table 2).

Unlike chemical biocides, UV does not introduce toxins or residues into process water and does not alter the chemical composition, taste, odor, or pH of the fluid being disinfected. This feature is especially important in food and drink processing plants, where the chemical dosing of incoming process water can cause off-flavors and alter the chemical properties of the product.

Ultraviolet treatment systems can be used as the primary disinfection system or as a back-up for other water purification methods, such as activated carbon filtration, reverse osmosis or pasteurization. As UV has no residual effect, the best position for a treatment system is immediately prior to the point of use. This ensures that incoming microbiological contaminants are deactivated and there is minimum chance of posttreatment contamination. Many users install UV systems after filter beds and storage tank outlet valves, to reduce the likelihood of contamination from these sources.

Ultraviolet systems can also be installed as an alternative to, or in conjunction with, air filtration systems. The UV source will deactivate any microorganisms present and prevent colonization of air-filtration systems.

Table 2 Experimentally determined UV dose, at 254 nm, required for a 90% kill rate (D_{10}) of various organisms

Organism	D_{10} *(mJ cm*$^{-2}$*)*
Bacteria	
Escherichia coli	5.4
Bacillus subtilis	7.1
Clostridium botulinum	12.0
Micrococcus candidus	6.05
Pseudomonas aeruginosa	5.5
Mold spores	
Aspergillus niger	100
Cladosporium herbarum	30–70
Mucor mucedo	50–70
Penicillium roqueforti	13
Yeasts	
Saccharomyces cerevisiae	6.0

Clean-in-place (CIP) Rinse Systems

It is essential that CIP final rinse water, which is used to flush out foreign matter and disinfecting solutions, is microbiologically safe. Fully automated UV disinfection systems can be integrated with CIP rinse cycles to insure that final rinse water does not reintroduce microbiological contaminants. Although most town supplies are free from coliforms, they are rarely sterile. Resistant to the effects of acid, detergents, steam and chemical sterilants, UV systems are an effective method of providing disinfected water for final rinse systems.

Sugar Syrups

Specially modified UV treatment chambers are routinely used in the brewing and soft drinks industry to disinfect concentrated sugar solutions and syrup. Although high-Brix syrups will not support microbial growth, any dormant spores present may become active after the syrup has been diluted. Treating the syrup and dilution water with UV prior to use will insure that any dormant microorganisms are deactivated.

Systems for syrup treatment are designed with a chamber of relatively small diameter. This helps to insure that sufficient UV light penetrates the liquid and deactivates spores, which generally require higher doses of UV than other microorganisms for complete deactivation. In food and dairy processing plants, the same equipment can be used to disinfect injection brine and cheese whey.

Air Disinfection

For machine blanketing, and in sanitary and food preparation areas, the exclusion of airborne contaminants, such as bacterial spores, yeasts and viruses, can be a major problem. Ultraviolet disinfection systems are now available for treating airflows entering a sterile environment. Air-disinfection systems are fitted into ductwork, and any microorganisms present are deactivated as they are exposed to the UV source. (*See* **Plant Design**: Designing for Hygienic Operation.)

Ultraviolet systems can also be used to disinfect displacement air for pressurizing tanks, or pipelines holding perishable fluids or free-flowing solids. Storage tanks are particularly susceptible to bacterial colonization and contamination by airborne spores. To prevent this, immersible UV treatment systems have been designed to fit in the tank head airspace and disinfect the air present.

Packaging Applications

Another aspect of contamination control that can benefit from UV technology is the disinfection of finished products and their packaging. A typical system incorporates a UV light source, shielded on three sides and mounted over a conveyor or production line. As foodstuffs or packaging pass under the light, any microbes present on the surface are deactivated.

After treatment by UV, the risk of microbial contamination in filling and packaging lines is reduced, and the shelf-life of treated products is extended. This surface sterilization equipment can also be used to disinfect bottle crowns, foil lids and plastic films. (*See* **Packaging**: Packaging of Solids.)

Recent Advances in UV

Modern UV treatment systems are microprocessor-controlled with automatic UV intensity and lamp status monitors. This facilitates the interfacing of UV systems with other process control systems to coordinate their operation.

Integral Wiping Systems

The development of integral wiping systems has increased the applications of UV to include treatment of turbid fluids containing processing residues or high solids concentrations. The wiping system is fitted to the outside of the quartz sleeve. At preset intervals during operation, a mechanical wiper moves along the lamp surface, displacing any processing residues. These would quickly foul conventional UV systems, inhibiting the transmission of UV light and reducing germicidal effectiveness. Wiped systems can constantly reduce contamination to acceptable levels in poultry, egg and meat processing, in the transport and cooling of vegetables, and in the disinfection of effluent flows. (*See* **Effluents from Food Processing**: Disposal of Waste Water.)

Lamp Output

High-output, single-lamp chambers emit the high energy levels required to penetrate the turbid waters that can be found in processing plants. This includes virtually opaque fluids, such as transport water for flour- and pasta-based products, and industrial effluent or recirculation water. Currently, the minimum single lamp power available is 8 W (low-pressure), increasing to a maximum of 5 kW (medium-pressure).

Limitations of UV Technology

System Sizing

In theory, UV systems can be built to treat any flow rate, air volume, or surface area. As UV demand increases in terms of size, degree of contamination and quality of water, the number and power output of the UV lamps are increased proportionally to maintain UV dose above the required minimum.

Obviously, practical constraints, such as the size of the UV system, pressure drop through the system, and power consumption, vary with each installation. Single-chamber UV systems treating up to 250 $m^3 h^{-1}$ are often more than adequate for process-water applications. Duty stand-by units, programmed to come on-line when flow exceeds preset levels, can also be installed as a back-up measure.

Ultraviolet systems have been successfully installed to treat water flows over 1×10^5 m^3 per day. At these flow rates, medium-pressure systems have the advantage of fewer lamps, compared with low-pressure systems, and therefore have lower maintenance requirements.

Residual Disinfection

The only potential drawback with UV water disinfection, compared with chemical treatment, is that UV does not leave a residual disinfectant effect. In food and drink manufacturing, this is a positive advantage as the presence of chlorine could adversely affect product quality. In industrial applications, the lack of residual is rarely a problem, provided that downstream pipework is maintained in a hygienic condition, and no 'dead legs' or leaks are allowed where recolonization could occur.

Ultraviolet systems are recommended for installation as close to the point-of-use as possible to reduce the likelihood of recontamination. It is mainly in the drinking-water treatment industry, where there may be miles of distribution pipework following disinfection, that a small chlorine residual is often added to the water after UV disinfection. A combination of UV disinfection and electrochlorination is most common, both systems requiring little maintenance and able to operate almost unsupervised.

With air and surface disinfection, there is a remote risk that an operator may be exposed to the UV light source. Prolonged exposure to high-intensity UV light an damage the eyes, but this kind of accident is very rare and can be avoided by carefully designed shielding around the UV source. In addition, access to the UV source can be interlocked with the power supply, ensuring that access can be obtained only when the power supply has been turned off.

Conclusion

The unique ability of UV light to deactivate microorganisms in water and air, and on surfaces, without creating by-products or residual effects, enables

UV disinfection to be used for a wide variety of applications. Whether installed as the main disinfection system, as a back-up to alternative methods, or in specific clean-room environments where high standards of sterility must be maintained, UV treatment systems can ensure that levels of microbial contaminants are effectively controlled.

URONIC ACIDS

F G Huffman, Florida International University, Miami, FL, USA

Chemistry

Uronic acids are produced by the oxidation of the alcohol group of monosaccharides. These compounds are named by substituting -ose with uronic acid. The structures of the most common uronic acids are shown in **Figure 1**. D-Mannuronic acid is the 2-epimer of D-glucuronic acid, and L-iduronic acid is the 5-epimer of D-glucuronic acid.

The uronic acids are important constituents of certain natural heteropolysaccharides. They play a significant role in the detoxification of substances such as drugs. Glucuronic acids are found in human urine bound with glycosidic linkages to hydroxylated compounds such as menthol, borneol, and estrogens. Owing to the increased solubility of hydroxylated compounds (when conjugated with glucuronic acid), they are readily disposed by the body. Glucuronic acid also forms a conjugate with bilirubin, a bile pigment.

The most important uronic acid in humans is the D-glucuronic acid. It, or its epimer, is a constituent of many glycosaminoglycans (GAG) as well as glucuronide derivatives of drugs and hormones. D-Glucuronic acid is also the precursor of L-ascorbic acid in animals. The schematic utilization of D-glucuronate in microorganisms, animals, and plants is shown in **Figure 2**. Glucuronic acid is synthesized from glucose in the uronic pathway, an alternative oxidative pathway for glucose without the production of adenosine triphosphate (ATP). In the uronic pathway, glucose 6-phosphate is converted to glucose 1-phosphate which subsequently reacts with uridine triphosphate to form uridine diphosphate glucose (UDPGlc). This compound is then oxidized at the six-carbon position in a two-step process by the

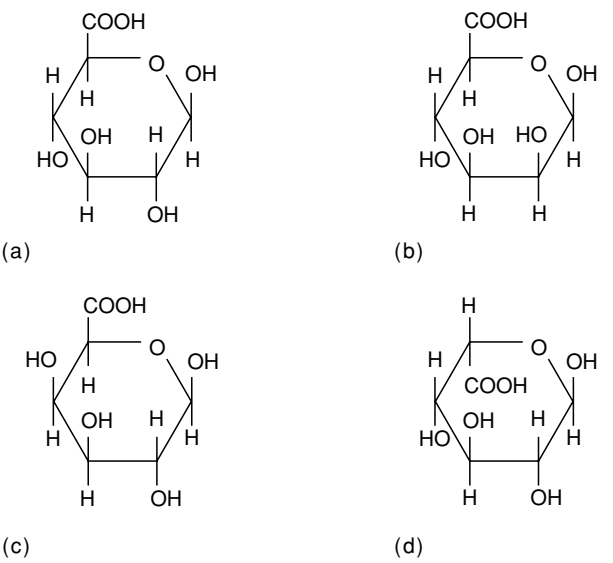

Figure 1 Structures of uronic acids: (a) D-glucuronic acid (Glu U);(b) D-mannuronic acid (Man U); (c) D-galaturonic acid (Gal U); (d) L-iduronic acid (L-guluronic acid; Gul U).

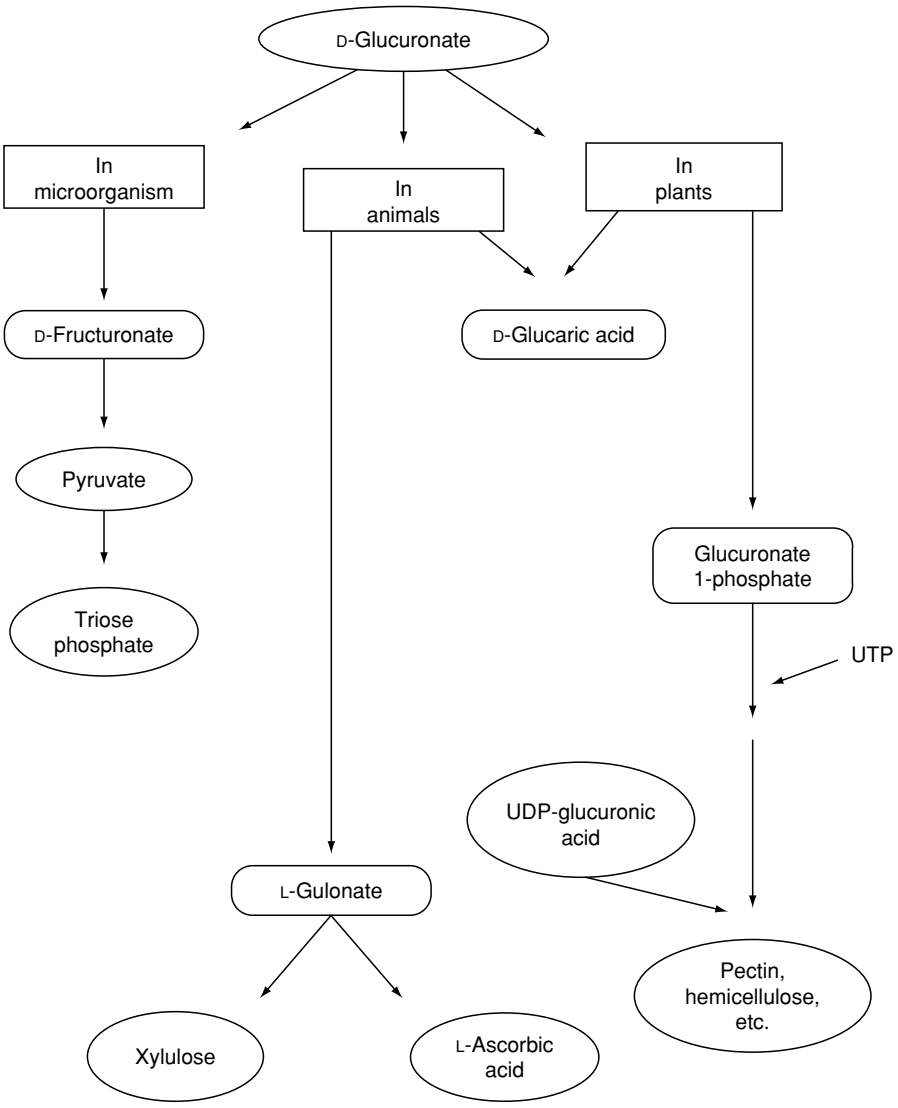

Figure 2 The fate of glucuronate in plants, animals and microorganisms. UTP, uridine triphosphate; UDP, uridine diphosphate.

nicotinamide adenine dinucleotide (NAD)-dependent enzyme (UDPGlc dehydrogenase) to form UDP-glucuronate.

UDP glucuronate is the form of glucuronic acid which can be incorporated into proteoglycans or conjugated with steroid hormones, certain drugs, or bilirubin. In bilirubin, two molecules of glucuronic acid are attached with ester linkages to the two propionic acid groups to form an acylglucuronide. This conjugation process increases the water solubility of bilirubin, thus allowing its secretion into the bile, ultimately to be excreted via the gastrointestinal tract.

A second product of the uronic pathway is L-ascorbic acid, which is produced in mammals, with the exception of humans, primates, and the guinea-pig. In a series of reactions glucuronate is reduced to L-gulonate, which is subsequently converted to L-ascorbic acid. The glucuronic acid pathway is most active in the liver, kidneys, and intestines. The primary function of the pathway is to produce UDP-glucuronic acid, which is needed for detoxification of various compounds by elimination of glucuronides in the urine or bile. Many carcinogens, and drugs, including antipyretics, hypnotics, and antimalarial drugs, may be eliminated by this mechanism. There may be certain organs which may have an active uronic pathway specific for a drug. Glucuronic acid synthesis may be stimulated when the consumption of substances that are excreted as glucuronides is increased, or when steroids and barbiturates, which induce the microsomal P-450 system, are consumed.

Table 1 Composition of glycosaminoglycans

Glycosaminoglycan	*Uronic acid composition*
Hyaluronic acid	β-glucuronic acid
Chondroitin 4-sulfate	β-glucuronic acid
Heparin	Sulfated iduronic acid
Dermatan	L-iduronic acid

Uronic Acids in Animal Tissue

Uronic acids are an integral part of GAGs, formerly known as the mucopolysaccharides. They have structural importance in vertebrate animals. Some important examples of GAGs are hyaluronic acid, the chondroitin sulfates of connective tissue, the dermatan sulfates of skin, and heparin (Table 1 and Figure 3).

Hyaluronic acid

Hyaluronic acid functions in the body as an agent which increases the viscosity of body fluids and acts as a lubricant. It is present in the joints and in the vitreous humor of the eye. Hyaluronic acid is composed of equal molecules of D-glucuronic acid and 2-acetamido-2-deoxy-D-glucose, which alternate in the heteropolysaccharide. The linkages from the amino sugar to the acid are β-1,4; those from the acid to the amino sugar are β-1,3. Hyaluronic acid is also present in skin, aorta, heart valve fibroblast, and the umbilical cord.

Chondroitin Sulfates

Chondroitin sulfates are the major constituents of hyaline cartilage. They are located in cartilage and also at the calcification site of the bone. The disaccharide unit of the chondroitin sulfates contains glucuronic acid and *N*-acetylgalactosamine. Glucuronic acids are connected by β-1,3 linkages. The two major chondroitin sulfates, A and C, differ from one another in the position of the sulfates. Chondroitin sulfate A is sulfated at position 4, and chondroitin sulfate C is sulfated at position 6. Thus the names chondroitin 4-sulfate and chondroitin 6-sulfate are used for these two polysaccharides.

The number of repeating uronic acids in the chondroitin chain varies depending on the source. The number may even differ within the same tissue. The ratio of chondroitin 6-sulfate to chondroitin 4-sulfate units increases progressively with age. In humans, a plateau is reached around the age of 50.

Dermatan Sulfate

Dermatan sulfate contains L-iduronic acid as the major uronic acid. Glucuronic acid is also present in smaller amounts. Dermatan sulfate is found in the cornea and the sclera of the eye, which helps to maintain corneal transparency and the shape of the eye. Many other tissues in animals and humans also contain dermatan, such as blood vessel walls, heart valve, and the umbilical cord. Dermatan sulfates may occur at the C4 or C6 positions of L-iduronic acid. They are found to increase normally with age, except in diseased conditions.

Heparin

Heparin is mainly stored intracellularly in the granules of the mast cells. It may be released in response to a specific stimulus. The main uronic acid of heparin is the L-iduronic acid, although D-glucuronic acid is also present. Heparin is a well-known anticoagulant that binds to factors IX and XI but, most importantly, it interacts with plasma antithrombin III.

Heparan

Heparan sulfate differs from heparin in many ways. The dominant uronic acid in heparan sulfate is D-glucuronic acid. The degree of sulfation is reduced in heparan sulfate because there are fewer L-iduronic acids. Heparan sulfates are located in the extracellular medium of mast cells. They differ in their physiological functions in that they may become receptors and participate in cell growth and communication.

Alterations in Glycosaminoglycans Metabolism

The preceding discussion shows that GAG has specific functions in vertebrate animals. Recent research in this field suggests that certain disease conditions may alter the functions, synthesis, and composition of GAGs. For example, increased chondroitin sulfate and uronic acids and decreased dermatan were observed in the breast biopsies of women with carcinoma, when compared with controls. Some tumor cells have less heparan sulfate, which may reduce their adhesiveness. Hyaluronic acid may facilitate tumor cell migration through the extracellular matrix and tumor cells are capable of synthesizing increased amounts of GAG. Samples of degenerated cartilage from human patellas had increased dermatan sulfate and hyaluronate and decreased chondroitin 6-sulfate and uronic acid content. Dermatan sulfate binds to low-density lipoproteins (LDL) in plasma and is believed to play a significant role in plaque development in arteriosclerosis. Significantly increased urinary excretion of glycosamines was reported in subjects with hypothyroidism. The levels of heparan sulfate and chondroitin sulfate were higher in subjects with hypothyroidism than the controls, indicating alteration in the metabolism of connective tissue in

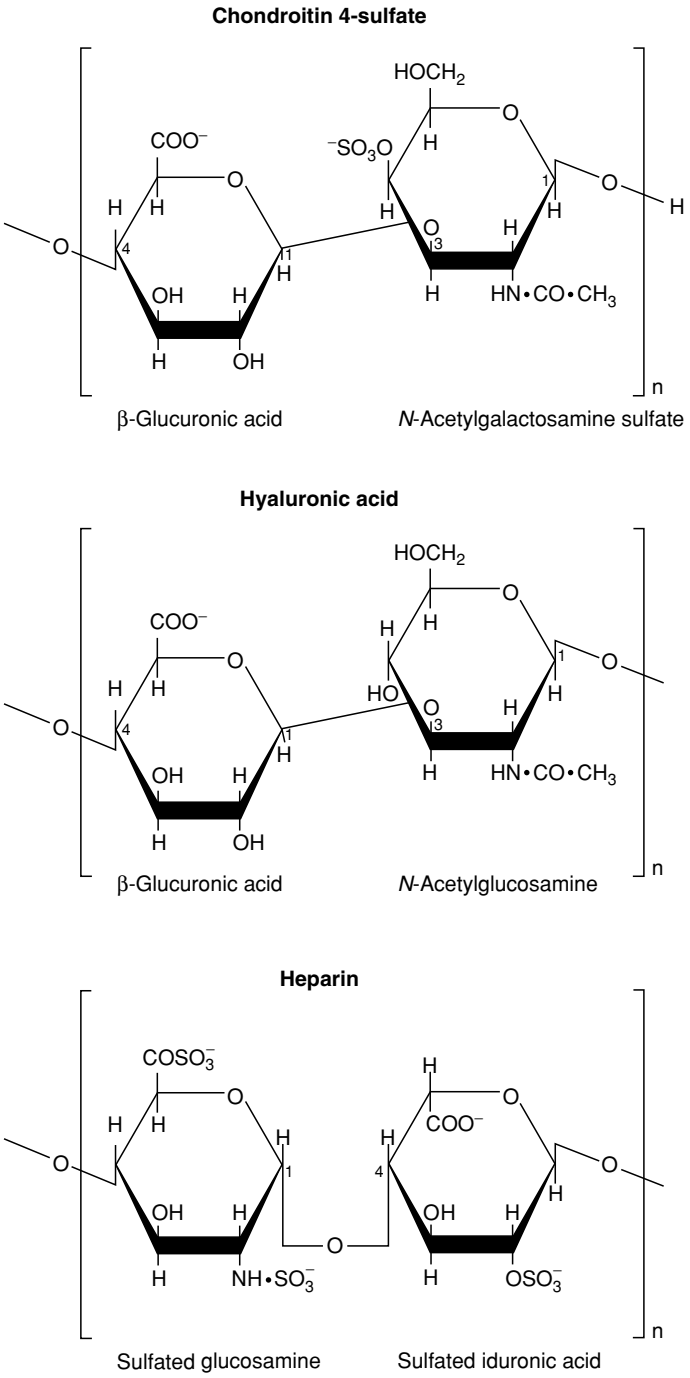

Figure 3 Structures of glycosaminoglycans.

hypothyroidism. Specific reactions responsible for these changes need to be studied.

In different types of arthritis proteins of GAG may act as autoantigens, causing additional symptoms of the disease. Recent research indicates that anti-DNA antibodies cross-reacting with GAG are present in patients with lupus erythematosus. Increased production of hyaluronic acid was observed with increased severity of the disease in patients with autoimmune thyroid disease. It appears that GAG not only plays a role in the pathogenesis of autoimmune diseases but also may be used as an activity marker of the disease.

Increases in hyaluronic acid and keratan and decreases in chondroitin sulfate may be contributing factors in the development of osteoarthritis. A recent surge in the use of chondroitin sulfate and

glucosamine by sufferers of osteoarthritis is currently being investigated.

Heparan and dermatan sulfates are found to inhibit calcium oxalate crystallization and thus prevent kidney stones. Recently a uronic acid-rich protein has been isolated from the urine of normal and stone-forming individuals. This protein appears to be a most efficient inhibitor of calcium oxalate nephrolithiasis.

Uronic Acids in Plant Tissue

In plants, uronic acids are associated with the fiber component of the plant cell. The fibers which have significance in human and animal life are called dietary fibers. Not all dietary fibers contain uronic acids.

Dietary fibers have three major components:

1. Structural polysaccharides and derivatives, such as cellulose and cellulose derivatives (microcrystalline cellulose, semisynthetic gums, and noncellulosic polysaccharides in land and sea plants).
2. Structural nonpolysaccharides, such as lignin.
3. Nonstructural polysaccharides, such as mucilages, seed gums, plant exudates, and microbial gums.

The uronic acids are found in the noncellulosic, structural polysaccharides, and derivatives – hemicellulose, pectic substances (land plants), and alginate (sea plant) – and in the nonstructural polysaccharides – mucilages, seed gums, plant exudes, and microbial gums (xanthan). These substances are also referred to as soluble dietary fiber. The most common uronic acids in the plants are D-galacturonic and D-glucuronic acids (Table 2). The uronic acid content and physiochemical properties of dietary fibers are as follows.

Hemicellulose

Hemicellulose is a branched polymer of pentose and hexose sugars, found in the plant cell wall. The uronic acid composition is mainly D-glucuronic acid and 4-*O*-methyl-D-glucuronic acid. There are two distinct hemicelluloses in plants: the acidic and the neutral. Acidic hemicelluloses contain a larger number of uronic acids than neutral hemicelluloses. Hemicelluloses are partially fermented by the microorganisms of the colon, producing some volatile fatty acids. Hemicelluloses are insoluble in water but soluble in alkaline solutions. They, along with other insoluble dietary fibers, decrease the intestinal transit time; hemicelluloses also increase fecal weight and slow down starch hydrolysis. Acidic hemicelluloses may bind to cations. These characteristics of hemicellulose may be responsible for its physiological effects.

Table 2 Uronic acid composition of fiber

Fiber	*Uronic acid composition*
Hemicellulose	D-glucuronic acid and/or 4-methyl D-glucuronic acid
Pectin	D-galacturonic acid
Gums, mucilages	D-glucuronic acid and/or D-galacturonic acid
Alginate	D-mannuronic acid and/or iduronic acid

Pectins

Pectins are a complex mixture of polysaccharides containing D-galacturonic acid as the main constituent. They are found in the primary cell walls and intercellular layers in land plants. Citrus fruits, apples, and pears contain large amounts of pectin. In the intestinal tract they are almost completely fermented by the microflora. Pectins are water-soluble and form gels under specific conditions. They are hydrophilic and have ion-binding and water-holding capacities. Pectins delay gastric emptying and increase bile acid excretion.

Gums and Mucilages

Gums and mucilages are water-soluble, viscous, and highly fermentable by the microorganisms of the intestinal tract. The uronic acids that dominate gums are D-glucuronic and D-galacturonic acids. The most important gums used in the food industry are gum arabic, gum karaya, tragacanth, carob, and guar, which are obtained as exudates from trees or shrubs. Xanthan gum, which is synthetically produced, contains D-glucuronic acid. Because of their gel-forming, water-holding ability, gums delay gastric emptying.

Alginate

Alginate is a noncell-wall component of seaweed which contains D-mannuronic and iduronic acids. It forms gels and is highly fermentable by intestinal microorganisms. Alginates are used in food processing and they enter into the human food chain as food additives.

Physiological Effects of Dietary Fiber

The physical and chemical properties of dietary fiber create physiological effects in animals. Because dietary fiber cannot be hydrolyzed by the intestinal enzymes it is unavailable for absorption and therefore continues to exert effects in the gastrointestinal tract. Soluble dietary fibers have been shown to reduce plasma levels of glucose and cholesterol. These physiological effects of soluble dietary fibers are attributed to their ability to form gels and delay gastric emptying. Viscous fibers bind to bile acids and

prevent their reabsorption, causing body cholesterol to be excreted and thus reducing plasma cholesterol. Second, fiber interferes with digestive enzymes by sequestering lipids, carbohydrates, and proteins, preventing their absorption. Fiber may also interfere with micelle formation, mixing of intestinal contents, and inhibition of cholesterol synthesis.

The viscous fibers are highly fermentable by the intestinal microorganisms, producing volatile fatty acids, which, by being absorbed into the portal blood, suppress hepatic cholesterol synthesis by inhibiting human menopausal gonadotropin coenzyme reductase activity. Some diabetics and hypercholesterolemics have experienced alleviation of their condition by increasing intakes of dietary fiber.

Isolated dietary fiber components have been used to elicit a specific response. However, It has become clear that fiber exerts its primary effect as a component of whole foods rather than as an isolated entity.

The low incidence of colon cancer in populations consuming high levels of fibrous foods has prompted scientists to study the effects of fiber on preventing colon cancer. The roles of specific dietary fiber are unclear, but diets high in fiber and low in fat are increasingly recommended.

Research indicates that the effect of fiber is not always favorable. Reduced bioavailability of certain vitamins and minerals has been reported. Among the vitamins studied, availability of vitamins B_{12}, B_6, A, and E was reduced as a result of high fiber intake. Among the minerals, the absorption of sodium, potassium, magnesium, calcium, zinc, and iron was reduced by dietary fiber, especially by the fiber fraction containing uronic acids. Research to determine the effect of fiber on nutrient bioavailability continues with vigor.

Methods of Analysis for Uronic Acids

Since uronic acids are found as integral parts of animal and plant tissues, they must be separated from their native materials.

GAGs which contain mammalian uronic acids may be separated by density gradient centrifugation and chromatography (ion exchange or gel). Hydrolysis by acid or by specific enzymes is used. Uronic acids may be measured either by colorimetry or by decarboxylation techniques.

There are two primary methods for quantification of dietary fiber. The gravimetric method measures total fiber content and uses enzymes or detergents to solubilize the nonfiber components, such as starch and protein. Defatting using organic solvents is usually performed prior to sample analysis. Acid and base solutions are used to separate acid- or base-soluble fractions.

The fractionation method, developed by Southgate in 1969, has gone through many modifications over the years. This method allows measurements of total dietary fiber as well as the fiber fractions. It is necessary to use the fractionation method for fiber analysis to be able to free uronic acids for quantification. Most fiber analyses have three steps:

1. Preparation of an extractive-free residue (alcohol-insoluble residue)
2. Removal of starch and protein from the residue (enzyme or detergent hydrolysis)
3. Analysis of destarched, deproteinated residue for neutral sugars and uronic acids

In recent years highly specific enzyme preparations have become available, improving recovery of various fiber fractions. The detergent method of fiber analysis is simple and fast, but the soluble fiber component, which contains the uronic acids, is lost during extraction. The method of choice for the quantitative analysis of uronic acids appears to be the enzymatic method followed by either colorimetry or decarboxylation.

Quantification of the Uronic Acids

Uronic acids may be determined in the hydrolysate of food samples following enzyme and/or acid hydrolysis. Dilutions of the hydrolysate to give 25–100 $\mu g\ ml^{-1}$ may be necessary and can be achieved with a mixture of sodium chloride and boric acid. Diluted samples are heat-treated in the presence of concentrated sulfuric acid. After cooling to room temperature, a 3,5-dimethylphenol solution is added and 10–15 min later the absorbance is read at 400 and 459 nm. Appropriate glucuronic acid standards are used to develop a standard curve. Differences in absorbance readings of the sample are plotted on the standard curve and sample concentrations are read.

The colorimetric methods using carbazole reagent may also be used in determining uronic acids. The sample hydrolysate is placed in a test-tube containing cold acid borate. The tubes are placed in a boiling water bath, followed by cooling to room temperature. Carbazole reagent is added and tubes are again placed in the boiling water bath. After cooling to room temperature, the intensity of the color is measured by reading absorbance at 530 nm. Sample concentrations may be calculated using values from standard curve. Recently a colorimetric method using 1,9-dimethylmethylene blue was used to determine GAG in partial urine from pediatric patients. Results indicated the efficiency and sensitivity of this method and it is recommended for widespread use. Decarboxylation of uronic acids with hydroiodic acid seems

to improve the accuracy of measurements over colorimetry procedures.

The gas–liquid chromatography (GLC) method has improved the accuracy and specificity of uronic acid determinations. Although free, low-molecular uronic acids are readily analyzed by GLC, it is impossible to measure the specific uronic acids by this method.

Recently a microtiter plate assay for the determination of uronic acids in biological samples has been validated. Modification of a commonly used procedure promises to have less risk in handling strong hot acid and increases accuracy of measurement.

V

VEAL

R G Cassens, University of Wisconsin-Madison, West Madison, WI, USA

Introduction

Veal is the meat from a young calf. It is tender, pale in color, and has a high moisture and low fat content. It is a delicate, almost bland, meat. Consumption of veal comprises a small proportion of total meat consumption, and demand for veal is often concentrated in geographic areas or within certain ethnic populations. Veal calves may be slaughtered soon after birth or they may be specially fed for several weeks.

Methods of Production

The traditional production of veal was a segment of the dairy industry. The calves were normally fed only their mother's milk and slaughtered at a few days of age in an effort to recover some value. The meat from such immature animals was pale, delicate and tender. It is pointed out in *Larousse Gastronomique* that the ancient method of feeding the calf exclusively on the mother's milk results 'in a very pale pink meat smelling of milk, with satiny white fat having no tinge of red.'

At present, there are three methods of veal production:

1. The calf may be fed only on milk and slaughtered at 3 weeks or less of age. This produces so-called bob veal. Another alternative is to feed the calves up to about 20 weeks of age.
2. Of greatest importance now is the production of special-fed veal, a process in which the calf is fed on milk replacers.
3. When some pasture, roughage, or grain is incorporated into the diet, the result is so-called pink veal.

In the USA, the current types of production and importance of the veal industry to a dairying state such as Wisconsin can be assessed from the findings of Piwoni and Kliebenstein. They reported that the approximately 1.8 million dairy cows in Wisconsin produce about 800 000 bull calves annually. About 20% are sold as feedlot or herd replacements. About 30% are sold and slaughtered as bob veal – milk-fed calves of 3 weeks or less age. The production of bob veal continues to decline. The remaining 50% are used in the production of special-fed, fancy, or prime veal. These calves are raised in confinement, receive only milk replacer, and are slaughtered at 14–17 weeks of age when they weight 145–170 kg.

The special feeding programs have evolved into a highly intensified industry. The producers follow a detailed plan which specifies all aspects such as purchase of replacement calves, housing, feeding, management, health, and marketing. These production systems have been criticized as being factory farms in which the animals are mistreated. Such is not the case. In fact, most of these production units are indeed family operations because of the close and frequent supervision required to raise the veal calves successfully. Adequate nutritional status and comfort of the animal are prerequisites to successful production.

Wholesalers characterize veal as follows. Baby veal (bob veal) is produced from calves of only a few days' age, but they may range up to a month. They are usually male calves from the dairy industry, and the carcasses range from 10 to 25 kg in weight. Vealers range in age from 1 to 3 months, and the carcasses weigh from 35 to 70 kg. They are also raised primarily on milk. Another category comes from calves of 3–8 months of age with carcasses weighing 55–135 kg. They have been grown primarily on feeds other than milk, and their meat is maturing to resemble beef more than veal. Nature veal is produced from calves approximately 16 weeks old, and the carcass weight varies from 80 to 110 kg. They are fed a controlled and scientifically designed diet, and they have limited activity, thereby minimizing muscular development. This controlled regimen of diet and activity produces a pinkish-white color of meat, and

this is the most expensive type of veal on the wholesale market.

Marketing

The US Department of Agriculture (USDA) has official standards for grades of veal. The final grade is based on evaluation of conformation and quality, with a consideration for maturity and color of lean meat. The grades are prime, choice, good, standard, and utility. In practice, nearly 90% of the veal carcasses in commerce are not graded by the USDA.

Veal is a delicate meat which is marketed fresh, and it is not transported or stored in the frozen state. In the USA, veal is produced in the dairy production areas and is then transported to the population centers, mainly along the East Coast. In Europe, it is produced primarily in Germany, France, and The Netherlands, and much of the production is then sold to other countries.

Characteristics of the Meat

The characteristics of veal arise from the fact that it is from an immature animal. It is tender, moist, and lean. It is tender because the connective tissue is not cross-linked to the extent it is in more mature animals. (*See* **Meat**: Structure.)

A distinguishing property of veal is the pale color. Color is due primarily to the iron-containing pigment myoglobin. The muscle of newborn or immature animals has a low content of myoglobin, and as the animal matures the myoglobin increases. In raising veal, the iron content of the diet generally does not exceed the amount required for adequate nutrition. This minimizes accumulation of myoglobin in the muscle and consequently keeps the color pale.

As an animal matures, the proportions of bone and muscle decrease while fat increases. The carcass from a newborn calf is approximately 25% bone, 68% muscle, and 7% fat. The carcass from a 12-week-old animal is about 20% bone, 65% muscle, and 15% fat, while that for pink veal (animal age 16–20 weeks) is about 17% bone, 64% muscle, and 19% fat.

Differences also exist in the composition of the muscle retail cuts, as has been documented in the USDA handbooks. Veal top round in the raw state contains about 74.8% water, 21% protein, 3.1% lipid, and 1.1% ash. When the top round is cooked, the values are 55.5% water, 36.2% protein, 6.3% lipid, and 1.6% ash. Obviously, the muscle from immature animals has more water and less fat. (*See* **Protein**: Food Sources.)

Further Processing

The vast majority of veal is consumed as fresh product. Some specialty sausages, such as bockworst, are made with veal as the major ingredient. As is the case with fresh veal, these types of sausages are also noted for their rather delicate flavor, and for the fact that they are highly perishable. (*See* **Meat**: Sausages and Comminuted Products.)

Consumption

The consumption of veal in the USA, although never high, has declined markedly during the past one-third century. In the early 1960s the per capita disappearance of veal on a retail weight basis was about 2.5 kg but by the early 1990s the value had fallen to about 0.5 kg. Veal accounts for only about 1% of the total consumption of red meat in the USA.

Such average values are difficult to interpret because of regional and ethnic differences. For grocery stores overall in the USA, the percentage of sales from veal is about 1.5%, but in the north-east and Middle Atlantic regions the percentages are 2.1% and 2.4%, respectively.

Annual per capita consumption values for veal in some of the European countries, expressed in kilograms and for the year 1987, are 6.49 for France, 4 for Italy, 2.1 for The Netherlands, and 0.1 for the UK.

The probable explanations for low consumptions of veal in some countries, e.g., the USA and the UK, are that it is not readily available at market and the cost is expensive. The complications of ethnic, regional, and historical patterns must be considered in such interpretations and conclusions.

Even though veal is a naturally low-fat meat, it is unlikely that demand will increase in the future.

VEGETABLE OILS

Contents

Types and Properties

E W Hammond, Greenisle-Consulting, Kettering, UK

Introduction

Vegetable oils are a group of fats that are derived from some seeds, nuts, cereal grains, and fruits. It is important to understand that not all of these vegetable oils are liquid oils at ambient temperatures. In addition, not all of the vegetable oils are produced in commercial quantities, and of those that are, not all are considered to be edible as in the sense of being a typical dietary component. This treatise will cover only edible vegetable oils.

Vegetable oils, as used in foods, are comprised of complex mixtures of triacylglycerols (TAGs; usually $>95\%$) with some minor amounts of diacylglycerols (usually $<5\%$). Other minor components are tocopherols/tocotrienols (up to $900\,mg\,kg^{-1}$) and phytosterol esters/phytosterols (up to 1%). The vegetable oil may be characterized confidently with expert chromatographic analysis by determining its TAG composition, together with the fatty acid composition and the minor components. **Tables 1–3** list some vegetable oils that are found in foods and give typical component analysis. The chemical and physical properties of such oils will affect how they can be used in the formulation and manufacture of foods. The main and important properties are described below.

Properties

General

When foods containing significant amounts of added edible fats are formulated, the added fat will affect three main characteristics of the food. The first is processability during preparation; the second is sensory quality (as related to taste and flavor); and the third is shelf-life, which may be physical or chemical in nature. **Figure 1** shows the relationship between some oil types, melting point, rancimat value, and total amount of both unsaturated and polyunsaturated fatty acids. Rancimat value is a measure of the oxidation potential of a fat or oil. It is the time in hours, at a stated temperature (typically 100°C) for

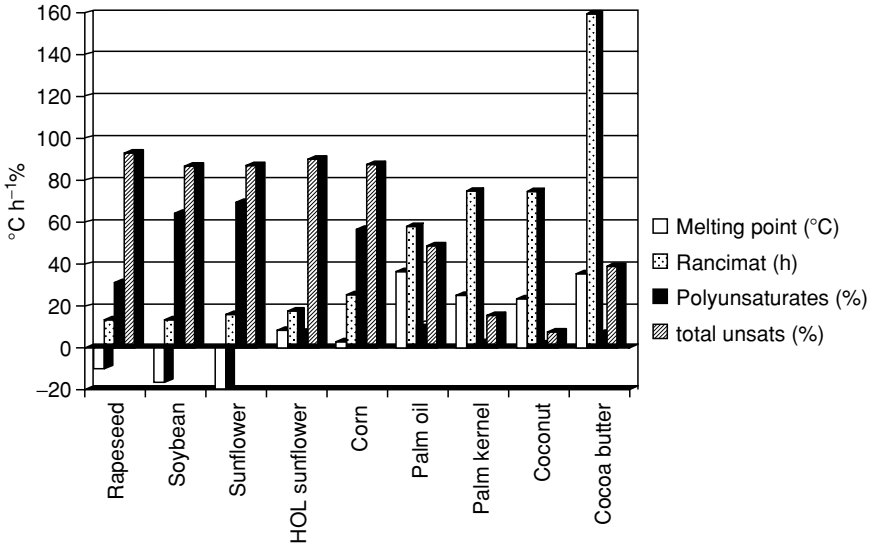

Figure 1 Relationship for different oils, between melting point, rancimat value and amount of total unsaturated and polyunsaturated fatty acids.

the fat or oil to pass through induction to a rapid oxidation rate. It can be seen that, in general, the amount of polyunsaturates has the greater effect on melting point: as polyunsaturates rise, the melting point reduces. This rise is accompanied by a reduction in the rancimat time. The rancimat time is a measure of the ease with which the fat oxidizes (becomes rancid) and therefore has a relationship to the ultimate shelf-life of a product made with that fat. Generally, as the level of total unsaturated fatty acids rises (particularly polyunsaturated fatty acids), so does the potential of the fat to oxidize and form rancid off-flavors. As an indicator, linoleic acid (two double bonds) will have an oxidation rate that is some 50 times greater than oleic acid (one double bond). Thus, it would be expected that normal sunflower oil will become rancid more quickly than high-oleic sunflower oil (Table 1).

These comparisons of properties are expressed as simple links here, although in reality the links can be quite complex. For example, comparing the data given for palm oil (PO) and palm kernel oil (PKO), both incidentally obtained from the palm fruits, shows that PKO has a lower melting point than PO, despite the fact that PO has a much higher level of polyunsaturated fatty acids. However, PKO has a

higher amount of shorter-chain fatty acids that create lower-carbon-number TAGs with reduced melting point temperatures (Tables 1 and 2). The rancimat value for PKO is higher than that for PO and this fully reflects the lower total amount of unsaturated fatty acids present in PKO (Table 1).

If corn oil is compared with sunflower oil, there appear to be anomalies also. The total unsaturates and polyunsaturates are similar and yet sunflower oil has the lowest melting point in the group shown. This is caused by the fact that sunflower oil has a high content of TAGs, with three linoleic acids in the structure.

From these points, it will be seen that the final physical properties of fats are dependent upon the 'finer' chemistry of TAG structure and this even includes the positional distribution of the fatty acids on the glycerol of TAGs.

Chemical

The main chemical property related to the use of fats in foods is the potential for oxidation and the development of rancidity. This chemical process is normally termed autooxidation and is an autocatalytic reaction with oxygen in the air. As stated above, this potential is closely related to the amount of polyunsaturated fatty acids present in the fat. Potent rancid taints can be obtained from soybean and rapeseed oils that have a descriptor of 'putty-like.' The oxidation of linolenic acid (C18:3) results in volatile compounds found in the process of setting linseed oil putty. Linseed oil is referred to as a 'drying' oil as it oxidizes rapidly in air, forming polymers that harden the putty. Sunflower oil oxidizes less rapidly, but it is linoleic acid-rich and produces potent taints with descriptors such as 'green bean' or 'cut grass.' As sunflower oil oxidizes it forms jelly-like polymers. Such taints (aromas) are found when green beans or grass are cut, although these are a result of the action of the lipoxygenase enzyme as it catalyzes the oxidation of linoleic acid.

The ultimate chemical shelf-life of a fatty food (or fat) is dependent on the unsaturation of the fat. However, the rate of oxidation of the fat will be modified by the amount and type of tocopherols present (Table 3). The tocopherols act as natural antioxidants. For example, the tocotrienols in PO are very important in controlling oxidation of the oil when it is being used as a frying medium. This activity is most important when the oil is being heated up to and used above 150 °C. However, the ambient shelf-life of fatty products is better protected by the presence of γ and δ tocopherols. Oils rich in α tocopherol appear to be less well protected.

A second chemical property that sometimes relates to shelf-life and taints is the possibility of oil hydrolysis. The glycerol ester group can be broken either with water, by straight reaction under slightly alkaline pH conditions, or through the action of lipase enzyme. The lipase can arise as a residue in the food materials or via a microbial action on the food. This latter process takes place naturally on the fats in, for example, unheat-treated wheat flours, producing free fatty acids (FFA). This process does not cause flavor taint, but may reduce the baking quality of the flour.

FFA do not normally cause flavor change at levels below 2% of the fat. However, they may cause surface activity changes in oils used, for example, in deep-frying. The result can be foaming of the oil, a deepening of the fried brown color, and a higher fat content in the product. The FFA changes the heat and moisture transfer properties at the product surface, producing an overfried effect. Where lauric oils (high content of C12:0, Table 1) are used, the production of FFA at $< 0.01\%$ of the fat can be tasted as a soapy taint. Thus, where coconut and palm kernel oils are used, FFA must be guarded against. However, FFA can be a positive property when it is present in fermented products such as soy sauce or yogurt-type products based on vegetable oils. (*See* **Fats**: Classification.)

Physical

The melting points given in Figure 1 are actually slip melting points. The slip melting point is the temperature at which 5% solid fat remains. To explain this, it is important to understand that fats are not pure compounds but are complex mixtures of TAGs. Each pure TAG type has its own melting point but when mixed with others the result will be different. Natural fats therefore do not have sharp melting points but will have a ratio of solid and liquid fat at any given temperature. The solid fat content (SFC) is an important physical property and it is measured using pulsed nuclear magnetic resonance (pNMR). The SFC may be described as a graphic curve and is used as a standard physical property when considering the function of fats in making certain foods. Figure 2 shows this type of data for a range of important food vegetable fats.

When making foods with fats that have solid properties at normal ambient temperatures, a further important physical property is the crystal form of the fat. Fats are polymorphic, that is, they have more than one crystal form, and this can be determined using X-ray diffraction. Typically, fats can crystallize in three different forms following the sequence:

$$\text{Alpha } (\alpha) \Rightarrow \text{Beta prime } (\beta') \Rightarrow \text{Beta } (\beta)$$

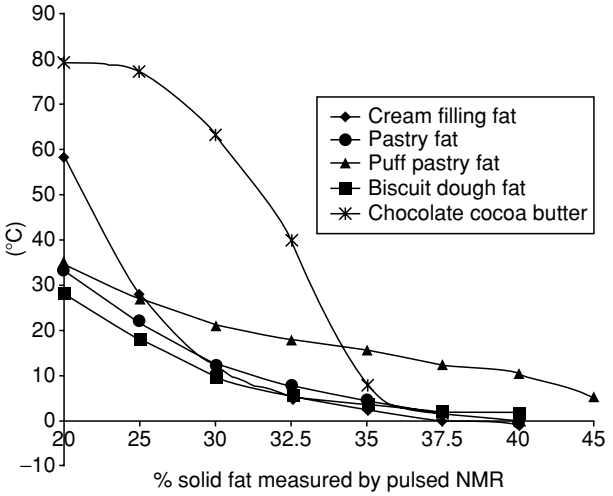

Figure 2 Comparison for different fats of percentage solid fat content over a range of temperature.

The rate of movement from one form to another is dependent upon the structure of the TAGs together with the time and temperature. It is a thermodynamic process. The α form is usually physically unstable above about 5 °C and rapidly transforms to β′. The β′ form is predominant in most fats used for food manufacture but may slowly transform over a period of weeks or months to the β form.

Cocoa butter (chocolate fat) is a special case, has a more complex crystalline nature, and can exist in six different forms. Cocoa butter has to be 'tempered' for use in chocolate so as to obtain specifically the crystal form five (form V). In this form, it retains high surface gloss and good structure. The six crystal forms and the shape of the SFC curve for cocoa butter (Figure 2) are a consequence of its special TAG structure. Cocoa butter has a predominance of symmetrical TAG, where positions 1 and 3 of the TAG are occupied by either 16:0 or 18:0, while position 2 is occupied by 18:1.

In all fats, the melting point increases as they attain the higher crystal forms. However, with the exception of cocoa butter and other fats associated with chocolate manufacture, the preferred form for use as a functional ingredient in foods is β′. The β′ and β forms are quite different and have different consequences in food products containing them. The β′ form can be likened to a bundle of needles. The crystals knit together to form a three-dimensional structure that can hold liquids such as oil or water droplets within it. The β form is more plate-like with larger crystals and these do not form a good stable three-dimensional structure.

The consequences of these physical properties are very important in food manufacture, the shelf-life of the food, and its sensory properties. It can be seen (Figure 2) that the SFC curves for dough fats are relatively flat. Most dough fats are plasticized before use, that is, they are crystallized using a scraped surface heat exchanger or rotator. This insures that the solid fraction of the fat at, say, 25 °C, is a fine distribution of β′ crystals in which is retained approximately 75% of liquid fat. This 'texturized' fat is plastic and cream-like and will also retain at least 20% of its volume of water if added at the plasticization stage. The resultant plastic fat material is easily mixed with other dough recipe components to make a cohesive and homogeneous dough. The relatively low solid fat content provides a luxurious lubricant effect in the mouth while eating the product.

Cream filling fats (Figure 2) have much higher solids at ambient temperatures, but the solids fall rapidly between 20 and 30 °C. The β′ crystal structure acts in the same way as for dough fats, retaining the liquid fat and allowing easy homogeneous blending. But in addition, the crystal network of these fats can be gas-filled to create a lower-density foamed cream filling. The steep decline in solids at the low-temperature end of the SFC curve provides a 'clean' palate, excellent flavor release, and a luxuriant cooling sensation. This latter point is caused by the rapid melting of fat and removal of heat from the tongue and palate of the mouth. At the mid-range temperature, cream fats are designed to have a particular slip melting temperature. This suits whether they are to be deposited or stencilled on to such materials as biscuit shells. The physical properties are very important for these processes to be successful.

Cocoa butter (Figure 2) shows a convex SFC curve. There is considerable resistance to melting up to 30 °C and this accounts for the ability of chocolate to stay hard and glossy over a wide ambient temperature range. Above 30 °C (mouth temperature) the fat begins to melt very rapidly. This provides a 'rush' of flavor release, a luxuriant creamy sensation, and (for high-quality chocolate) a distinct cooling of the palate. By the time body temperature is reached (37.5 °C) there is no solid fat remaining. (*See* **Cocoa: Chemistry of Processing.**)

The physical properties described above provide for a good eating product with a relatively long shelf-life. However, foods are dynamic materials and thermodynamic processes strive to obtain the least energy or lowest enthalpy in, for example, the fat. The appearance of fat bloom, softening or shrinkage of fat cream fillings, and softening and bloom of chocolate coatings can limit shelf-life. The transformation of a β′fat system to a β fat crystal in a product will almost certainly be accompanied by

the development of fat bloom or graining of the fat phase. In these cases the liquid fat is released and the product may become 'oily.' Fat bloom is shown as either excessive crystal growth (graining) or a frosted or moldy appearance on, for example, chocolate coatings or biscuit surfaces.

While β′ fat systems do retain the liquid fat efficiently it is inevitable that, with time, the liquid phase will migrate out. This is seen particularly where two fat-containing phases are in contact. Fat migration changes the composition of the fat and therefore the SFC. The outcome is usually a softening of, for example, a chocolate coating. Often the properties of vegetable fats are not optimum for an application; in this case the physical properties can be changed. Blending different fats or chemically modifying them by hydrogenation or interesterification will do this. In all cases, the chemical make-up is changed and this has a direct effect on the physical properties.

Oil Production and Processing

W Hamm, Harpenden, UK

Background

Vegetable oils are principally recovered from oilseeds, with oil-rich fruit such as the fruit of the oil palm and of the olive tree providing important additional sources. Solvent extraction is used for oil recovery from oilseeds, but in the case of palm and olive oil, the oil is recovered by separating it from the aqueous phase present in the fruit after crushing. Vegetable oils are for the most part refined before consumption, refining comprising a series of steps designed to produce a bland, stable oil. Refined oils may be modified in order to change their physical properties. Virgin, i.e., unrefined, olive oil plays an important part in the market for vegetable oils.

Both refining and oil modification processes are increasingly being improved in order to conform to modern standards of a healthy food product. This entails avoiding the formation of undesirable artefacts as well as minimizing the removal of valuable minor components.

Oilseeds and Oil-rich Fruits Used in the Production of Edible Oils

Vigorous growth in the last half-century of production and consumption of vegetable oils has meant that the world-wide per capita consumption of oils and fats has risen significantly, with many parts of the developing world sharing this growth with that in the industrialized regions. A direct consequence of this increase in availability has been a substantial increase in international trade in oils and oilseeds. At the same time, vegetable oils also find substantial use in the oleochemicals industry, which therefore serves as an additional outlet for a limited number of vegetable oils.

The oils used for edible purposes fall into two categories. The seed oils are produced from annually planted seeds, and this category includes, besides soyabeans, rapeseed, sunflower seed, cottonseed, groundnuts, and many other oil-rich seeds. The oil content of the major seeds covers a wide range, the soyabean normally containing less than 20% oil, whereas many of the others contain in excess of 40% oil after dehulling. The second category of vegetable oil sources is a smaller group of tree crops, primarily comprising the fruit of the coconut and oil palms as well as that of the olive tree. Being tree crops, these do not have to be replanted annually, but in consequence, the fruit only becomes available after some years of cultivation. The fruit of the oil palm shows a unique characteristic in that the kernel of the fruit contains an oil (palm kernel oil) that has a composition that differs radically from the oil in the fleshy part of the fruit, the mesocarp.

From the point of view of applications, it is also useful to consider vegetable oils on the basis of the chain length of their major fatty acid components. Oils containing large proportions of shorter-chain fatty acids (C12 and C14 chain length), of which coconut oil and palm kernel oil are the principal representatives, comprise one group, whereas the group of oils where the major fatty acids are of C18 chain length includes the majority of the seed oils (see **Table 1**).

Table 1 Oil production: oil yield and quality

Seed/fruit	*Seed crushed 1999–2000 (million tonnes)*	*Oil production 1999–2000 (million tonnes)*	*Oil yield (%)*	*Oil yield calculated on*	*FFA of oil*

Oil Recovery

Oilseeds

The extraction of oil from the various oilseeds requires the application of heat and moisture to prepare the oil-containing cells for rupture and pressure to press the oil from the seed after size reduction, size reduction generally being achieved by flaking. Screw-press expellers have made it possible to operate virtually continuously but leave 3–5% of oil in the protein-rich cake. The development of the solvent extraction process has increased oil recovery and at the same time has made it economically attractive to process seeds relatively low in oil content such as soyabeans. However, the oil obtained using a screw press contains fewer of the minor components present in the oil, e.g., phospholipids, and is consequently easier to refine.

Industrial hexane is the solvent used universally for the solvent extraction of oil from oilseed, although research into extraction with other solvents, including supercritical carbon dioxide, has been reported. Solvent extraction is carried out using countercurrent percolation of solvent through a bed of seed flakes. The oil-rich solvent leaving the extractor is then desolventized in a multiple-effect evaporator. The solvent recovery sections of the process generally account for a large share of the capital investment in a solvent extraction plant, and despite the use of sophisticated energy-recovery techniques, the energy required for solvent recovery makes the operating costs for the process considerably higher than the costs of screw-press oil recovery. This additional cost of production must be offset by the value of the increased oil recovery.

In the case of seeds having a high oil content, the oil recovery process in many cases comprises a screw-press operation followed by solvent extraction of the partially deoiled cake. Oils containing high levels of phospholipids, e.g., soyabean and rapeseed (canola) oil, are water-degummed after extraction and desolventization as the phospholipids precipitate during storage and thus interfere with oil handling and downstream processing. Degumming with water reduces the phospholipid content of an oil of good quality to approximately 200 p.p.m., expressed as phosphorus, equivalent to 0.5–0.6% phospholipids (see Figure 1). (*See* **Phosphorus**: Properties and Determination.)

Cold-pressed oils, i.e., oils recovered from seed with minimum application of heat during pretreatment and without use of solvent, are becoming popular in some countries.

Oils Obtained from Tree Crops

Palm oil Recovery of the oil from the fruit of the oil palm (*Elaeis guineensis*) requires early sterilization of the harvested fruit bunches if the formation of free fatty acid in the oil resulting from the action of an enzyme present in the fruitlets is to be avoided. The oil palm plantation should therefore be closely linked, both geographically and organizationally, to a mill capable of processing the harvested fruit with minimum delay. The fruit is steam-sterilized, and the fruitlets are then stripped from the bunch. This operation is followed by pressing to recover the crude palm oil, with the palm kernels left in the press cake. After clarification and drying, the crude palm oil is ready for downstream processing. One hundred tonnes of fresh fruit bunches (FFB) can be expected to produce approximately 23 tonnes of crude palm oil. Crude palm oil from South-east Asia normally contains 4–5% free fatty acids (FFA), but palm oil containing 2–3% FFA can be produced. The crude oil

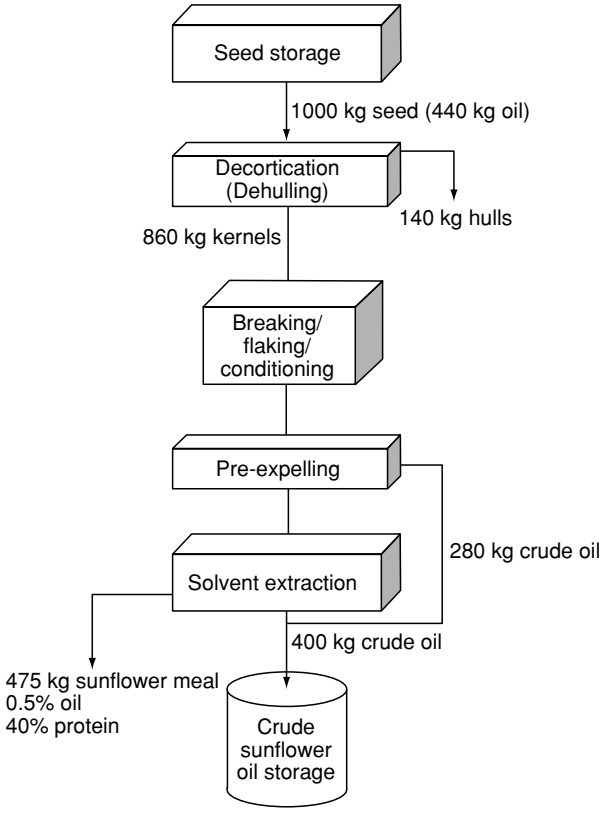

Figure 1 Sunflower oil production: average values for processing of decorticated sunflower seed. Note that oil may be recovered from either whole or partially decorticated seed.

is rich in β-carotene, tocopherols, and tocotrienols, and this feature of the oil is used to enhance its value.

The palm kernels, after separation from fibrous material, are processed for oil recovery using a solvent extraction process, as described above for seed oils. One hundred tonnes of FFB should produce approximately 2.5 tonnes of palm kernel oil, an oil rich in short-chain fatty acids.

Olive oil The olive oil production process involves crushing the fruit followed by a two-stage centrifugal system that serves to separate the oil and then wash it. The fruit contains an average of 20% oil, and the bulk of the oil in the fruit is produced to the standards required to classify it as virgin or extra virgin oil. Olive-pomace oil is the oil obtained by solvent extraction of the residue after the first separation stage. In the European Union, this oil must be refined and then blended with a specified amount of virgin olive oil before it can be sold for human consumption. Internationally agreed specifications for the various grades of olive oil require extra virgin olive oil to have a FFA content not exceeding 1.0% (as oleic acid), whereas virgin olive oil may contain up to a maximum of 2.0% free fatty acid. (*See* **Olive Oil.**)

Rice bran oil Rice bran oil, a byproduct of rice processing, is mainly produced in East Asia. Like the palm fruitlet, rice bran contains an enzyme that rapidly attacks the oil if it is not heat-deactivated immediately after separation from the crop. In practice, unrefined rice bran oil often contains high levels of FFA as a result of delays in processing. The presence of important antioxidants in rice bran oil, ferulic acid esters generally referred to as γ-oryzanols, has recently led to its use as a component of frying oils in order to extend the useful life of industrial frying oils.

Coconut oil Coconut oil is the oil obtained from the dried 'meat,' generally known as 'copra,' of the coconut fruit. The drying of the copra, a necessary step, prior to oil extraction, is sometimes carried out with hot gases containing polycyclic aromatic hydrocarbons (PAHs). These must be removed during refining of the oil. Coconut oil has been the most important of the so-called lauric oils, although palm kernel oil production is now comparable with that of coconut oil. (*See* **Coconut Palm.**)

Oil Movements

The pattern of growth in edible oil production and consumption has meant that large quantities of crude edible oil are moved intercontinentally from producer to user countries. In order to avoid contamination of vegetable oil cargoes with residues of cargoes previously carried by the same vessel, various international bodies such as the London-based Federation of Oils, Seeds and Fats Associations and the US National Institute of Oilseed Products introduced regulations governing the type of cargo that may be carried by a parcel tanker in the three loadings immediately prior to loading an oil to be used for edible purposes.

The possibility of overheating of the oil during the voyage or at the time of discharge is also a cause of oil quality deterioration in the course of long-distance transportation. Table 2 is a schedule of recommended cargo temperatures cited in a recent Codex Alimentarius Commission report.

Ingress of water into the cargo while at sea can also be troublesome, as this can lead to hydrolysis of the triacylglycerols, the major component of the oil, which manifests itself in an increase of the FFA content, the process of hydrolysis being considered to be autocatalytic.

A consequence of these oil movements is the need for substantial storage capacity for vegetable oils at the receiving port, and large tank farms have been

established over the years in the major receiving ports, Rotterdam, Hamburg, and New York. As Malaysia mainly ships refined palm oil fractions (though this may be re-refined by the receiver), there is a growing demand for high-quality storage at the major ports. Nitrogen blanketing of cargoes either during shipment or in port storage has been recommended. In the case of higher-value fats, e.g., confectionery fat components, shipment in special containers has been used.

Oil Processing

Although filtered crude oil is sometimes consumed without any conventional refining, for all practical purposes, vegetable oils must be refined in order to make them suitable for consumption in one of the forms in which oils and fats are used. The refining processes in use nowadays have a number of objectives, the most important of these being

- to produce a clear, stable oil free of undesirable minor components;
- to ensure that the refined oil has a good keepability and retains, as far as possible, those minor components that are considered to be desirable, e.g., tocopherols;
- to avoid structural damage to the oil, e.g., by the formation of *trans*-fatty acids and polar compounds (diacylglycerols, polymers);
- to minimize direct and downgrading losses intrinsic to the process;
- to minimize the cost of processing.

These objectives are achieved by subjecting the oil to either of the two main processes used by the industry. Chemical refining relies on the reaction of the FFA present in the crude oil with an alkaline solution, normally sodium hydroxide, to reduce the FFA content of the oil to an acceptable level. Physical refining, however, makes use of the relative volatility of these FFA to separate them from the major constituents, the triacylglycerols, in a steam-stripping operation carried out at high temperature and low pressure, each process having advantages and disadvantages (Table 3). Both processes (see Figure 2) are considered in more detail in the following sections.

Table 2 Recommended schedule of cargo temperatures (°C)

Oil	*During voyage*		*On discharge*	
	Min	*Max*	*Min*	*Max*
Sunflower	Ambient	Ambient	Ambient	20
Soyabean	Ambient	Ambient	20	25
Groundnut	Ambient	Ambient	20	25

Palm olein, RBD	25	30	32	35

Schedule produced by International Seed Crushers' Association.

Degumming

An important characteristic of vegetable oils is their phospholipid content, the seed oils being richest in these (see Table 4). For processing reasons, the phospholipids are often divided into those readily hydratable by water, and the remainder that can only be hydrated (and become insoluble in oil) by the addition of acids. The water-hydratable phospholipids, which are frequently removed immediately after extraction, are useful as a source of lecithin and its derivatives.

The removal of nonhydratable phospholipids is sometimes combined with chemical removal of FFA but can also be carried out as a separate operation, an option that becomes particularly important when the oil is to be refined physically.

Citric acid, though more costly to use than phosphoric acid for the hydration of phospholipids not

Table 3 Advantages and disadvantages of chemical and physical refining of oils

Advantages	*Disadvantages*
Chemical refining	
1. Flexibility (ability to process small batches, dark oils)	1. Refining loss (oil downgrading) can be high
2. Moderate deodorization temperature required	2. Relatively high level of effluent formation
3. Better for recovery of valuable minor components in deodorizer distillate	
Physical refining	
1. Lower refining loss	1. Higher stripping/deodorization temperatures required
2. Reduced effluent formation	2. More sensitive to residual levels of phospholipids and metals
3. Less labor-intensive	3. Increased bleaching earth consumption
	4. Unsuitable for dark oils

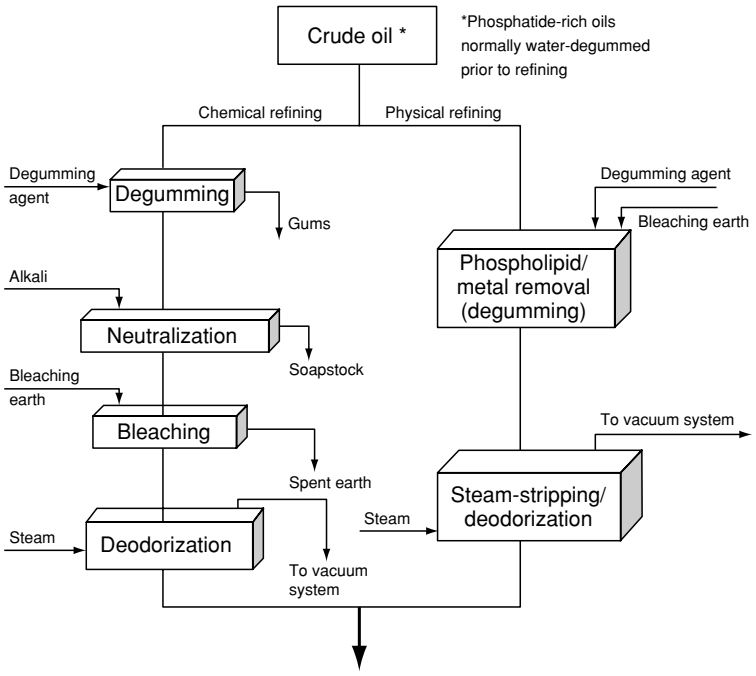

Figure 2 Refining options for edible oil.

Table 4 Phospholipid contents of major oils

Oil	*Phospholipids (%)*	*Phosphorus (p.p.m.)*
Rapeseed	0.5–3.5	200–1400
Soyabean	1.0–3.0	400–1200
Sunflower	0.5–1.3	200–500
Corn	0.7–2.0	250–800
Cottonseed	1.0–2.5	400–1000
Palm	0.03–0.1	15–30

hydrated by water, offers a greater versatility in use and poses no risk of acid residues in the processed oil. Table 5 shows the processes used for degumming oils and their effectiveness in reducing the phospholipid content of oils. Ultrafiltration of the oil (in solvent) to remove the phospholipids is also effective but more costly than other processes.

Removal of the phospholipids present in the oil facilitates the subsequent stages of refining, as it reduces the tendency to form emulsions during neutralization of the FFA and also permits operation at high temperatures (> 200 °C) without any risk of discoloration. When the oil is to be refined physically, i.e., using stripping steam to remove the FFA from the crude oil, the degumming process must also remove traces of metals such as copper and iron, which would discolor the oil at the temperatures used for steam-stripping.

Chemical Refining

Neutralization All crude vegetable oils contain FFA that should be removed in the interests of refined oil quality. The seed oils for the most part contain 0.8–1.5% FFA, but palm oil may contain up to 5.0% FFA as the result of enzymic action in the interval between fruit harvesting and sterilization. Oils such as ricebran oil and several of the more exotic fats, e.g., sheanut butter and illipe fat, may contain more than 5% FFA.

Although, in principle, any alkali may be used to neutralize the FFA present in the crude or degummed oil, sodium hydroxide solution (strength 8–24%, depending on the oil to be refined – a dark oil will normally be neutralized with a stronger alkali than an oil that is light in color) is used almost universally in industrial chemical refining of fatty oils. The neutralization reaction is carried out at 80–90 °C (see Figure 3). In the conditions of intense mixing, as practiced in modern centrifugal refining, it requires contact times between crude oil and alkali of less than 60 s. The soaps formed by neutralization, known as soapstock, are insoluble in the oil and are separated centrifugally, the disk centrifuge being the preferred type nowadays. As the soaps have a low but finite solubility in the oil at the processing temperature (soap content of oil = 150–200 p.p.m.), it is necessary to follow separation of the soapstock by a washing

Table 5 Degumming processes

Process	*Suitable for*	*Residual phospholipids (p.p.m. phosphorus)*
Water degumming	Crude oil	100–250
Acid degumming	Crude oil	20–50
Acid refining	Crude oil	< 20
Superdegumming (Unilever)	Crude or wdg oil	5–15
TOP degumming (Vandenmoortele)	Crude or wdg oil	5–10
Enzymatic degumming	wdg oil	5–10
SOFT degumming (Tirtiaux)	Crude oil	< 5
IMPAC degumming	Crude oil	3–10

wdg, water-degummed.

stage, in which soft water is used to reduce the soap content of the oil to below 30 p.p.m. The FFA content of the neutralized oil should be below 0.1%.

The soapstock contains a certain amount of neutral oil owing to spontaneous emulsification taking place at the oil–alkali interface in the course of the neutralization reaction. This is reflected in the refining loss experienced by refiners, defined as the ratio of oil loss at the neutralization stage to the FFA present in the crude oil and known as the refining factor. For most oils, the refining loss in chemical refining can be expected to be in the range of 1.5–2.0, although lower refining factors have been obtained when using nonturbulent alkali–oil contactors. The downgrading of sound oil to the lower-valued soapstock or acid oil produced by acidulation of soapstock results in a significant cost charge against the process.

The effluent resulting from chemical neutralization has been recognized as an environmental problem, and this has resulted in a change to physical refining, particularly in Europe. When chemical refining is used to remove only low levels (< 0.15%) of FFA, as in the case of an oil already refined in the country of origin and then transported intercontinentally, it is possible to use a hydrogel silica or a modified magnesium aluminum silicate to adsorb the soaps formed,

instead of washing them out of the oil. Similarly, these materials can be used to replace the wash centrifuge in normal refining in order to remove the soap content remaining in the refined oil after soapstock separation, thus again avoiding the formation of additional liquid effluent.

Bleaching The neutralized oil to be bleached is deaerated and dried at a pressure of approximately 50 mbar to a moisture content of not more than 0.1%. Use of acid-activated bleaching earth (bleaching clay in the USA) will remove traces of metals such as copper and iron from the oil in addition to pigments and residual soap, which is important from the point of view of oil keepability. Cocurrent or countercurrent bleaching may be used to reduce the bleaching earth requirements, with savings of 10–15% relative to batch bleaching being reported for the cocurrent option and up to 40% for countercurrent processing. Oil leaving the bleacher is filtered to separate spent bleaching earth, but this retains high levels of oil unless it is processed further, e.g., by blowing steam or nitrogen through the press. Spent earth destined for disposal to a landfill site will generally still contain approximately 30% oil. This therefore becomes a charge against the process, additional to the refining loss explained above. The spent bleaching earth is also a fire hazard.

In recent years, a number of alternatives to acid-activated bleaching earth have been developed for use in edible oil refining. The use of silica as an adsorbent and filter aid, generally in admixture with bleaching earth, has been shown to be feasible, though the cost is higher than that of the more traditional bleaching earths. A number of multistage bleaching processes are available, their purpose being to reduce the bleaching earth requirement per tonne of oil processed.

An oil contaminated with polycyclic aromatic hydrocarbons (PAH) requires the addition of a small quantity of activated carbon to ensure that the PAH content of the fully processed oil is reduced to acceptable levels.

Deodorization The final stage of oil processing, deodorization, has the function of removing volatile components remaining in the oil after the previous stages of refining as well as those volatile compounds formed during deodorization itself. In addition, some heat-bleaching is likely to occur at this stage, owing to the high temperatures used. The removal of volatile components is achieved by the passage of open steam through the oil at temperatures of 200–220 °C at a pressure of 4–10 mbar. Stripping steam consumption in the process can be expected to be in the range of 0.5–3.0%. In order to ensure stability of the processed oil, its peroxide value should be below 1.0, preferably below 0.5 meq of O_2 per kilogram of oil, which requires rapid cooling of the oil after the completion of deodorization.

Deodorization can be carried out batchwise, semicontinuously or fully continuously, and in the case of a fully continuous operation, either a crosscurrent or countercurrent mode of steam–oil contact may be used. The extent of removal of volatile components is directly proportional to the volatility of the component and is therefore a function of the operating temperature. At the same time, it is also inversely proportional to the operating pressure. Since deodorization is a dynamic process, the interfacial area between the stripping medium and the oil to be deodorized is a vital parameter in determining stripping efficiency.

Modern deodorizers, almost all of which operate semicontinuously or fully continuously, are fitted with heat-recovery systems that can recover up to 80% of the energy needed to heat the incoming oil to the operating temperature. The vacuum system, normally consisting of a series of steam jet ejectors, also uses substantial quantities of steam in the form of motive steam, a ratio of 5–7 kg of motive steam per kilogram of stripping steam evacuated being required in temperate regions when operating at a head pressure of 4–6 mbar. The motive steam requirement can be reduced by chilling the water used to condense the mixed vapors from the deodorizer or by using a 'dry' vacuum system that makes use of mechanical vacuum pumps instead of steam jet ejectors.

Apart from high-energy consumption, the environmental impact of deodorization manifests itself in the liquid and gaseous emissions created by the process. Entrainment of oil in the stripping vapors leaving the deodorizer constitutes a process loss, generally 0.2–0.3% of the oil processed, but if not trapped in a scrubber or condenser, this entrainment will appear in the effluent stream leaving the plant. In recent years, steps have also been taken to reduce the odoriferous gaseous effluent from the deodorizer.

In addition to removing the undesirable minor components of the oil reaching the deodorizer, the stripping steam will also remove, at least partially, valuable components such as tocopherols and sterols. The tocopherols constitute a valuable byproduct that can be converted to natural vitamin E concentrates. However, the α-tocopherol content of most vegetable oils accounts for only a small proportion of the total tocopherol content (Table 6), and the deodorizer distillate requires removal of the nontocopherol components but also conversion of the other tocopherol isomers to the α-form if the product is intended as

Table 6 Typical tocopherol contents of major vegetable oils

Oil	*Total tocopherol (p.p.m.)*	*α-Tocopherol (p.p.m.)*	*β-Tocopherol (p.p.m.)*	*γ-Tocopherol (p.p.m.)*	*Reference*
Soyabean	811	179	28	604	1

a diet supplement. It is also possible to recover sterols, which can be converted to pharmaceutical products, from the deodorizer distillate when refining soyabean oil.

Physical Refining

Physical refining of a vegetable oil requires operation at a temperature significantly higher than the temperature used in the deodorization stage of chemical refining, as the process depends principally on the volatility of the FFA present in the oil, which are removed by reaction in chemical refining. Processing temperatures in the stripper are therefore generally in the range of 220–250 °C, which means that the oil being processed is subjected to greater thermal stress than the oil deodorized following chemical refining.

Degumming As already indicated, degumming of an oil that is to be physically refined must be designed to achieve higher standards of removal of undesirable components than when degumming as part of a chemical refining process. Acid refining, in which phosphoric acid is used to hydrate the phospholipids not hydrated by water and alkali is then added to neutralize the excess acid, can be used to reduce phospholipids to below 10 p.p.m. Bleaching earth is then added to adsorb the precipitated material, and the mixture of oil and earth is filtered conventionally. With the simultaneous removal of metals, the acid-refined oil is suitable for physical refining.

The bleaching earth requirement for the physical refining process is higher than that for chemical refining, and this fact counterbalances to some extent the lower refining losses in physical refining. Table 7 compares the bleaching earth requirements for various oils in chemical and physical refining.

Table 7 Bleaching earth consumption in physical and chemical refining

Oil	*Percentage of bleaching earth*	
	Fully degummed oil (for physical refining)	*Neutralized (chemical refining)*
Sunflower	0.3	0.1–0.2
Rapeseed	0.7	0.5
Corn	0.8	0.5

From Kokken M (1996) *World Conference on Oilseeds and Edible Oils, Istanbul*.

Stripping/deodorizing The requirement for removal of FFA by steam-stripping in physical refining distinguishes this operation from the apparently closely related operation of deodorization in a number of important respects – a significantly higher operating temperature is needed in order to reach fatty acid vapor pressures at which stripping becomes practical; the molar fraction of fatty acids in the vapor stream leaving the stripper contributes significantly to the total vapor flow and therefore to the design of the condenser used to recover material from the vapour stream; and the higher operating temperature leads to a greater loss of other volatile components, e.g., tocopherols, from the oil. A further consequence of the higher process temperature is the greater possibility of *trans*-fatty acid (TFA) formation.

Stripper design is generally similar to the design of deodorizer discussed earlier, but batch operation is not appropriate. In practice, steam-stripping of fatty acids uses slightly higher quantities of stripping steam per unit of oil processed than deodorization. The condensed stripper vapors, being richer in FFA than deodorizer distillate, have a proportionately lower content of the valuable tocopherols than the distillate and therefore constitute a lower-value byproduct.

Oil Modification

The three oil modification processes – hydrogenation, fractionation, and interesterification – have made a major contribution to the greater use of oils and fats since their introduction in the twentieth century. These processes principally serve to modify the relationship between liquid and solid content of an oil or fat as a function of temperature, thus enhancing their

functionality. Hydrogenation is the most versatile of these processes, primarily because at least three process conditions can be used to modify process performance.

Although the modification processes are used individually in many cases, their coupling, e.g., hydrogenation followed by fractionation, or fractionation coupled with interesterification, can lead to enhanced versatility in the use of different oils and fats.

Hydrogenation

Hydrogenation is used to reduce the unsaturation present in oils and thereby to increase their solid fat content. The conditions for hydrogenation must take into account the different reaction rates for the range of molecular species present in the oil. Nickel, in various forms designed to maximize the active catalyst surface area, is generally used as the reaction catalyst, although other catalysts, e.g., platinum, palladium, and copper, are also effective. The catalyst is precipitated on a carrier for the purpose of maximizing the catalyst surface area available for the reaction. Sulfur addition to the nickel catalyst is used to promote steep melting curves in the hydrogenated fat, but this is achieved by increasing the proportion of TFA in the fat.

When processing a well-refined oil, it is now possible to hydrogenate an oil with catalyst concentrations as low as 40–50 p.p.m. (Table 8). The process conditions employed, including hydrogen pressure, temperature, and catalyst concentration, are chosen to produce a hydrogenated product best suited to the required functionality of the fat produced, bearing in mind that the rate of conversion of linoleic acid (C18:3) to linoleic (C18:2) acid is approximately 40 times greater than that of oleic (C18:1) acid to stearic (C18:0) acid. The selectivity required in the hydrogenation reaction, which expresses the above relationships between the relative reaction rates for the different triacylglycerols present, provides guidance on the choice of catalyst. The process is mostly carried out batchwise or, by linking a series of batch reactors, in a semicontinuous manner. The autoclave may be operated with or without hydrogen recirculation. The loop reactor offers an alternative form of the gas–liquid contactor.

Table 8 Typical hydrogenation conditions

Temperature (°C)	100–250
Catalyst concentration (% Ni)	0.01–1.0
Hydrogen pressure (bar)	1–10
Hydrogen consumption (m^3 per tonne of oil per unit iodine value drop)	0.93
Reaction rate (units of iodine value fall per minute)	1–3

The exothermic hydrogenation reaction leads to a rise in temperature of the bulk oil of approximately 1.6 °C per unit decrease in iodine value (the iodine value of an oil is the standard measure of unsaturation of oils and fats). Efficient cooling must therefore be provided during the reaction in order to maintain the oil at a stable temperature. After hydrogenation the oil must be re-refined in order to remove traces of catalyst from the oil.

Hydrogenation is particularly useful in situations where it is important to maximize the use of one oil, as the process conditions can be used to create a range of hardened oils having different melting characteristics and therefore suiting different applications. In the case of soyabean oil, it is used to convert the relatively unstable linolenic (C18:3) acid to more stable fatty acids.

In recent years, the formation of TFA when hydrogenating has given rise to much reconsideration of the process, since these fatty acids are considered to be health risk (see Figure 4). However, *trans*-isomerization is favored where a fat with a high melting point but without excessive reduction of its degree of unsaturation is required. The formation of TFAs can be controlled by limiting the reuse of catalyst, although this obviously increases process costs. A solution to this problem that is increasingly finding favor is to hydrogenate the oil completely and thereafter interesterify the fully hardened oil with a liquid oil.

Fractionation

In the harvesting year 1999/2000, palm oil accounted for 25% of a total global vegetable oil production of 84 million tonnes, whereas in the year 1974/1975, this oil accounted for only 8% of a total production of approximately 30 million tonnes. The eight fold increase in palm oil production reflected in these figures largely accounts for the important role of fractionation in modern edible oil processing, as palm olein has become a major industrial frying oil.

Fractionation, the separation of liquid and solid fractions of vegetable oils, is based on the reduction in solubility of the more unsaturated in the more saturated triacylglycerols as the bulk temperature is reduced. Thus, cooling of the oil leads to progressive crystallization of, in the first instance, trisaturated triacylglycerols and thereafter disaturated triacylglycerols. As crystallizing triacylglycerols exhibit different polymorphic forms, it is essential to control crystallization conditions in such a way as to minimize occlusion of liquid (uncrystallized) material in the crystallized phase. This normally requires slow

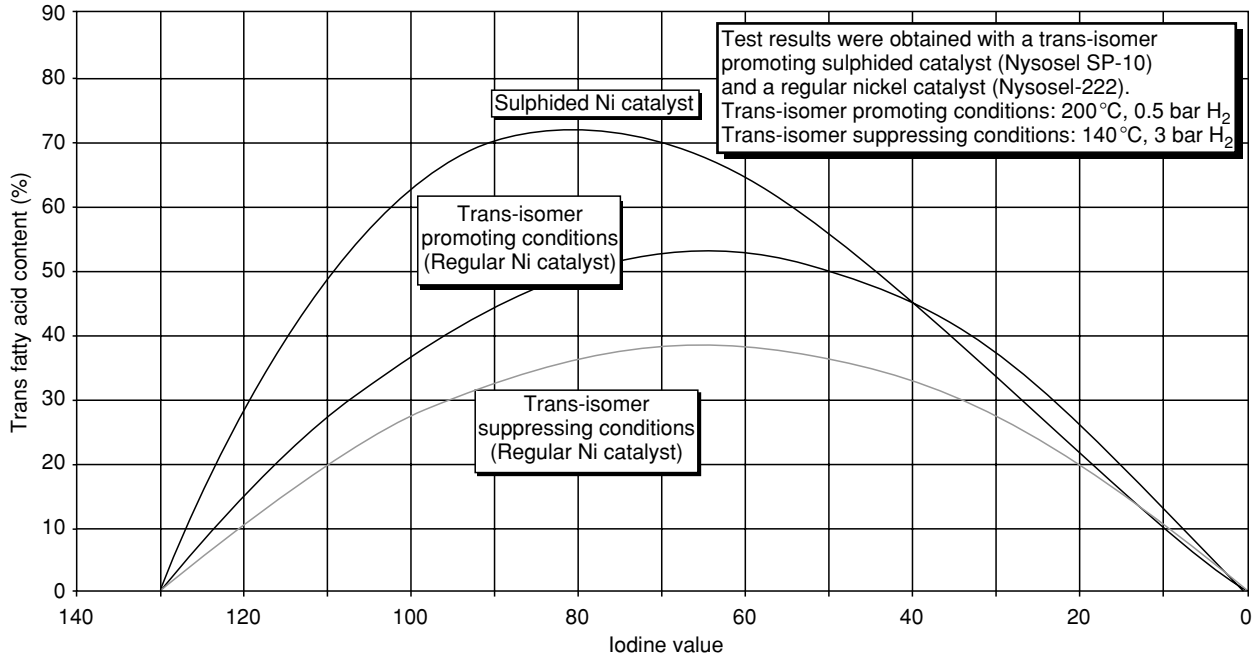

Figure 4 Hydrogenation of soyabean oil using sulfided and nonsulfided nickel catalysts.

cooling of the oil to be fractionated. Separation of the crystallized material from the liquid phase is generally carried out by filtration. The occlusion of liquid oil in the crystallized material means that the yield of filtrate is reduced, which is an important consideration if the filtrate is the primary fraction. Where the filter cake represents the primary fraction, this occlusion reduces its 'purity,' which has an adverse effect on its quality if this is required for specialized applications, e.g., confectionery fats.

The replacement of vacuum filters by the membrane filter press in the 1980s reduced entrainment of liquid oil in the filter cake, but membrane filter press separation at 6 bar still leaves a cake containing 40–60% liquid oil.

When fractionating expensive fats, it becomes commercially feasible to fractionate oils in solvents such as acetone or hexane, as this reduces oil entrainment in the cake to less than 10% and at the same time allows crystallization to be carried out far more quickly.

Fractionation is also used in combination with hydrogenation in the case of soyabean oil. In this case, the conversion of linolenic (C18:3) to linoleic (C18:2) acid is accompanied by the formation of some stearic acid. In order to produce an oil clear at ambient temperature, the hydrogenated oil is then fractionated.

Fractionation has the advantage over other oil modification processes of being a purely physical process, carried out in conditions that do not affect any of the components present beyond crystallizing and melting them. The mild process operating conditions also have the benefit of requiring only moderate processing costs, but the process has the disadvantage of depending on finding rewarding markets for its secondary fractions.

Dewaxing of sunflower oil may be regarded as a fractionation process, though in this case, the purpose of the process is to remove minor quantities of wax esters present in the oil, as these precipitate slowly at low temperatures and give the oil a cloudy appearance. The quantity of wax esters present in the oil depends on whether whole seed or only the kernels have been used for oil production, as more than 80% of the wax present in the whole seed is found in the hull. Oil from undehulled seed may contain more than 1500 p.p.m. wax, whereas oil from dehulled seed is likely to contain less than 500 p.p.m. Dewaxing is normally carried out by chilling the oil, which should have had its phospholipid content reduced to below 10 p.p.m., to approximately 0 °C over a period of 24 h in order to enable the wax to crystallize in discrete form. The subsequent filtration can be accelerated by the addition of a filter aid to the wax–oil slurry. The wax content of the processed oil should not exceed 30 p.p.m. in this case. If a less stringent specification applies, wax separation by centrifugation is feasible.

Interesterification

The fatty acid groups in triacylglycerols can be rearranged within a single oil (intraesterification) or by exchange of fatty acid groups with those of other oils, the latter being known as interesterification. As is the case with the other oil modification processes, the purpose of interesterification is to alter the melting properties of the fat or fat blend in order to improve the functional properties of the product. The reaction requires the presence of a catalyst, and alkaline catalysts are generally used. In particular, sodium methylate, also referred to as sodium methoxide, is extensively used, but metallic sodium has also been used.

In the early stages of the development of this process, both directed interesterification and random interesterification were proposed for use, the former involving interesterification and simultaneous cooling in order to crystallize the saturated triacylglycerols being formed and thus move the equilibrium towards the formation of more saturated triacylglycerols. Random interesterification, however, simply aims to randomize the distribution of the available fatty acid groups on the glycerol molecule and thereby to alter the melting properties of the fat or oil blend.

The aggressive nature of the catalyst makes it essential that the moisture content and the FFA content of the oil to be processed are reduced to the lowest practical values, as hydrolysis of the catalyst results in significant oil losses. It is also of crucial importance that the catalyst is handled with great care by the process operators, as exposure to it is likely to inflict serious injury.

Interesterification (Figure 5) has now become an important tool in the use of fully hardened oils, as this enables an oil processor to minimize the content of TFA in an oil blend. The process finds application in the production of fat blends for use in spreads and of bakery fats, as it facilitates the tailoring of the melting properties of fats to specific requirements (Table 9). It is also used in the production of cocoa-butter replacers.

Immobilized lipases have been used successfully to achieve interesterification on an industrial scale. Lipases have been developed that will retain activity at temperatures up to 80 °C, but increased

temperatures result in higher FFA and diacylglycerol contents, which either require removal by refining or can adversely affect the product properties. Although reuse of the immobilized enzyme has been shown to be feasible, the cost of the immobilized enzyme remains too high for general applicability of enzymic interesterification. Present use of this process appears to be confined to high-value fats.

Applications

The principal use for oils and fats is in the form of liquid oil, either as salad oils or as frying oils. A salad oil must principally display oxidative stability and clarity in appearance, and a wide range of refined oils can meet this requirement. Olive oil is the most obvious example of an oil satisfying these criteria without having been refined, but other oils are sometimes also used in the unrefined state. Frying oils must be resistant to oxidation at high temperature, a high smoke point, and a minimum tendency to foam in use. In the case of oils used for industrial frying, oil cost is an important consideration, and refined, bleached, deodorized palm olein is widely used for this purpose in Europe and various Asian countries. Lightly hydrogenated soyabean oil is the first choice for industrial frying in the USA.

Margarine and spreads have been a major source of fat supply to the Western consumer. In the second half of the twentieth century, the fat component of margarine has increasingly been softened (by skillful use of the various modification processes discussed above) in order to make the product spreadable at refrigerator temperatures. Spreads have a lower fat content than margarine, and are rapidly displacing them. The scraped surface heat exchanger, which replaced the rotary cooler in the production of margarines, has played an important role in the growth of the margarine and spreads industries.

Fats for baked products are widely used both domestically and industrially, with the latter category dominant. In some cases, these fats are blends of individually partially hardened fats, blended to achieve melting properties suitable for a specific application. Emulsifiers may be added to the blend in order to facilitate the incorporation of air in an application.

Confectionery fats constitute a minor, but high-value, part of the total applications field. Their special characteristics of melting over a narrow temperature range has meant that much work has gone into identifying fats suitable for this application. They are characterized by their high content of symmetrical triacylglycerols, obtained by fractionation in the case of cocoa-butter equivalents (CBEs). Cocoa-butter substitutes, however, are based on the oils rich in C14 fatty acids. As these are incompatible with C18-rich fats in crystallized form, care must be taken to exclude the lauric oils from CBEs.

Nutritional aspects of oil and fat consumption can be considered in terms of three characteristics – the type of fatty acid present in the oils and fats consumed, the modification of fatty acids by processing, and the effect of processing on minor components. Clearly, the ongoing debate about healthy eating has favored the consumption of more liquid oils (and thereby a reduction in the consumption of hardened fats) in regions where such choices exist. The choice between polyunsaturated and monounsaturated fatty acids constitutes a second level of consumer choice. The virtual elimination of erucic (C22:1) acid from rapeseed oil grown

in Europe and North America has vastly increased the quantity of this oil suitable for use in the food world. Essential fatty acids are present in only a few vegetable oils, and are often removed by hydrogenation in the interests of oil stability.

The most important modification of fatty acids present in vegetable oils in the course of processing is the formation of TFA. Hydrogenation is the main source of TFA in edible oils, and earlier sections consider some of the changes that have been made in order to reduce the formation of TFA. Although it is generally only a minor contributor to TFA content, high-temperature deodorization (at temperatures of $>250\,^{\circ}C$) does produce measurable quantities of these fatty acids. High-temperature deodorization may also result in an increase in polar lipids, including polymers.

Tocopherols present in crude oils are lost to some extent in the bleaching stage as well as in deodorization, but the latter stage is responsible for the major share of the loss, particularly where very high temperatures are used for this operation. In Europe, deodorization temperatures have therefore been modified in order to reduce this loss. When using chemical refining, the deodorizer distillate is easier to process for tocopherol recovery, and in North America – where chemical refining is preferred to physical refining – addition of tocopherol concentrate to oils is sometimes used to compensate for the loss of tocopherols in the deodorizer.

Analysis

Free Fatty Acids

Free fatty acids (FFA) are not present to any significant level in healthy plant cells. Any fatty acid present is esterified to lipid or associated in some way with protein or other cell constituents. However, FFA at up to 5% (15% in very bad cases) might be found in commercial crude vegetable oils whether pressed or solvent-extracted. The FFA is present as a consequence of cell damage in the vegetable tissue during harvesting, storage, transport, or initial processing. It is a particular problem for the edible oil industry as it must be removed by refining. The cell damage can be caused by bruising of the fruit or seed, freeze–thaw cycling or hot and humid conditions or microbial activity (e.g., fungal growth). The FFA level can also rise during storage of the extracted oil, if the conditions of storage are poor involving humid and warm conditions. The consequence of fruit or seed damage can be easily demonstrated by carefully extracting the lipids from very freshly harvested oil seed. The composition of the lipids is compared with that of an extract of the same batch of seed after it has been frozen at $-20\,^{\circ}C$ for several hours and then left to thaw at room temperature for three or more hours. The freeze–thaw action causes cell damage and the release of hydrolytic enzymes, with resultant lipid hydrolysis and elevated FFA. This can be particularly dramatic in some oil seeds and also can lead to the presence of fatty acids that are not in the native unspoiled oil. Such an example is the seed from *Vernonia anthelmintica* which has (+)*cis*-12,13-epoxyoleic acid (*vernolic acid*) naturally as part of its composition. If the seeds are damaged either by crushing or freeze–thaw action and then left in warm moist conditions, even for a short time, (+)*threo*-12,13-dihydroxyoleic acid is found increasingly to be present at the expense of the vernolic acid. Cell damage causes the release of a lipase and an epoxide hydratase enzyme. While this is an unusual case, it serves to demonstrate the care required when harvesting, storing, and processing vegetable oil crops, particularly so when research is to be undertaken on the lipids of the seeds or fruits. (*See* **Fatty Acids**: Properties.)

The determination of total and individual FFA is covered in detail under the entries on Fatty Acids and will not be repeated here. (*See* **Fatty Acids**: Analysis.)

Fatty Acid Composition

Refined vegetable oils are virtually 100% triacylglyceride (TAG). The analysis of the fatty acid (FA) composition of TAG is covered under Triacylglycerides and Fatty Acids entries. These sections cover the FAs typically found in edible oils including methods of derivatization for chromatography. (*See* **Triglycerides**: Structures and Properties; **Triglycerides**: Characterization and Determination.)

The FAs in most vegetable oils are straight-chain homologous series of saturated and unsaturated carboxylic acids of even-numbered chain lengths from C_8 to C_{24}. The unsaturated series contains one to three methylene-interrupted, *cis* double bonds. Some vegetable oils contain nontypical FAs, but their presence in nutritious edible oils is usually undesirable. For this reason, their analysis is not covered here. A broad review of the types and occurrence of these other FAs can be found in *The Lipid Handbook* (see Further Reading).

Triacylglycerides

The general analysis of TAG is covered under the entry Triglycerides. Some detail on carbon number analysis by nonpolar high-temperature gas chromatography is given there. This technique produces good quantitative information on the overall TAG composition, giving a 'finger print,' which, if linked with fatty acid analysis, enables the determination of fat type. The demanding and detailed analysis of isomeric TAG composition is described here. However, it should be stated that, to obtain the best information, some experience of interpretation and a good knowledge of technique are essential.

High-temperature Polar-phase Gas Chromatography

Polar phases for GC such as the polysiloxanes have a greater selectivity than the nonpolar silicone phases; however, they are also less resistant to high temperatures (>250 °C). This limits their use for lipids of higher molecular weights. TAG have a molecular weight of about 900 and require a temperature of up to 370 °C for efficient chromatography on the nonpolar silicone phases such as OV1, OV101, or SP2100. (*See* **Chromatography**: Gas Chromatography.)

Much excellent work has been published on the application of high-temperature, polar phenylmethyl silicone phases to the analysis of TAG. In this technique, a 25 m × 0.34 mm fused silica column is used, with a bonded phase of 65% phenylmethyl silicone at 0.1 μm film thickness. The separation is in groups of increasing molecular weight, but the groups are further well resolved into both positional isomers and TAG of increasing unsaturation. Quantitation should be expected to be good but is complicated by unequal recoveries due to losses on the column. These losses increase with unsaturation of the TAG and can be severe with highly unsaturated TAG. One has to assume that the phase is responsible since such losses are not seen in the nonpolar phase application. However, reducing the column length to 15 m reduces losses. *Calibration must be used*.

A 15 m × 0.34 mm fused silica column with an 0.1 μm bonded film of 65% phenylmethyl silicone, fitted with a 1 m × 0.53 mm fused silica retention gap is typical for reasonable quantitative analysis. Hydrogen (linear velocity 40 cm s^{-1}) is the preferred carrier gas, although helium (linear velocity 20 cm s^{-1}) will provide good results, but with longer retention times and the possibility of higher losses of the polyunsaturated TAGs. Typically, the initial column temperature is 70 °C with a 2-min hold, then programmed to 320 °C at a 6 °C min^{-1} rise.

Reversed-phase High-performance Liquid Chromatography

This is a nonaqueous type of reversed phase (RP) high-performance liquid chromatography (NARP-HPLC). The resolution achieved is similar to that with the high temperature GC polar-phase technique, but the separation order is much more complex. Because of this, the interpretation of results can be difficult and requires a good table of standardized equivalent chain lengths obtained by analysis of TAG of known structure. The separation achieved is a function of molecular weight, level of unsaturation, and fatty acid position on the TAG. The presence of a double bond is virtually equivalent to a reduction in chain length of two carbon atoms. As an example, triolein (C54) elutes near to tripalmitin (C48). (*See* **Chromatography**: High-performance Liquid Chromatography.)

The separation is achieved using two 25 cm × 4 mm ID Merck Lichrocart Supersphere 100 RP-18 (end capped) columns linked in series. A guard column should always be fitted. The column should be maintained at a constant temperature according to what is being analyzed, but typically 22 °C. Two solvent mixtures are used; A = 10% methanol in acetonitrile and B = 10% tetrahydrofuran in dichloroethane. The start solvent ratio is 52%-A to 48%-B, pumped for 48 min (or an appropriate time to elute all peaks) at 1.0 ml min^{-1}. The system is then reset in between

each sample to a solvent ratio of 95%-A to 5%-B, pumped for 15 min at 1.0 ml min^{-1}. This column equilibration step and time are important for consistent retention times and separations. An HPLC system with an autosampler that will time this period accurately is a great advantage.

RP column packings are not tolerant of high sample loadings and are sensitive to small amounts of other solvents used to dissolve samples. Thus, sample sizes should not exceed 100 µg in 20 µl of solvent. If the sample solvent cannot be that used as the initial mobile phase for HPLC, then its behavior in modifying the column condition must be ascertained. Chloroform should be avoided as it often causes peak splitting, whereas alcohols and hexane create solubility problems. Toluene is a suitable general purpose solvent in this application. Typical chromatography data are shown in Figure 1.

Argentation High-performance Liquid Chromatography

Vegetable fats used for confectionery production, such as for chocolate, require fats with specific physical properties. Such a fat is cocoa butter (CB) and any of the CB equivalents derived by blending of native and fractionated fats of vegetable origin. The specific melting properties and solid/liquid ratios (measured by pulsed nuclear magnetic resonance and plotted as solid fat curves) are created by the presence of a high level (up to 90%) of 'symmetrical' monounsaturated TAG. This TAG has oleic acid (O) at position 2 and a saturated fatty acid, palmitic (P) or stearic (St), at positions 1 and 3, thus producing POP-, POSt-, and StOSt-type TAGs. Perhaps the most rapid method of obtaining quantitative evaluation of such a fat is via argentation HPLC. In this technique, the silver atoms form transient 'complexes' with the π electrons of the unsaturated centers (double bonds). Separation of TAG species depends upon the number of double bonds, their geometry (whether *cis* or *trans*), and the amount of hindrance caused to any 'complex' formation. Thus, monoenes separate from dienes, from trienes, etc. 'Complexes' with *trans* double bonds are less efficient than those with *cis* double bonds and therefore also separate; *trans* being relatively less polar than *cis*. Where there is hindrance to 'complex' formation (due to fatty acid position on the TAG), separation may also occur. For instance, in StOSt, the double bond in oleic is more hindered than in StStO, resulting in StOSt being relatively less polar than StStO causing the two to separate. Figure 2 shows a typical example of the separation of TAG. (*See* **Cocoa**: Production, Products, and Use.)

To achieve the separations in Figure 2, a 20 cm × 4 mm column of LiChrosorb Si-60, 5 µm silica (Merck) coated with 5% silver nitrate, was used. This packing is not available commercially but can be prepared freshly for each column. The silver nitrate, in a foil-covered round flask, is dissolved in acetonitrile and diluted with methanol. The silica is slurried in this and the solvent carefully removed by

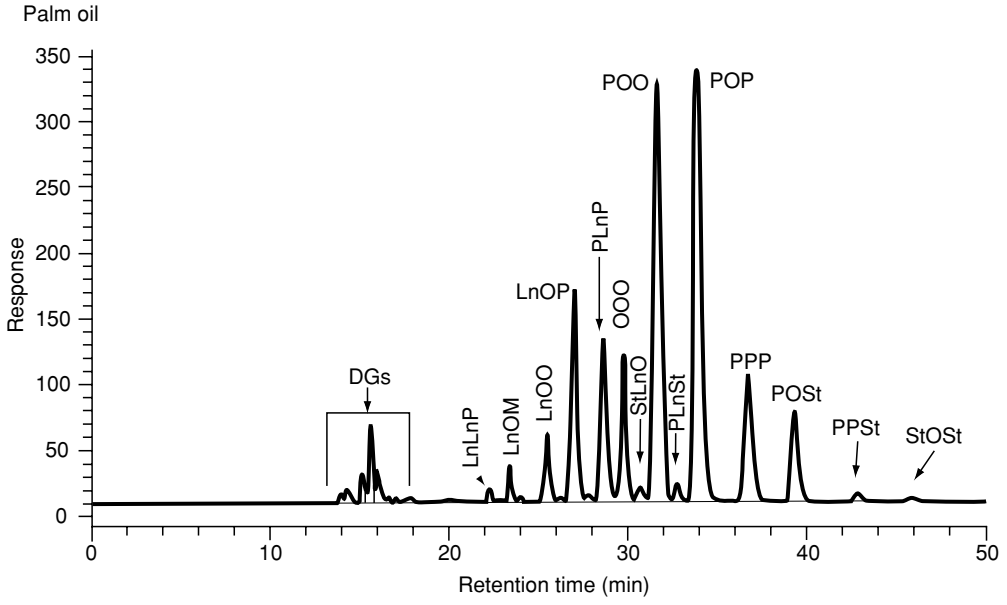

Figure 1 NARP-HPLC of refined, bleached, and deodorized Malaysian palm oil. St, stearic; P, palmitic; O, oleic; Ln, linoleic; M, myristic; DGs, diacylglycerides.

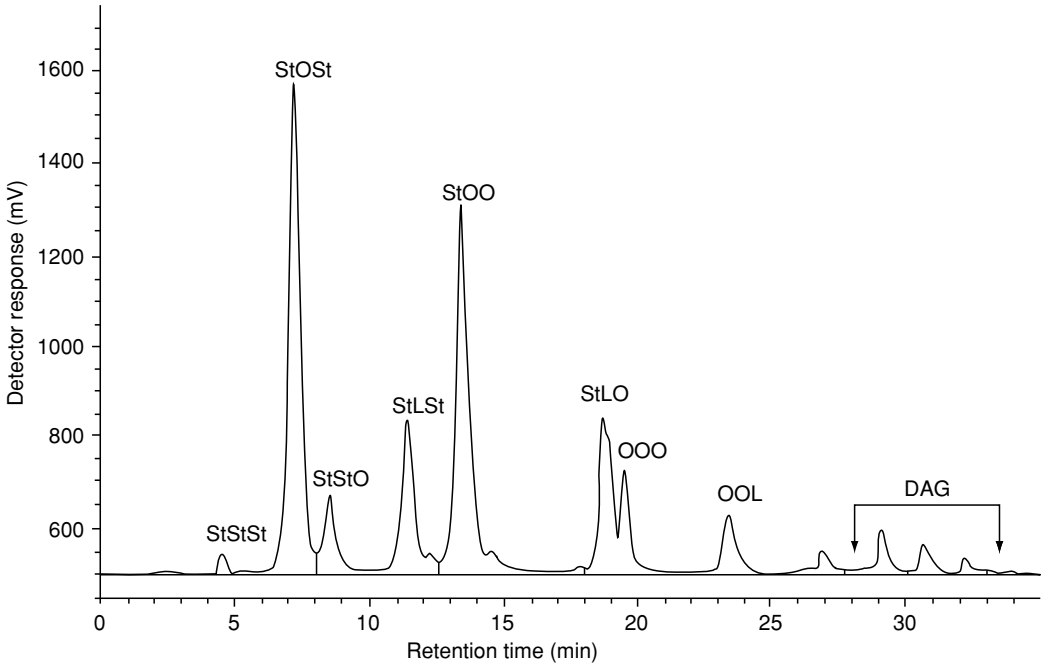

Figure 2 Argentation HPLC of refined palm oil triacylglycerides. The peak labeling corresponds to fatty acids in the order of occurrence on the glyceride: St, saturated (i.e., palmitic, stearic, arachidic); O, oleic; L, linoleic.

rotary evaporation, ensuring constant mixing. When the packing is apparently dry, the last traces of solvent are removed by heating the flask to 70 °C under vacuum for 10 min. This material is slurried in chloroform for column packing and the column packed to 28 MPa (4000 psi) with toluene for 45 min.

The sample size can be up to 600 μg in 30 μl of toluene. The three solvents for HPLC are:

- A = toluene/hexane (1:1, v/v);
- B = toluene/ethyl acetate (3:1, v/v);
- C = toluene with 10 ppm formic acid.

A concave solvent gradient is used from 8%-B to 90%-B in A over 28 min. The regeneration step is very important and uses solvent C for 12 min followed by 8%-B in A for 7 min. Solvent flow is 1.5 ml min^{-1}. Detection of the eluted TAG has to be done by evaporative system detectors such as the Tracor 945 (flame ionization type, not now commercially available), or light-scattering instruments such as the PL-ELS 1000 (Polymer Laboratories). It should be noted that the quantitative behavior of the two instrument types is different. The response curves of the Tracor 945 are essentially linear, while those of light-scattering instruments are curved and sigmoid. Calibration is very important if reliable data are to be obtained, and this should be part of a written procedure. The analysis time is relatively long with a turnaround time of about 40 min per sample, but improvements have been made upon this.

Minor Components

Crude vegetable fats are usually at least 95% TAG. After accounting for any FFA, other minor components can be present, which can include tocopherols, carotenes, gums, waxes, polar lipids (lecithins), unsaponifiable matter, chlorophyl pigments, hydrocarbons, and mineral constituents (present possibly as metal soaps of fatty acids). Refer to individual constituents.

There are standard methods published by the American Oil Chemists' Society (AOCS) and the Association of Official Analytical Chemists (AOAC) for the analysis of the above components. The procedures are fully documented and tested and may be updated at suitable periods, so they will not be reproduced here. However, it is worth mentioning that some of the older published methods have escaped improvement, and more up-to-date procedures can often be found.

For instance, tocopherols have traditionally been estimated as a group, after isolation from the nonsaponifiable fraction of an oil, by reaction with α,α-dipyridyl and colorimetric analysis. However, it is known that the tocopherol composition can aid the identification of a fat and also that different tocopherol compositions lead to different stabilities of a fat to oxidation. Accurate analysis of individual tocopherol compositions can be readily done by HPLC. Essentially, the extracted and dry

fat is dissolved in the mobile phase solvent. A 15 cm × 4 mm column packed with 5-μm Chromegasphere silica (E.S. Industries, Marlton, NJ) is used with a fluorescence detector (e.g., Kontron SFM25 with a flow cell). Excitation is set at 294 nm and emission at 325 nm. The HPLC system is isocratic using a solvent of 3% THF in 2,2,4-trimethyl pentane (iso-octane) as the mobile phase at a flow of 1.5 ml min^{-1}. The sample is applied via a 25-μl loop and Rheodyne valve. Complete separation of tocopherols and tocotrienols is achieved (Figure 3). The column requires flushing with 10% methanol in chloroform every 200 samples to remove any build-up of polar lipid material. Figure 3 shows a typical chromatogram from the analysis of palm oil.

Authentication of Oils

The purity of composition of a natural vegetable oil may be extremely important to the ultimate user. Fats or oils can be among the most expensive ingredients used in the manufacture of foods. Thus, there are situations where, for reasons of unfortunate cross-contamination or adulteration for profit, it becomes important to know the authentic composition of a natural oil. (*See* **Adulteration of Foods**: History and Occurrence.)

The chemical composition of natural vegetable oils is readily obtained by chromatographic analysis. Information on structure can also be obtained by specific enzyme techniques, and minor components can be analyzed either by chemical techniques or again by

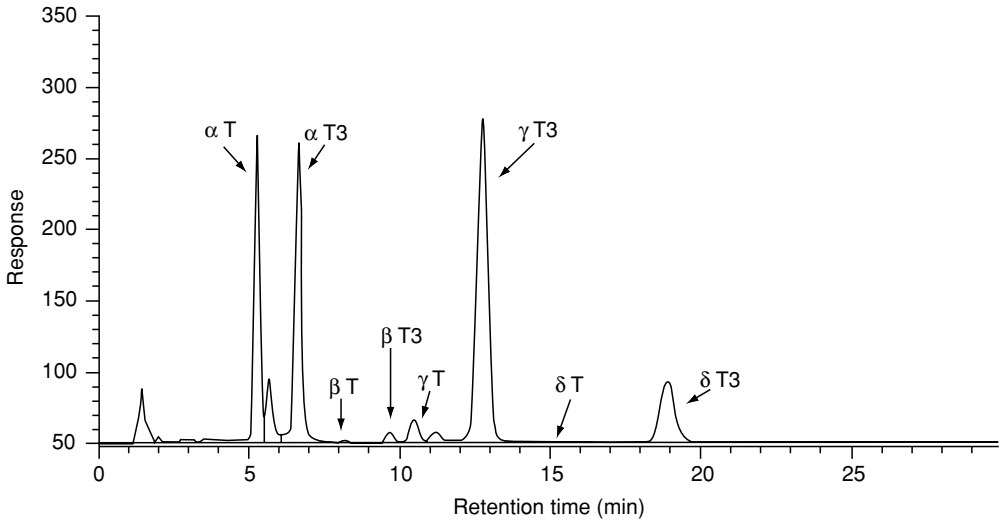

Figure 3 HPLC analysis of palm oil tocotrienols and tocopherols (conditions are described in the text).

[a]Genetically Modified Crop (trade name of Calgene).

chromatography. All this information characterizes the sample being analyzed, but does not necessarily apply exactly to another oil of the same species from a different part of the world. Also, it is important that data be obtained via more than one technique, since actual differences in oil composition may only become apparent with certain techniques.

Within a single species of plant, for instance rapeseed, there can be a number of varieties. It is almost certain that the oil composition of the varieties will be different. This statement is even more important now that genetic modification of oil composition is being done. Also, if one variety is grown in different environments, created either by countries or even by areas of a single country, these situations can lead to oils of variable composition. The differences may be small or large, but they will provide statistical range bands (with statistical means) within which any particular oil composition might lie. This shows that to authenticate a particular oil unambiguously, there must be sufficient world data on the composition as measured by a number of techniques. Table 1 shows typical analytical data that we have found for a range of rapeseed crops. Further data about many vegetable oils are published in *The Lipid Handbook*.

Dietary Importance

J Dupont, United States Department of Agriculture, Beltsville, MD, USA

Background

Vegetable oils are derived from oil seeds grown mainly for their oil. The major food oils consumed as cooking and salad oils are canola (rapeseed), corn, cottonseed, olive, palm, palm kernel, coconut, peanut, safflower, soya bean and sunflower. They are all triacylglycerols that are liquid at room temperature, but differ greatly in fatty acid composition (**Table 1**). They are classified as short-chain ($C_{6–8}$), medium-chain ($C_{10–12}$), and long-chain ($C_{14–18}$). The plant oils may be saturated (completely hydrogenated) or have one, two, or three double bonds of the *cis* configuration. (*See* **Fatty Acids:** Properties.)

Energy Value

Long-chain acylglycerols provide $38\,kJ\,g^{-1}$, whereas protein and carbohydrate provide $17\,kJ\,g^{-1}$. Because of the difference in energy value of oils as compared with the other energy-yielding nutrients, concentration in the diet is often expressed as a percentage of energy (en%). Vegetable oils are highly digestible (greater than 95%). They are hydrolyzed in the gastrointestinal tract, yielding free fatty acids (FFAs) and *sn*2-monoacylglycerols. By formation of bile micelles, the FFAs and monoacylglycerols come into contact with the mucosal cell membranes and diffuse through the membrane. Within the mucosal cells, they are reesterified to triacylglycerols. They are made water-soluble by incorporation into chylomicrons in the mucosa.

Medium-chain fatty acids occur in triacylglycerols (medium-chain triacylglycerols; MCT) of coconut and palm kernel oils. The MCTs are much more water-soluble than are long-chain triacylglycerols. They are hydrolyzed and enter the mucosal cells but are partially transported as FFAs in the portal circulation.

Chylomicrons and albumin-bound fatty acids are transported to the liver, adipose tissue, and other organs. In the process, chylomicrons are hydrolyzed

by the action of lipoprotein lipase, and the fatty acids enter the cells by diffusion and are reesterified to triacylglycerols. During fasting, the triacylglycerol fatty acids are released from adipose tissue by hydrolysis for use as energy. Fatty acids that enter the liver are resecreted as very-low-density lipoproteins, which are hydrolyzed similarly to chylomicrons, yielding low-density lipoproteins (LDLs), which are taken up by tissues via a receptor-mediated process. The LDLs are hydrolyzed to yield fatty acids for energy or reesterification and storage. (*See* **Lipoproteins**.)

Fatty acids are used for energy production in the mitochondria and peroxisomes of cells. Saturated fatty acids (SFAs) are oxidized by β oxidation to yield acetyl coenzyme A (acetyl CoA), which enters the tricarboxylic acid cycle. Unsaturated fatty acids require two more enzymatic steps that are needed for SFAs to change the existing double bonds from *cis* to *trans* and to move them from a γ to a β position. Even so, oxidation of C18:2 *n*-6 is more rapid than that of C18:1 *n*-9. Medium-chain triacylglycerol acids are preferentially oxidized by peroxisomes rather than mitochondria. Some of the acetyl CoA produced is oxidized to hydrogen peroxide, which requires catalase for dismutation to water and oxygen, yielding heat. This reduces the yield of these fatty acids to less than the 37.66 kJ g^{-1} assumed for fats in general. (*See* **Fatty Acids**: Metabolism; Dietary Importance.)

Table 2 Relationship between dietary linoleic acid and biological effects

Dietary concentration of linoleic acid (en%)		*Reported biological effects*
0		Rat: dermatitis, growth retardation, infertility, cellular and humoral immune system defects
		Human: dermatitis
1	Deficient	Rat: increase in triene: tetraene ratio to 0.4, decrease in eicosanoid production
		Mouse: immune system impaired, plaque formation
		Human: increase in triene: tetraene ratio to 0.4, decrease in clotting time
2–3		Rat: maximal amount of C20:4 *n*-6 in cellular lipids, increased eicosanoid production
		Mouse: normal plaque formation
	Saturation	Human: increased plasma cholesterol, decrease in triene: tetraene ratio to 0.1
4		Rat, guinea-pig, mouse: normal mitogenic response
5		DMBA rat: mammary cancer
8		Human: decreased plasma cholesterol
10		Rodents: delayed hypersensitivity normalized
		NMU rat: mammary neoplasia
	Excess	Guinea-pig: decreased mitogenic response
15		Rat: prostatic neoplasia, rat colon cancer

Essential Fatty Acids

Vegetable oils generally have a relatively high concentration of polyunsaturated fatty acids (PUFAs) (Table 1). Exceptions are coconut, palm, and palm kernel oils, which are primarily saturated, and olive and canola oils, which have relatively less PUFAs and more monounsaturated fatty acids. The most abundant PUFA is linoleic acid (C18:2 *n*-6), with canola and soya oils having appreciable concentrations of α-linolenic acid (C18:3 *n*-3). Because these fatty

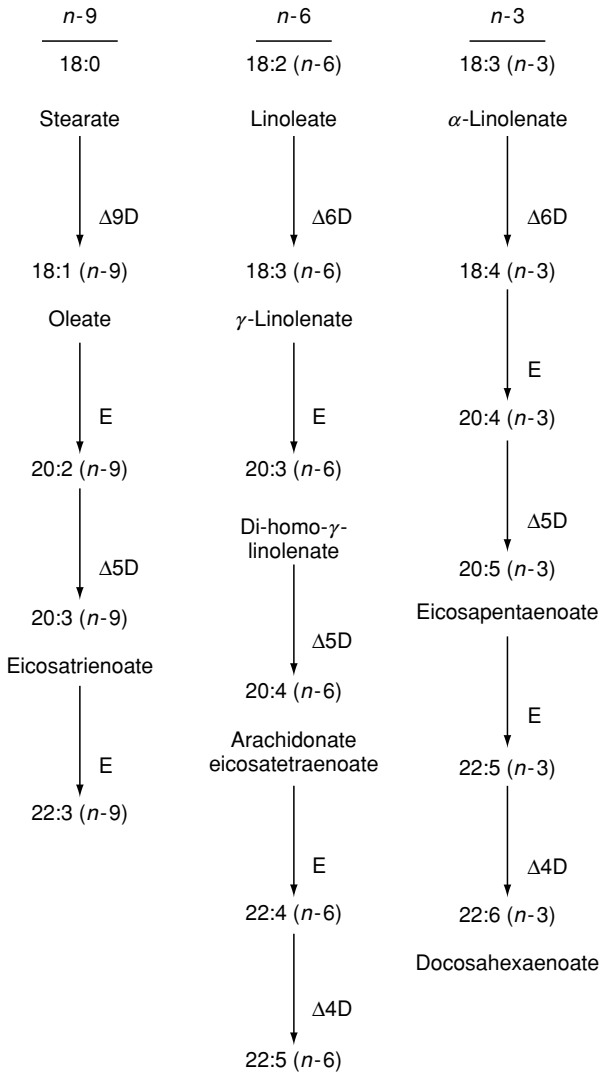

Figure 1 Families of fatty acids formed from C_{18} precursors by desaturation (D) and elongation (E). The *n*-9 pathway is exhibited in mammals only when there is insufficient *n*-6 present in the diet. Reproduced from Vegetable Oils: Dietary Importance, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

acids (1) cannot be synthesized by animal cells and (2) have essential metabolic functions, they are deemed dietary essential fatty acids. Table 2 summarizes current knowledge of the effects of different dietary levels of linoleic acid. (*See* **Essential Fatty Acids.**)

Linoleic acid is a component of ceramides, which are necessary to maintain the transdermal water barrier of the epidermis. It is the precursor by elongation and desaturation (Figure 1) of arachidonic acid (C20:4 *n*-6). Arachidonate is the precursor of the eicosanoids: prostaglandins, thromboxanes, prostacyclin, and leukotrienes (Figure 2). The eicosanoids are autocrine and paracrine factors, which are physiologically active at concentrations of pico- and nanograms. They are required for functions of the cardiovascular, renal, gastrointestinal, immune, and reproductive systems. (*See* **Prostaglandins and Leukotrienes.**)

Many studies indicate that essential fatty acids are necessary for normal immune function. Essential fatty acid deficiency impairs B- and T-cell-mediated responses. These impairments are normalized by inclusion of essential fatty acids in the diet. Most studies have used rodents, and the results cannot be readily extrapolated to humans because the immune systems of different species respond differently to dietary fat alterations. (*See* **Immunology of Food.**)

α-Linolenic is the precursor for eicosapentaenoic acid (C20:5 *n*-3) and docosahexaenoic acid (C22:6 *n*-3) that are required for brain and retinal development and function in animals.

Vitamin E

The vegetable oils that contain high concentrations of PUFA generally contain appreciable quantities of α- and γ-tocopherols (vitamin E) (Table 3). Vitamin E is a membrane-bound, lipophilic antioxidant closely associated with arachidonic acid in the membrane. Vitamin E may protect membranes by trapping lipid peroxyl free radicals produced from PUFA under conditions of oxidative stress. (*See* **Tocopherols:** Physiology.)

Table 3 Vitamin E content of fats and oils (mg per 100 g)[a]

Oil or fat	*α-Tocopherol*	*γ-Tocopherol*	*Total*[b]
Butter	1.76 ± 0.41	0	1.76

Cardiovascular Effects

Saturated fatty acid in the diet raises plasma cholesterol, and PUFA lowers it. Many published studies indicate that lowering plasma cholesterol decreases the population risk of heart disease. Levels of LDL-cholesterol are lowered by reducing SFA intake; the effect of concomitantly increasing PUFA is greater than that of merely reducing the SFA. Vegetable oils that increase the percentage of PUFA in the diet contribute to reducing plasma cholesterol. Enrichment of the diet with PUFA reduces blood pressure and has favorably influenced the progression of diabetic angiopathy in adult-onset diabetes mellitus. (*See* **Cholesterol:** Role of Cholesterol in Heart Disease; **Coronary Heart Disease:** Antioxidant Status.)

Oncogenic Aspects

Human surveys and animal experimentation support a role for total fat (excess energy) intake in the development of cancer, particularly in mammary tissue. The impact of linoleic acid intake on mammary and pancreatic tumorigenesis is not documented in human studies, nor is its impact on colon carcinogenesis as in animal studies. A hypothesis arising from human studies is that it is displacement of protective foods such as fruits, vegetables, pulses, and cereals from the diet by fat-rich foods that is detrimental, rather than any direct effects of fat in the diet. (*See* **Cancer:** Diet in Cancer Prevention; **Colon:** Cancer of the Colon; **Margarine:** Dietary Importance.)

VEGETABLES OF TEMPERATE CLIMATES

Contents

Commercial and Dietary Importance

S K Roy and A K Chakrabarti, Indian Agricultural Research Institute, New Delhi, India

Introduction

Vegetables are considered as protective foods supplying carbohydrate, protein, minerals, vitamins, and crude fiber, which are essential ingredients of a balanced diet. In addition to their role in nutrition, they increase the attractiveness and palatability of a diet by providing sensory appeal through their variety of color and flavor.

General Nutrient Composition

Vegetables in general, except for a few, are not considered to be the primary source of carbohydrate, protein, and fat. However, some of them with storage roots and tubers are rich in carbohydrate, particularly starch, in amounts comparable to the cereal crops, and the leguminous vegetables supply as much as 14% protein, while dry seeds supply still more. The lipid content in most vegetables is less than 0.1%. Most leafy vegetables and root crops are rich in minerals. Carrot and leafy vegetables are also high in carotene (provitamin A) and vitamin C. Deep-green leafy vegetables are rich in folate (folic acid). Besides, there are some trace elements required by the body like copper, manganese, and zinc, which act as enzyme cofactor. These are found in appreciable quantities in cole crops, roots crops, and some leafy vegeables. (*See* **Carotenoids:** Physiology.)

The nutrient content of a vegetable is dependent on several factors. The environment in which the crop is grown, such as temperature, light, moisture, nutrients, and physical and chemical properties of the soil, plays an important role. The amount of nutrient can vary with variety, cultural practices, stage of maturity, postharvest handling, and storage conditions. Once the vegetable is harvested, its composition goes on changing as a result of physiological and biochemical activities, which are natural processes.

In addition, methods of cooking also influence the nutrient content of vegetables; in particular, leaching losses and oxidative changes are considered as deteriorative processes. The composition of the same vegetable grown in different parts of the world is so different that it becomes difficult to use a general table of composition as a source of precise information of nutritive value of the crop used in the diet. However, such a table gives an estimate of the proximate composition of the nutrients. The nutrient composition of individual vegetables is given in **Tables 1** and **2**, and trace elements in **Table 3**. Refer to individual nutrients.

Table 1 Macronutrient composition of temperate vegetables per 100 g edible portion

Dietary and Commercial Importance

Apart from major nutrients, vitamins, and minerals, there are some phytochemicals present in vegetables which have been indicated by rapidly growing scientific evidence to play a major role in promoting health and in preventing certain diseases. These chemicals have often been referred to as phytonutrients or phytoceuticals. Besides, there are some key micronutrients, flavor compounds, and toxic substances found in vegetables which deserve attention.

Phytoceuticals

Phytoceuticals can be grouped on the basis of their therapeutical activities or their physical and chemical constitution. Some of these groups are bioflavonoids, phenols, phytosterols, thiols, indoles, glucosinolates, and organosulfur compounds.

Bioflavonoids are one of the largest groups of secondary plant metabolites found in several vegetables. They have been reported to increase the effectiveness of vitamin C and are recognized as potent antioxidants. Together with vitamin C they strengthen the capillaries and protect the body from free radicals. They are also antiviral and antiinflammatory. Some of the important bioflavonoids identified from vegetables are quercetin, kaempferol, myricetin, and luteolin. There are reports which suggest that quercetin (found in onion) can inhibit the growth of several types of cancer cells, including breast cancer, ovarian cancer, and leukemia.

The higher content of phenols has been linked to disease resistance in plants. Phenols have also been found to protect our body from oxidative damage caused by free radicals. Some tropical root vegetables like yam, elephant-foot yam, and other vegetables like green banana and eggplant are rich in phenols.

Phytosterols occur in most plants, especially in the seeds of green and yellow vegetables. Phytosterols prevent the absorption of cholesterol and facilitate its excretion from the body. There are some reports which suggest that phytosterols prevent the development of tumors in breast, colon, and prostate glands.

Thiols are important sulfur compounds found in brassicaceous vegetables like broccoli, cabbage, cauliflower, and kale, and in garlic. There is strong evidence to suggest that these compounds can prevent cancers of colon, rectum, and breast. Indoles found in Brassicas bind chemical carcinogens and activate detoxification enzymes, mostly in the gastrointestinal tract.

Glucosinolates, which are secondary plant metabolites, found mostly in cole crops and other Brassicas, are powerful activators of enzymes in the liver which detoxify carcinogens.

There are several organosulfur compounds found in onion and garlic which appear to possess antimicrobial properties and offer protection against cardiovascular diseases.

Key Micronutrients

Vegetables are the major source of vitamins and minerals essential for our body. They are the most important source of vitamin A; deficiency of vitamin A in the diet causes blindness. Vitamin A is essential for growth, bone development, vision, reproduction, and functioning of the immune system. Vitamin A is synthesized in our body from carotene which is present in abundance in green leafy vegetables, carrot, pumpkin, squash, melon, and tomato. Of about 600 carotenoids identified from natural sources, less than

10% are precursors of vitamin A. In human beings, β-carotene, α-carotene, and cryptoxanthin are converted to vitamin A, whereas lycopene (present in tomato) and lutein are not. Most important is β-carotene. Some of the carotenoids are powerful antioxidants and have been shown to offer protection against breast, lung, uterine, prostate, and colon cancers.

Vitamin C (ascorbic acid) is essential for wound healing, immune response, and allergic reaction. It is a powerful antioxidant and is found in many vegetables like broccoli, cauliflower, Brussels sprout, tomato, pepper, and potato. It protects our body by scavenging free radicals.

Vitamin E is also an antioxidant which prevents peroxidation of polyunsaturated fatty acids in our body. Increased intake of vitamin E is believed to reduce the incidence of heart attack. The combined action of vitamin E, C, and A has been reported to

delay the onset of cataract. Several vegetables, like broccoli, spinach, parsnip, and watercress, are good sources of vitamin E.

Folic acid, commonly referred to as folate, is an essential vitamin which is especially crucial in fetal development in the early weeks of pregnancy. It is essential for DNA synthesis and its action is interrelated with that of vitamin B_{12}. The Food and Agriculture Organization/World Health Organization (FAO/WHO) expert group has recommended a daily dietary intake of 200 μg of free folate for adults, 400 μg during pregnancy, and 300 μg during lactation. Recent studies have associated folate with a reduced risk of cardiovascular diseases. Deep-green leafy vegetables like spinach, kale, Swiss chard, and parsley, and some beans are rich in folate. Light-green leaves are generally not rich in this vitamin.

Flavor compounds

The flavor compounds contribute to the overall sensory quality of the vegetables. They are a complex mixture of a large number of volatile compounds. Vegetables contain some volatile flavor compounds in the intact tissues and some are produced enzymatically after the tissue is damaged or crushed. These compounds undergo further changes after heating. Flavor compounds of vegetables include (1) nonvolatiles like sugars, amino acids, fatty acids, and organic acids and (2) volatiles like aromatic hydrocarbons, aldehydes, acetals, ketones, alcohols, esters, and sulfur compounds. When used as side-dishes with cereal staple foods, these flavor compounds make the cereal more palatable.

Dietary Fiber

Leafy, root, and a few other vegetables provide dietary fiber, essential for bowel movement and possibly for the prevention of several diseases such as appendicitis, colon cancer, diabetes, diverticulosis, gallstones, and obesity. Dietary fiber consists mainly of cellulose, hemicellulose, pectin, lignin, and mucilage of plants.

Toxic Substances

Some vegetables contain harmful chemical compounds such as trypsin inhibitors in bean seeds, phytate in beans, and oxalate in amaranth and rhubarb, which pose serious nutritional problems. In addition, chemicals such as glucosides induce toxicity by producing hydrogen cyanide (HCN). Other toxicants are nitrates in leafy vegetables, some alkaloids in cucurbits, potato, and asparagus, and glucosinolates in Brassicas. These, when taken in higher amounts, may cause harm.

A balanced diet should contain the amount of essential nutrients needed to supply energy and prevent nutritional deficiencies. Vegetables contain combinations of nutrients and other protective substances. Dietitians recommend an adult daily uptake of 75–125 g of green leafy vegetables, 60–80 g of other vegetables, and 75–100 g of roots and tubers for a balanced diet. (*See* **Dietary Fiber**: Physiological Effects; **Flavor (Flavour) Compounds**: Structures and Characteristics; **Trypsin Inhibitors**.)

With the growing consciousness of health and with the recognition that a diet primarily of animal origin is hazardous to health, the consumption of vegetables has increased considerably, and vegetables have become an important item of commerce. Vegetable growers are able to obtain a better economic return, and this is a great incentive for cultivation of this commodity. Vegetables are items of daily consumption and large quantities are marketed every day; the market in vegetables can, therefore, never stagnate. Increased demand for fresh temperate vegetables in the more affluent countries during winter months has created an opportunity for the tropical and subtropical countries to improve their economy by increasing exports.

Many agro-based industries use vegetables as their raw material. Tomatoes and potatoes are two vegetables which are processed into a wide range of products. Frozen vegetables are also of great commercial importance as they retain most of the qualities of fresh vegetables. In addition, vegetables are utilized by many food-processing units for the production of various vegetable sauces, fermented, and pickled vegetables. (*See* **Freezing**: Structural and Flavor (Flavour) Changes; **Tomatoes**.)

The importance of individual vegetables in commerce, and in different diets with special reference to nutrition, is discussed under the Importance of Specific Temperate Vegetables below.

International Trade

Among all the temperate vegetables discussed in this article, potato occupies the topmost position in world trade. According to an FAO estimate, the total world export of potato in 1997 was 6.87 million tonnes and the European countries ranked first, exporting 5.29 million tonnes. The next important crop in international trade is onion. Out of a total world export of 3.23 million tonnes during 1997, the highest quantity was exported by the European countries with a share of 34.84%, followed by Asian countries with 27.83% share. Besides world trade in the fresh form of potato, both these commodities are exported in various processed products prepared from them.

Potato chips and dehydrated onion occupy a prominent position among them. In tropical countries of Asia, mostly short day varieties of onions are grown. These varieties are more pungent and have higher total soluble solids than the long day types grown in temperate countries. Because of high total soluble solid and pungency, they store well under high temperature conditions with less storage rot and can stand long-distance shipping without refrigeration. Because of these qualities, the demand for these types is very high in world trade, particularly in tropical countries.

Cole crops and root vegetables are much in demand in temperate countries during winter. In tropical and subtropical countries these are grown in the open during winter and thus the cost of production is less compared with those grown under protective cover. Many of these vegetables are exported from Latin American and Asian countries to meet the demand of the European and North American markets. Recently, the demand for minimally processed vegetables has increased considerably in the developed countries, mainly because of convenience. There is a great potential for exporting minimally processed temperate vegetables grown in tropical and subtropical countries during the winter season.

Importance of Specific Temperate Vegetables

Bulb Crops

Bulb crops, such as onion (*Allium cepa*), garlic (*A. sativum*), and leek (*A. porrum*), are cultivated in both the temperate and tropical regions. Leek is particularly adapted to cold weather. (*See* **Onions and Related Crops**.)

Onions are high in energy and rich in calcium and riboflavin (vitamin B_2). The bulbs do not contain starch and most of the carbohydrates are sucrose, glucose, fructose, and fructosan (polymer of fructose). Green onion tops have a high carotene (provitamin A) content. Onions are an indispensable item in every kitchen as a condiment and as a vegetable. Green leaves and immature and mature bulbs are eaten raw in salads or used as flavoring agents in vegetable dishes. Multiplier onion bulbs (shallot) are pickled in vinegar or brine. Dehydrated bulbs and onion powder are in great demand in world trade. The distinctive odor (pungency) of onion is due to a volatile sulfur compound, allyl propyl disulfide. Compounds responsible for alliaceous odors (and flavors, at least in part) are only formed after the onion has been cut or injured. Treatments such as heating or freeze-drying which destroy or suppress enzyme activity, reduce the formation of odor. (*See* **Freeze-drying**: Structural and Flavor (Flavour) Changes; **Sensory Evaluation**: Aroma.)

Garlic is consumed more in Asia, South America, North Africa, and southern Europe. Garlic cloves (bulbs) are rich in protein, carbohydrate, and some minerals. They are used primarily as a flavoring agent in a variety of dishes and vegetable soups, meat, sausage, spaghetti, and vegetable curries. They are used for the preparation of garlic bread and garlic butter. The pungency of garlic is due to a volatile sulfur compound, diallyl disulfide, which is produced by the action of allinase enzyme on the amino acid, alliin, present in the garlic.

The leek is an important ingredient in European dishes and its use in North America is increasing. Leek stalks are used as a base for soups, and they are steamed, boiled, or eaten raw in salads. After boiling or crushing, most of the pungent flavors disappear and this treatment gives a mild flavor to the product.

Onion and garlic have a traditional place in folk medicine in many countries. It has been shown that half a medium-sized raw onion a day can trigger shifts in the ratio of 'good' to 'bad' cholesterol, replacing a significant amount of destructive low-density lipoprotein (LDL) cholesterol with heart-protective high-density lipoprotein (HDL). The HDL boost is greatest from raw white and yellow onions and is reduced with cooking. Onion and garlic are rich sources of quercetin, a bioflavonoid with potent anticarcinogenic activity. They are also known to reduce blood sugar. An antihypoglycemic agent, diphenylamine, has been identified in onion recently. The allicin which is produced in garlic when the tissues are injured by cutting or crushing has been reported to have hypocholesterolemic action. It reduces blood stickiness, thus preventing coronary thrombosis, heart attacks, and strokes. It has been indicated that garlic constitutents like allicin, allistalin, garlicin, diallyl disulfide, diallyl trisulfide, and essential oils are active against certain bacteria and other microorganisms. (*See* **Lipoproteins**.)

Cole crops

Cole crops are one of the largest groups of temperate vegetables, comprising important crops like cauliflower (*Brassica oleracea* var. *botrytis*), cabbage (*B. oleracea* var. *capitata*), sprouting broccoli or broccoli (*B. oleracea* var. *italica*), Brussels sprout (*B. oleracea* var. *gemmifera*), kale (*B. oleracea* var. *acephala*), and knol khol (*B. oleracea* var. *gongylodes*). Cole crops are rich in vitamin C and they are good sources of minerals. Broccoli and kale are rich in

carotene (provitamin A). Several volatile sulfur compounds are responsible for the characteristic flavor of the cole crops. Dimethyl trisulfide has been indicated as the major aroma component in cooked Brassicaceous vegetables. These vegetables contain compounds known as indoles and dithiolthiones which have been linked with the prevention of cancers of the colon, rectum, and breast. (*See* **Cancer**: Diet in Cancer Prevention; **Colon**: Cancer of the Colon.)

Cabbage and broccoli are used raw in salads. Cabbage is used steamed or boiled alone, or in a mixture of other vegetables as main dishes with meat or in casseroles. Sauerkraut is the main processed product from cabbage. Some cabbage is dried after blanching and also pickled. Cauliflower is cooked or steamed. It is used in a mixture with other vegetables for the preparation of curry and fried rice in the Orient. It is also pickled along with other vegetables. Broccoli, Brussels sprout, and cauliflower are frozen. Broccoli is steamed and used in the preparation of many casserole dishes. It may be chopped or prepared whole or as florets. Its versatility of use has made it a staple item in the American diet. Knol khol is a popular vegetable of Germany. It is used raw or uncooked, and the tender leaves are used as greens. Cooked knol khol is scooped out, stuffed with onion and sausage, and then baked.

Leafy vegetables

Spinach (*Spinacea oleracea*), Swiss chard (*Beta vulgaris* var. *cicla*), spinach beet (*B. vulgaris* var. *bengalensis*), and kale (*Brassica oleracea* var. *acephala*) are the major leaf vegetables. The first three crops belong to the family Chenopodiaceae and the last one to Cruciferae (Brassicaceae). Of these, spinach beet is primarily grown in the tropics, usually during winter. Spinach, Swiss chard, and spinach beet leaves are rich sources of carotene and some minerals. Kale is one of the most nutritious vegetables. It is rich in carotene and vitamin C. Besides, there are some vegetables like knol khol, lettuce, spinach, and turnip, the leaves of which contain a good amount of protein. The essential amino acid composition of these leaves is given in Table 4.

Spinach and Swiss chard leaves and tender petioles are cooked, steamed, or boiled for the preparation of dishes like pastries, soufflés, and soups. The stems of chard are cooked and used like celery. Sometimes spinach and chard are cooked combined to give a blend of their pleasant flavors. Some quantity of spinach is frozen and canned. Spinach beet is a popular leaf vegetable of the Indian subcontinent. Leaves and petioles are cooked for preparing stews. Kale is steamed and served with butter or vinegar, or in soups.

Pea and Broad Bean

Pea (*Pisum sativum*) and broad bean (*Vicia faba*) are leguminous vegetables which are characteristically rich in protein. Peas are high in thiamin (vitamin B_1), niacin, and phosphorus. Broad beans are rich in vitamin C. The pea is one of the major vegetables of the temperate and subtropical world. It is cooked with other vegetables or used in soups. It is also used in salads. In India, it is cooked with milk casein to prepare a delicious dish. A large portion of the pea crop is canned, frozen, or dehydrated. The broad bean is cooked with other vegetables or processed like peas. (*See* **Legumes**: Legumes in the Diet; **Peas and Lentils**.)

The essential amino acid composition of pea and broad bean has been given in Table 5. Both of them are deficient in the amino acid tryptophan. Studies have shown that food legumes reduce blood cholesterol concentration and increase bowel movement. Phytic acid (inositol hexaphosphoric acid), which is present in mature seeds of peas and beans, can

Table 4 Essential amino acids content (g) of vegetable leaves per 100 g protein

Amino acids	*Knol khol*	*Lettuce*	*Spinach*	*Turnip*

combine with calcium and iron from other foods in the diet and render them unavailable. (*See* **Phytic Acid**: Nutritional Impact.)

Perennial Vegetables

Major perennial vegetables are asparagus (*Asparagus officinalis*), artichoke (*Cynara scolymus*), and cardoon (*C. cardunculus*). Asparagus greens are rich in carotene, thiamin, riboflavin, and niacin. Various plant parts of asparagus, such as new shoots or spears, petioles, flower buds, tubers, and roots, are used for the preparation of different dishes. Asparagus is prized for its spears. Fresh asparagus is usually steamed or boiled. It is also frozen and canned. It is especially rich in vitamin E and 60 g of it can provide our daily requirement. It contains an amino acid asparagine which has calming properties. It is diuretic and helps in the elimination of water through urination. It is also helpful in cleaning cholesterol from arteries. However, in excessive amounts, it can irritate the kidneys.

In artichoke and cardoon, the edible portion consists of fleshy bracts, receptacle, and petals. Fleshy petioles of the cardoon are sometimes blanched to make them more succulent. The fresh bud is usually cooked whole and served hot or cold with melted butter, salad dressing, or sauce. The canned or frozen small buds or 'hearts' are popular as an hors d'oeuvre. Artichoke stimulates bile evacuation and acts as a diuretic.

Potato

The potato (*Solanum tuberosum*) ranks first among all the vegetables in terms of area and production in many countries. It occupies a prominent position in the diet as a staple food, as well as a vegetable for the preparation of side-dishes. Potatoes are boiled, baked, mashed, roasted, and fried (French fry). The potato goes well in combination with most vegetables. It is also one of the major vegetables which is processed as chips, dehydrated, and granulated. (*See* **Potatoes and Related Crops**: Processing Potato Tubers.)

Potatoes are rich in starch, minerals, and vitamin C. They are easily digested and assimilated, and thus are considered as a good food for the sick and invalids. Though the tubers contain only about 2% protein on a fresh-weight basis, the content on a dry-weight basis comes to about 10%, which is comparable to wheat flour. This makes the potato an important source of dietary protein in countries where consumption is high.

Potato tubers when exposed to light produce an alkaloid, solanin, which is bitter in taste and has toxic effects when consumed in large amounts. (*See* **Alkaloids**: Toxicology.)

Root crops

Though carrot (*Daucus carota*), radish (*Raphanus sativus*), turnip (*Brassica rapa*), garden beet (*Beta vulgaris*), parsnip (*Pastinaca sativa*), and rutabaga (*Brassica napus* var. *napobrassica*) are major root crops of the temperate region, there are distinct tropical types of the first three crops which are grown extensively in tropical Asia. Of all the vegetables, carrots, particularly yellow and orange flesh cultivars, are the richest source of carotene (provitamin A) which helps prevent night blindness and cancer. The cortical region contains more carotene than the core. Dark red cultivars, mostly of tropical types, contain more anthocyanin pigment and contribute less provitamin A to the diet. Turnip and rutabaga are rich in vitamin C. Turnip and radish greens are rich in provitamin A. Radish is astringent and diuretic and is used to promote bile flow. Garden beet is not nutritionally rich. However, it has a number of useful medicinal properties such as purification of blood, improving circulation, and bowel stimulation. Its red color is due to the pigment betacyanin, the chemical properties of which resemble anthocyanin. It also contains a yellow pigment, betaxanthin. Parsnip is rich in starch. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Carrots are primarily consumed in salads and are used in soups, curries, stews, and pies. They are used in the preparation of a popular sweetmeat in the Indian subcontinent. They are frozen or pickled. It has been indicated that there is an inverse relationship between a diet which is rich in carotene and cancer of the lung. Turnip roots are steamed or cooked and the tender leaves, apart from use in salads, are also cooked. In western countries, the radish is primarily used as a salad crop. In the Orient, it is cooked and also pickled. The rutabaga is used almost in the same way as turnip. It is used in salads, soups, and in baked products on account of its pleasant flavor. Parsnip, belonging to the carrot family, gives a pleasant flavor when steamed or cooked, and it is used in the preparation of various dishes. In beet, both roots and tops are steamed or boiled, and a considerable quantity of beetroot is canned, frozen or pickled. Beet juice is used for the coloring of many food products.

Salad crops

Salad crops comprise lettuce (*Lactuca sativa*), celery (*Apium graveolens*), chicory (*Cichorium intybus*), endive (*C. endivia*), and parsley (*Carum petroselinum*). The lettuce is the major salad vegetable in most of the countries of North America, South

America, Europe, Australia, and New Zealand. Its production is increasing in the Middle East, Africa, and Japan. It is rich in provitamin A and minerals. Leaf lettuce is more nutritious than the head types. Celtuce (*L. sativa* var. *augustana*) is very popular in China and Taiwan. Its succulent thick stems and tender leaves are used raw or cooked. Celery is primarily used as a salad crop, and is also used for the preparation of soups, stews, and sauces. Its seeds are used as a spice. It contains a compound, 3-*n*-butyl phthalide, which lowers blood pressure. Chicory (witloof, chicon) and endive are used in salads in Europe. The blanched cluster of leaves (head) has a delicate flavor as compared to the strong flavor of the green, unblanched head. It is considered as a delicacy in France, The Netherlands, and Belgium. The roots of chicory are dried, roasted, and blended with coffee to give it a strong flavor. Parsley leaves are mainly used for garnishing and flavoring. (*See* **Salad Crops**: Dietary Importance; Leaf-types; Root, Bulb, and Tuber Crops.)

Cabbage and Related Vegetables

R Fordham, Ludgvan, Cornwall, UK
P Hadley, University of Reading, Whiteknights, Reading, UK

Introduction

Cabbages and closely related vegetables belonging to the same species are collectively referred to as cole crops, which include a number of the world's most commonly cultivated vegetables. They are classified into a number of readily identifiable groups based on morphological differences in their vegetative and reproductive stages. This article deals with those members primarily distinguished by vegetative differences. Members of the species differing in reproductive characters are discussed in a separate article. (*See* **Brassicas**.) Chinese cabbage is a different species and is dealt with separately in the article on Oriental vegetables.

Cabbage: Brassica oleraceae Capitata Group, Family Cruciferae

The cabbage is a biennial plant grown as an annual for its edible leaves, which, at maturity, form a compact head. The species is thought to have originated in western Europe along the coast of the Mediterranean where wild forms still occur. It subsequently spread along the Atlantic coast as far north as Scotland. Earliest selections were probably made to reduce the content of bitter glucosinolates, which are at high levels in the wild types. The crop has a long history of cultivation; the Ancient Greeks grew it primarily for medicinal purposes and its cultivation in Germany took place as early as the twelfth century. Over time a wide range of cultivars has been selected to suit different environments, seasons, and markets. Cabbage production is now worldwide and, although better adapted to cooler climates, it is also grown in tropical regions. Data on world production are presented in **Table 1**.

Table 1 Estimated world production of cabbage

Country	*Production (Mt)*
World total	48 872 193
China	18 502 086
India	4 200 000
Russian Federation	2 850 000
Korea, Republic of	2 755 000
Japan	2 400 000
USA	2 150 000
Poland	1 709 154
Indonesia	1 459 232
Ukraine	1 015 000
Uzbekistan	894 000
Romania	812 000
Germany	791 364
Turkey	732 000
Korea, Democratic People's Republic	600 000
Italy	522 000

Source: FAO (1999) Food and Agriculture Organisation. Website: http://apps.fao.org.

Although there are marked differences between cultivars in terms of their environmental responses, the optimum temperature for growth in cabbage is between 16 and 18 °C. Growth is arrested above 25 °C and below 0 °C, although cold-hardened plants will survive temperatures as low as −10 °C without severe damage.

The dense terminal cabbage head is produced on a short stem. Harvesting is usually carried out at around the time of maximum head density, although immature plants may also be harvested as 'spring greens' in order to extend the season of supply. If harvesting is delayed beyond maturity, further expansion of the inner leaves and continuation of stem growth will result in splitting of the head. Flowering in cabbage, although a necessary prerequisite of seed production, will detract from crop quality. Young plants pass through a juvenile period during which they are unable to flower but following this, exposure to vernalizing temperatures of between 4 and 10 °C may induce premature flowering, referred to as bolting. The stem lengthens to bear a terminal raceme of yellow to white flowers. Following pollination seed development occurs within a fruit called a siliqua. Normal flowering, however, usually occurs in the second year following exposure of the mature plant to vernalizing temperatures during its first winter in the field. The duration of exposure required to initiate flowering depends on the precise pattern of temperatures and on the sensitivity of individual cultivars, but generally varies between 10 and 50 days or longer.

Cabbage cultivars also differ in head shape, varying from pointed to round; leaves may be green or red and smooth or wrinkled. Savoy types, which are particularly tolerant to cold conditions, have deeply wrinkled dark green leaves. For production purposes, cabbages are classified on the basis of their season of maturity. The earliest types for spring harvesting may be cut before they develop hearted heads and are then marketed as spring greens. These are followed by a wide range which mature throughout the summer, fall, and winter. Winter white cultivars, often referred to as Dutch White, have dense-hearted heads of blanched leaves which store well.

Nutritional Value and Chemical Composition

The nutritional value of cabbages depends on their vitamin and mineral contents, which vary significantly with cultivar and method of preparation. Carotene levels, for example, depend on the amount of chlorophyl, and outer green leaves may contain 50 times as much as inner white ones. As a consequence, carotene content in Savoy and kale, for example, are significantly higher than in Dutch White cabbage. Heat treatment will also cause changes in composition and vitamin C levels are markedly reduced by boiling. Estimates of nutritional value and chemical composition of cabbage and related vegetables are summarized in Table 2.

Handling and Storage

Cabbages are a relatively low-value vegetable and are normally grown on a large field scale, either from direct drillings or transplanting. A range of cultivars is available to provide spread in maturity dates but the season can also be extended by growing transplants under protection in glasshouses. Earliness can also be achieved by covering field crops with plastic film covers or nonwoven agritextiles. Under favorable conditions, appropriate cultivars can be harvested throughout the year, using Savoy types and unhearted spring cabbages or greens to cover the winter months.

Continuity of supply can also be maintained by both cold and controlled-atmosphere storage, although the latter is more commonly used for higher-value vegetables. Winter white cabbage, for example, can be stored for at least 6 months in cold stores at an optimum temperature of 0–1 °C, and 95% relative humidity. Storage for longer periods can be achieved under controlled-atmosphere conditions of lower oxygen and higher carbon dioxide relative to ambient conditions, although different vegetables and cultivars vary markedly in their response to specific levels and off-flavors may develop. The optimum concentrations for cabbage lie between 2.5 and 3% oxygen and 2–5% for carbon dioxide which, combined with cold storage, enables white cabbage to be stored for around 9 months.

[d]Value for inner leaves.
Reproduced from Holland B, Unwin ID and Buss DH (1991) *Vegetables, Herbs and Spices: Fifth Supplement to McCance and Widdowson's. The Composition of Foods*. London: HMSO, with permission.

Uniformity and head size are important marketing requirements and are achieved through the appropriate choice of cultivar and carefully controlled plant spacing. Spring greens, for example, are grown at densities of up to 40 plants per square meter, in contrast to 9 per square meter for hearted summer harvests and 3–4 for winter and fall crops. Earlier harvests may be by selective hand-cutting, although the majority of commercial crops are now harvested mechanically.

Domestic and Industrial Use

Cabbages may be cooked by boiling or stir-fried, or used raw in salads and in the preparation of coleslaw. Red types are generally sliced and pickled in vinegar. Sauerkraut is manufactured industrially from sliced white cabbage by controlled anaerobic fermentation and the addition of salt. A small proportion of the crop may be dried.

Kale: *Brassica oleraceae* Acephela Group, Family Cruciferae

Kale is a biennial closely related to the cabbage, grown as an annual for its edible shoots and young leaves. It probably originated along with other varieties of the species in western Europe, but is now widely distributed throughout the world. It is one of

the hardiest of all brassicas, capable of withstanding winter temperatures as low as −15 °C. It is also tolerant of high summer temperatures. There are two main groups of kale, the curly-leaved types referred to as Scotch kales or borecole, and the broader, smooth-leaved types. Rape or Siberian kales are similar to the curly-leaved kales but belong to the species *Brassica napus*. Unlike cabbages, kales produce no head, but leaves are borne on a tall stem, the height of which is dependent on cultivar. The crop is mainly used for winter supplies when other green leafy vegetables may be in short supply.

Cultivation of the crop is similar to that for cabbage. Shoots and leaves of kale are cooked by boiling in a similar manner to cabbage. They provide a valuable source of minerals and vitamins. These are summarized for raw curly kale in Table 2.

Brussels Sprout: *Brassica oleracea* Gemmifera Group, Family Cruciferae

The Brussels sprout is a single-stemmed, tall biennial growing to a height of around 1 meter in its first season. The main edible portions of the crop are the small, tightly formed axillary buds that develop in the axils of the expanding leaves. Its loose head of large leaves may also be used as a substitute for cabbage. Flower production in Brussels sprouts is similar to that for cabbage, being triggered by exposure of mature plants to relatively low temperatures. Cultivars vary in their sensitivity to vernalizing temperatures, but Brussels sprouts generally require a longer period of exposure than cabbage, ranging from around 50 to 80 days. The crop has developed from the wild cabbage and is believed to have originated in Belgium where it was cultivated during the nineteenth century. Its cultivation has spread to other European countries: production is carried out on a relatively large scale in the UK. Its importance is more limited outside Europe. In the USA it is mainly cultivated in California.

Brussels sprouts are adapted to relatively cool conditions, and in warmer regions the axillary buds may develop into loose sprouts, in contrast to the preferred tightly formed round buds. Cultivars have been selected to provide a spread in harvests and later-maturing ones are able to withstand temperatures down to −10 °C. Cultivar selection for sprout uniformity has been achieved for use in mechanical harvesting.

Food Value and Chemical Composition

In comparison with other *Brassica* crops, only a relatively small portion of the total plant is consumed. The composition of the edible sprouts is indicated in Table 2. Mineral and vitamin content determines their main value.

Handling and Storage

The cultivation of Brussels sprouts is similar to that of cabbage and other *Brassica* species. Crops may be grown either from direct seeding or from transplanted seedlings raised in open seed beds or, more generally, under protection. Typically, seeds are sown in early spring and harvesting is carried out from fall until the following spring. Continuity of production is achieved primarily through choice of cultivars, but raising transplants under protection enables an advancement of the earlier crops. The sprouts on older cultivars develop from the base of the stem upwards, necessitating selective harvesting by hand. Modern hybrid cultivars, however, mature more uniformly and commercial production is now mainly conducted using mechanical harvesters.

Sprouts are trimmed and marketed loose. Short-term storage in cold stores at 0–1 °C and high humidity can be used to maintain freshness.

Domestic and Industrial Use

Brussels sprouts are cooked by boiling. Processing is primarily by freezing, although a small proportion of the crop is canned.

Leaf Vegetables

R Fordham, Ludgvan, Cornwall, UK
P Hadley, University of Reading, Whiteknights, UK

Introduction

In addition to the diverse selections of the species *Brassica oleraceae* which include nonheading leafy members, there are other species within the genus *Brassica* and also in the family Chenopodiacea which are cultivated as vegetables principally for their edible foliage.

Spinach (*Spinacia oleracea*): Family Chenopodiacea

Spinach is an annual crop grown for its edible leaves. It initially develops as a rosette of leaves on a short stem. Following stem elongation, branching occurs from leaf axils, from which further laterals develop. It is believed to have originated in central Asia and there are records of its cultivation in China in the seventh century and in Europe in the fourteenth century. The Moors introduced it to Spain and the word 'spinach' is derived from the Spanish *hispania*. It is now widely cultivated, particularly in the USA. It has a long history of cultivation. Recent production statistics for the principal growing areas are summarized in **Table 1**.

It is a cool-season crop and grows best at average temperatures in the range 16–18 °C. Young plants can withstand freezing temperatures down to −9 °C. Flowering is induced by long day conditions; the critical day-length ranges from 12.5 to 15 h depending on cultivar and temperature. High temperatures can also cause premature flowering or bolting. A combination of cold exposure followed by high temperatures and long days causes rapid bolting with consequent cessation of leaf growth. Most cultivars produce between 22 and 26 leaves.

The species is mainly dioecious, producing male and female flowers on separate plants, although monoecious plants occur.

Cultivars differ in day-length response and also in their leaf morphology, which may be either smooth or wrinkled (savoyed).

Nutritional Value and Chemical Composition

Spinach is rich in vitamins and is particularly high in carotene, a precursor of vitamin A. It is also rich in iron and calcium, but the calcium is said to be unavailable as it unites with oxalic acid to form calcium oxalate. **Table 2** summarizes the nutritional value and composition of raw spinach leaves. Spinach leaves contain relatively high levels of nitrate (1075–2300 p.p.m.), although these are influenced by a number of factors, including cultivar, fertilizer regime, growing temperatures, and nitrate reductase activity. It has been suggested that frequent consumption of leafy vegetables containing high levels of nitrate may be hazardous as a result of the nitrate being reduced to nitrite by saliva and the upper gastrointestinal tract. It has been shown that nitrate levels are reduced by exposure of light prior to harvesting and that levels increase during storage. Thus, agronomic practices can have a significant influence on the levels of nitrate in the marketed leaves. Processing and culinary treatment will also affect levels of nitrates and other components. For example, canning and freezing at −18 °C can lead to cell rupture and hence ion loss. This has been reported particularly in relation to nitrate

reduction. Sun-drying of spinach before storage is carried out in a number of developing countries but the practice markedly reduces carotene content.

Handling and Storage

Leaf production is at its optimum just below the critical day-length and thus appropriate cultivars are needed to suit latitude and season of production. The crop is established from direct seeding. For overwintering, a hardier form of spinach having prickly seeds is preferable. Spinach leaves can either be harvested individually as required or the entire shoot can be cut off just above ground level, leaving the plant to produce a new growth under favorable conditions. Mechanical harvesting is used commercially, particularly for the processing industries.

Continuous refrigeration just above 0 °C from packaging through to retail is desirable. Hydrocooling or vacuum cooling should be carried out as soon as practical after harvesting in order to remove field heat. Storage at ambient temperatures for as little as 24 h can lead to significant losses in ascorbic acid and vitamin A. Controlled-atmosphere storage can prolong the shelf-life of spinach by about 1 week at 5 °C.

Domestic and Industrial Use

The leaves are prepared by boiling and can also be used raw in salads. The crop is also processed by both freezing and canning.

New Zealand Spinach (*Tetragonia tetragoniodes*): Family Aizoaceae

New Zealand spinach is a minor crop unrelated to true spinach. It is a perennial, trailing vine reaching 2 m in length and cultivated for its edible young shoots and dark green succulent leaves. It is indigenous to New Zealand and the south and western coastal regions of Australia and Tasmania and was introduced to England in the eighteenth century. It has the advantages of being drought-resistant and heat-tolerant but is not as hardy as spinach and is therefore established in the spring after the risk of frost. It can be raised from either direct seeding or from transplants. Seed germination is slow. Harvesting commences about 70 days after sowing by cutting off the terminal 7–8 cm of shoot growth. This may be repeated two or three times during the season following regrowth. The crop is a useful substitute for spinach in hot dry weather. Young shoots are edible either raw or cooked. Information on the nutritional value and chemical composition of New Zealand spinach is included in Table 2.

Swiss Chard *Beta vulgaris* ssp. *cicla*: Family Chenopodiacea

Swiss chard was first recorded in the Mediterranean region and Canary Islands and was popular as long ago as 350 BC. It was introduced to the USA in 1806 by Swiss settlers.

Swiss chard is a biennial cultivated as an annual for its edible leaves. It has a number of synonyms, including silver chard, seakale beet, silver beet, spinach beet, and perpetual spinach.

There are a range of types, including those with dark green spinach-like leaves to examples with large crisp crinkly leaves, pronounced fleshy midribs, and swollen petioles. The latter types are referred to as chards and after removing the leaf lamina the central portions are used as a separate vegetable which may be cooked and served like asparagus. Leaf stalks occur in a range of colors, including white, pink, red and silver.

The crop is less prone to bolting in warm weather than true spinach and forms a useful substitute during the summer when other leafy species are less readily available. Establishment is by seed which is formed in clusters necessitating early thinning. The thinnings can be used as greens and leaves and stems are then harvested 50–60 days later, leaving crowns which form more leaves for later use. The leafy beets are closely related to the beetroot (*B. vulgaris* ssp. *rubra*) and probably developed from an ancestral form native to the Mediterranean region. Cultivation on a small scale is widespread in temperate regions.

The nutritional value and chemical composition of raw Swiss Chard are included in Table 2.

Orache *Atriplex hortensis*: Family Chenopodiacea

Orache or mountain spinach is a tall annual, growing to a height of over 1.5 m. Its edible leaves may be used as a substitute for spinach. They may be eaten raw in salads, stir-fried, and used in soups and various Chinese and Japanese dishes. The crop is established from seed and continuity of supply of tender young leaves may be achieved from successional sowings made between spring and early summer. It is not widely grown as a food crop but colored varieties are more often cultivated as ornamentals.

Texsel Greens *Brassica carinata*: Family Cruciferae

Texsel Greens, also known as Abysinnian cabbage, was introduced into Texas, USA in 1966 as an oil seed crop from which a selection was made with suitable leaf qualities to be used as a vegetable. This annual, originating from the highlands of Ethiopia, initially produces a rosette of leaves from a very short stem. The leaves have slender petioles and are oval or oblong in shape, light green in color, and smooth in texture. They are reported to have a high protein content (3.74%) relative to spinach and they provide a useful source of vitamin C. It has a good flavor, being milder than collard greens and less pungent than mustard greens.

The crop is not frost-hardy but grows rapidly from successional sowings from early spring to produce harvests until autumn. The crop has been trialed in the USA and the UK but is not widely grown.

The young leaves have a short shelf-life. They can be eaten either raw in salads or boiled lightly as a substitute for spinach.

Oriental Brassicas

R Fordham, Ludgvan, Cornwall, UK
P Hadley, University of Reading, Whiteknights, Reading, UK

Introduction

Brassica species have been cultivated since antiquity for food and animal fodder. Extensive hybridization and selection over many generations have led to difficulties in classifying crops at the species level. This is particularly true of the brassicas of oriental origin, which occur in many different forms. The present section deals with the main groups of oriental origin within the species *Brassica rapa*, the Alloglabra group of *B. oleraceae*, and finally, the species *Chrysanthemum coronarium* or edible chrysanthemum.

Pak Choi (*Brassica rapa*, Chinensis Group): Family Cruciferae

The Chinensis group includes a number of leafy cultivars referred to as pak choi, plus other flowering types in which the developing flowering shoot is also consumed. The terms Chinese white cabbage, celery mustard, and Chinese mustard are also used to describe this group. Although a biennial, the species is primarily grown as an annual for its edible

leaves. It can, under adverse conditions, flower and produce seed during its first year of growth.

Cultivation of the Chinensis group has been recorded in China since the fifth century. It is now in widespread production throughout the temperate regions of the world and cultivars have also been developed for use in tropical regions. Various sizes, leaf shapes, and green and white leaf stalks are available.

Nutritional Value and Chemical Composition

The oriental brassicas are an excellent source of vitamins and minerals, in particular having high levels of calcium, iron, and vitamin A. Data on nutritional value and composition for pak choi and other oriental brassicas are summarized in Table 1.

Table 1 Nutritional value and chemical composition of pak choi[a], Chinese cabbage[b], and Spinach mustard.[a] Values are based on 100 g raw flesh

Handling and Storage

There are many cultivars, ranging from large types over 60 cm tall, to low rosetting forms less than 10 cm. The heads of the larger cultivars can weigh over 2 kg. Plants are established from seed, and spacing is dependent on cultivar. The crop can be harvested in the leaf stage either whole or by picking individual leaves. Flowering shoots are also edible. The leaves are generally consumed fresh but in China, leaves are also dried following blanching in boiling water and stored for winter use in soups.

Chinese Cabbage (*Brassica rapa* Pekinensis Group): Family Cruciferae

Chinese cabbages (also known as Chinese leaves or celery cabbage) are broadly divided into the headed types and the loose-headed types, depending on their propensity to produce tight, compact heads of internal leaves. The crop originated in China and is believed to have been derived from a cross between the Chinensis form from the south and the turnip from the north.

Heading Chinese cabbage is one of the most important vegetables in Eastern Asia. They are the most widely grown vegetable in China and in northern areas of the country account for more than one-quarter of the total annual vegetable consumption. Other major areas of production include Korea and Taiwan. They are also cultivated throughout the world and in recent years have become firmly established as an important vegetable crop.

The Chinese cabbage occurs in both annual and biennial forms but is cultivated as an annual. It forms an upright head of either tightly overlapping leaves or sometimes a looser head of more separated leaves. Shape and size differ markedly between cultivars and head weight may vary between 1.4 and 4.5 kg. Leaf color in the hearted centers is usually a creamy white, but outer leaves vary from dark to light green. The swollen bases of the pronounced mid-ribs often form a solid white 'butt' to the base of the harvested heads.

The headed types vary in shape from tall cylindrical forms which can be 35–45 cm tall and 10–15 cm in diameter to the more squat, barrel-shaped cultivars 20–25 cm in height and 15–23 cm in diameter. There are also loose or semiheading types which are generally easier to grow than the heading types.

Nutritional Value and Chemical Composition

Estimates of nutritional and compositional data are included in Table 1.

Handling and Storage

Chinese cabbage can be either direct-seeded or raised as transplants. A succession of crops can be achieved from a combination of raising early transplants under protection followed by a succession of outdoor sowings. The time from sowing to harvest can vary from around 50 to 100 days depending on cultivar and season. The loose-headed types are more cold-tolerant and can be used to extend the period of supply. The crop is generally consumed fresh but storage at 0–1 °C and high humidity can extend shelf-life for up to 2 months. Trials in Germany have demonstrated the possibility of storage of some cultivars for up to 3 months under controlled atmosphere and low temperatures.

Domestic and Industrial Uses

Chinese cabbage are eaten raw or lightly cooked by, for example, stir-frying. More than 90% of the Chinese cabbage harvested in Korea is used for making Kimchi, a fermented side-dish eaten throughout the year by virtually every family.

Spinach Mustard (*Brassica rapa* Perviridis Group): Family Cruciferae

Spinach mustard or tendergreen is an annual to biennial. It is a type of leafy turnip and has a thickened and tuberous root crown. It is a tall plant, reaching a height of 45 cm and having large leaves, on average 30 cm long and 18 cm wide. It has the main advantage of being cold-tolerant, surviving temperatures down to −14 °C. Although largely unknown in China, it is grown in Japan, Korea, and Taiwan but not grown on a large scale elsewhere. Leaves of spinach mustard are eaten raw in salads to add flavor.

Nutritional Value and Chemical Composition

Estimates of nutritional and compositional data are included in Table 1.

Mizuna and Mibuna Greens (*Brassica rapa* Nipposinica Group): Family Cruciferae

These two vegetables are relatively recent introductions to the west from Japan. Botanically they are closely related to leafy turnips. Mizuna forms a bushy clump of finely dissected, feathery, dark, glossy green leaves. The white leaf stalks are slender and juicy. Plant height is around 23 cm and spread is about 45 cm.

Mibuna has long (30–45 cm), narrow (1–4 cm) leaves in clumps which can be 56 cm in diameter. Mibuna is a cool-weather plant which can survive temperatures below freezing, but, of the two, mizuna is both more heat- and cold-tolerant.

These vegetables are usually eaten raw in salads.

Chinese Broccoli (*Brassica oleraceae* Alboglabra Group): Family Cruciferae

Chinese broccoli or Chinese kale is more closely related to the European cabbages than the Chinese cabbages. It is an annual grown primarily for its flowering stem. It grows to a height of about 45 cm to produce a smooth, succulent flowering stem 1–2 cm in diameter. There are both yellow and white flowering cultivars. It is a vigorous, fast-growing species able to withstand both frost and high temperatures. The flower stems are harvested at an early stage while flowers are still in bud. It is usually cooked by stir-frying.

Chrysathemum Greens (*Chrysanthemum coronarium*): Family Compositae

The edible chrysanthemums are known under a wide range of names, including chop suey greens, Japanese greens, crown daisy and garland chrysanthemum. It originated in the Mediterranean region and spread through Europe into Africa and Asia. In the west, selections have been entirely towards its value as an ornamental species and it is only in China, Japan, and South-East Asia that it has been adopted as a vegetable.

The edible chrysanthemum is an annual, growing to about 30 cm until flowering, when it may reach almost a meter. It is grown mainly for its leaves and young stem which can be used raw in salads, lightly boiled, or in the preparation of soups. The small yellow, daisy-like flowers may also be eaten but have a strong aromatic flavor. Removing flowers as they develop on the growing plant helps to maintain leaves in a tender, mild-flavored condition.

There are three main types distinguished on the basis of leaf form and size. Those with finely divided, narrow leaves are darker in color and generally considered to be more cold-tolerant than those with larger leaves. Other types include those with medium and larger leaf forms.

The crop may be established from seed, either from direct sowings or transplants, and by the use of rooted cuttings taken in the spring from plants overwintered under protection.

Carrot, Parsnip, and Beetroot

P Hadley, University of Reading, Whiteknights, Reading, UK
R Fordham, Ludgvan, Cornwall, UK

Introduction

Carrot, parsnip, and beetroot together represent the most popular root vegetables consumed in temperate areas of the world. Carrot and parsnip are largely grown as a fresh vegetable whereas beetroot is also processed and sold either as boiled roots or diced or sliced and pickled in vinegar.

Carrot – *Daucus carota* var. Sativus, Family Umbeliferae

Carrots are a popular vegetable crop throughout most temperate regions of the world (**Table 1**), with only Brassicas and peas ranking higher in terms of importance. Consumption has increased considerably over the last 40 years. Carrots are generally grown on a large farm scale, using a high degree of mechanization. Large-scale farm operation has become more important for carrot-growing over the last decade, with the increasing need to supply supermarket chains and multiples rather than wholesale markets. Here, success is measured in terms of being able to program carrot production carefully so that supermarket demands can be accurately met throughout the year. Developments in production and storage techniques in recent years now enable carrot growers to achieve this.

Carrot originated from middle Asia (Punjab or Kashmir) but later spread to the Near East and, through further domestication, to Europe and China. It was originally used as a medicinal plant and it was not until the tenth to the twelfth centuries that it became used as a food crop. The taproot is woody in the wild form. However, breeding and selection have enabled the root of the cultivated form (subsp. *sativus*) to become thickened and succulent. Modern European cultivars have resulted from selections made in the seventeenth century, for orange roots, in Holland, and subsequently in France.

Carrot grows vegetatively in the first year, during which it develops an enlarged hypocotyl and a prominent taproot. The root is composed of an internal pith or core composed of xylem and an outer cortex composed largely of phloem. Higher quality is associated with roots composed largely of cortex with a smaller proportion of pith. Color is also important: high quality is associated with a uniform deep orange coloration. The roots have a sweet flavor which is associated with a high concentration of soluble carbohydrates. The roots also have a high carotene content that is associated with the orange pigmentation of the root.

The orange color has been developed through continuous selection and is not a characteristic of its wild forebears. Prior to this, cultivated carrots were purple-rooted owing to the presence of anthocyanin pigments, but white and yellow anthocyanin-free types became preferred and it was from these that modern orange-rooted cultivars have been derived. Some large-rooted white and yellow forms remain in use for stock-feeding.

The leaves form a rosette and are characteristically two- to three-pinnate. During the second year, the stem elongates and flowers are produced initially as terminal umbels and later as secondary umbels. Flowers are pollinated by bees and other winged insects. The seeds are spiny, hooked, and slightly curved.

Cultivars

Carrots fall into different classes according to their shape, size, and time to maturity (Figure 1). Well-known groups of cultivars are as follows:

- Chantenay – Medium-sized, conical, stump-rooted types. Late-maturing. Widely grown for canning whole, for dehydrating, and for the fresh market. Medium and large-sized roots may be sliced or diced and then either canned or frozen.
- Amsterdam forcing – Small to medium-sized, slender, cylindrical, stump-rooted types of good quality. Early maturity. Grown for early-season bunching crops and for prepacking.
- Nantes – Medium, cylindrical, stump-rooted types. Medium maturity. Grown for prepacking and to a lesser extent for the fresh market and for canning.
- Berlicum – Large-sized, cylindrical, stump-rooted types. Late-maturing. Grown for the fresh market and for prepacking.
- Autumn King – Very large-sized, tapering rooted types. Late-maturing and heavy-yielding but flesh color is generally inferior with a rough skin texture. Grown mainly for the fresh market but also to a limited extent for dicing prior to canning and freezing.

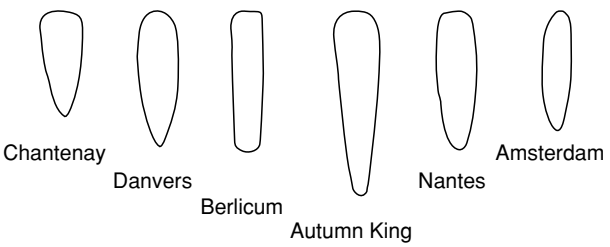

Figure 1 Root shape in carrot types. Reproduced from Vegetables of Temperate Climates: Carrot, Parsnip and Beetroot, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Handling and Storage

Carrots are capable of growing in any area where the growing season is cool; the optimum growth temperature is typically 16–18 °C. Under excessively cool conditions there is a tendency for the plants to bolt (produce flower stalks in the first year); under hot conditions, plants produce excessive leaf growth at the expense of root growth. Soil needs to be free from stones and clods, as this often leads to fanged roots. The crop requires a steady supply of available soil moisture in order to produce high yields and good quality. The crop has a relatively low fertilizer requirement. It is possible for UK carrot growers to supply produce all year round. This has been possible by extending the main growing season using a combination of field and refrigerated storage together with early production under plastic film and nonwoven agrotextile crop covers. In the UK, the earliest sowings for conventional production of carrots (i.e., without the use of plastics) are possible from the last week in February and continue through to the end of April under UK conditions. This provides production of carrots from July until October. Earlier production from the end of May until the beginning of July is possible from sowings made during January and February under perforated plastic-film crop covers. Such early crops (often referred to as second earlies) are typically grown under 200-hole polyethylene (200×1 cm diameter holes m^{-2}) supported by the crop. Certain carrot cultivars can also be overwintered under plastic-film crop covers to get even earlier maturity. This is achieved by sowing in September. Sowing date is critical as, if this is too early, the crop will bolt due to the large plants being sensitive to the vernalizing effect of cold winter temperatures. Alternatively, if the sowing date is too late, the crop will not be large enough to survive the winter satisfactorily. The latest sowings are made in late April and May. These sowings supply crops from October to May through crop storage under field conditions, or until the end of June if carrots are stored in refrigerated cold stores. Seed spacing is varied to produce roots of different sizes. Densities vary from 55–110 plants m^{-2} for large carrots suitable for dicing (greater than 45 mm), 160 plants m^{-2} for medium-sized roots for prepacking (32–43 mm), 380 plants m^{-2} for small roots for canning (18–32 mm), to 430 plants m^{-2} for freezing (20–25 mm).

Harvesting is now fully mechanized. When ready for harvest, roots are typically loosened, lifted by their tops, and the roots and tops conveyed to an

area where the tops are removed. The carrots are then washed and sorted before placing in pallet boxes for storage. Early-season carrots are marketed with the tops attached (bunching carrots). These are still hand-pulled and tied into bunches, washed, and cooled. Baby carrots are produced by growing carrots at high densities. These carrots are harvested using modified radish-harvesting equipment. After removing the tops, the roots are loosened using an undercutting device. The roots are then lifted on a conveyor, and the soil is shaken free to leave the carrots which are then washed.

Carrots are moderately resistant to frosts, and crops can usually be stored in the field during winter until required. Field storage is achieved by earthing up with 150 mm soil or placing 300 mm depth of straw over the crop in November to December to protect the crop from frosts. The stored crops are then lifted as and when required. For longer-term storage, carrots are lifted under good weather conditions and placed in cold stores (normally in bulk bins) at 0–10 °C and 95–98% relative humidity. Carrot roots have high respiration rates and their temperature needs to be closely monitored during storage to insure that carrot temperatures remain low to avoid loss of quality.

Domestic and Industrial Uses

Carrots are marketed washed in prepacks, nets, bags, or in bulk (the latter is common for supermarkets that allow customers to select and weigh out the produce they require). Prepackaging is now common and usually consists of half or 1 kg of produce in perforated plastic bags. Approximately half the UK crop is sold to households for home consumption; the remainder is grown for processing (canning, frozen foods, soup manufacture) or is sold to caterers. Although carrots are mainly marketed as a fresh product, there is a trend, particularly in the USA, for carrots to be processed as a prepared vegetable. Here it is peeled and sliced.

Carrots can be eaten fresh or, with very little preparation, the roots can be boiled, steamed, fried, roasted with meats, sautéed, and pickled. They are processed for canning, freezing, and diced for incorporation into soups. The crop is also processed for production of carrot juice.

Food Value and Chemical Composition

Cultivars grown for human consumption have about 11% dry-matter content, of which approximately 40–50% consists of sugars. The orange color is derived from the high β-carotene content. β-carotene is a precursor of vitamin A and carrots have been recognized as a remedy for night-blindness, which is brought about by vitamin A deficiency. Food value and chemical composition of raw old and young carrots are summarized in Table 2.

Parsnip–*Pastinacea sativa*, Family Umbelliferae

Parsnip is grown for its edible taproot. It is characteristically very hardy, producing a creamy white root that has been valued as a winter vegetable, although there is increasing demand for parsnip all the year round. It differs from carrot in having simple pinnate leaves and a creamy-white, fleshy root. It also has a longer growing season than carrot. It originates from either the Mediterranean or northern Europe. In the UK, the wild parsnip (subsp. *sylvestris*), which has a

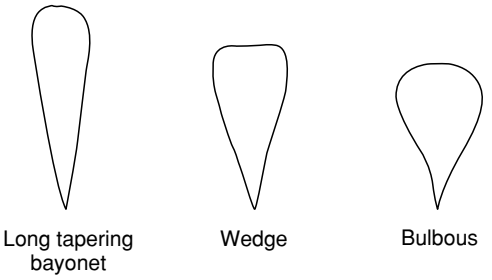

Figure 2 Parsnip root shape. Reproduced from Vegetables of Temperate Climates: Carrot, Parsnip and Beetroot, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

slender woody taproot, inhabits limestone soils. It has had a long period of domestication and was grown as a food crop by the Ancient Greeks.

Parsnip is a biennial producing a fleshy taproot in the first year and developing a flower stalk in the second year: this is terminated by a flower which is a broad, compound umbel. Flowers are pollinated by bees and blowflies. Parsnip types are distinguished by the shape of their roots. Three broad categories can be distinguished: bulbous cultivars, wedge-shaped cultivars, and long, tapering or bayonet cultivars (Figure 2). Long, tapering roots are the more traditional cultivars, although wedge and bulbous cultivars are now favored as they are less prone to breakage during mechanical harvesting. Breeding has largely been toward canker-resistant, shallow-crowned types that are more suitable to mechanical harvesting. Average yields are approximately 20 t ha^{-1}. Generally parsnips are grown in the same areas as those used for carrot production.

Handling and Storage

The crop is slow-growing, preferring a deep, rich, friable sandy loam soil which allows the development of straight roots without fanging. In the UK, the earliest crops are produced in small quantities from July onwards, although the main market for this crop is during the winter months. It is very hardy and resistant to frosts. Frosting the roots during the winter months improves their sweetness.

Parsnips are grown for the fresh market, prepacking, and processing. Small roots (40–65 mm diameter) are required for prepacking, whilst a larger root is required for the fresh market (40–130 mm diameter). Very large roots are suitable for processing in soup manufacture. A range of plant densities are used to achieve these different root sizes. Typically, parsnips for the fresh market are grown at a density of 20 plants m^{-2}, whereas the smaller roots required for prepacking are grown at a density of 40–60 plants m^{-2}. For early crops, sowings in the UK occur in February whilst the main crop is sown from the end of March until the end of April. Seed is slow to germinate and has an unusually short period of viability of between 1 and 2 years. The seed has an unusual flat shape and is difficult to drill. In addition, because of its notoriously poor germination (generally no better than 60%), it is one of the few crops for which there is no statutory minimum germination rate.

Harvesting is similar to that described for carrots. Although the crop can withstand frosts, it is generally lifted and stored in unheated barns for 3 weeks prior to marketing. This short-term storage is to provide stocks if subsequent weather conditions make harvesting difficult.

Domestic and Industrial Uses

Parsnips are generally eaten cooked. They are processed for canning, freezing, and diced for incorporation into soups.

Food Value and Chemical Composition

Food value and chemical composition of raw parsnips are summarized in Table 2.

Beetroot – *Beta vulgaris* subsp. *rubra*, Family Chenopodiacae

Beetroot has been used for human consumption for over 2000 years. The crop was introduced into Europe during the middle of the sixteenth century. Genotypes that are currently cultivated are probably derived from eastern Mediterranean types. Beets (of the same species, *B. vulgaris*) also grown for their swollen roots include sugar beet, mangles, and fodder beet. The wild ancestor grows on the coasts of Europe and North America. Although well-known varieties have deep red flesh with characteristic concentric circles of vascular tissue, yellow and white varieties also exist, although the latter are not commercially important and are grown mainly for their novelty value. The deep red color is caused by anthocyanin pigments within the cell sap and selection has aimed at producing roots of even and very dark color. Beetroot varieties are classified into three groups according to their shape: (1) round beet, which are the most wildly grown, being favored for their tender, sweeter-tasting flesh, e.g., globe Detroit; (2) intermediate-shaped

beet; and (3) long beet, e.g., Cheltenham greentop, which can reach up to 30 cm long and is popular for certain markets. Round, long, and intermediate-rooted cultivars are grown for main crops for winter use; round or flat cultivars are used for earlier production and for forcing. Many cultivars are available; choice is determined by the shape desired, bolting resistance (particularly for early-season production), and internal color.

Domestic and Industrial Uses

Although the root can be marketed fresh, it is often sold ready-cooked. For early and forced beet, the foliage is trimmed and the roots bunched into sixes; later crops are topped and loose-packed. For the supermarket and greengrocery trade, beetroots are now cooked and usually presented in the form of prepacks. Processed beet is the major outlet for beetroot where it is pickled whole, sliced or, to a lesser extent, diced into glass jars. Processors demand beet to be graded into specific sizes for particular outlets.

Handling and Storage

The crop is sown relatively late as plants sown too early in the season are prone to bolt (run to seed). The seed is actually a fruit enclosing one, two, or three seeds. The fruit tissue often contains germination inhibitors which can delay germination. Since the 'seed' can give rise to clusters of up to three seedlings, this tends to increase variability in root size at harvest and thus a significant fraction of roots that lie outside their market specifications. This problem is reduced in new monogerm varieties which only contain one seed per fruit. Seed is sown from late March for early bunched crops and from April until the end of July for the main crop. Early forced beetroot can be ready as bunched beetroot, when the roots are about 35 mm diameter in late spring and early summer (June to July). On light soils, lifting can be carried out by hand. Roots of early red beet are easily damaged by bruising and so care is needed at all stages of handling. Main crop beetroot is generally ready to lift between the end of September and the beginning of November. Maturity is generally indicated when the leaves fall away from the upright position.

The crop is normally topped in the field and harvested mechanically with a digger elevator. The roots are damaged by frosts and must be lifted prior to the onset of winter. Beetroot can be stored in clamps, as for other root crops or potatoes. There is a continuous demand for red beet throughout the year that is met either from the field or from clamps for 10 months of the year. These supplies fall off from the end of April until the middle of June. This is met either through imports or from improved extended-storage methods that have been introduced over the last decade.

Food Value and Chemical Composition

Cooked beet contain approximately 10% carbohydrate, 1.5–2% protein and a calorific value of 46 cal per 100-g root. Its vitamin content, in contrast, is low, and its vitamin C content is reduced to less than 50% by cooking. Food value and chemical composition of raw beetroot are summarized in Table 2.

Glossary

Bolting The premature running to seed of a biennial crop before harvesting. This results, in the case of root crops, in coarse, unmarketable roots.
Clamp An outside store for root crops, consisting of layers of straw and soil covering a heap of roots to protect them from frost.
Digger elevator A harvestor for lifting root crops.
Monogerm seed A seed cluster which germinates to give one seedling.

Swede, Turnip, and Radish

P Hadley, University of Reading, Whiretnights, Reading, UK
R Fordham, Ludgvan, Cornwall, UK

Introduction

The family Cruciferae includes some of the most important temperate vegetables, of which there are three commercially important root crops.

Swedes – *Brassica napus* L. var. *napobrassica Peterm*, Family Cruciferae

Swede (also known as rutabaga, Swedish turnip, or Lapland turnip) is usually considered to be a root crop. However, the 'root' is mainly the swollen hypercotyl of the plant. The crop is grown as an annual, as a fodder crop, or for human consumption, and is generally grown on a farm scale. It is thought to be a relatively recent vegetable that originated as a natural hybrid of *Brassica rapa* (turnip) and *B. oleracea* (cabbage). This hybrid may have occurred first in Bohemia in the seventeenth century, although some reports suggest that its origin is much earlier. The swede was initially grown in Sweden (from where it takes its name) and later spread to the rest of Europe and North America. Swedes have an elongated globe shape with a swollen neck bearing a number of leaf scars; this neck differentiates swedes from turnips.

Roots may be globe or tankard-shaped, or intermediate between the two. The flesh is either white or yellow/orange and has a milder flavor and a higher sugar content than winter turnips. Yellow-fleshed types are more commonly grown. The root develops anthocyanin and/or chlorophyl in its outer skin where it is exposed to the light, giving rise to a range of skin colors. Four skin colors exist: green, light or dark purple, and orange. Green-topped swedes are the poorest croppers, but the best keepers, whilst the reverse is true for purple-topped swedes.

Handling and Storage

Swedes can be grown in a wide range of soils; however, the crop is best suited to a well-drained, medium loam. The crop has a relatively low nutrient requirement and it rarely needs irrigation except on light, sandy soil. In the UK, seeds are sown from March to the end of June and are ready for harvesting 15–21 weeks later. Average yields are 32 t ha^{-1} and good yields are typically 68 t ha^{-1}. The crop is pulled by hand or is machine-harvested by digger elevators. The root is removed and the neck is trimmed off. The crop is sold for both the prepack and the wholesale markets. For prepacking, small roots are required, normally between 80 and 150 mm. Swedes for the wholesale markets are normally marketed in nets with minimum grading.

Storage normally commences in the autumn in traditional clamped heaps covered with straw or soil and is used to supply the market over the winter period. Flavor is improved after the roots have been exposed to early frosts. A more modern approach to storage is to harvest into bulk bins and then surround the bulk bins with straw bales. The crop is a low-value crop and does not merit more sophisticated storage conditions, although, for the longest storage period, the roots can be stored in an insulated store with forced ventilation at a temperature of 0 °C and a relative humidity of 90–95%. The crop can be left standing in the field and harvested as required.

Domestic and Industrial Uses

Swedes are normally eaten as a cooked vegetable but they can also be shredded raw in salads. They are processed for canning, and included in pickles and mixed and diced vegetables.

Food Value and Chemical Composition

Food value and chemical composition of raw swede are summarized in Table 1.

Turnips – *Brassica rapa*, Family Cruciferae

Turnips are very similar vegetables to swedes and the two crops are often confused. Roots are either globe-shaped or have a more flattened shape, with white or yellow flesh, and have a high water content. The turnip is believed to have originated from a wild form of Eurasian origin and has been known for about 4000 years. The same species is believed to have been responsible for Chinese cabbage and other similar oriental vegetable crops. Although the turnip (like swede) is described as a root, it is actually a swollen hypocotyl and contains very little root tissue. The color of the skin may be white, purple, green, or mottled. The yellow-fleshed types are hardier than white types. Roots are generally small and may be round, flat long, half long, or globe-shaped. They rarely exceed 100 mm in diameter. The number of different types allows turnips to be produced throughout the year, although the crop is mainly winter- or spring-grown.

Handling and Storage

Turnips tend to be an intensively grown crop. A sandy loam soil is preferable for early-spring-sown crops;

however, the crop can be grown in most soils providing that they are reasonably deep, friable, and free-draining. The time from sowing to harvest is generally short (between 6 and 10 weeks, depending on the season). The crop season usually begins in early April in the UK; these crops are normally picked when the roots are approximately 50 mm in diameter, washed, and sold as bunches of three, six, or eight tied together with about 75 mm of the leaf stalk left attached to the root. (Average yields are approximately 24 t ha^{-1}.) The main crop is harvested through to November. Turnips require similar storage conditions to other root crops and can be stored in clamps (as for swedes). The main crop is washed, graded, and marketed in nets (chiefly to the greengrocery trade) and polyethylene film bags (for the supermarkets).

Domestic and Industrial Uses

Turnips are normally eaten as a cooked vegetable. As with swedes, the crop is processed for use in pickles, and in mixed and diced frozen vegetables. Turnip tops are also eaten as an early spring-green vegetable.

Food Value and Chemical Composition

Food value and chemical composition of raw turnips are summarized in Table 1.

Radish – *Raphanus sativus* L., Family Cruciferae

Radish is a fast-maturing root crop, probably originating from central and western China and India. It has been cultivated for thousands of years and was grown by the Egyptians and ancient Greeks. It was first grown in western Europe in the mid sixteenth century.

The main edible part of the plant is a swollen hypercotyl and primary root. The lack of lignification of the vascular tissue and the presence of considerable thin-walled parenchyma are responsible for the succulence of the root system. The enlarged roots are available in a wide range of sizes, shapes, and colors, depending on cultivar. Early-maturing European salad types can be round, oval-shaped, or cylindrical, red, white, or red with a white tip and with crisp white flesh. Winter and oriental radishes are often white (although red and purple skins are also found) with a large conical shape and white flesh. Early-maturing radishes produce small roots which are harvested when approximately 1.25 cm in diameter. Winter and oriental radish roots are often 25–40 cm in length and can weigh approximately 2–3 kg (although even larger roots are available).

Handling and Storage

European cultivars Early radishes are grown under glass or perforated polyethylene and nonwoven agrotextile crop covers to provide a crop before outdoor crops are mature. Commercially, the crop is produced by specialist growers and market gardeners. The crop is grown sequentially to provide a continuous supply to meet market demand. The crop is normally lifted after 3–6 weeks when the plant has approximately four true leaves. The crop can be harvested by hand, although harvesting machinery is available, particularly for growers supplying the prepack market. For the fresh market, plants are bunched (usually 10–12 roots per bunch) and secured with an elastic band. It is possible to store the crop for 3–4 weeks at 0–1 °C.

Winter and oriental cultivars These types take longer to mature. Radishes grow best in moisture-retentive, rich sandy loam soils whilst heavier soils often cause misshapen roots. They are normally harvested during the autumn until the onset of hard frosts between 8 and 14 weeks after sowing. After this radishes can be stored through the winter (typically for up to 6 months) using the same storage conditions as for carrots.

Domestic and Industrial Uses

Early-maturing radishes are eaten raw in salads, whilst winter and oriental radishes are either eaten raw or as a cooked vegetable, rather like turnips. The very characteristic flavor is popular in Japan, the Philippines, and Hawaii and roots are used to prepare food products such as takuwan and cabaizaku. Leaves and pods of some cultivars can be boiled and eaten as a vegetable. Roots have been used medicinally in the treatment of liver and gallbladder complaints.

Food Value and Chemical Composition

Pungent flavor is due to isothiocyanates. Radishes are a good source of ascorbic acid (15–40 mg $100\,g^{-1}$); a higher concentration is found in pink-skinned cultivars. Catechol has been reported to be present in the red cultivars and flavinols have been detected in minute quantities. Food value and chemical composition of raw red and white radishes are summarized in Table 1.

Miscellaneous Root Crops

P Hadley, University of Reading, Whiteknights, Reading, UK
R Fordham, Ludgvan, Cornwall, UK

Introduction

A number of commercially less important temperate root crops exist. These are either grown as domestic crops, or on a limited scale by specialist commercial growers.

Salsify – Tragopogon porrifolius, Family Compositae

Salsify (also known as white oyster, vegetable oyster, or oyster plant because of its oyster-like flavor) is a root crop that is little known by general consumers. It therefore has little importance commercially and is only produced by specialist growers. The root is long and tapering (20–30 cm long and 2.5–5 cm in diameter), with a creamy white skin and a pale yellowish flesh. The leaves are long and grass-like and have a grayish-green color. It is favored as a winter vegetable. Large purple flower heads are produced in the second year. The flowers can be eaten if they are cut before they get too woody.

Handling and Storage

Salsify is usually sown at the end of March in the UK and roots can be harvested from the middle of October onwards. A long growing season is required in order to produce large roots. A sandy loam or peat soil with good water retention provides the best growing conditions. Salsify is winter-hardy and can withstand freezing conditions; indeed, it is suggested that freezing can improve the oyster-like flavor. Salsify is treated in the same way as parsnips and can be stored in clamps or can be left in the ground to be lifted as required. It is possible to extend the storage period using controlled-atmosphere storage

with the temperature maintained at 0 °C, carbon dioxide at 3%, and oxygen at 3%. High humidity is essential to prevent shriveling. In the spring the unlifted roots develop young and succulent shoots known as chards.

Food Value and Chemical Composition

Salsify has a similar nutritive value to parsnips but has a lower calorific value (40 cal 100 g^{-1}) and is valued as a source of fiber. It is low in sodium, its vitamin content is low; it is low in fat and cholesterol-free. Food value and chemical composition of raw salsify are summarized in Table 1.

Celeriac – *Apium graveolens*, Family Unbelliferae

Celeriac is also known as turnip-rooted celery or knob celery. It belongs to the same species as celery; however, in this case the wild ancestor has been bred to produce a 'root' that resembles a turnip. Celeriac is not a true root but is a stem which has developed with a large mass measuring up to 15 cm in diameter. It is produced half in the ground and half above, and from this a rosette of leaves is produced with a fibrous root system produced below. The roots have a cream-colored flesh with a characteristic celery flavor. The foliage resembles that of celery but is coarse and not edible.

Handling and Storage

Cultivation of the crop is very similar to that of celery, except that plants are not earthed up during the growing season. As with celery, it cannot tolerate drought conditions, although it can be grown successfully on a wide range of soil types providing that they are free-draining. It can tolerate heavier soils than celery. Celeriac is usually transplanted as the seeds are too small to direct-drill. The crop is usually sown in greenhouse conditions planted in the spring (typically early to mid April in the UK) and is ready to harvest by the middle of September onwards. Like celery, it is a heavy feeder and responds well to bulky organic manures. Roots are usually lifted early in October and stored in dry, cool conditions until required. Roots can remain in the field if soil is drawn up around them or, alternatively, the crop is covered with straw in mid-October to provide some winter protection. Roots can then be lifted as required.

Domestic and Industrial Uses

Celeriac is peeled and can be boiled and served as a hot vegetable or served cold in salads.

Food Value and Chemical Composition

Food value and chemical composition of raw celariac are summarized in Table 1.

Scorzonera – *Scorzonera hispanica*

Scorzonera (also known as black salsify or Spanish salsify) and salsify are usually classed together because their roots have the same root shape and flesh color. However, taxonomically they are unrelated. The skin color of the root of scorzonera is dark purplish, whilst the leaves are broader and shorter than those of salsify. However, crop treatment is similar,

maturing in approximately 120 days, and it is prepared for the table in a similar way. Although it is usually grown as an annual to provide a winter root vegetable, scorzonera can be left in the ground for a second season. This will result in a larger root without any apparent loss in quality. Scorzonera has similar storage requirements to salsify.

Domestic and Industrial Uses

The root can be eaten as a cooked vegetable and the leaves can be eaten in salads.

Food Value and Chemical Composition

These are not available.

Hamburg Parsley – *Petroselinum crispum*, Family Umbelliferae

Hamburg parsley (also known as turnip-rooted parsley) is a type of parsley in which the root, rather than the shoot, has been developed as the harvestable part. The white, parsnip-shaped roots which have a parsley/celery flavor can be eaten raw or boiled. The leaves can also be served like spinach. It is more often grown as a domestic crop than grown commercially. The crop needs a long growing season. Hamburg parsley is hardy and can withstand moderate freezing conditions in the open. Roots may be left in the ground or lifted and stored like carrot and parsnip.

Domestic and Industrial Uses

Hamburg parsley is typically peeled and eaten as a boiled vegetable.

Food Value and Chemical Composition

These are not available.

Jerusalem Artichoke – *Helianthus tuberosus* L., Family Asteracea

Jerusalem artichoke (also known as girasole, topinambur, and sunchoke) has edible tuberous roots which are fleshy and irregular in shape and possess a somewhat nutty flavor. The plant is vigorous, with the shoot growing to 3 m or more. It is a native of North America where it was grown by American Indians. It was introduced into France in the early seventeenth century and later appeared in England, Holland, and Italy. The name 'girasole' was given to this plant in Italy and 'Jerusalem' is a corruption of this word. The name artichoke was given to denote a similarity in taste and flavor of the tuber to the globe artichoke. It is now widely grown in temperate, subtropical, and tropical areas, although it has never been very popular and the area under cultivation is not extensive.

Handling and Storage

The crop is grown from sets which are small tubers or pieces of tuber normally weighing approximately 60 g with at least two to three eye buds. A typical spacing would be 30–60 cm apart in rows 90–129 cm apart. Jerusalem artichoke is frost-sensitive and requires at least 125 frost-free days to be grown successfully. The crop normally reaches maturity in 18–24 weeks, although early-maturing types can be harvested after 10–12 weeks. The crop can be harvested as soon as the leaves begin to die back. The tubers can be lifted by hand or by machine using a suitable elevator after first cutting back the tops. Tubers are perishable but can be stored at 0 °C and 90–95% relative humidity for 4–5 months. Yields average approximately 25–30 MT ha^{-1}.

Domestic and Industrial Uses

Tubers are boiled, baked, fried, or steamed and eaten in much the same way as potatoes, but can also be eaten raw in salads. Tubers are also grown for stock feeding, particularly to pigs. The green tops can also be used for stock feeding. Tubers can be utilized for flour, as a source of fructose, and for the preparation of 5-hydroxy-methyl-furfurol. They can also be used as a source of industrial alcohol and for a beer-like beverage.

Food Value and Chemical Composition

The principal storage carbohydrate present is inulin rather than starch. Food value and chemical composition of boiled Jerusalem artichokes are summarised in Table 1.

Chinese Artichoke – *Stachys tuberifa*, Family Labiatae

Chinese artichoke is also known as crosnes and kon loh. There are two other similar and closely related species within the same genus (*S. affinis* and *S. sieboldii*). The plant is a perennial grown for its small edible tubers. It has rough, nettle-like leaves and grows to a height of 30–45 cm. The tubers produced from its creeping root system are 5–8 cm long and 1.5–2 cm in diameter, constricted at the internodes into rows of bead-like segments. It is a native of the Far East and is cultivated in China and Japan.

Handling and Storage

Plants are propagated vegetatively from tubers. They can be overwintered in cool temperate areas providing frosts are not too severe. Discoloration of tubers following harvesting is reduced by storage in the dark at low temperature and high humidity.

Domestic and Industrial Uses

Tubers have a taste similar to those of the larger Jerusalem artichoke and may be roasted, boiled, or fried.

Food Value and Chemical Composition

The major storage carbohydrate in the tubers is tetrasaccharide stachyose. Other nutritional data for this crop are not available.

Stem and Other Vegetables

R Fordham, Ludgvan, Penzance, Cornwall, UK
P Hadley, University of Reading, Whiteknights, Reading, UK

Introduction

In addition to the relatively small number of vegetable groups grown on a large scale in the temperate regions of the world, there are many lesser-known species whose production is labor-intensive and/or whose shelf-life is short, thus inhibiting large-scale commercial exploitation. Many of these crops are confined to home gardens. However, with increasing public taste for novelty and growers prepared to innovate in order to gain the potentially high market prices, such crops are taking on an increased economic significance, although global statistics are rarely available to quantify their status. This article discusses a number of such vegetables which are representative of a diverse range of plant structures: stems (asparagus and bamboo), leaf petioles (cardoon and seakale), flower buds (globe artichokes), and fruits (okra).

Globe Artichoke (*Cynara scolymus*), Family Compositae

The globe artichoke is a herbaceous perennial about 1.5 m tall. Its large erect leaves are gray-green and it bears large thistle-like flowers about 10 cm in diameter. The floral bracts have a sharp terminal spine, although thornless cultivars are being selected for commercial production. The globe artichoke is unknown in the wild but probably derives from the cardoon (*C. cardunclus)*. It is grown primarily for its immature flower buds, which are partly edible, but young leaves may also be eaten as chards. Globe artichokes were eaten fresh and preserved for year-round use by the Romans centuries before Christ. It was later rediscovered in Italy during the reign of the Medicis, from where it was introduced into France and, via Spain, to America. It is now grown widely in southern Europe and Italy is a major producer. See **Table 1** for an estimation of world production and leading producers.

Nutritional Value and Chemical Composition

The nutritional value and chemical composition of the edible portion of the globe artichoke are indicated in **Table 2**.

Handling and Storage

Propagation is either from seed or vegetatively from suckers of selected cultivars. The crop is a short-term

perennial and it is usual to replant after approximately 3 years depending on soil and environmental conditions. The crop grows well in temperate climates but cannot survive severe frosts. The flower buds are harvested throughout the summer and early crops can be produced under protection in glasshouses or plastic tunnels.

Globe artichokes do not store well but can be kept for a few days in cold stores at 0 °C and 95% relative humidity.

Domestic and Industrial Use

Harvested flower buds are trimmed and boiled before serving entire hot or cold, usually as an hors d'oeuvre. The edible parts are the fleshy basal portions of the bud scales or bracts and the heart or basal portion of the flower. The 'choke,' consisting of immature florets, is inedible and should be discarded. The young shoots of the plant may also be forced and blanched in the dark and used as a substitute for celery in salads.

Asparagus (*Asparagus officinalis*), Family Liliaceae

Asparagus is a dioecious perennial reaching a height of about 1.5 m, grown for its edible young shoots. It originated in the eastern Mediterranean region and occurs wild in maritime regions throughout Europe.

Table 3 Estimated world production of asparagus (Mt)

It has been used for over 2000 years, first as a medicine and later as a vegetable. It is now widely grown throughout the world and, although more suited to the cooler temperate regions, it is also a valued export crop for a number of warmer countries. The main producing countries are listed in Table 3, along with estimates of recent production figures.

Nutritional Value and Chemical Composition

Data on the nutritional value and chemical composition of the edible portion of asparagus shoots are included in Table 2.

Handling and Storage

Plants are mainly propagated from seed but direct seeding in the field is not recommended as germination is slow and emergence poor. For this reason plants are usually established from 1-year-old crowns raised by specialist propagators. As asparagus is dioecious, seedlings will normally give rise to a mixture of male and female plants, of which male plants are more productive. For this reason plant breeders have selected for all male cultivars, although the alternative approach of propagating selected male plants by tissue culture is also practiced commercially. By maintaining separate male and female lines through tissue culture it is also possible to produce F1 hybrid seed and a number of improved cultivars have been introduced in this way.

Field production is usually carried out from 1-year-old crowns established in the spring which produce a canopy of fern-like leaves throughout the growing season. This replenishes and builds up the store of carbohydrates in the root system which are necessary for regrowth of new shoots the following year. In temperate regions the leaves die back and the plants become dormant prior to regrowth of shoots the following spring. The earliest shoots are harvested for consumption while later-produced ones are allowed to develop to reinstate a photosynthetic canopy to provide carbohydrates which are stored in the roots for the following year's crop. During the first year of production harvesting is light in order for the plants to build up in size. Once a plantation is established it can remain productive for 20–30 years, although commercially it is usual to replant more frequently with improved stock. The management of the crop requires a careful balance to be made between harvesting and retaining sufficient fern growth in the growing season. In warmer regions of the world, fern growth may be continuous and plants fail to achieve dormancy. It is then necessary to regulate cropping by defoliating a portion of an asparagus plantation which then initiates a crop of new harvestable shoots, a number of which must be left to reestablish new leaf growth. In this way it is possible to harvest shoots throughout the year, in contrast to temperate countries where most of the crop is produced in the spring and early summer.

Crowns may be established either in ridges or flat beds: the choice depends on a number of factors, including soil drainage and the method of harvesting, Shoots may be harvested either green or white. Shoots are cut below ground level when about 25 cm long either when only the tips are showing and the stem is blanched or alternatively when a portion of the shoot has developed above the soil surface and become green. White asparagus production predominates in Europe, South Africa, and Taiwan, whereas green asparagus is more common in North America and Australia. It is possible to advance cropping in cooler regions by using plastic film covers which are removed prior to harvesting.

Due to its high respiration rate, fresh asparagus has a short storage life but this can be extended to around 3 weeks in cool stores set at approximately 2 °C and high humidity, although there is danger of changes in flavor and texture.

Domestic and Industrial Use

Young shoots are cooked by boiling and either served entire or made into soup. The crop may also be processed by freezing, canning, or dehydrating.

Bamboo Shoot – A Large Number of Genera within the Family Graminae

The bamboos constitute a large number of species (as many as 1000 within 90 genera) of the family Graminae or grasses. These multipurpose perennials include many of the world's fastest-growing woody plants. The mature shoots are used as timber for construction purposes but the young blanched shoots of many species are also harvested as vegetables. The most important edible species are mainly natives of China and include mousou-chiku (*Phyllostachys edulis*), ku-chiku or mandake (*P. bambusoides*), and *P. dulcis*. Other important genera include *Dendrocalamus, Bambusa*, and *Sasa*. Production statistics are not readily available but the major producers include China, Japan, Taiwan, and Thailand. New plantations of *D. asper* and *D. latiflorus* have recently been introduced in Australia.

Handling and Storage

Bamboo cultivation is in many ways similar to that of asparagus in that the mature shoots provide photosynthates for the developing shoots which are harvested immature for consumption. The new shoots are blanched by a covering of compost to exclude the light and mature shoots are harvested at intervals, providing a timber crop and stimulating further shoot growth. Exposure of the young emerging shoots to light can result in the photoactivated synthesis of bitter and potentially toxic cyanogenic glycosides. Plantings, which may be dedicated bamboo plantations or intercropped with other crops, are established vegetatively by division of the older crowns. Yields may be as high as $10\,000\,\mathrm{kg\,ha^{-1}\,year^{-1}}$ of edible shoots.

Nutritional Value and Chemical Composition

Bamboo shoots form an important component of Chinese cooking in which they contribute to the mineral and vitamin components of the diet. Estimates of nutritional value and chemical composition for *Phyllostachys* spp. are provided in Table 2.

Domestic and Industrial Use

Fresh bamboo shoots are cooked by boiling for 30 min to tenderize and remove bitter flavors caused by cyanogenic glycosides. Precooked shoots are also conserved by canning and drying.

Cardoon (*Cynara cardunculus*), Family Compositae

Cardoon is a perennial crop, closely related to the globe artichoke, grown for its fleshy petioles which are sometimes blanched to render them more succulent. It is a large plant, reaching a height of around 2 m, and is thistle-like in appearance. It was introduced into the UK during the nineteenth century but has never been grown on a large scale, although it is more popular on the European continent.

Nutritional Value and Chemical Composition

Estimates of nutritional value and chemical composition of cardoon are included in Table 2. Shelf-life is short but may be extended under cold-store conditions of around 0 °C and high relative humidity.

Domestic and Industrial Use

The crop is harvested in the autumn when the petioles and thinly sliced hearts can be eaten raw in salads or boiled in salt water until tender. Shoots may be blanched prior to harvest by excluding light from the lower portion of the stem with, for example, black plastic.

Okra (*Abelmoschus esculentus*), Family Malvaceae

Okra was formerly classified as *Hibiscus esculentus*. Its center of origin was most likely West Africa but transfer to parts of India and South-east Asia occurred early on in the crop's development. It is a traditional vegetable of many tropical and subtropical countries but following its increasing popularity its production has extended to more temperate areas such as the southern USA. It is commonly known as lady's finger. Estimates of world production and leading producers are shown in Table 4.

Table 4 Estimated world production of okra (Mt)

Yemen	19 100

Source: FAO (2001) http://www.apps.fao.org.

The species is very variable; commercial cultivars are erect annuals which become woody at maturity. The plant is primarily grown for it long, finger like fruits which are harvested immature. The mature seeds are relatively large and heavy (60 g per 100 seed) and show potential in various food supplements.

Nutritional Value and Chemical Composition

Tender immature fruits provide dietary fiber, protein, and vitamin C in human nutrition. As fruits mature the increase in fiber content renders them unpalatable. The species is characterized by a high mucilage content made up of acidic polysaccharides and having viscous colloidal dispersion properties in water, valued in soup and stew preparation. Okra seeds contain 12–17% oil, mainly monounsaturated fatty acids, and have potential in cereal-based diets due to their high lysine level. They also show promise for use as meat analogs as their protein concentrates and seed flour are more soluble than commercial soya products. Nutritional value and chemical composition are summarized in Table 2.

Handling and Storage

Okra requires a long growing period of relatively high temperatures. It is sensitive to frosts and commercial production is confined to summer months in subtropical and warmer parts of the temperate zone. Most cultivars require short day lengths for floral initiation and day-neutral selections are therefore required for cultivation in temperate countries. Commercial selections are also available based on visual characters

such as absence of spines and fruit color. The crop is established from seed sown *in situ* as soon as spring temperatures are favorable. Fruit production is not synchronized and selective harvesting must be carried out manually throughout the summer. Exudates from the fruit surface and other plant parts can cause skin inflammation.

Fresh fruits have a short storage life and suffer chilling damage at 6 °C and below. Controlled-atmosphere storage at 5% oxygen and 10% carbon dioxide at 11 °C and 90–93% relative humidity extend shelf-life to 2 weeks.

Domestic and Industrial Use

The fresh immature fruits may be boiled or fried or used as a thickening agent in soups. Processing may be by canning and freezing and cultivars are selected for these outlets. Sun drying of fruit is conducted in developing countries for off-season use.

Seakale (*Crambe maritime*), Family Cruciferae

Seakale is a perennial cultivated for its edible leaves and young shoots. It has a delicate flavor when forced and can be used as a substitute for asparagus. The species is adapted to cool maritime climates and has been collected from the wild since early times. Cultivation has been recorded since the early nineteenth century, although on a relatively small scale. Traditionally, seakale roots were lifted in the autumn and forced in cold frames and covered with horse manure topped with straw. Modern techniques involve raising crowns under field conditions prior to forcing in the dark under controlled environments of 15 °C and high humidity. The young succulent shoots are harvested about 4 weeks later when they will have reached a length of approximately 20 cm. They may be eaten raw in salads or lightly boiled, as for asparagus.

Handling and Storage

The crop is propagated by seed or vegetatively from root cuttings, the latter resulting in earlier and more uniform establishment. Once plants have built up sufficient carbohydrate storage within its root system, they are ready for forcing. This is achieved by covering the dormant crowns in the autumn to produce a crop of young blanched shoots the following spring. Following harvest, plants may remain *in situ* and the process is repeated for the following year. Earlier harvesting can be achieved by lifting crowns and forcing under protection at warmer temperatures. The young freshly harvested shoots do not store well.

Domestic and Industrial Use

Seakale has a unique nutty flavor and crisp texture. It may be used raw in salads or the young shoots may be boiled and used in a similar manner to asparagus.

VEGETABLES OF TROPICAL CLIMATES

Contents

Commercial and Dietary Importance

S K Roy and A K Chakrabarti, Indian Agricultural Research Institute, New Delhi, India

Background

Tropical vegetables are many and varied. They contain a large number of leafy and legume vegetables, some of which are not only rich in proteins but also rich in several vitamins, minerals, and fiber. Tropical root vegetables are rich sources of carbohydrate, and they serve as a staple food in many tropical countries. They have a long shelf-life and have a good export potentiality. Some tropical fruits, e.g., banana, jack fruit, bread fruit, papaya, are consumed as vegetables at the tender stage. These fruit vegetables are rich in carbohydrate, phenolic compounds, and dietary fiber as well as minerals and vitamins. Some of the tropical vegetables are known to have curative properties for certain ailments and are popular in traditional medicine in several countries.

General Nutrient Composition

Tropical vegetables include many roots and tubers like sweet potato, cassava, taro, and yam, which are rich in starch and serve as staple foods in many countries. Most leafy vegetables are rich in carotene (provitamin A), riboflavin (vitamin B_2), and minerals. It has been estimated that 100 g of tropical leafy vegetables can provide 60–140 mg of ascorbic acid (vitamin C), 100 μg of folic acid, 4–7 mg of iron and 200–400 mg of calcium. Consumption of 100 g of leafy vegetables per day can supply 15% or more of the total protein intake. Only 30 g of the leaves will be sufficient to meet the requirements of vitamin A and C. The B vitamins (thiamin, riboflavin, and niacin) will increase by 15–30%, and the entire requirement of folic acid will be met. (*See* **Carotenoids**: Physiology.)

The nutrient composition of the major tropical vegetables is listed in Tables 1 and 2 and is discussed in detail in the section Importance of Specific Tropical Vegetables. The essential amino acid profile of selected, protein rich tropical leafy vegetables is given in Table 3. Refer to individual nutrients.

Dietary and Commercial Importance

The general importance of vegetables in commerce and diet, as discussed for temperate vegetables, holds for the tropical vegetables also. Their commercial value and importance in different diets are discussed in the section Importance of Specific Tropical Vegetables. (*See* **Vegetables of Temperate Climates**: Commercial and Dietary Importance.)

International Trade

Several tropical vegetables, such as sweet potato, taro, yam, dried chilli, squash, and pumpkin, have a good keeping quality. These vegetables are cultivated in the tropical countries of Asia, Africa, and South America, and are new to many people of Europe and North America. These vegetables have added attractions in those countries, and their export is growing steadily.

Some vegetables like the bitter gourd have a therapeutic value and have been in use in traditional medicine in India and China for centuries. Scientific evidence that bitter gourd contains some phytoceutical chemicals that reduce blood sugar rapidly has stimulated interest in Western countries and thus increased its export potential.

Some vegetables like tomato, capsicum, cucumber, and French bean are in great demand in Western countries during the winter. The tropical and subtropical countries that can grow these vegetables in the open during winter have been able to meet the demand to a great extent by exporting these commodities. Those vegetables that are grown in the open fetch a higher price than those grown under protective cover because of their better quality attributes. With the improvement in handling and storage of vegetables by the introduction of modern

Table 1 Nutrient composition of tropical vegetables per 100-g edible portion

Crop	Macronutrients					Vitamins				Minerals		
	Energy (kcal)	Moisture (g)	Protein (g)	Fat (g)	Carbohydrate (g)	Thiamin (mg)	Riboflavin (mg)	Niacin (mg)	Ascorbic acid (mg)	Ca (mg)	P (mg)	Fe (mg)

techniques like cold chain, refrigeration, and controlled-atmosphere storage, and with the development of rapid transport by land, sea, and air, trade in such highly perishable commodities is growing steadily. (*See* **Controlled-atmosphere Storage**: Effects on Fruit and Vegetables.)

The USA imports tropical vegetables from Mexico and other Latin American countries, the European countries import these vegetables from the Middle East and some countries of North Africa, and the Persian Gulf countries import vegetables mostly from the Indian subcontinent and other South Asian countries. Apart from fresh vegetables, processed products enjoy a good international trade. Taiwan is the major country exporting processed vegetables to several countries.

Information on international trade in some of the vegetables dealt with is meager, but from the point of view of their nutritive value, these vegetables deserve attention for future exploitation in the world market.

Importance of Specific Tropical Vegetables

The importance of individual vegetables in nutrition, diet, commerce, and world trade is discussed under separate groups.

Beans

The major crops are the cluster bean (*Cyamopsis tetragonoloba*), cowpea (*Vigna unguiculata*), French bean or kidney bean (*Phaseolus vulgaris*), hyacinth bean (*Lablab purpureus*), lima bean (*Phaseolus lunatus*), and winged bean (*Psophocarpus tetragonolobus*). Beans (also called legumes) are second only to cereals as a source of human food. Nutritionally, they are rich in proteins, soluble carbohydrates, and vitamins. The essential amino acid composition of tropical beans is given in Table 4. Most beans are deficient in sulfur-containing amino acids, and a few are deficient in tryptophan. Sprouted seeds contain more vitamin, particularly vitamin C. Consumption of food legumes has been reported to decrease the concentration of cholesterol. (*See* **Beans**; **Legumes**: Legumes in the Diet.)

Legumes offer a variety of edible products. Mature seeds, known as pulses, serve as the major item of diet in the Indian subcontinent and China. Immature pods along with seeds of all the beans listed, except lima bean, are used as a cooked vegetable before the fibers lignify and harden. Lima bean seeds (green or dried) are boiled or baked and used as a side-dish. Only lima beans and French beans are canned or frozen. Canned beans in tomato sauce are an important item of commerce.

Cucurbits

Cucurbits constitute the largest group of tropical vegetables, consisting of the bitter gourd (*Momordica charantia*), bottle gourd (*Lagenaria siceraria*), cho cho or chayote (*Sechium edule*), cucumber (*Cucumis sativus*), Indian squash (*Praecitrullus fistulosus*), ivy

Table 3 Essential amino acid content (g) of vegetable leaves per 100 g of protein

Source: Duke JA (1981) *Handbook of Legumes of World Economic Importance*. New York: Plenum Press; Summerfield RJ and Roberts EM (eds) (1985) *Grain Legume Crops*. London: Collins.

gourd (*Coccinia indica*), kakrol (*Momordica dioica* and *M. cochinchinensis*), muskmelon or cantaloupe (*Cucumis melo*), pumpkin (*Cucurbita moschata*), summer squash (*Cucurbita pepo*), winter squash (*Cucurbita maxima*), ridge gourd (*Luffa acutangula*), sponge gourd (*Luffa cylindrica*), snake gourd (*Trichosanthes cucumerina*), pointed gourd (*Trichosanthes dioica*), watermelon (*Citrullus lanatus*), and wax or ash gourd (*Benincasa hispida*). (*See* **Melons, Squashes, and Gourds**.)

Cucurbits, in general, are not rich in calories, minerals, or vitamins. There are a few exceptions like the bitter gourd, which is rich in vitamin C, the squash, pointed gourd, and muskmelon, which contain large amounts of carotene (provitamin A), the kakrol, which is high in protein, and the pointed gourd, which is rich in calcium. Some of the species of *Cucumis, Luffa, Coccinia*, and *Momordica* exhibit varying degrees of bitterness in the fruits, leaves, and twigs, caused by terpenes called momordicins. Owing to its bitter principle, the bitter gourd is used in the Ayurvedic system of medicine in India. Scientists have isolated a hypoglycemic phytoceutical, cheratin, in the fruit, which causes a lowering of blood sugars. (*See* **Hypoglycemia (Hypoglycaemia)**.)

The cucumber is mostly used as a salad crop. Immature fruits, also called gherkins, are pickled in various ways. Muskmelon and watermelon are used fresh as dessert fruits, alone or in combination with other fruits in salads. Watermelon rind is pickled. In Russia, beer is produced from watermelon juice. Pumpkin and squash fruits are cooked with other vegetables or used in pie-making. Luffa, bottle gourd, ash gourd, bitter gourd, pointed gourd, and Indian squash are cooked, and some are fried for the preparation of various dishes. Mature ash gourd fruits are used in making sweet candy in India. Leaves, twigs, and flowers of squash, pumpkin, and ash gourd are consumed in the tropics.

Most cucurbits are used fresh. Some of the cucurbits, such as bitter gourd, pointed gourd, coccinia, squash, and pumpkin, are canned and some frozen. Squash, pumpkin, melons, and cucumber are shipped to distant markets. During the winter, cucumbers from tropical countries are exported to Europe and North America. A variety of muksmelon called Sarda, which is grown in Afghanistan, is exported to several countries.

Leafy vegetables

In the tropics, apart from cultivated leafy vegetables, a large number of leaves from different sources such as perennial trees, aquatic plants, and annuals other than vegetable crops are consumed. The most important of these are amaranth (*Amaranthus* sp.), Basella (*Basella alba*), bitter gourd (*Momordica charantia*), bottle gourd (*Lagenaria siceraria*), cassava (*Manihot esculenta*), Chinese cabbage (*Brassica chinensis*), cowpea (*Vigna unguiculata*), drumstick (*Moringa oleifera*), fenugreek (*Trigonella* sp.), jute (*Corchorus olitorius*), mustard and rape (*Brassica* sp.), pumpkin (*Cucurbita moschata*), purslane (*Portulaca oleracea*), sweet potato (*Ipomoea batatas*), taro (*Colocasia esculenta*), water spinach (*Ipomoea aquatica*), and winged bean (*Psophocarpus tetragonolobus*). Most leafy vegetables are rich in carotenes, fibre, and minerals. Several studies have demonstrated an inverse relationship between a diet rich in carotenoids and lung cancer. Dietary fibre may help prevent certain cancers, such as cancer of the colon and rectum. (*See* **Amaranth**; **Mustard and Condiment Products**.)

Some of the leafy vegetables contain toxic ingredients. Cassava leaves contain glucosides that may liberate hydrocyanic acid by the action of enzymes. It is highly volatile, and therefore, any preparation that involves heating will render the leaves harmless. Amaranth, *Portulaca, Celosia*, and *Basella* contain

appreciable quantities of oxalic acid and oxalates. Oxalic acid converts calcium from food consumed to insoluble calcium oxalate, rendering it unavailable for absorption. In amaranth, under certain conditions, the nitrate content of leaves exceeds tolerable limits. Both of these problems can be eliminated by boiling and discarding the cooking water. Calcium oxalate, present in the form of fine crystals in the leaves of taro, causes itching of the fingers and a pricking sensation on the tongue and throat. This can be removed by adding a little tamarind or citric acid to the cooking water and then discarding the water. (*See* **Cassava**: The Nature of the Tuber; **Plant Antinutritional Factors**: Detoxification.)

Leafy vegetables are mostly used fresh as they are highly perishable. They are fried or boiled singly or in combination. Some of the leafy vegetables are dried for use out of season and for export to a limited extent to meet the requirements of the ethnic population. Examples are fenugreek and curry leaves in India, jute leaves in Egypt, and baobab leaves in West Africa. Mustard leaves are considered an item of delicacy in the Indian subcontinent and are exported, after canning, for the ethnic population abroad. Some of the dried and powdered leafy vegetables, which are rich in carotene and minerals, can be blended with cereal flours to improve the nutritional status of people of the developing world who often suffer from nutritional deficiency diseases.

Okra

Okra (*Abelmoschus esculentus*) fruits are not a rich source of nutrients, but they do supply some minerals and vitamins. A considerable amount of okra is processed by drying, freezing, canning, and pickling. Okra pods have a mucilaginous substance that interferes with processing and remains in the canned product also. To overcome this, slices can be canned in tomato sauce.

A considerable quantity of okra is air-freighted from India to distant markets in the Persian Gulf countries.

Solanaceous Vegetables

Major crops are tomato (*Lycopersicon esculentum*), brinjal or egg plant (*Solanum melongena*), sweet pepper or *Capsicum* and hot pepper or chilli (*Capsicum annum*). (*See* **Potatoes and Related Crops**: Fruits of the Solanaceae; **Tomatoes**.)

In most countries, the tomato ranks second after the potato in production and consumption. It is a low-calorie vegetable and is a good source of vitamins A and C. The content of these vitamins is less in fruits ripened off the vine than in those ripened on the plants. The red color of tomato is due to a carotenoid pigment, lycopene. Egg plants contain substantial amounts of some vitamins and minerals. Several chemicals that help lower cholesterol have been detected in brinjal in a recent study. Brinjal is also rich in bioflavonoids, which can provide protection from stomach cancer. Peppers are rich in vitamins A and C, and the pungency of hot peppers is due to capsaicin.

Tomatoes serve as the major ingredient of salads. Tomatoes are commercially the most important vegetable used for processing to make sauce, ketchup, purée, etc. and are also preserved by canning. In the present fast-food era, the tomato is an indispensable ingredient of hamburgers, pizzas, and pastas. Sweet peppers are boiled, stuffed, and baked to produce various dishes. Hot peppers are dried and used as spices, mostly in the tropics. They are also pickled in oil. The mild, nonpungent varieties of chilli, commonly known as paprika, are valued chiefly for their brilliant red color and mild flavor and are used for coloring dishes. Chilli extracts are used in the preparation of ginger beer and are also used in the preparation of chilli sauces. The eggplant is an important vegetable of Asia, and the fruits are fried, roasted, baked, or cooked to prepare various dishes. Boiled and hollowed eggplants are stuffed with potato, fish, or meat and are also canned.

The tomato occupies a prominent position in world trade, mostly in the form of processed finished products or as an intermediate, tomato paste. Some quantities of fresh fruits are also air-freighted. According to an FAO estimate, the total world export of tomato and all types of pepper (*Capsicum*, chilli, paprika, etc.) during 1997 was 2.80 million tonnes and 0.21 million tonnes, respectively. The European countries rank first in tomato export, exporting 1.99 million tonnes with a market share of 71.07% and for pepper, Asian countries are the largest exporters, with a 61.90% market share, exporting 0.13 million tonnes. India is the largest exporter of dry chillies and oleoresin. There is considerable demand for paprika powder in the Western countries.

Starchy Roots, Tubers, and Corms

The major root crops are sweet potato (*Ipomoea batatas*) and cassava or manioc (*Manihot esculenta*), a tuberous crop is yam (*Dioscorea* sp.), and the corm crops are arum or taro (*Colocasia esculenta*), tannia (*Xanthosoma* sp.), and elephant-foot yam (*Amorphophallus campanulatus*). These crops are important sources of energy in many tropical countries. These vegetables are high in starch. The yellow-fleshed sweet potato is rich in carotene (provitamin A). Cassava and sweet potato contain considerable amounts of vitamin C. Cassava roots contain a toxic

hydrocyanic glucoside, which, on enzymatic action, liberates HCN; the harmful effect can be destroyed by peeling, washing, and boiling. Some species of *Dioscorea* contain a toxic alkaloid, dioscorine, which can be destroyed by roasting or boiling. (*See* **Alkaloids**: Toxicology.)

Sweet potatoes are baked, boiled, fried, or prepared mixed with other vegetables. They are used for the production of alcohol. Taro, tannia, cassava, and yam are fried, roasted, baked, or boiled for the preparation of various dishes. Taro is recommended for gastric patients, and its flour is a good baby food. In Hawaii, a fermented product prepared from taro is very popular. In Africa, a paste prepared from taro, after boiling, is consumed. The leaves and young shoots are used as greens. Cassava roots are processed to produce starch and tapioca granules. Yam is used for the preparation of chips, flakes, and flours. A sapogenin compound called diosgenin, present in some species of yam, is used for the production of cortisone and contraceptive drugs.

Cassava is an important staple food of Africa. Being perishable in nature, it is mostly consumed locally where it is grown. Some fresh cassava roots are air-freighted to the USA from Venezuela. Yams are also a staple food in some African countries and South-east Asia. Mostly, they are consumed locally where they are produced, but some quantities are shipped to distant markets. Taro and tannia can be shipped to distant markets because of their good keeping qualities. Taro is more popular in Asia and tannia in Africa.

Other Vegetables

There are several other vegetables, like plantain (*Musa paradisiaca*), bread fruit (*Artocarpus altilis*), jack fruit (*A. heterophyllus*), papaya (*Carica papaya*), drumstick (*Moringa oleifera*), and lotus (*Nelumbo nucifera*), which are popular in the tropics. The plantain is high in carbohydrate and provitamin A. The fruits, pseudostem, and inflorescence are cooked, as they contain a considerable amount of tannin, which renders them unpalatable even when ripe because of astringency. The fruits are boiled or cooked to prepare various dishes and are also used for making alcohol. The inner sheaths of the pseudostem of banana are cooked in India, and the immature, male flower buds, after removal of the boat-like fibrous bracts, are cooked in many South Asian countries. (*See* **Papayas**.)

Immature bread fruits and jack fruits are used as vegetables in many countries of Asia; the fruits, when tender, contain a high level of starch. After removing the skin and outer layer of the fruit, the flesh is sliced or cubed and then boiled, cooked, or fried. In India, seeds of mature jack fruit are cooked, and drum stick is a popular vegetable. Lotus rhizomes, commonly called roots, are cooked in many Asian countries.

Maize (also called sweetcorn) is popular in Western countries and is rich in starch. The tender cobs are consumed raw, boiled, or roasted and can be canned or frozen.

These vegetables have local demand and are mostly consumed where they are produced.

Root Crops of Uplands

S K O'Hair, University of Florida, IFAS, Tropical Research and Education Center, Homestead, FL, USA
D N Maynard, University of Florida, IFAS, Gulf Coast Research and Education Center, Bradenton, FL, USA

Introduction

Highland and midaltitude tropical root crops include several little-known crops that are regionally valued as stable foods in the South American Andes. Nearly all are ancient foods, domesticated possibly by pre-Incan people. All are either solely or mainly propagated through vegetative cuttings. It has been speculated that somatic mutations are a likely source of many of the varieties, since flowering and seed set are rare in many. Several are considered to be underexploited and deserving of considerably more scientific and commercial attention. Since these crops are mostly propagated vegetatively, appropriate methods to control the spread of diseases should be observed.

Ahipa

Ahipa (*Pachyrhizus ahipa* (Weddell) Parode, Family Fabaceae), also known as ajipa or Andean yam bean, is one of the few leguminous plants cultivated for its edible roots. When *Rhizobium* is present, the plant can fix nitrogen. Its crisp, white roots are very similar to those of its close relative, jicama (*P. erosus*).

Production is mainly limited to Peru and Bolivia at elevations of 1500–3000 m. Although there is little commercial importance for this crop, the potential exists for it to be grown as a vegetable in temperate regions for use as a fresh or salad vegetable. There are no recorded varieties of this crop. However, landraces are known to exist.

Each plant produces one enlarged root weighing 0.5–0.8 kg. A relatively thin, pale yellow skin covers the white flesh. Root production is significantly increased by manual removal of entire inflorescences.

Most plant parts are toxic, except for the enlarged edible storage root. Roots can be eaten raw or cooked. Specific nutritional data are not known. However, they are likely to be similar to its close relative, jicama.

Little is known about either handling or storage after harvest. Roots are normally harvested as needed since they lose moisture quickly after harvest.

There are no current industrial uses for the crop.

Arracacha

The arracacha or Peruvian carrot (*Arracacia xanthorrhiza* Bancroft, Family Apraceae) is grown for its edible roots, which have been described by the noted naturalist, David Fairchild, as one of the tastiest of all vegetables.

Of the crops covered in this article, arracacha production has spread to other food production areas the most. Current production areas include much of South America, Puerto Rico, Mexico, and parts of Africa. In the Andean region, production is found between 1800 and 2600 m. At higher latitudes, production is found at lower elevations. Commercial trade is limited to local markets. Plants are normally propagated vegetatively as clones of three general types: white, yellow, and purplish. Viable seeds are produced on older plants, resulting in possibilities for numerous varieties.

Storage organs arise as enlargements of a main cylindrical rootstock with enlarged edible lateral, parsnip-like roots near the base of the plant. The young blanched stems can also be eaten.

Peeled roots have nutritional qualities similar to other root and tuber crops (Table 1). Refer to individual nutrients.

Harvested roots have a short shelf-life of 1 week or less. Thus, roots are harvested as needed. However, as the roots age, they become fibrous and, eventually, unpalatable. Little research has been carried out regarding postharvest handling of the roots. Refrigerated storage at 3 °C extends the storage period. They can be frozen, like cassava, for shipment to foreign markets. (*See* **Cassava**: The Nature of the Tuber.)

Table 1 Average composition (per 100 g of raw product) of tropical root crops

Constituent	*Arracacha*	*Yacon*	*Canna*	*Oca*	*Mashua*	*Ulluco*
Moisture (g)	72	79	75	82	85	86
Carbohydrate (g)	25		24	16	11	11

Ash (g)	1.6	1	1.4	0.5	0.5	0.7
Calcium (mg)	24					
Phosphorus (mg)	65					
Iron (mg)	0.7					
Vitamin A (IU)	40					
Ascorbic acid (mg)	21.5					

Data from Kay DE (1973) *Root Crops*. London: Tropical Products Institute; King SR (1987) Four endemic Andean tuber crops: promising food resources for agricultural diversification. *Mountain Research and Development* 7: 43–52; National Research Council (1989) *Lost Crops of the Incas*. Washington, DC: National Academy Press, with permission.

There is no commercial processing of arracacha. However, it is a popular source of carbohydrate among children. Starch can be extracted from both the main rootstock and lateral roots.

Edible Canna

Achira (*Canna edulis* Ker-Gawler Family Cannaceae), sagu, or Queensland arrowroot, is similar in appearance to its close relative, the ornamental canna. A related species grown in South-east Asia is *C. discolor* Lindl.

Production is found throughout the low- to mid-altitude tropics, with most concentrated in South America, especially in Peru, where it is a valued crop. Its commercial importance is limited to starch production in a few regions and production as a staple food in parts of Peru, Ecuador and South-east Asia. Starch extracted from rhizomes is used to produce noodles in Asia. Two main types are described, one with white corms and green foliage, and a second with violet-skinned corms. There are many variations in plant characteristics.

The storage organ forms at the lower part of the stem, at or below the soil surface, forming a corm. Occasionally, plants form a rhizome, which may be a factor of clonal variation or environmental conditions.

Nutritional composition is similar to most of the root and tuber crops (Table 1). The rhizomes are high in food value, containing 70% carbohydrate, 12% protein, and 22% fiber on a dry-weight basis. Edible canna is one of the few root and tuber crops that can be eaten raw. Thus, nutritional value is maximized if the corms are eaten uncooked. The starch granules are among the largest known and considered to be easily digested by infants and invalids.

Little is known about the handling and storage of this crop. Usually, the plant is harvested as needed. However, as the corms age beyond 8–10 months, the fiber content increases.

Mechanization exists for most stages of production, and the crop is widely adaptable. Thus, there is potential for greater exploitation of this crop as a source of speciality starch.

Maca

The turniplike maca (*Lepidium meyenni* Walp., Family Brassicaceae) is among the least-known of the Andean root and tuber crops. There are at least 29 cultivated varieties in the Andes.

Nearly all of the production is between 3500 and 4000 m in the Peruvian and Bolivian Andes. Because of their altitude constraints, the potential for commercialization is limited. Elite plants are selected and cultured with added care to procure botanical seed for the next crop. Yellow-fleshed types are preferred.

Storage organs arise as enlargements of the root region of the plant.

Roots have high concentrations of sugars and starch. Low quantities of alkaloids, fatty acids, tannins and saponins in the roots have been reported. (*See* **Alkaloids: Properties and Determination**; **Saponins**; **Tannins and Polyphenols**.)

Roots are aromatic and occasionally used as a flavoring agent. They are dried and stored for 1 or more years in protected, cool locations. However, the flavor deteriorates over time. In Peru maca is processed and marketed for its medicinal and therapeutic properties.

Mashua

Mashua or añu (*Tropaeolum tuberosum Ruiz* and Pav., Family Tropaeolaceae) is little known outside of its native production areas in the high Andes of South America. However, it resembles its close relative, the ornamental nasturtium.

Most of the production is limited to altitudes above 3000 m in Bolivia and Peru, with little commercialization. The area of production in Peru is estimated to be 4000 ha. Plants are vegetatively propagated as clones, with over 100 being recognized by their variation in tuber coloration.

Edible tubers are conical or ellipsoidal, 5–15 cm in length and 3–6 cm in width. Skin colors can be very attractive, ranging from white or yellow to red or purple. The flowers are also edible.

In comparison with other root and tuber crops, some mashua tubers have a relatively low moisture content of 55%. Most are comparable with the other root and tuber crops (Table 1), yet genetic variation in protein content and quality has been documented. Tubers provide an adequate balance of amino acids, with leucine being low (Table 2). Some clones are reported to have medicinal properties through the production of a mustard oil, which is used for treatment of kidney and liver diseases. Others reportedly have low degrees of antiaphrodisiac properties. Nutritional information for the flowers is not available. (*See* **Protein**: Quality.)

Little is known about handling and storage, since there is little commercial trade in this crop. Typically, one would expect the handling and storage requirements to be similar to those of potato. In the high Andes, tubers are frozen like chuño, a freeze-dried whole tuber that can be reconstituted in water.

Currently, there is little or no production of mashua for industrial purposes. Some cultivars have pesticidal properties.

Table 2 Average amino acid content in tropical root crops

Amino acid	*Amino acid content (mg per gram of protein)*		
	Oca	*Mashua*	*Ulluco*
Lysine	58	38	48
Threonine	46	23	26
Valine	37	36	35
Isoleucine	38	31	41
Leucine	56	39	49
Phenylalanine plus tyrosine	62	26	60
Tryptophan	7	5	9
Methionine plus cystine	30	14	30

Data from King SR (1987) Four endemic Andean tuber crops: promising food resources for agricultural diversification. *Mountain Research and Development* 7: 43–52, with permission.

Oca

Of the Andean root and tuber crops, oca (*Oxalis tuberosa* Molina, Family Oxalidaceae) is possibly the oldest and is second in importance in Andean regions only to potato. However, it is considered to have the potential of great consumer appeal, because of the brilliant color and pleasant flavor of the tubers.

Until recently, production of oca has been limited to altitudes of 2500–4000 m the Andes and parts of Mexico. In Peru, there are more than 16 000 ha in production. It has recently been commercialized in New Zealand. Reportedly, the potential exists for it to become a temperate region crop. In the Andes, there are approximately 50 cultivated clones. Andean germplasm collections have over 400 accessions.

Storage organs are formed on underground stolons, resulting in the production of elongated or rhizomic tubers 3–20 cm long.

Large amounts of variation in nutritional qualities are present among oca clones. In general, they are considered to have a food value comparable with potato (Table 1). The protein is of a high quality, being low in valine and tryptophan (Table 2). The carbohydrate component is largely sugar. Some tubers have levels of oxalic acid that are detectable when tubers are eaten raw, giving them a slightly acid taste. Oxalic acid concentrations can be as high as 500 p.p.m., but are generally only 1% of those found in spinach.

Little information on handling and storage is available. In the Andes, tubers are placed in the sun for a few days to increase the sugar content. However, owing to the high moisture content, handling should include means to control moisture loss. Alternatively, the tubers can be dried, producing a high-carbohydrate food. In the high Andes, tubers are 'freeze-dried' and stored for several years. (*See* **Drying**: Drying Using Natural Radiation; **Freeze-drying**: The Basic Process.)

Currently, there are no industrial uses for the crop. The starch is considered to be a quality product.

Ulluco

Ulluco or ullucu(s) (*Ullucus tuberosus* Caldas, Family Basellaceae) is one of the more popular members of the Andean root and tuber crops, being considered a delicacy by many.

Production is mostly limited to the Andean region. Unlike most of the other crops discussed in this article, there is commercial trade of this crop in larger South American cities. There are more than 15 000 ha under cultivation in Peru. Plants are propagated vegetatively as clones, with most being separated according to their flesh color, which almost covers the color spectrum. It is estimated that there are at least 50–70 distinct clones in the Andean region.

Tubers, resembling small potatoes, are produced on underground stolons. Most are elongated or slightly curved. The tuber skin is thin and soft, with inconspicuous buds. The flesh is low in fiber content.

The nutritional value of ulluco is similar to the other crops discussed in this article (Table 1). Undocumented reports suggest a much higher protein content. The amino acid balance is adequate; valine and tryptophan content are low (Table 2). Detectable levels of saponin are present in plant parts.

Tubers are usually harvested as needed. If stored, they must be kept in dark locations. In the light, tuber skins turn green, like potatoes stored in areas exposed to light. In the high Andes, tubers are 'freeze-dried.'

Tubers are dried and milled into flour. They can also be used to make chuño.

Yacon

Yacon or jiquima (*Polymnia sonchifolia* Poepp & Endl., Family Asteraceae), a native of North America, is a perennial herb being somewhat similar to Jerusalem artichoke.

Most of the yacon production is in the tropical and subtropical Andes of Peru, Bolivia, Colombia, Ecuador, and Argentina at altitudes of 900–2800 m. There is currently little commercialization of the crop. However, it has been proposed as a potential source of high-fructose syrup. The crop is propagated vegetatively as clones, which are separated according to shape and chemical composition.

Tuberous, fusiform roots 20 cm in length and 3 cm in diameter are produced at the base of the plant. The raw flesh is crisp. The main stem of the plant is used as a cooked vegetable.

Tuberous roots contain about 46 % inulin on a dry weight basis. They are also higher in protein than

most other tropical root and tuber crops (Table 1); and they are a good source of potassium. Dried leaves contain 11–17% protein and could be used for livestock feed.

Undamaged roots have a long shelf-life. Roots can also be dried for extended storage.

An alternative use for yacon is as a fodder crop. The inulin has commercial value as a sweetening agent for diabetics and in the production of fructose. (*See* **Fructose**.)

Root Crops of Lowlands

D N Maynard, University of Florida, Bradenton, FL, USA
S K O'Hair, University of Florida, Homestead, FL, USA

Crops

Low-land root and tuber crops, which include sweet potato, yam, and, to a lesser extent, yam bean, provide a low-cost and readily available carbohydrate source in the diets of large populations in the tropics. Their value, both economic and nutritional, is based on production of starch-filled storage organs. Furthermore, their usefulness is extended somewhat through in-ground or common storage to provide high-caloric food during drought or other times of shortage.

Sweet Potato

The sweet potato (*Ipomoea batatas* (L.) Lam., Family Convolvulaceae) can be grown throughout the subtropics and tropics for use as a staple food source. Its growth habit is conducive to interplanting with other food crops, and vine tips are often used as a green vegetable in many cultures.

Global Distribution, Commercial Importance, and Varieties

Although widely distributed, sweet potato production historically has been concentrated in Asia; in 2001, production there accounted for about 90% of world production. Africa, the second most important area, contributed only about 7% of world production (**Table 1**). The area devoted to sweet potato production has decreased considerably in the last 20 years; however, yield increases of more than 100% in Asia have more than compensated for the smaller area. Asian yield increases can be attributed in part to improved varieties and production technology developed at the Asian Vegetable Research and Development Center, Tainan, Taiwan. In other parts of the world, sweet potato production area, yields, and total production have remained about the same or have declined.

There is little international trade in sweet potato because of its relatively low value as a world crop, the relatively short postharvest life of uncured roots, limited use in industrial products, and legal restraints associated with the introduction of plant diseases and insects with the roots. In the tropics, sweet potatoes are usually left in the ground until needed and sold in local markets within 1–2 weeks of harvest.

Distinct sweet potato clones that differ in growth habit and pigmentation of vines and roots have been selected by small growers in the tropics. The clones are named according to the source of planting stock or according to some characteristic that distinguishes it from other clones. Thus, a single clone may be known under several different names.

However, cultivars developed by breeding in the USA, the International Institute for Tropical Agriculture in Nigeria, and the Asian Vegetable Research and Development Center in Taiwan are known by specific names and/or number. The principal cultivars grown in the USA are Beauregard in the southeast and Garnet and Beauregard in California.

Morphology and Anatomy of the Root

An enlarged tuberous root, possessing typical root structures and the unique capability of initiating adventitious shoots, is the principal edible portion of the plant. Shortly after transplanting, some fibrous roots begin enlarging, probably in response to endogenous growth regulators. The length of the enlarged root is largely achieved in the first 8 weeks after planting, whereas increases in diameter continue as long as photosynthate is produced by the aerial portions of the plant. Storage parenchyma accounts for a major portion of the storage root, but cortex, secondary phloem, and secondary phloem parenchyma also account for a significant portion of the storage root.

Root shape varies from elongated to nearly globular; the skin color may be white, tan, yellow–orange, salmon, red, or copper, and the flesh color may be white, yellow–orange, orange, salmon, purple, or red. Normally, each plant produces five to 10 roots that usually vary in weight from 100 to 300 g each.

Nutritional Composition

In common with other root crops, sweet potato roots are rich in carbohydrate, which provides high energy value (Table 2). The yellow and orange-fleshed sweet potatoes are exceptional sources of pro Vitamin A, but white-fleshed types do not provide this advantage. Sweet potatoes also provide a good source of vitamin C. A 100 g serving may provide 25–40% of the recommended dietary allowance (RDA) depending on cultivar, root size, harvest date, and storage conditions. Sweet potato is not a superior source of amino acids, but generally exceeds yam and yam bean in amino acid composition (Table 3). The sweet potato protein and amino acid pattern is affected by cultivar, environment, cultural management, and growth duration. Nonetheless, it is generally high in lysine and provides a supplemental protein to cereals. Genotypic variability in provitamin A, ascorbic acid, protein content, and protein quality offer the possibility of enhanced nutritional quality through plant breeding. The potential for increased carbohydrate production from sweet potato can be best achieved by total yield increases derived from improved cultivars and production practices. In order to achieve acceptable levels of digestibility, it is necessary to cook sweet potato roots by boiling or roasting, because of the presence of a trypsin inhibitor in raw roots.

The nutritional composition of sweet potato leaves complements that of the roots (Table 2). Leaves are much lower in carbohydrates and food energy but are substantially higher in the essential elements calcium, iron, magnesium, phosphorus, and potassium. Leaves have a higher thiamin, riboflavin, niacin, and vitamin B_{12} content than roots but are inferior to roots in ascorbic acid and pro Vitamin A content.

Handling and Storage

Harvest of sweet potato may be on an as-needed basis by hand-digging of the roots to be eaten or sold on local markets; this is the pattern in much of the tropics. In the USA, and elsewhere where sweet potatoes are grown on an extensive commercial basis, they are harvested when the maximum number of roots is appropriate to be marketed; depending on cultivar and environmental conditions, this may vary from 90 to 130 days after transplanting. In this case, the entire crop is harvested mechanically on a once-over basis.

Sweet potato roots are subject to a number of postharvest rots that gain entry through wounds inflicted during harvest. Accordingly, it is critical to use harvesting methods that minimize wounds. Fortunately, harvest by hand, as in small-scale tropical agriculture, results in little root damage, so roots can be sold within the usual 1- or 2-week marketing period. With mechanical harvesting and the need for long-term storage to provide orderly marketing as in the USA, it is necessary to insure healing of wounded areas of the roots. This is accomplished by curing, i.e.,

Table 2 Composition (per 100 g of raw product) of tropical root crops

holding the roots at 29 °C and 90–95% relative humidity (RH) in a well-ventilated storage for 4–7 days. Subsequent storage at 13–16 °C and 85–90% RH will maintain sweet potatoes in good condition for several months.

Industrial Uses

Although there is potential for numerous industrial products, only canning of whole, sliced, or puréed sweet potatoes for long-term preservation has achieved any measure of commercial importance. Dehydration of fresh or cooked chips by sun-drying is practiced in some tropical countries for preservation or later conversion to flour. Commercial starch production has been tried in several countries, including the USA, but has not proved to be economically feasible. The same has been true of glucose, pectin, and carotene production on a commercial basis. Recently, there has been considerable interest in utilizing sweet potato roots as a raw material for alcohol production. Where the environment permits continuous sweet potato production, yields surpass those of cassava, and ease of mechanization favors sweet potato production. However, it is likely that cassava or other crop products will be more suitable raw materials under seasonal production conditions. However, cull sweet potatoes have consistently provided a high-energy feed for livestock, especially hogs in the USA and elsewhere.

Yam

The yam (*Dioscorea* spp., family Dioscoreaceae) is a carbohydrate-rich food crop grown in some tropical areas, especially Africa, where its importance exceeds that of sweet potato. In the USA, the term yam is incorrectly applied to orange, moist-fleshed sweet potatoes in the market place. Accordingly, there is some confusion in popular terminology. True yams are not grown commercially in the continental USA, but are occasionally seen in ethnic markets.

Global Distribution, Commercial Importance, and Varieties

About 96% of world yam production occurs in Africa, principally West Africa (Table 4). Other production centers include South America, the Caribbean islands, and Oceania. Nigeria alone produces over two-thirds of the world yam crop. World production has increased in recent years, due primarily to increased area devoted to its production.

International trade in yams is limited to small markets in North America and Europe. For the most part, yams are used within the family or are sold locally. Where yams and other carbohydrate-rich root crops such as cassava and sweet potato are available in the same market, yams usually command a higher price. Furthermore, yams are favored over other root crops for special occasions and to serve to guests.

Five species of *Dioscorea* are grown commonly for food (Table 5) and an additional five of about 60 known species are occasionally used for food. *Dioscorea alata*, the greater yam, is widely distributed throughout the tropics, including South-east Asia, Africa, and the Caribbean islands. The yellow yam (*D. cayenenis*) is grown primarily in West Africa and the Caribbean. *D. esculenta*, the lesser yam, is distributed widely in the tropics, but production is mostly in South-east Asia, the south Pacific islands, and the Caribbean islands. The white yam (*D. rotundata*) is the most important yam in West Africa and is grown extensively in the Caribbean, and to some extent in East Africa. *Dioscorea trifida* is the only yam of New World origin, and its cultivation is mostly in the Caribbean. Distinct varieties of some yam species are available, but different names are used for the same yam in different parts of the world so that variatal designations are not particularly useful.

Morphology and Anatomy of the Edible Portion

The edible part of the yam plant is the tuber that varies in shape according to species (Table 5) and environment in which it was grown. Individual tubers

Table 4 World yam production

Region	Area harvested ($\times 10^3$)			Yield (kg ha^{-1})			Production ($\times 10^3$ t)

Table 5 Descriptions of the most common *Dioscorea* species grown for food

Species	Common name	Origin	Tuber number and shape	Flesh color	Leaf shape and phyllotaxy	Stem appearance
D. alata L.	Water or greater yam	South-east Asia	Single, cylindrical	White to purple	Ovate, opposite	Winged
D. cayenensis Lam.	Yellow or yellow guinea yam	Western Africa	Single, variable	Yellow	Pointed, opposite; alternate	Spiny
D. esculenta Burk.	Lesser yam Potato yam	China	4–20 ovoid	White	Simple, alternate	Spiny
D. rotundata Poir.	White or white guinea yam	Western Africa	Single, cylindrical, spherical	White to yellow	Simple, opposite	Circular, smooth-spiny
D. trifida L.	Cush-cush	Tropical America	Numerous, elongate	White to purple	Lobed, alternate; opposite	Winged

Janick J (1990) Tropical root and tuber crops. *Horticultural Reviews* 12: 157–196. Reprinted by permission of Timber Press, Portland, OR, USA.

may range from a few grams to over 50 kg in weight, and tubers 2–3 m long have been produced under special cultural conditions.

Single or multiple tubers develop from a corm-like structure at the base of the vine. The tubers are covered by a thick layer of cork that often bears many cracks caused by tuber expansion. Roots may arise from the tuber, resulting in a somewhat hairy appearance before the dried roots slough off. The tuber has three general morphological sections – the head, middle, and tail. Buds are initiated from the head section after dormancy has been broken.

The bulk of the tuber is composed of starch-filled, thick-walled parenchyma cells in the central core. Vascular bundles having both xylem and phloem are scattered throughout the central core. A layer of meristematic cells that give rise to the buds surround the central core, and in turn is surrounded by a layer of thin-walled cortical cells. Finally, the entire tuber is surrounded by several layers of cork arranged in radial rows that arise from cork cambia.

Nutritional Composition

The principal nutritional component of yam is carbohydrate (Table 2). Like sweet potato, yam is a good source of ascorbic acid; however, it does not have the advantage of the high pro Vitamin A found in sweet potato. Yam is generally inferior to sweet potato in terms of amino acid content (Table 3). Exceptions are cystein, arginine, histidine, and glutamic acid, the levels of which are slightly higher in yam. However, other literature sources site yam as having a superior-quality protein compared with sweet potato, and being similar to potato in protein quality.

Handling and Storage

Dormant yams of some species may be stored in the ground for as long as 4 months. Harvested yams are stored in 'yam barns' in West Africa; the tubers are tied to vertical poles under a shelter to give the appearance of a barn with walls. Yams will remain in good condition during the dry period with only loss of weight from shrinkage and respiration, but loss from rots occurs quickly with the return of the rainy season. Postharvest applications of gibberellic acid prolong harvest life, and fungicide treatments retard rots, but these treatments are rarely practiced. Care during harvest to prevent cuts and bruises is required for long-term tuber storage. Yams can be cured like sweet potatoes to assist healing of wounds and prolong storage life, but this practice is uncommon. Yams can be stored under refrigeration, if available, at 16 °C and 70% RH, but are subject to chilling injury at temperatures lower than 12 °C.

Industrial Uses

Currently, there is little processing of yams, but the potential is great because the demand for yam as a food is high since fresh yams are not available until the next harvest season once tuber dormancy is broken and sprouting occurs. Dehydrated products such as chips or flour serve to fill the demand for yams to a minor extent, but consumer acceptance of these products is not universal.

Yam Bean

The yam bean (*Pachyrrhizus erosus* L., Family Fabaceae) is a minor tropical root crop known by many common names throughout the world. Jicama or some variation thereof is used most frequently.

Global Distribution, Commercial Importance, and Varieties

Yam bean is native to Mexico and northern Central America and is still cultivated there. In addition, yam bean is produced in South-east Asia, China, the Philippines, South America, the Caribbean islands, and East Africa.

For the most part, yam bean is used locally and does not enter into international trade. Production data are not available, but Mexico is likely to be the leading producer with an estimated 4000 ha under cultivation. Experimental yields of 80–90 t ha^{-1} have been reported from several countries. Traditionally, creole types of yam bean have been grown in Mexico, but they are being replaced by two new varieties – Agreadulce and Cristalina.

Morphology of the Edible Portion

The brownish roots are mostly turnip-shaped, but long and slender types are known. The preferred market size is 10–15 cm in diameter, which is attained in approximately 90 days from planting of seed. However, the root will continue to grow and reach a diameter of 30–45 cm and weight of 2–3 kg if not harvested at market maturity. The thick, tough skin is easily peeled to reveal the white flesh, which is crisp and succulent. Thinly sliced roots are eaten raw with a garnish or used in salads, and occasionally, it is cooked or pickled. In the USA, yam bean is often used as a substitute for water chestnut in oriental cuisine.

Nutritional Composition

Yam bean root is more succulent than that of sweet potato and yam and considerably less carbohydrate-rich (Table 2). Of the vitamins, only ascorbic acid is provided in significant amounts in yam bean. Except

for histidine and aspartic acid, yam bean is inferior to sweet potato and yam in amino acid content (Table 3). Typically, yam bean does not play a major role in the diet, in contrast to sweet potato and yam.

Handling and Storage

Yam bean roots are usually harvested by hand, washed, and stored in baskets or crates until sold. Refrigerated storage at 13–18 °C and 65–70% RH provides conditions for storage of roots for 1–2 months. Chilling injury occurs at temperatures less than 12 °C, and sprouting may occur at temperatures above 18 °C.

Industrial Uses

All yam bean roots are consumed in the fresh state. The mature seeds have 0.12–0.43% rotenone, an insecticide, but this has not been exploited for commercial use.

Edible Aroids

S K O'Hair, University of Florida, Homestead, FL, USA
D N Maynard, University of Florida, Bradenton, FL, USA

Background

There are plants from five genera within the Araceae family that are cultured for their starch-filled storage organs or herbaceous leaves. Most thrive in moist to flooded conditions and are among the most shade-tolerant of terrestrial food crops. Many are grown in moist tropical environments where other starchy food crops fail to flourish.

The edible aroids are known by many common names, often being confused with one another by the untrained eye. Part of the confusion arises from the low flowering frequency of most species. Some are cultured as foods of famine, and others are valued as staple foods. In the Caribbean, they are often the only food crops remaining after tropical storms.

All plant parts contain varying concentrations of an acrid factor, which appears to be carried on the surface of the needle-like calcium oxalate raphide crystals. It is believed to be either a cysteine proteinase or a glucoside that causes considerable irritation or swelling of affected tissues. Concentrations vary considerably among genera, species, and varieties, also being affected by plant age and cultural conditions. Cooking or other processing procedures destroy the acrid factors in the more popular clones. Naturalized or 'wild' clones need extensive processing to render them palatable. Levels of acridity and fiber content are factors that determine consumer acceptance of varieties. Production figures are not available for most of the crops, since they are grown as subsistence crops in small, often mixed plantings. Taro (*Colocasia*) and tannia (*Xanthosoma*) figures are combined with an estimated 5×10^6 t being produced world-wide.

As with all tropical root and tuber crops, yields and the size of individual edible portions vary considerably with planting density and length of time that the crop was allowed to remain in production. As the density diminishes, the size of individual edible parts increases. However, after a point, the marketable yield or crop value for the area planted declines. Thus, sizes of individual parts can be misleading if planting densities are not included. Early plant growth is characterized by the development of a root system and foliage production. Once total plant leaf area has reached a peak, well into the production period, the rate of corm and cormel production increases. This phase lasts two or more months.

Once the corm or cormel production phase is through, the plants of some species go dormant, and others must be harvested to prevent excessive amounts of sprouting and a decline in starch content and product quality.

Since all are propagated from vegetative cuttings, the development of certified insect and disease-free planting material is essential for optimal crop productivity. Dasheen mosaic virus (DMV) is commonly found throughout all genera, even in symptomless plants. Yield reductions due to DMV infection have been reported in both food and ornamental species.

With the exception of taro and tannia, postharvest and processing technology is very limited, since most are considered minor crops, and mechanization is not well developed. Like potato, the starches and carbohydrates have food and industrial uses.

Elephant (Foot) Yam

Plants in the genus *Amorphophallus* are unique among food crops as the plant produces only one petiole with a single umbrella-like compound leaf at the top. A flattened edible corm is produced at the base of the single compound leaf, enlarging from one year to the next if left unharvested. By the end of the first year, corms can weigh as much as 7 kg. Sections, up to 0.5 kg, of the corm are used as planting material for the next crop.

Amorphophallus is most commonly found in certain Pacific islands and much of Asia. In China and Japan, a popular species is known as konjac or konjac with production in China dating back 2000–3000 years. Its commercial value is greatest in Japan, where it is a valued food crop. Most *Amorphophallus* varieties are separated only by species names. Of 80–90 species, only a few are edible, with elephant foot yam (*Amorphophallus campanulatus* Bl. ex Decaisne) and konjac (konnyaku) (*A. rivieri* du Rieu (syn. *A. konjac* K. Koch)) being the most popular. Others are valued as novel ornamentals or as medicinal plants. Since flowering and seed set are commonn a few improved varieties and interspecific hybrids, many with reduced levels of acridity, exist.

The main carbohydrate, mannose (glucomannan), is a soluble dietary fiber that is not absorbed by humans. Otherwise, corms are similar in nutritional value with the other aroids (Table 1), with the exception of vitamin A levels, which are higher. The corms of some are considered to have medicinal value. In Japan, consumption is believed to reduce blood cholesterol and triglyceride levels in humans. Refer to individual nutrients. (*See* **Carbohydrates:** Classification and Properties; **Cholesterol:** Determining Blood Cholesterol Levels.)

At the end of the warm moist growing period, plants pass through a dormant period, at which time the corms are harvested as needed. Little information is available on postharvest storage. In general, corms are stored under ambient conditions.

The corms are processed to extract mannan, to make a wine, and as konjac curd for food. Glucomannan extracts have value as a fruit and vegetable preservative and as a sweetening agent.

Giant Taro

Alocasia or giant taro (*Alocasia macrorrhiza* (L.) Schott) is probably better known as an ornamental tropical plant than as a food crop. It is easily recognized by the spear-like appearance of the leaf laminae and petioles. Other species, including *A. indica* (Roxb.) Schott, *A. cucullata* Schott and *A. fornicata* Schott have been utilized as food crops.

Alocasia is among the oldest of food crops in Oceania, where, at one time, it was a staple food. Its spread as a food crop has been limited to Oceania and the Asian tropics. Its commercial importance is currently greater as an ornamental, than as a food crop.

Table 1 Average composition (per 100 g of raw product) of edible aroids

Constituent	*Elephant yam*	*Giant taro*	*Swamp taro*	*Tannia*	*Taro*
Moisture (g)	79	84	68	64	75
Carbohydrate (g)	10	15	29	32	21

Iron (mg)	0.6	1	1.3	0.9	1.2
Vitamin A (IU)	270				
Ascorbic acid (mg)		5		8	8

Data from Leung WTW, Burtrum RRB and Chang FM (1972) *Food Composition Table for Use in East Asia*. Rome: Food and Agriculture Organization; Murai MF, Pen F and Miller CD (1958) Some Tropical South Pack Island Foods. Honolulu, HI: University of Hawaii Press, with permission.

There are only a few cultivated clones, most of which are found in the South Pacific. Nevertheless, one Indonesian germplasm collection reportedly contains 70 accessions. Flowering is common. However, there is little research in breeding for improved varieties.

The edible portion is the large semicompressed stem containing many starch-filled parenchymatous cells. During the first year of growth, the stems can reach 12 m in height with a diameter of 6 cm and a weight of approximately 18 kg. The plants can be left unharvested until needed.

There is little nutritional information for the stems. However, the carbohydrate content is among the highest of the edible aroids (Table 1). Owing to the nature of erect stems, the structural carbohydrate content is high. Of the edible aroids, alocasia is generally considered to be less palatable and more acrid.

There is no handling or storage information on this crop. It is harvested as needed for local consumption.

There is currently no industrial use for giant taro.

Tannia

Tannia (*Xanthosoma sagittifolium* (L.) Schott), also known as coco(yam), malanga, tanier, or yautia, originated in the wet valleys of northeastern South America. It was domesticated and carried throughout the Caribbean basin by migrating Indian tribes. There is much confusion within this genus, with the same plant being given more than one species name. In addition, tannia is often confused with taro. In parts of Africa, both are known as cocoyam, and in a few other places, both are listed as taro.

Tannia is a valued food crop in most of the Caribbean islands, Florida (USA), western Africa, parts of Egypt, India, and Oceania. In most regions, it is grown for sale in local markets. However, in Florida, the crop is valued at $\$8.6 \times 10^6$ annually. Costa Rica and the Dominican Republic are exporters of the crop. There are only a few varieties of tannia, and most have white flesh. Pink and yellow-fleshed types are less common and occasionally classified as *X. violaceum* Schott and *X. atrovirens* C. Koch, respectively. The same clone may have more than one common name. Common varieties in the English speaking Caribbean are South Dade White, Bruce and Rabess, which are white-fleshed. Vinola and Jamaique are purple- to pink-fleshed. Flowering is rare, and hand pollinations are required for seed production, thus accounting for the few varieties. Formal breeding programs in West Africa have focused on developing root rot-resistant genotypes.

The main stem of the white- and pink-fleshed types is an inedible corm, which is occasionally boiled for animal feed. The edible portions of these two types are club-shaped, underground offshoots of the main corm that develop into cormels weighing as much as 1 kg each. The main corm of the yellow-fleshed types is the part that is consumed. Young leaves are occasionally cooked as potherbs. In the western hemisphere, tropics plants of *X. brasiliense* (Desf.) are occasionally grown solely for their edible leaves.

Table 2 Average composition (per 100 g of raw product) of edible aroid leaves

Constituent	*Tannia*	*Taro*
Moisture (g)	90	90
Carbohydrate (g)	5.3	5.7
Protein (g)	2.5	2.4
Fat (g)	1.0	0.6
Fiber (g)	2.1	1.5
Ash (g)	1.3	1.3
Calcium (mg)	95	98
Phosphorus (mg)	388	49
Iron (mg)	2.0	2.0
Vitamin A (IU)	3300	180
Ascorbic acid (mg)	37	11

Data from Leung WTW, Burtrum RRB and Chang FH (1972) *Food Composition Table for Use in East Asia*. Rome: Food and Agriculture Organization, with permission.

The cormels are mostly starch, possessing the highest starch concentrations among the edible aroids (Table 1). The nutritional value of the leaves is considered to be comparable to spinach, complementing the high energy level of the cormels (Table 2). (*See*: **Starch:** Sources and Processing.)

Cormels of the favored clones have a natural dormancy period of 1–3 months and are planted year-round in moist production areas. They are planted and harvested as needed. Cormels can be removed individually or the entire plant can be uprooted. In commercial settings, cormels are washed and packaged in waxed boxes prior to shipment. The storage period of the cormels can be extended by several months by holding them at 7°C and 80% relative humidity (RH). Although not common, cormels can be dried and stored for extended periods. (*See* **Controlled-atmosphere Storage:** Effects on Fruit and Vegetables.)

Processing of tannia is limited to freezing of peeled cormels and bagging them in consumer packs in the form of a ready to cook frozen food. There are many potential uses similar to those described for taro.

Taro

Taro (*Colocasia esculenta* (L.) Schott), also known as eddoe or dasheen, originated in the Bay of Bengal region of South-east Asia. It was carried by early Polynesians throughout Oceania, where it became a staple food. It is an ancient crop in Asia, being

introduced into Japan more than 2500 years ago. Compared with tannia, it is better adapted to excessively moist areas. Many clones are grown like rice in flooded conditions.

Taro has lost some popularity in the traditional areas of production in the South Pacific and Asia owing to significant crop losses attributed to taro leaf blight disease. Nevertheless, it is still widely grown in this region, being the most important food crop. Promising levels of genetic resistance and other control methods for this malady should help to return this crop to traditional levels of production. Other areas where taro is grown include most islands in the Caribbean, Hawaii, parts of western and northern Africa, the Philippines, Japan, and South-east Asia. There are more varieties of taro than all the other edible aroids combined, with estimates exceeding 1000. Some clones flower and set seed under natural conditions, providing for genetic variability. Formal breeding programs in the Pacific basin and Asia have resulted in the development of improved genotypes. Bun long and Lehua maoli are popular varieties in Hawaii. Varieties are most commonly separated by coloration of the leaves and corms as well as by habit of cormel formation. One of two basic types, the dasheen, produces one large, edible corm up to 3–5 kg in weight, with few offshoots. The other type, the eddoe or Chinese taro, produces a much smaller main corm with several slightly smaller edible offshoot corms.

The corms are the primary edible portion of the plant. Young leaves and blanched leaves are also eaten as potherbs.

The nutritional composition of taro corms (Table 1) and leaves (Table 2) are very similar to those of tannia.

At harvest, approximately 2–3 cm of the petioles should be left attached to the corm in order to minimize problems associated with invasion by rot-causing organisms. Losses can be reduced by allowing time for wound periderm formation before placing corms in bulk storage. Since there is no distinct dormancy period, the shelf-life of taro is shorter than that of tannia. Temperatures as low as 5 °C can be used to extend the storage life.

In the USA, corms are sliced thinly and cooked in hot oil, resulting in a product similar to potato chips or crisps. Experimental procedures indicate that taro products can include flour, cereals, bread, noodles, cake, infant and invalid food, and beverage powder, as well as flaked, canned, or frozen corms.

Swamp Taro

Swamp taro (*Cyrtosperma chamissonis* (Schott) Merr) is pre-Polynesian and considered to be among the oldest of the South Pacific food crops.

Swamp taro flourishes in warm, humid climates. Production is mostly limited to the low islands of Micronesia, where it is primarily grown as a traditional food crop. Varieties are differentiated by their acrid factors, leaf shape, color, spininess of the petiole, and flowering habit. The time to maturity (measured in years) and tolerance to saltwater intrusion vary slightly.

The main corm is the edible portion of the plant, increasing in size from one year to the next; 10-year-old corms can weigh as much as 300 kg. Side-shoots are used as propagules.

The carbohydrate content of swamp taro is similar to that of taro and tannia (Table 1).

Plants are harvested as needed, except when storms raise the salinity levels of the coastal bogs. At such times, plants are harvested immediately and stored until planting conditions are favorable.

There are no industrial uses for swamp taro.

VEGETARIAN DIETS

J Dwyer, Jean Mayer US Department of Agriculture, Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA

Introduction

Individuals mean different things when they refer to themselves as vegetarians. Those who provide dietary counseling must probe further to determine what foods are actually avoided and also the degree of adherence to the dietary pattern so that dietary recommendations will be appropriate.

Prevalence and Trends in Vegetarian Eating

The prevalence of vegetarian eating patterns varies, depending on the definition employed. Currently approximately 7% of Americans consider themselves to be vegetarian, but fewer than 1% are lactoovo vegetarians who abstain from all meat, fish, and poultry products, and even a smaller percentage – perhaps 0.1% – are vegans, who eat no animal foods at all. Many of those who define themselves as vegetarians are probably actually semivegetarians who limit their consumption of some or most animal products in favor of a plant-based diet, although they have not adopted a dietary pattern consisting exclusively of plants. The growing popularity of meatless meals and meat alternatives is due in large part to increased consumption of these products by individuals who are not necessarily vegetarian, but who want to eat a meatless diet.

Reasons for Adoption of Vegetarian Patterns

Individuals choose vegetarian diets for many reasons. In western countries, the major motivation for adopting vegetarian diets is for health reasons. Some believe that avoidance of animal products yields health benefits because it decreases the risks of bacterial or other foodborne diseases (e.g., bovine spongiform encephalopathy) that are particularly common in unhygienically prepared animal products, or that are associated with excessive intakes of saturated-fat cholesterol and sodium. Others focus on the putative health benefits of plant foods, including not only nutrients but also phytochemicals such as fiber, flavonoids, and other compounds that may have as yet unrecognized health benefits. Individuals who describe themselves as 'ethical vegetarians' often do so because of personal convictions such as opposition to the slaughter of animals for food or to what they view as the inhumane treatment of animals raised for food. Still others adhere to philosophies that encourage vegetarianism among their followers, (e.g., transcendental meditators, anthroposophists), or have religious beliefs that include vegetarian eating patterns (e.g., Seventh-Day Adventists, Buddhists, some Hindus, and other religious groups). Other people are motivated by environmental concerns, such as the conviction that raising food animals consumes natural resources that could otherwise be diverted to raising plant foods. Finally, there are some individuals who follow vegetarian diets simply out of habit. In developing countries vegetarian eating patterns may result from one or more of these motivations or simply because animal foods are expensive or unavailable to some segments of the population.

The degree of adherence to the chosen vegetarian eating pattern depends on motivation, habits, and circumstances. Until recently, the degree of animal food avoidance often predicted the extent of other food avoidance and divergence in other lifestyles from omnivores. Thus, vegans tended often to have belief systems that extended not only to extensive prohibitions against food ingredients made from or by animals (such as honey, casein, whey, rennet, and gelatin) but also to nonuse of animal products such as leather, wool, or silk and nonviolence toward animals. Today, however, the links between diet and belief are not so strong. Some vegans focus solely on the eating pattern for what they view as its health advantages but they do not necessarily subscribe to all the other aspects of the traditional vegan belief system and lifestyle. They are more willing to use meat analogs, nutrient-fortified foods, and vitamin mineral supplements, making it easier to attain nutritional adequacy.

Classification of Vegetarian Eating Patterns

The five major vegetarian dietary patterns are described in Table 1. However, myriad vegetarian dietary patterns exist and they are not easily described by focusing on the single dimension of animal food intake. Many vegetarians' food intakes differ from those of nonvegetarians in other ways as well. For example, some vegetarians eschew the use of vitamin–mineral supplements, and foods that they regard

Table 1 Common types of vegetarian dietary patterns

Pattern	*Comments*
Meat avoiders	Limit or avoid red meat and other flesh foods; may also restrict poultry, fish, and seafood
Lactoovo vegetarians	Avoid all meat, fish, poultry, and often fish but consume milk products and eggs
Lactovegetarians	Avoid all meat, fish, poultry, fish, and eggs
Macrobiotics	Currently popular diets are less restrictive than those popular in the 1970s but still involve numerous restrictions, generally including avoidance of all meat, poultry, milk, and eggs, but may consume fish in small amounts. Also avoid sugar and other refined sweeteners, members of the nightshade family (peppers, eggplant, tomatoes, potatoes) and tropical fruits
Vegans	Avoidance of all animal products including meat, fish, poultry, eggs, and dairy products
Other	Raw food eaters and 'living food' eaters avoid animal foods and eat raw plant foods, including fruits, vegetables, and cereals, with special health foods such as wheatgrass or carrot juice. Fruitarians consume diets mostly of fruits, nuts, honey, and olive oil. Rastafarians eat vegan-like diets but avoid alcohol, salt-preserved foods, and additives

as processed or nonorganic. Others include special foods such as organically grown foods, soy products such as miso, or sea vegetables that they regard as healthful.

A vegetarians eating patterns therefore encompass a continuum of animal and other food use and varies in the extent, intensity, and degree of alterations in both animal and other types of food consumption, and in its involvement with belief systems and other lifestyles. Some vegetarians limit only animal foods. Others may also proscribe processed foods, 'nonorganic' foods, or foods produced through biotechnology such as cheeses made with recombinant enzymes and genetically modified plant foods. At the same time, vegetarians' dietary diversity may be considerable owing to the wide variety of fruits, vegetables, nuts, legumes, meat analogs and fungi they consume.

Dietary intakes

Energy

Vegans often have lower energy intakes and lower weights than omnivores; differences are smaller and less consistent among those who consume other vegetarian patterns. Vegan and, to a lesser extent, vegetarian diets tend to be relatively low in caloric density, somewhat lower in fat, and occasionally lower in protein than those of omnivores. While lower energy intakes pose little problem for most adults, for vegan infants, weanlings, and small children, unless they are fed frequently, energy intakes may be low. Nuts, nut butters, oils, and fruit juices are concentrated sources of calories that are usually acceptable.

Fat and Saturated Fat

Most vegetarian diets eaten in western countries, and especially vegan diets, are lower in fat, saturated fat, and cholesterol, and higher in polyunsaturated and monounsaturated fats than are nonvegetarian patterns. Their low saturated fat and cholesterol and high dietary fibre and polyunsaturated fatty acid content decrease risk factors for coronary artery disease.

Carbohydrate

Intakes of carbohydrates, especially complex carbohydrates and dietary fiber, tend to be higher among vegetarians than among omnivores, and more in line with current dietary recommendations.

Protein

Vegetarians usually consume less total protein and less animal protein than omnivores but their intakes are usually satisfactory and sustain good nutritional status if energy intakes are adequate. Energy intake, protein quantity, quality, and digestibility must all be monitored on extremely restrictive vegetarian diets, however. Sufficient energy intake is important so that protein is available for its unique functions rather than being utilized for energy. Protein quality is also of potential concern, since some plant sources of protein are limited in one or more amino acids. For example, lysine is low in most cereal grains, sulfur-containing amino acids (methionine and cysteine) are lower in legumes and fruits than in other plant sources and animal foods, threonine is lower in cereals, and tryptophan is lower in fruits than in most animal foods. Thus, the biological value of vegan diets based on single cereal staples may be poor, especially at times of rapid growth.

However, the protein quality of appropriate mixtures of plant foods is entirely satisfactory and promotes good nutritional status. When dietary patterns include several plant protein sources (e.g., legumes, cereals, nuts and seeds, fruits, and other vegetables), protein quality is satisfactory since the deficits in one plant food source can be complemented by other plant or animal products that are higher in the

amino acid. Soy-based infant formulas are usually supplemented with small amounts of methionine, and these sustain good growth in infants. If animal foods are also included, protein quality is further increased. Digestibility of protein sources is a concern on some vegan diets that are fed to infants and young children because uncooked cereals and legumes are not well absorbed. Cooking or processing can improve their absorption and inactivate amylase inhibitors, lectins, tannins, and other substances in foods that decrease bioavailability.

Iron

The iron intakes of vegetarians are usually similar to those of omnivores. However, iron bioavailability may be decreased because nonheme iron absorption from plant foods is influenced by the presence of inhibitors, such as polyphenols, phytates, fiber, and tannins. Unleavened and unrefined cereals often contain many inhibitors. However, enhancers of nonheme iron absorption such as citric, ascorbic, and other organic acids that are often high in vegetarian diets may increase absorption. Also small amounts of animal foods, especially flesh foods, enhance absorption. Nevertheless, in infancy, pregnancy, the adolescent growth spurt and during other times of high iron requirements, without supplementation iron needs may not be met. Cereals highly fortified with iron or iron supplements may be acceptable iron sources to supplement other iron-rich foods.

Zinc

Vegetarian diets tend to be lower in zinc than nonvegetarian diets because approximately half of the zinc intake of western populations is from meat, fish, and poultry. The bioavailability of zinc is lower in cereal and other plant sources because phytate, fiber, and other inhibitors of zinc absorption are present, especially in unrefined foods. The presence of inhibitors is highest on vegan diets. Vegetarian diets should be planned to include adequate amounts of this nutrient, but supplements are not recommended since evidence is lacking that they are needed.

Calcium

Vegetarians who consume milk products have intakes of calcium as high as those of omnivores. Vegans have lower calcium intakes, and their intakes of vitamin D are also low. The major source of calcium in most western diets is dairy products. If they are not consumed or consumed in only small amounts, care must be taken to choose plant and other foods that are high in calcium. These include dark leafy green vegetables (chard, broccoli, kale, dandelion, mustard greens) and almonds that are high in calcium, fish such as sardines with bones, calcium-fortified soy milks and formulas, and calcium-set tofu. In recent years calcium-fortified cereals, orange juice, soy milks, and many other products have become widely available and are acceptable options for those who eschew milk. Supplemental calcium is another option, Calcium nutriture is compromised when vitamin D nutritional status is marginal since the vitamin is needed for absorption of the mineral.

Cobalamin (Vitamin B_{12})

Vegan diets are low in vitamin B_{12}, and other vegetarian diets are also somewhat lower than nonvegetarian diets. The reason for concern is that vitamin B_{12} deficiency causes not only a macrocytic megaloblastic anemia but, if long continued, serious, irreversible, neurologic and neuropsychiatric abnormalities. These are difficult to diagnose since the characteristic megaloblastic anemia of vitamin B_{12} deficiency is masked by high intakes of folic acid. Vitamin B_{12} is only found in products of animal origin, foods that contain microorganisms capable of incorporating the vitamin (nutritional yeast grown on vitamin B_{12}-enriched media), and vitamin B_{12}-fortified foods (B_{12}-fortified soy milk, nut milk, and cereals). Individuals such as some vegans who often do not consume any of these foods are at special risk.

Reliable and hygienic sources of vitamin B_{12} are important for those who consume no animal foods. Spirulina, kombu, tempeh, and miso contain inactive forms of the vitamins that cannot be utilized by human beings, and the plankton in seaweeds such as nori are unreliable and highly variable sources of the vitamin. Food and water are sometimes contaminated with vitamin B_{12}-producing bacteria but these are due to poor hygienic practices and are not reliable sources of the vitamin. Among individuals who are likely to have low intakes of vitamin B_{12}, high intakes of folic acid may mask the development of the megaloblastic anemia of vitamin B_{12} deficiency – another reason for insuring adequate intakes of vitamin B_{12} in all persons. For those over 50, regardless of their diets, vitamin B_{12} supplementation is recommended from fortified foods or supplements because the bioavailabiliy of food sources of B_{12} may be limited owing to the presence of unrecognized atrophic gastritis.

Folic Acid

Folic acid intakes are often higher among vegetarians than among omnivores because of high intakes of fruits and vegetables. However, there is the risk of possible inadequacy arising in persons who consume diets consisting of vegetables which are braised or

fried at high temperatures, few fruit juices, and cereals fortified with the nutrient. For women who are at risk of becoming pregnant, regardless of their dietary pattern, supplementation with 400 μg folic acid is currently recommended to decrease risks of neural tube defects.

Vitamin D

Vitamin D is only found in animal foods such as vitamin D-fortified dairy products and highly fortified cereals, and liver. Cod liver oil and menhaden oil contain high but variable amounts of vitamin D. More acceptable sources are water- or fat-soluble vitamin D supplements, commercial infant formula (both soy- and cows' milk-based), and fortified cereals. Sunlight exposure may be insufficient in young infants at weaning and thereafter, and among the elderly, especially those in northern climes with inclement weather.

Riboflavin

The major source of riboflavin in most western diets is milk, and those who avoid milk need to select other foods high in this nutrient.

Fiber

Intakes of whole-grain cereals and nonrefined foods and thus of dietary fiber are higher on most vegetarian diets. On some vegan diets fed to small children, fiber intakes are several times expert recommendations of $0.5\,g\,kg^{-1}\,day^{-1}$, and the sheer bulk of the diet may pose a problem. In adults, vegetarians' fiber intakes tend to be closer to expert recommendations than are those of nonvegetarians.

Other Nutrients

Certain other nutrients such as carnitine and taurine may be low on vegan and some restrictive vegetarian diets, but at present the health significance of these differences is not established. Intakes of sodium vary on vegetarian diets; there are some reports that sodium intakes are lower among vegans than among omnivores. Lower sodium intakes are generally recommended.

Usually vegetarian diets are higher in thiamin, vitamin C, β-carotene and other carotenoids, and vitamin E than are nonvegetarian diets. Currently there is much interest in the health effects of phytochemicals other than nutrients that are present in plant foods, such as the flavonoids, plant stanol esters, and other compounds, which are likely to be higher in the diets of vegetarians than in those of omnivores. The beneficial health effects of these dietary constituents are still under study.

Benefits

Vegetarians who have chosen such an eating pattern generally enjoy their diets and are satisfied with their lifestyles. Those who consume vegetarian diets because of economic necessity may add animal foods when their means permit. Differences in all-cause mortality between vegetarians and nonvegetarians are equivocal, although differences in specific causes of mortality do seem to differ. The health effects of vegetarian diets are more difficult to interpret since vegetarians often not only have divergent dietary patterns but lifestyles that differ in ways that also affect their risks for disease. These include increased physical activity, decreased use of tobacco and alcohol, and moderation in food intake, all of which can be expected also to decrease chronic disease risks regardless of what diet is consumed. Nevertheless, even after taking these factors into account, decreased risks and later onsets for several chronic degenerative diseases are apparent that appear to be due to dietary pattern. In adults, vegetarian diets are positively associated with reduced risks of obesity, coronary artery disease, hypertension, non-insulin-dependent diabetes mellitus, and possibly some types of hormone-dependent cancers. Osteoporosis does not seem to be different from that of the general omnivorous population among vegetarians. It may be higher in vegans, especially if they are very low in weight, and have low intakes of calcium and vitamin D. However, other factors that affect risks, such as weight-bearing exercise and nonsmoking, may help to decrease risks. Differences in infectious diseases between vegetarians and nonvegetarians are not as apparent as are those with the chronic diseases mentioned above. Foodborne illnesses that are more frequently associated with animal foods are probably less common among vegetarians, although there is no evidence that other foodborne diseases are lower among them. Although some vegetarians are more likely to self-treat and less likely than their nonvegetarian counterparts to seek medical care for mild illnesses, for severe illnesses the vast majority of vegetarians seek medical care. Therapeutic diet manuals are available for those with vegetarian eating patterns. However, the claims of macrobiotics, living foods advocates, and fruitarians that their regimens are especially or uniquely helpful for treating cancers or other maladies are not supported.

Risks

Like their omnivorous counterparts, vegetarian diets can be well or poorly planned. The risks to dietary inadequacy increase with the number and degree of

restrictions on the food groups and foods that are consumed, the willingness to use fortified foods or nutrient supplements, and to accept medical advice, and the physiological state of the individual. Vegetarians who consume unplanned regimens or feed them to their children are no more immune to nutritional problems of excess, inadequacy, and imbalance than are omnivores. Particular risks arise when many food groups and foods are eliminated without due care being given to providing alternative sources of nutrients either from other conventional foods, fortified foods, nutrient supplements, or a combination of these. This is a particular problem for those who by virtue of their increased nutritional needs or their health status are especially nutritionally vulnerable. A vegetarian diet, which might suffice for good health in other groups, may not meet their nutritional needs and may be inappropriate for them. Such groups include the very young (weanlings and young children), those who are growing rapidly (adolescents), those likely to become pregnant, pregnant and lactating women, the very old, and the sick. For example, infants who are weaned to vegan diets may develop rickets, iron-deficiency anemia, protein-calorie malnutrition, and other dietary deficiency diseases. There is also a small minority of vegetarians whose convictions and practices place them at increased health risk. They refuse to use prescription drugs, reject immunizations using animal antiserum, medications using recombinant products such as epoietin-α, human recombinant insulin, and blood transfusions, or avoid or delay other conventional medical care. Such practices may increase disease risks or severity. They may self-treat using unproven remedies including herbal and botanical preparations without due caution to make sure that they are safe. Therefore not only dietary patterns but also associated health behaviors need to be assessed.

The most common dietary deficiencies observed on unplanned vegetarian diets are iron-deficiency anemia (particularly in weanlings, young children, and pregnant women), rickets in weanlings and young children, megaloblastic anemia due to vitamin B_{12} deficiency (in pregnant and lactating women, infants and young children, and the aged), and osteomalacia and low bone density in vegan adults and the elderly.

Dietary Planning

Table 2 presents some key points for dietary planning for each of the common vegetarian dietary patterns. Well-planned vegetarian diets that meet the dietary standards for nutrients as determined by scientific expert groups are in line with current dietary recommendations. Balance, variety, and moderation are essential and can be achieved by focusing on alternative sources for nutrients high in foods that are excluded on the vegetarian pattern. The use of a wide variety of plant foods, the advent of nutrient-fortified plant foods, and the judicious use of vitamin and mineral supplements at times of particularly high needs may be helpful. Sound vegetarian dietary guides have been published that assure adequacy of nutrient intakes, and these facilitate dietary planning, especially for vegans. Since periods of rapid growth or physiological stress are times when risks of nutritional deficiencies are greatest, special attention is warranted to planning dietary intakes during these nutritionally vulnerable times during the life cycle, especially for those who consume vegan diets. Because diets that permit good health in adults may not do so during these times of particular stress, special guidance from a dietitian is often helpful as

Table 2 Considerations in dietary planning for vegetarian patterns

Dietary pattern	*Key issues and comments*
Meatless, partial or semivegetarian	These diets are similar in most respects to nonvegetarian diets and fit well with dietary recommendations to decrease risks of chronic degenerative diseases
Lactoovo vegetarian	Liberal amounts of vitamin D-fortified dairy products and some eggs in the diet allow for adequate intakes of nutrients, with the possible exception of iron, which can be obtained from fortified cereals. Low-fat dairy products are preferred to keep intakes of saturated fat and total fat moderate
Lactovegetarian	Same as above
Macrobiotic	Current variations of this diet are less restrictive than versions used two decades ago, but deficiencies of energy, iron, calcium, vitamin B_{12}, vitamin D, and other nutrients may still arise in weanlings, pregnant women, and young children, especially if diets are unplanned
Vegans or 'pure vegetarian'	Without careful planning, energy and vitamins B_{12}, D, and bioavailable sources of iron may be low. Concentrated sources of energy can increase caloric intakes. Vitamin B_{12}, D, and calcium can be supplied through use of soy milk, cereals, and/or supplements of these nutrients. A variety of protein food sources assures adequate complementary proteins. Iron intakes may be enhanced by iron-fortified cereals, green leafy vegetables, and iron supplements if these are acceptable. A vegan food guide can be helpful

well. If there is doubt as to the nutritional adequacy and healthfulness of vegetarian diets, the assistance of a dietitian and dietary assessment of food records of typical intake is warranted. Many computerized dietary assessment programs are available that can assist in this task.

Conclusion

Plant-only (vegan, macrobiotic, and fruitarian), plant-based (lactovegetarian, lactoovo vegetarian, meatless), and plant-rich omnivorous diets that are planned to insure dietary adequacy and minimize chronic disease risk are compatible with good nutritional status and health.

VERMOUTH

P Liddle and L Boero, Martini & Rossi, Pessione, Torino, Italy

History

The origins of vermouth date back to ancient Mediterranean history. The maceration of herbs and spices in wine was common practice in antiquity, and the invention of aromatized wine, the ancestor of vermouth, has been attributed to Hippocrates. Greece abounds in aromatic plants and Crete in particular provided the plants dittany and wormwood, both of which possess tonic and digestive properties. It is reported that Hippocrates macerated the flowers of these plants in strong, sweet Greek wine, thereby obtaining a satisfying and digestive beverage which throughout antiquity and the Middle Ages was called 'Hippocratic wine' or *vinum absinthianum*. Later, the Romans elaborated on the production of such wines by introducing other herbs such as thyme, rosemary, myrtle, and celery.

In the Middle Ages the Venetians, who had the monopoly of the spice trade, introduced aromatic plants into Italy which until then were unknown in that country, and they were used in the preparation of Hippocratic wine. These plants (cardamom, cinnamon, myrrh, cloves, rhubarb, ginger, and sandalwood) came from East Africa, India, and Indonesia.

Turin, along with Florence and Venice, was one of the major Italian centers of production of Hippocratic wines and liqueurs from the late eighteenth century. Piedmont in particular possessed two assets: aromatic plants abounded in the Piedmont Alps and their foot-hills, and the bouquet of Piedmont dry and sweet white wines combined very well with the fragrance of herbs. These two factors doubtless explain why this area became the major center of the vermouth industry in the nineteenth century, when the leading names in that sector emerged.

The term 'vermouth' derives etymologically from Wermut, the German name for wormwood. While the latter English term refers to the use of the plant as a vermifuge, the German name is supposedly derived from Wer (man) and Mut (courage, spirit). When it was introduced into Bavaria in the first half of the seventeenth century by the Piedmont producer Alessio, *vinum absinthianum* was probably translated literally as Wermutwein, which when it reached France became vermouth.

Today, most of the world's vermouth is produced in Europe (essentially in Italy, France, and Spain) and to a lesser extent in South America, but local varieties are always to be found in all wine-producing countries.

Definition

In basic terms, vermouth is a combination of wine, aromatic plants (hereafter referred to as 'botanicals'), sugar, sometimes grape must in limited quantities, and alcohol. Caramel is the only coloring substance authorized, and is used for red vermouths.

The difference between the various types of vermouth lies essentially in the presence or absence of certain botanicals in their formulas. Broadly speaking, there are two main families – sweet and dry – which differ in their sugar content. Sweet vermouths contain around 150 grams of sugar per liter, while the dry varieties contain less than 50 g l^{-1}. Dry vermouths are all white, and serve mainly as a base for well-known cocktails, although they may also be drunk straight.

In the European Union (EU), vermouth is defined within the European Council Regulation 1601/91 and subsequent amendments. This Regulation applies to 'the definition, description and presentation of aromatized wines, aromatized wine-based drinks, and aromatized wine-product cocktails.' Article 2 (1) (a) of the Regulation states:

> aromatized wine shall mean a drink:
> – obtained from wines defined in points 12 to 18 of Annex I to Regulation (EEC) No. 822/87 (11), as last amended by Regulation (EEC) No. 1325/90 (12), with the exception of retsina table wine, and possibly with added grape must, grape must in fermentation and/or fresh grape must with fermentation arrested by the addition of alcohol, as defined by Community legislation,
> – to which alcohol has been added as defined in Article 3 (d), and
> – which has been flavoured with the aid of:
> – natural flavouring substances and/or natural flavouring preparations as defined in Article 1 (2) (b) (i) and (c) of Directive 88/388/EEC . . .
> – aromatic herbs and/or spices and/or flavouring foodstuffs,
> – which has generally been sweetened and, subject to the exceptions provided for in paragraph 2, has possibly been coloured with caramel,
> – which has a minimum actual alcoholic strength by volume of 14.5% vol or more and a maximum actual alcoholic strength by volume of less than 22 % vol . . .

The wine used in the preparation of an aromatized wine must conform to the relevant EU wine legislation (in particular as far as the minimum alcohol content is concerned), and be present in the finished product in a proportion of not less than 75%.

Vermouth itself is further defined in Article 2 (2) (a) as an:

> aromatized wine . . . the characteristic taste of which is obtained by the use of appropriate derived substances, in particular of the *Artemisia* species, which must always be used; this drink may be sweetened only by means of caramelized sugar, sucrose, grape must, rectified concentrated grape must and concentrated grape must.

Denominations relating to the sugar contents, e.g., sweet, extra-dry, are defined in Article 2 (5). In addition, EU Regulation 122/94 allows for the use of the pure flavoring substance vanillin, identical to that found in natural sources.

Definitions in other parts of the world are broadly similar, with slight variations on the minimum wine content (70% in some cases), and minimum/maximum alcohol contents. In all cases, the base wine and botanicals used must comply with the relevant local legislation concerning these ingredients.

Finally, contrary to some popular beliefs, vermouth is not a 'vin cuit' (cooked wine), and, to put to rest another long-standing rumor, it is not a particularly acidic product – in fact, the acidity is often less than that of the average table wine.

Ingredients

Wine

Quantitatively, wine is the most important ingredient of vermouth, since in the EU it accounts for at least 75% of its volume. The quality of the final product therefore depends on the quality of the wine employed. Generally speaking, only neutral white wines that do not oxidize are employed; they must be low in tannin if they are not to maderize with age, and turn a darker color.

Botanicals

The botanicals (leaves, flowers, fruits, seeds, roots, and barks) are the natural sources of flavor which characterize vermouth. There are so many of these that it would be impossible to list them exhaustively and, of course, the composition of the mixture is a closely guarded secret of each producer, but some examples are given in Table 1, together with their respective Latin botanical names.

As with other foods and beverages, use of traditional botanicals may introduce trace levels of compounds which in their pure (or, at least, more concentrated) form may be suspected of negative effects on the health of consumers, based on toxicological studies. These compounds, usually present at or below the mg l^{-1} level, are hence subject to quantitative limitation by the legislation of different countries. In Europe, these limits are set by the Directive 88/388/EEC, and limits of similar magnitude are found in other national or international legislation.

In the particular case of vermouth, the use of *Artemisia* species forms part of the EU definition of the product, and virtually all of the *Artemisia* species contain thujone, a compound often associated with the negative aspects of the drink absinthe. However, the most common source of thujone in foodstuffs is sage, a botanical whose name and history are synonymous with good health, and which is widely and traditionally used as a culinary herb in many countries.

The EU Directive, for example, currently fixes a maximum limit for thujone of 5 mg kg^{-1} in alcoholic beverages of less than 25% alcohol. Sweet vermouths are well within these limits, generally containing less

Table 1 English and Latin botanical names of examples of natural sources of flavor used in the production of vermouth

English name	*Latin botanical name*
Angelica	*Angelica archangelica*
Artemisia species	Various
Bay	*Pimenta racemosa*
Camomile	*Anthemis nobilis*
Cardamom	*Elettaria cardamomum*
Cinchona	*Cinchona species*
Cinnamon	*Cinnamomum zeylanicum*
Citrus species	Various (orange, lemon, etc.)
Clary sage	*Salvia sclarea*
Clove	*Eugenia caryophyllus*
Coriander	*Coriandrum sativum*
Dittany of Crete	*Origanum dictamnus*
Elder	*Sambucus nigra*
Gentian	*Gentiana lutea*
Ginger	*Zingiber officinale*
Hops	*Humulus lupulus*
Juniper	*Juniperus communis*
Lemon balm	*Melissa officinalis*
Licorice	*Glycyrrhiza glabra*
Marjoram	*Origanum vulgare*
Nutmeg and mace	*Myristica fragrans*
Orris	*Iris florentina*
Quassia	*Quassia amara*
Raspberry	*Rubus idaeus*
Rhubarb	*Rheum officinale*
Rose	*Rosa damascena*
Saffron	*Crocus sativus*
Sage	*Salvia officinalis*
Savory	*Satureia hortensis*
St John's wort	*Hypericum perforatum*
Star anise	*Illicium verum*
Thyme	*Thymus vulgaris*
Vanilla	*Vanilla planifolia*

than 1 mg kg^{-1}, a level considerably lower than those in past or current versions of absinthe; most dry vermouths contain even less.

Other such compounds may be introduced into traditional flavored alcoholic beverages by botanicals that also often have long-standing histories of culinary use. In all cases, careful selection of raw materials, and if necessary the mode of preparation of the botanical extracts, results in products which respect current limits. In addition, it should be remembered that the very presence of alcohol in flavored wines and spirits constitutes an 'automatic' limiting factor on the ingestion of such compounds during moderate consumption of these products.

Alcohol

Ethyl alcohol also enters into the composition of vermouth, both to fortify the wine and as a means of extracting the flavoring substances from the botanicals. It must be of agricultural origin, very pure, and conform to standards laid down by legislation (e.g., concerning the maximum level of methanol and other natural fermentation byproducts). In Europe, such specifications are given in Annex I to Regulation 1601/91.

Water

Although not a major ingredient, the water used (mainly together with alcohol for the botanical extracts) must usually conform to the standards for drinking water. This is the case in Europe, as embodied in the current and future requirements of EU Directives concerning potable water (80/778/EEC and 98/83/EC).

Sugars

In order to give vermouth its required sugar content, mistelle (muted grape must) or a good dessert wine may be added to the base wine, as well as the necessary amount of good-quality white sugar. The sugars slightly attenuate the bitterness of certain substances that would otherwise be too strong on the palate. They give the vermouth body, firmness, and smoothness, and thus play a very important role in the preparation. As mentioned above, sweet vermouths contain about 150 g l^{-1} of sugar, and dry vermouths less than 50 g l^{-1}.

Caramel

Red vermouth generally owes its amber hue to caramel, which in Europe is the only coloring matter authorized under Regulation 1601/91. Apart from imparting color, it also confers a special flavor specific to red vermouth, contributing to the body and smoothness.

Production

Prior to the marriage of the ingredients of vermouth, the base-wine blend and the botanical extracts must be prepared.

Base-wine blend

The preparation of the base-wine blend is performed using traditional processing aids common to all wines and wine-based products, e.g., gelatin, bentonite, charcoal, etc. Colloid formation and coagulation reduce the levels of high-molecular-weight compounds and of traces of iron and other metals, all of which could compromise the clarity and stability of the finished product. As with all wine processing, small amounts of potassium ferrocyanide may be necessary to reduce the trace metals. Due to losses from the base wines during the transfer and blending, small amounts of sulfur dioxide may be added to maintain the antiseptic and antioxidant effects of the latter. After a suitable contact time (up to several days), the blend is decanted and filtered.

Although alcohol is generally added at a later stage of the process, the base wines of some vermouths (particularly in France) may be fortified by the addition of this ingredient at an earlier stage. They are then subjected to a physical aging in wood (sometimes up to a year), as well as a form of biological aging similar to the flor sherry process used in Spain, to enrich the organoleptic qualities of the wines.

Botanical Extracts

The botanicals are usually incorporated into the vermouth in the form of an extract (strictly speaking, a tincture) produced by macerating them in aqueous alcohol or a distillate obtained by distilling them in the presence of aqueous alcohol (an alcoholate).

Maceration is the most commonly used process. The botanicals are placed in a tank, covered with a mixture of aqueous alcohol, and are agitated periodically so that they remain constantly covered by the liquid. The operation is frequently performed in rotating tanks and may last for several weeks. At the end of this time, the extract is drawn off and the botanicals are pressed.

Distillation is used when it is desired to make particular use of the volatile substances contained in the botanicals (e.g., fruits, St John's wort), and to exclude higher-molecular-weight compounds which could have negative physical or organoleptic effects. The botanicals are distilled in the presence of a mixture of alcohol and water, with or without an initial period of maceration. The actual strength of the aqueous alcohol used, and the complete or partial recovery

of the distillate, together form part of the traditional recipe that characterizes a particular vermouth.

In some cases, in particular in the production of a well-known French dry vermouth, the botanicals are macerated directly in the wine, which has already been fortified by alcohol.

Blending the Ingredients

The sugar required in the product is generally incorporated into the base-wine blend, which is then mixed with alcohol, water, and the botanical extracts, together with caramel if required, in blending tanks, which often have a capacity of up to 200 000 l. After careful homogenization of the liquid, the vermouth is then allowed to mature for up to several weeks, in order to achieve a proper harmony and balance of its ingredients.

Stabilization

At the end of this maturation time, the vermouth undergoes cold stabilization treatment. It is refrigerated, and is held for several days at around $-8\,^{\circ}C$, close to its freezing point. This precipitates substances (mainly potassium bitartrate) which may form a natural deposit later if the vermouth is subjected to low temperatures during storage and transport, or to contact with ice when served. The precipitate is removed by a low-temperature filtration, guaranteeing the physical stability of the product under all conditions.

Finally, to insure perfect clarity and brilliance, and also biological stability in the case of products with an alcohol strength of less than 16% vol, the vermouth is generally subjected to a very fine sterilizing filtration immediately prior to bottling. The latter is carried out using the modern techniques common to other sectors of the beverage industry.

An example of an overall production process is shown in Figure 1.

Analysis

Most of the routine analyses of vermouth are of necessity those used for the analysis of wines, since wines form the basis of all vermouths. In addition, modern techniques of gas and liquid chromatography are used to analyze for the volatile and nonvolatile compounds which are derived from the botanicals used, and which contribute to the specific aroma and taste of vermouth. In both cases, these chromatographic techniques often need to be coupled to mass

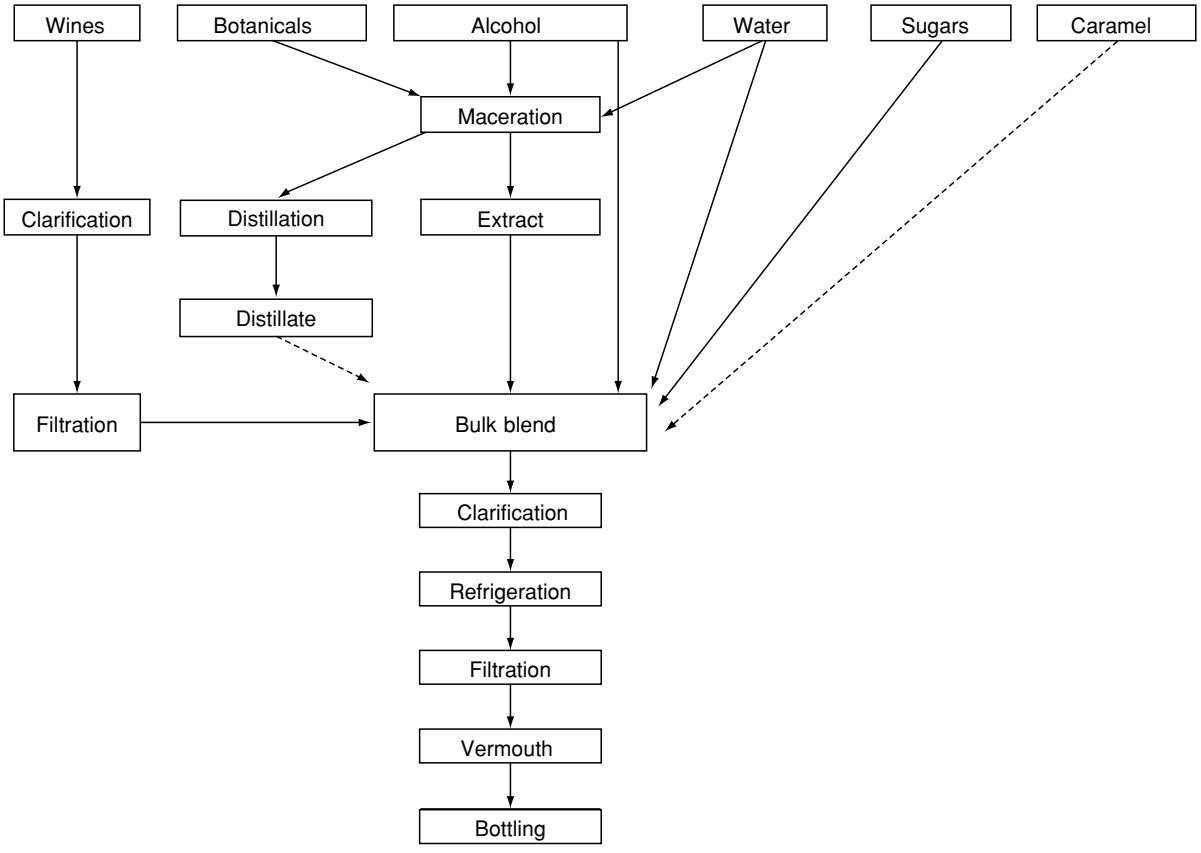

Figure 1 Typical overall production process for vermouth.

spectrometry in order to identify and monitor the low levels of these compounds (typically a total of the order of less than a few tens of $mg\,l^{-1}$).

In common with the rest of the food industry, great care is also taken today to monitor and limit any low levels of contaminants, using these same techniques, which may potentially be introduced by contact with processing or transport equipment, or packaging materials.

VIBRIOS

Contents

Vibrio cholerae

J G Morris, Jr, University of Maryland School of Medicine, Baltimore, MD, USA

Introduction

Vibrio cholerae is a curved, Gram-negative bacilli. The organism is widely distributed in aquatic environments, where it is a natural, free-living organism. A subset of *V. cholerae* strains, carrying the genes for cholera toxin (CT) and the *Vibrio* pathogenicity island (VPI), cause cholera, a disease characterized by severe, dehydrating diarrhea; virtually all of these latter 'epidemic strains' are within either O group 1 or O group 139. Cholera remains a persistent cause of morbidity and mortality in Asia and Africa. In 1998, the World Health Organization (WHO) received reports of 293 121 cholera cases and 10 586 deaths from 74 countries, with the actual number of cases (including unreported cases) probably greatly exceeding this figure. Cholera can also move explosively through populations that have been free of the disease for generations, as demonstrated by the occurrence of over 100 000 cases in Peru in 1991 and the subsequent rapid spread of cholera to other South American countries.

V. cholerae strains which lack the virulence factors necessary to cause epidemic cholera ('nonepidemic strains') have in the past been referred to as non-O1 *V. cholerae*, nonagglutinable (NAG) *Vibrio*, or noncholera *Vibrio*. While the majority of these environmental, nonepidemic strains appear to be nonpathogenic for humans, some have been linked with human disease.

Cholera

Cholera has been endemic in the delta of the Ganges and Brahmaputra rivers since the beginning of recorded history. Seven pandemics of cholera have occurred since 1817. The seventh pandemic began in Indonesia in 1961, with subsequent spread through Asia, Africa,

parts of Europe, and, beginning in 1991, South America. Transmission during an epidemic is thought to occur primarily through contamination of potable water. However, foodborne transmission is well recognized, and may play an important role in the introduction of the organism to a new area or transmission in areas of low endemicity, such as the USA.

Illness in cholera is due primarily to the action of CT, a protein enterotoxin that stimulates profuse, watery diarrhea, leading to dehydration and death. *V. cholerae* strains may be classified by O group, and prior to 1992, it was assumed that epidemic cholera could only be caused by strains in O group 1 (*V. cholerae* O1). In 1992, cholera caused by a new serogroup, subsequently designated as O group 139 (*V. cholerae* O139), appeared in epidemic form in India and Bangladesh. Genetic studies have demonstrated that O139 strains are virtually identical to O1 strains, except for the replacement of a 22-kb DNA fragment responsible for O1 antigen biosynthesis with a 35-kb capsular polysaccharide biosynthesis region. With this change in surface antigens, *V. cholerae* O139 strains were able to cause cholera in persons with prior immunity to *V. cholerae* O1. Key cholera virulence factors can be transferred among *V. cholerae* strains by phage, and it is likely that other serotypes (such as O37), when carrying an appropriate complement of virulence genes, can also cause cholera.

Occurrence in the Environment

As previously noted, *V. cholerae* is a free-living organism in the aquatic environment. Growth is influenced by salinity (isolation generally occurs in water with a salinity of 2–20 parts per thousand) and water temperature (optimally > 17 °C). *V. cholerae* produces a chitinase, and may bind to and colonize plankton and other aquatic organisms. The bacterium can shift to a 'rugose' morphologic form, in which it produces an amorphous exopolysaccharide that contributes to the formation of biofilms. Strains in the environment may also assume a 'viable but nonculturable' form. Studies in Peru demonstrate that seasonal cholera epidemics are often preceded by increases of *V. cholerae* in the environment, with subsequent 'spill-over' of the bacterium into human populations. As humans become infected, *V. cholerae* present in their feces can contaminate food and water sources and further increase environmental *V. cholerae* levels, resulting in amplification of the organism and initiation of the epidemic cycle.

Entry to Food Chain

Entry of *V. cholerae* into the food chain is most clearly described in association with shellfish. In areas of low endemicity, such as the USA, the occurrence of illness has been linked with the consumption of raw or undercooked shellfish (crabs, oysters) harvested from areas in which the organism is known to be present. Outbreaks of illness have also been reported in association with consumption of raw or undercooked mussels, cockles, and fish. Environmental and/or fecally derived organisms may contaminate other foods as a result of irrigation or when water is used for cleaning or washing of fruits and vegetables or other foods eaten without cooking. Direct fecal contamination of cooked foods within a household can also serve as a route of transmission, particularly if foods are left at ambient temperature for a period of hours after contamination.

Fate on Processing/Storage

There is an extensive body of literature on the survival of *V. cholerae* in food, beginning with the observation of Babes in 1885 that cholera *Vibrio* remained alive up to 48 h on fresh nonacid vegetables, potatoes, and cheese, but not longer than 24 h on sour fruit and vegetables. In general, cooked foods appear to be a more favorable milieu than raw foods as cooking destroys many competing bacteria. Growth is inhibited by low pH and enhanced by neutral or alkaline pH. Recent studies suggest that cooked rice is a particularly good growth medium.

Survival on shellfish has been reported for 15–45 days, depending on the holding temperature. *V. cholerae* are readily killed by high temperatures (5 min at 65 °C, 'seconds' at 80–100 °C). However, studies conducted by the US Centers for Disease Control during the Louisiana cholera outbreaks in the late 1970s demonstrated that, after experimental inoculation of the organism, *V. cholerae* O1 could be cultured from crabs that were boiled up to 8 min or steamed for up to 30 min; crabs boiled for 8 min or steamed for 25 min were red, and the meat was firm and appeared well-cooked. In recent studies with cockles, mild heat treatment for up to 25 s was inadequate to eliminate *V. cholerae* O139; the persistence of *V. cholerae* O1 in frozen shrimp, with shell, has been reported for over a month.

With the rapid means of transportation now available, any raw or undercooked food (particularly raw or undercooked seafood) imported from an area with epidemic or endemic disease has the potential for carrying the organism. This was dramatically illustrated with the 1991 South American epidemics, where transmission of the disease across national borders (and across continents) was associated with importation of food items such as ceviche (raw, marinated fish) and crab meat. The risk of such transmission is dependent on the level of sanitation in the

country of origin, the extent of the disease within the country (i.e., products from a country with low levels of endemic disease constitute a much smaller risk than products from a country in the midst of a major epidemic), and the handling of the product during shipment. In this context, it should be noted that WHO feels that the risk of cholera transmission associated with trade in food products is 'very small,' and considers restrictions on food and beverage importations to be 'inappropriate cholera control measures.'

Detection in Food, Water, and Physiological Samples

Isolation of the organism from environmental samples generally requires an enrichment procedure. Enrichment broths rely on the ability of *Vibrio* species to grow at alkaline pH in the presence of bile salts, or upon the ability of *Vibrio* to use gelatin as the only available carbon and nitrogen source: commonly used enrichment broths include alkaline peptone water and gelatin phosphate saline broth. The enrichment broth should be streaked within 6–8 h after inoculation on to a selective media such as thiosulfate citrate bile salts sucrose (TCBS) agar. Isolation of the organism from stool samples also requires the use of a selective medium such as TCBS, and may be facilitated by an enrichment step in alkaline peptone water.

Identification of typical colonies from TCBS plates is based on standard biochemical characteristics. Epidemic strains can be tentatively identified by serotyping with O1 and O139 specific antisera. *V. cholerae* of O group 1 can be further divided into two serovars, Ogawa and Inaba, and a rare third type, Hikojima, as well as two biotypes, classical and El Tor. Confirmation that an isolate is capable of causing epidemic disease requires demonstration that the strain has the ability to produce cholera toxin. DNA probes are now available for identification of strains carrying the genes for cholera toxin, VPI, and other critical virulence factors. These probes have proven to be extremely useful in epidemiologic studies and in the screening of environmental isolates.

Symptoms and Characteristics

Despite the dread inspired by the term 'cholera', the majority of persons infected with epidemic *V. cholerae* strains do not have severe illness: 75% of persons infected with strains of the classical biotype have inapparent or mild disease, while 93% of infections with biotype El Tor strains (which are responsible for the most recent pandemic) have illnesses that are inapparent or mild. The infectious dose is dependent to a large degree on gastric acidity and the associated buffering capacity of the vehicle carrying the organism. When normal, healthy, adult North American volunteers ingested 10^6 *V. cholerae* O1 organisms in water, neither illness nor infection resulted. However, volunteers consistently became infected after ingesting 10^6 organisms with 2 g of sodium bicarbonate or with food; 10^3 organisms caused illness in four of six volunteers when administered with sodium bicarbonate.

The incubation period for cholera varies from several hours to 7 days. Although there may be premonitory symptoms such as anorexia and abdominal pain, in most cases onset is sudden, with profuse diarrhea. Initially the stool is brown with fecal matter, but soon the evacuations assume a pale gray color; mucus in the stool imparts the characteristic rice-water appearance. Tenesmus is absent; instead, there is a feeling of relief as enormous amounts of fluid are passed effortlessly. Vomiting may be present, occurring within a few hours of the onset of diarrhea. Temperature is usually normal or subnormal. Peak stool losses occur within 24 h of the onset of diarrhea and in cholera gravis (the most severe form of cholera) may exceed 1 l of fluid per hour, resulting in profound dehydration and circulatory collapse.

In epidemic settings there is no other disease that can consistently cause severe, life-threatening diarrhea and dehydration in adults. In individual cases, diarrhea approaching the severity of cholera can be caused by other diarrheal pathogens, including enterotoxigenic *Escherichia coli* and strains of non-O1 *V. cholerae*. Among children, rotavirus can also be a cause of severe, dehydrating diarrhea.

Treatment, Prevention

Treatment of cholera is based on replacement of fluids lost through diarrhea: this can almost always be accomplished by oral rehydration, although in the most severe cases intravenous rehydration may be necessary. Antibiotics such as tetracycline can shorten the duration of diarrhea and reduce the period of carriage. However, antibiotics should always be regarded as ancillary therapy to vigorous rehydration.

Prevention is based on the maintenance of good sanitation, provision of safe potable water, and avoidance of raw or undercooked foods in or from highly endemic or epidemic areas. Currently available parenteral vaccines are of low efficacy, and their use is not recommended. Several oral vaccines are under active development; their role in disease prevention remains to be determined.

'Nonepidemic' *Vibrio cholerae*

Strains of *V. cholerae* that do not carry virulence factors necessary to cause cholera have been implicated as a cause of diarrheal disease and, in

susceptible hosts, may cause septicemia. Epidemiologic studies, and studies with volunteers, have linked the occurrence of diarrheal illness with the production of a heat-stable enterotoxin (NAG-ST) similar to that produced by enterotoxigenic *E. coli*; diarrheal illness has also been linked with the production of cholera toxin or a cholera toxin-like toxin, and with the ability of a strain to colonize the intestine.

Occurrence in the Environment

As previously noted, nonepidemic strains of *V. cholerae* are ubiquitous in the estuarine environment: these organisms have been isolated from surface water at multiple sites in North America, Europe, Asia, and Australia, and it is likely that they are present in coastal and estuarine areas throughout the world. Nonepidemic strains have also been isolated from a variety of wild and domestic animals, including 6% of seagulls sampled in England; 14% of dogs in Calcutta, India; cows, goats, dogs, and chickens in India; ducks in Denmark; and horses, lambs, and bison in Colorado.

Entry to Food Chain

Nonepidemic *V. cholerae* can be isolated from a high percentage of oysters and other filter-feeding shellfish, particularly during warm summer months when counts of the organism are the highest in estuarine waters. Isolation is not associated with the presence of fecal coliforms. Results of a US Food and Drug Administration study of random oyster lots are shown in Table 1: overall, nonepidemic (non-O1) *V. cholerae* strains were isolated from 14% of 790 oyster lots tested, ranging from a high of 38.5% in July to a low of 0% in December and March. Not unexpectedly, epidemiologic studies in the USA have shown a significant association between non-O1/non-O139 *V. cholerae* diarrhea and eating raw oysters.

Table 1 Frequency distribution of oyster samples positive for *Vibrio cholerae* by month of harvest

Month of harvest	*No. of samples*	*No of samples with* V. cholerae[a]	
		O1	*Non-O1*
January	73	0 (0)	1 (1.4)
February	68	0 (0)	3 (4.4)
March	68	0 (0)	0 (0)
April	64	0 (0)	5 (7.8)
May	53	1 (1.9)	7 (13.2)
June	62	2 (3.2)	22 (35.5)
July	104	3 (3.2)	40 (38.5)
August	85	1 (1.2)	20 (23.5)
September	93	0 (0)	11 (11.8)
October	53	0 (0)	1 (1.9)
November	40	0 (0)	1 (2.8)
December	27	0 (0)	0 (0)

[a]Percentages are given within parentheses.

From Twedt RM, Madden JM, Hunt JM *et al*. (1981) Characterization of *Vibrio cholerae* isolated from oysters. *Applied Environmental Microbiology* 41: 1475–1478.

Outbreaks of non-O1/O139 *V. cholerae*-associated diarrhea have also been associated with other foods, including chopped egg (on an airplane flight to Australia), and preprepared gelatin (Mexico). In a study in the Ban Vinai refugee camp in Thailand, nonepidemic strains were isolated from a number of food items, including 4% of vegetables and 39% of meat samples. Routes by which the organism entered the food chain in these instances are unclear.

Fate on Processing

Characteristics of nonepidemic *V. cholerae* strains during processing have not been extensively investigated; preliminary studies suggest that they are similar to those described for epidemic strains.

Detection in Food, Water, and Physiological Samples

Isolation and identification techniques are identical for epidemic and nonepidemic strains. Strains shown by DNA probes or other genetic techniques to carry genes for CT or NAG-ST would appear to have the highest risk of causing illness. However, given our current state of knowledge, it is not possible to differentiate clearly nonepidemic *V. cholerae* which are potentially pathogenic from those which are nonpathogenic.

As noted below, nonepidemic *V. cholerae* can also cause wound infections and septicemia. Isolation is readily made from blood agar or other standard media used in culturing wounds; the organism grows well on standard blood culture media. Isolates from patients with septicemia tend to be more heavily encapsulated than general environmental isolates.

Symptoms and Characteristics

The most common manifestation of nonepidemic *V. cholerae* infection is diarrhea. Based on outbreak reports and volunteer studies, the incubation period appears to be short (< 24 h). Abdominal cramps may be prominent; bloody diarrhea is occasionally reported. Illness is usually mild and self-limited, although a diarrheal stool volume of 5.3 l was seen in one volunteer receiving 10^6 CFU of one nonepidemic strain.

Nonepidemic *V. cholerae* strains have also been isolated from persons with septicemia. Mortality rates in these cases exceed 50%. Illness appears to be confined to persons with underlying liver disease

or persons who are immunocompromised in some way. The route of entry of the organism in these cases is not well defined, although foods containing the organism would be a likely source.

Treatment/Prevention

As with epidemic *V. cholerae*, treatment of diarrhea is dependent on adequate rehydration. Septicemia requires aggressive antibiotic therapy and supportive care. Prevention in the developed world is based on the avoidance of raw or undercooked shellfish. In the developing world prevention is similar to that for other enteric pathogens, including avoidance of raw or undercooked foods of all types.

Vibrio parahaemolyticus

R Sakazaki, Japan Institute of Biological Sciences, Chiyodaku, Tokyo, Japan

Introduction

Vibrio parahaemolyticus, the causative organism of gastroenteritis associated with the consumption of raw or undercooked seafish, shellfish, and other contaminated foods, is one of the best described of pathogenic vibrios. Although several synonyms have been suggested for it, the name *V. parahaemolyticus* has been formally accepted.

Characteristics

V. parahaemolyticus is a short, slightly curved or straight, Gram-negative, facultatively anaerobic, motile rod. Sometimes it reveals polymorphism with coccoid cells, especially in older strains. In broth cultures, cells each exhibit a single polar, sheathed flagellum, but on the surface of solid media young cultures may also show unsheathed peritrichous flagella.

V. parahaemolyticus is a halophilic organism. It can grow on/in ordinary media containing 1–8% NaCl, but the most abundant growth occurs in the presence of 2–4% salt. It fails to grow on/in media lacking salt. It grows between 10 °C and 44 °C, but the optimal temperature for growth is between 30 °C and 37 °C. It fails to grow at 4 °C and lower temperatures not only arrest multiplication of the organism but also cause a rapid decrease in viable cell numbers. The vibrio can grow at a pH range from 5.6 to 9.6 but grows best at pH 7.6–8.6. Under optimal conditions, the generation time of the vibrio in the exponential phase of growth is estimated at 9–13 min.

Cultures of *V. parahaemolyticus* produce moist, circular colonies, opaque in appearance, attaining a size of 2–3 mm on ordinary agar media containing 2–3% salt after incubation at 37 °C for 24 h. Sometimes mucoid and viscid colonies may be seen. After several subcultures, however, dissociated translucent or rugose colony variants may also occur. Cultures of this vibrio, especially those isolated

from environmental sources, often show swarming on the surface of nutrient agar. In broth containing 2–4% salt, most strains produce heavy homologous turbidity, but rugose variants form a pellicle on the surface of the broth.

With few exceptions, *V. parahaemolyticus* produces both lysine and ornithine decarboxylases as well as indole. Arginine dihydrolase is not produced. It gives a negative reaction in the Voges–Proskauer test, and a positive reaction in the oxidase test. It ferments glucose, maltose, mannose, trehalose, and mannitol without gas production but fails to attack lactose, sucrose, xylose, and sorbitol. The majority of strains ferment arabinose, but occasional strains fail to do so. Urea is not usually decomposed, but some strains are able to hydrolyze it. It has been suggested that the ability to hydrolyze urea may be a marker for those Kanagawa-negative strains which are associated with illness but which nevertheless produce a thermolabile TDH-related hemolysin (TRH) related to, though different from, the direct thermostable direct hemolysin (TDH) of Kanagawa-positive strains.

The vibrio is susceptible to most antibiotics except penicillin, ampicillin, and polymyxin B, but resistant mutants do occur. It is also susceptible to the vibriostatic agent O/129 (2,4-diamino-6,7-diisopropyl pteridine) at a concentration of 150 μg ml^{-1} but resistant at 10 μg ml^{-1}.

Strains of *V. parahaemolyticus* may be typed with a combination of both somatic O and capsular K antigens, based on a serological scheme in which 13 O and 75 K antigens were established. The number of K antigens has since been extended to 84. Most strains of the vibrio are inagglutinable with O antisera in the living state, but after heating suspensions for 30 min at 100 °C they become O-agglutinable. H antigens are not included in the antigenic scheme, since in all strains they are regarded as serologically identical, although antigenically the polar flagellum and the peritrichous flagella are different.

Incidence in the Aquatic Environment
