This research into the importance of human versus cows' milk, or formula feeding, was stimulated by animal studies that had indicated that dietary nucleotides may be required for maintenance of normal immune function in neonatal mice. A subsequent study in healthy term infants demonstrated that in those either breast-fed, or fed formula supplemented with nucleotides, some indices of immune function were indeed significantly higher (natural killer cell cytotoxicity and interleukin-2 production by stimulated mononuclear cells) compared with nonsupplemented formula groups. However, this was found only in the newborn. The rate of growth and incidence and severity of infections did not differ significantly among these different dietary groups at 2 months. It was concluded that nucleotides may be a component of human milk that contributes to the enhanced immunity of the breast-fed infant. Another study implied that allergic diseases develop during feeding of cows' milk, but not human milk. It may be that the dearth of uridine nucleotides in cows' milk after 1 month of lactation could be implicated, since these effects were independent of any difference in the gut flora demonstrated in breast-fed, as distinct from formula-fed, infants.

This debate and the problems addressed arose from the use of animals. As indicated elsewhere in this chapter, rodents have both XDH and uridine phosphorylase everywhere. By contrast, in humans, uridine phosphorylase is confined to the liver, and XDH is confined to the liver, intestinal mucosa, and breast milk. This problem highlights the general lack of awareness of the two curious and unexplained differences in the synthesis of nucleotides in humans. First, pyrimidines derived from nucleotide degradation are salvaged at the nucleoside (uridine) level, purines as the base. Second, whereas purine nucleotides are derived exclusively from endogenous sources in humans, pyrimidine nucleotides can be formed from uridine orcytidine ingested in the diet as well. These important differences are underlined by the successful treatment with oral uridine of patients with uridine monophosphate synthase (UMPS) deficiency, which presents generally as macrocytic anemia. A few patients are also immunodeficient. UMPS is the complex catalyzing the last two steps of pyrimidine *de-novo* synthetic (DNS). Long-term follow-up of such patients confirms that humans cannot only survive without pyrimidine biosynthesis, but also reproduce. Thus, uridine certainly can restore immune function in humans as well.

Role of Endogenous Nucleotides, Nucleosides, and Bases in Cellular Metabolism

Purines and pyrimidines are effectively anchored inside the cell as the nucleotide by attachment to a pentose linked to a mono-, di- or triphosphate group (Figure 1a and 1b), principally the triphosphate. It was originally assumed that all reactions of biological significance took place intracellularly at the nucleotide level. Attention has been focused recently on the extracellular regulatory functions of purine nucleosides (base plus pentose), or the bases themselves. The pentose may be either ribose (ribonucleoside) or

2′-deoxyribose (deoxyribonucleoside) bound by the C1 atom through a glycosidic linkage to the N9 atom of the purine group, or to the N2 of the pyrimidine group (Figure 1).

The importance of purine and pyrimidine nucleotides in cellular metabolism is twofold. In addition to their role in the storage, transmission and translation of genetic information (as the polynucleotides DNA and RNA), as mononucleotides, they play an equally vital role in lipid and membrane synthesis (in the form of purine and pyrimidine sugars or lipids), signal transduction, and translation (in the form of guanosine triphosphate, cyclic adenosine monophosphate, and cyclic guanosine monophosphate), as well as providing the energy (adenosine triphosphate (ATP)) that drives many cellular reactions and forms the basis of the coenzymes (nicotinamide adenine dinucleotide, nicotinamide adenine dinucleotide phosphate, flavin adenine dinucleotide, etc.) (*See* **Coenzymes**.)

All cells require a balanced supply of purine and pyrimidine nucleotides for growth and survival, but this may vary from cell to cell, depending on function. Liver, for example, has a very complex nucleotide profile, compared with heart. These nucleotides may be built up by one of two routes: the energetically expensive multistep synthetic route, or the single-step so-called 'salvage' pathway. In normal circumstances, salvage predominates over synthesis. Figure 2 illustrates the different metabolic pathways involved in the *de-novo* synthesis of these nucleotides, as well as the efficient recycling of the nucleotides or bases derived from them during the wear and tear of daily life (muscle work, wound healing, erythrocyte senescence, protein glycosylation, providing essential nourishment for the brain, etc.). Interestingly, whilst this recycling takes place at the base level for purines, it is the pyrimidine nucleosides that are actively recycled in humans, with only a small proportion being degraded further in either case (Figure 2). The importance of these different pathways to the overall control of nucleotide concentrations in the body is the subject of many excellent reviews and for this reason is summarized only briefly here.

Nucleotide Triphosphate Production and Nucleic Acid Synthesis

Purine and pyrimidine ribomononucleotides built up by either the *de-novo* or synthetic routes are phosphorylated via the correponding diphosphate to the triphosphate, which is the active intracellular form of most mononucleotides. In addition to the variety of vital individual cellular functions described above, these ribomononucleotides are essential intermediates in the synthesis of the polynucleotides RNA and DNA respectively (Figure 2), being incorporated into DNA following the formation of the deoxyribonucleotide from the corresponding diphosphate by the enzyme ribonucleotide reductase. The latter is an allosteric enzyme; its activity and specificity are controlled in a complex manner by both purine and pyrimidine ribo and deoxyribonucleotides. This process is particularly active in cells and tissues with a high rate of turnover (e.g., lymphocytes, gut epithelium, skin, bone marrow, etc.). There is approximately five times as much RNA and DNA in the body.

Breakdown of Nucleic Acids

The polynucleotides DNA and RNA, although relatively stable in most tissues, turn over rapidly in dividing cells. Both DNA and RNA first must be degraded to the constituent mononucleotides, which are themselves degraded further. A variety of enzymes capable of hydrolyzing the phosphodiester bonds have been described and include ribonucleases specific for RNA and deoxyribonucleases for DNA as well as nonspecific nucleases, phosphorylases and phosphomonoesterases. The mononucleotides have the highest turnover rate, DNA the lowest. Further catabolism of the resulting monophosphate will differ depending on whether it is a pyrimidine or purine ribonucleotide of deoxyribonucleotide. For example, whereas adenine ribonucleotides are predominantly deaminated at the nucleotide level in humans by AMP-deaminase, deoxy-AMP is not a substrate for this enzyme and must first be degraded to deoxyadenosine and deaminated at the deoxynucleoside level (Figure 2).

Purine and pyrimidine (deoxy) nucleotides are degraded to the corresponding (deoxy) nucleosides by specific 5′ nucleotidases. Different purine endo- or ecto-5′ nucleotidases have been identified with different substrate specificities and may be of particular importance in providing bases for nucleotide resynthesis in tissues where there is rapid cell turnover and massive cell death (e.g., thymus, spleen, bone marrow). As mentioned above, whereas the normal metabolic route for pyrimidines is salvage at the nucleoside level, that for purine nucleosides and deoxynucleosides is degradation to the corresponding base by purine nucleoside phosphorylase, prior to salvage. This degradation is favored by the high intracellular inorganic phosphate and low ribose 1-phosphate levels in most tissues. Interestingly, these phosphorylases are not reactive toward either adenosine or cytidine, or their analogs, in human cells and first must be deaminated at the (deoxy) nucleoside (or nucleotide) level.

Salvage is an active process for both pyrimidines and purines. Consequently, only a small fraction of

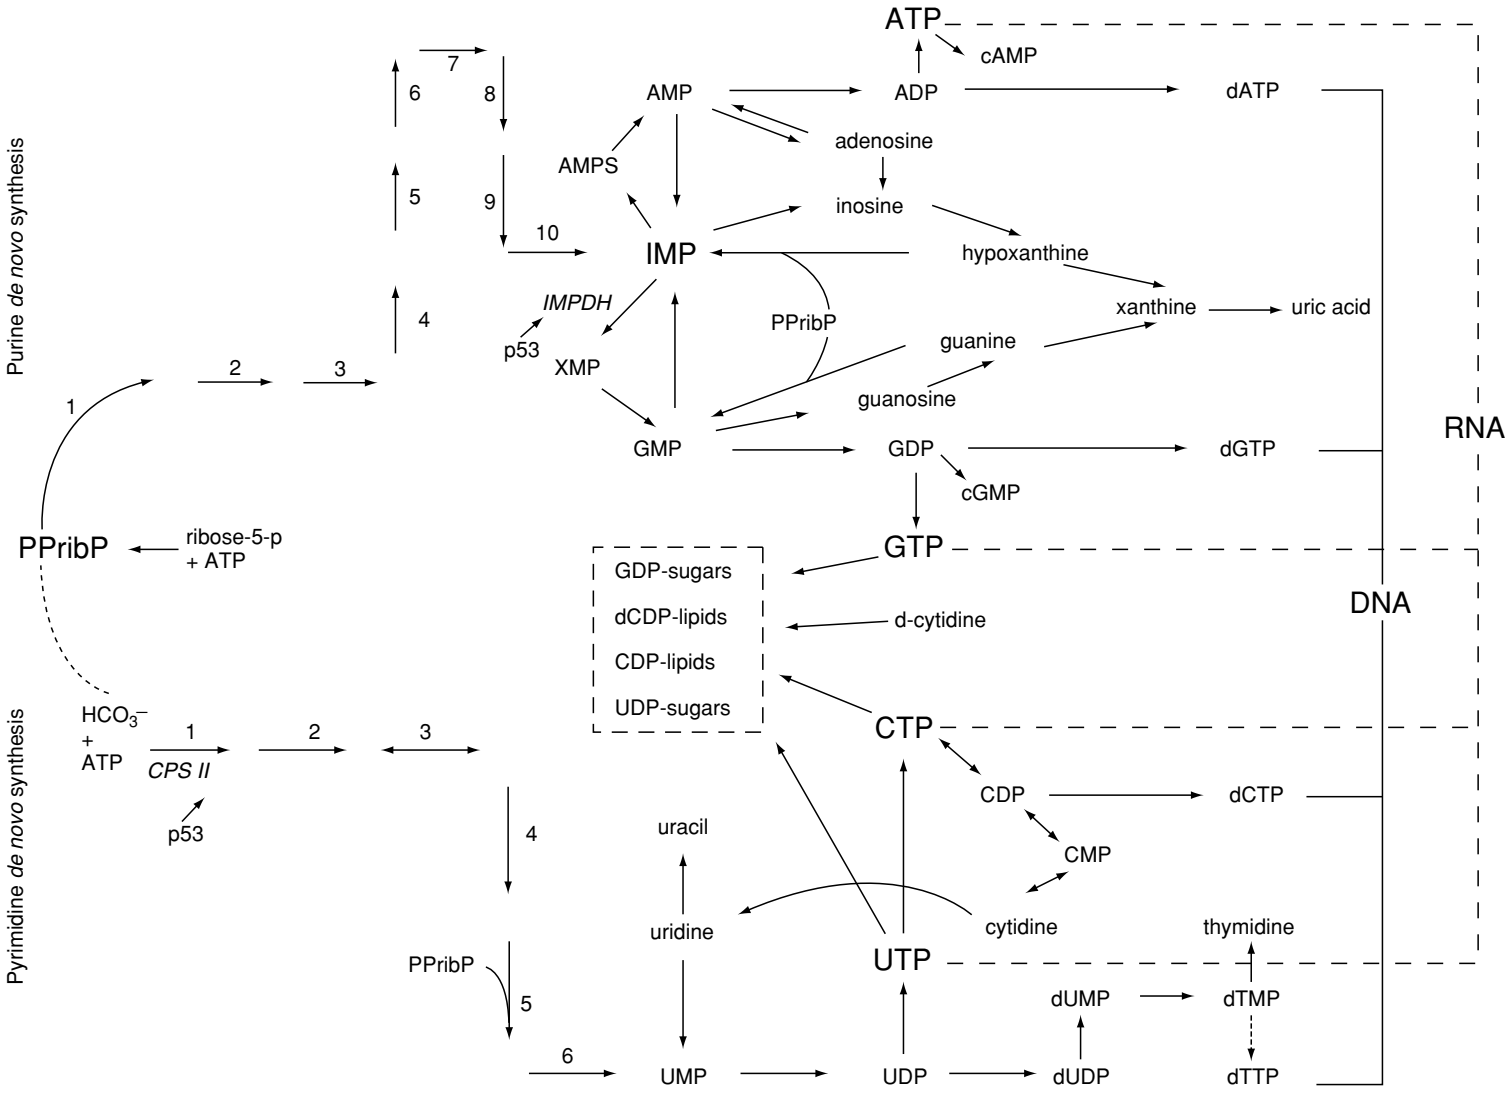

Figure 2 Multistep purine and pyrimidine nucleotide de novo synthetic (DNS) routes and single-step salvage (hypoxanthine, guanine, uridine, cytidine, D-cytidine) pathways, indicating the enzymes inosine monophosphate dehydrogenase (IMPDH) and carbamoyl phosphate synthetase 11 (CPS 11) targeted by analogs which deplete nucleotide pools, reportedly associated with a p53-dependent Go/G1 arrest. Note the involvement of 5-phosphoribosyl pyrophosphate (PPribP) in both purine DNS and salvage as well as in pyrimidine DNS. The role of ATP, GTP, UTP, and CTP in DNA and RNA synthesis, of ATP and GTP in 2nd messenger synthesis, of UTP, CTP, and GTP in the synthesis of the glycoconjugates (dashed box) essential for membrane synthesis, structure, and function and protein glycosylation, is also evident.

the nucleotides turned over daily is actually degraded and lost to the body. The pyrimidine bases, uracil and thymine, derived from nucleosides not recycled are degraded further to the β-amino acids, and there is thus no measurable end product. However, such loss is probably comparable with that for purines, the normal end product of which in humans is uric acid, formed from the precursor purine bases xanthine and hypoxanthine by the action of xanthine dehydrogenase (Figure 2).

Rates of Nucleotide Synthesis and Degradation in Different Cells

It has become apparent that the original concept of endogenous metabolism and its overall control, involving a complex interplay between *de-novo* synthesis and salvage, does not apply to all cells but is governed by a tissue- or cell-specific complement of enzymes and/or controls on them, depending on the function of that cell or tissue. The human erythrocyte, for instance, is anucleate and lacks the ability to use either salvage or *de-novo* synthesis to maintain its ATP levels, being dependent on adenosine scavenged from other tissues for this. In addition, the pyrimidine nucleotides found in nucleated cells are absent from mature erythrocytes, the only pyrimidines normally present being in the form of uridine diphosphate (UDP) sugars. ATP is also the most important purine in both skeletal and heart muscle, adenine nucleotides making up 95 and 90% of the total nucleotide complement, respectively. Although DNA in most tissues is considered relatively stable, it is evident from the two inherited disorders associated with immunodeficiency that cell death and rapid turnover of cells of the hemopoietic system (e.g., extrusion of the nucleus during erythrocyte maturation, or mounting an immune response) normally produces significant amounts of deoxyribonucleosides, as well as ribonucleosides, which must be degraded further. These disorders have highlighted the fact that removal of metabolic waste from DNA catabolism is vital to the normal immune response; failure to do so can result in the accumulation of deoxy-ATP and deoxy-GTP. These deoxynucleotide triphosphates are extremely toxic to T-lineage stem cells, resulting in severe combined immunodeficiency affecting both T- and B-cells in subjects deficient in adenosine deaminase, or a T-cell-specific immunodeficiency, in purine nucleoside phosphorylase deficiency (Figure 2).

Endogenous Nucleic Acid Synthesis in the Gut

It was originally reported from studies in guinea-pigs that the gastrointestinal tract was incapable of *de-novo* synthesis. However, subsequent workers have shown significant synthetic activity in rat intestine, as evaluated by the incorporation of radiolabeled glycine into RNA. The nucleic acid content of intestinal mucosa is high, as is the rate of cell turnover in the luminal villi, and it has been calculated in rat that about 30 mg of endogenous nucleic acid enters the lumen daily. This implies a considerable loss of both purines and pyrimidines, which can only be replaced by *de-novo* synthesis. Studies of nucleotide concentrations in rat intestine have shown both pyrimidine and purine nucleotides at concentrations equivalent to those in liver, supporting active nucleotide metabolism in the intestine.

Intestinal absorption is obviously related to intestinal motility and local blood flow. The presence of adenosine receptors on rat jejunal mucosal cells may be particularly important in the regulation of fluid and electrolyte absorption as well as the active transport of nutrients. Such adenosine may be generated slowly from nucleotides by nucleotidases physically or functionally coupled to the adenosine membrane translocator.

It is evident from the above that the pathways leading to the formation and degradation of nucleic acids are complex, and that many factors determine the origin as well as amount of endogenous pyrimidine or purine nucleotides turned over daily. Moreover, this will differ depending on the cell or tissue.

Role and Fate of Dietary Nucleic Acids

The metabolism of nucleic acids ingested in the diet difers from that of endogenous nucleic acids. The intestinal mucosa plays an important role in this. The above studies confirm that pyrimidine as well as purine nucleotides in intestinal mucosal cells are derived from endogenous sources. However, a growing body of evidence supports a role for dietary nucleotides derived from the gut in intestinal development, turnover, and repair. Suggested effects include enhancement of the host mucosal defense system and an influence on neonatal lipid metabolism and on iron bioavailability, implying a novel role for nutrition in the modulation of gut function.

Most of our knowledge relating to dietary nucleic acid metabolism in the intestine is derived from studies of the absorption of exogenous purine in different species – mouse, dog, rat, pig, etc., as well as humans – which date back as far as the latter half of the nineteenth century. Investigations in animals have shown that whereas the ribose attached to nucleosides derived from RNA was further metabolized, the phosphate was absorbed and excreted in the urine.

Recent studies using ^{13}C-labeled nucleic acid to supplement the diets of rats and chickens have

provided further evidence for the incorporation of dietary pyrimidine nucleosides, but not purine nucleosides, directly into hepatic RNA. The successful lifelong treatment with uridine of patients with hereditary oroticaciduria – a defect in pyrimidine *de-novo* synthesis – confirms that dietary uridine is certainly absorbed and salvaged into mono- as well as polynucleotides in humans. The lack of effect of oral uracil in this disorder also confirms that uracil is a metabolic waste and that pyrimidine salvage occurs at the nucleoside level in humans.

Recent investigations have addressed the supposedly beneficial effects of dietary CDP-choline (citicholine) in patients with stroke or trauma, theoretically by increasing acetylcholine production in cholinergic neurons, as well as the amount of cell membrane. These studies confirmed that, when taken orally, CDP-choline elevates plasma levels of both choline and uridine (not cytidine) in humans, but no benefit was demonstrated in clinical trials.

Metabolism of Dietary Purines by Gut Bacteria

Animal studies have shown that the metabolism of dietary nucleic acid and the corresponding purine nucleotides, nucleosides, and bases in the gut is rapid. Isotope studies demonstrated that up to 50% of the radiolabeled purine is recovered as carbon dioxide within 30 min. The role of gut bacteria in this process was indicated by experiments using the XDH inhibitor, allopurinol, concomitantly, when the radiolabel was recovered *in toto* (in urine and feces only), presumably relating to inhibition of bacterial XDH. Allopurinol not only inhibited purine degradation but also decreased the absorption of dietary purine, a seemingly beneficial effect that may explain the reduction in total purine excretion noted in human subjects on a normal diet taking allopurinol.

Intestinal Mucosa Degrades Dietary Purines to Uric Acid

Interestingly, the above radiolabeling studies in pigs (where, as in humans, XDH activity is significant only in intestinal mucosa and liver), confirmed a lack of any radiolabel incorporation from dietary purine into tissue nucleotides. These studies demonstrated conclusively that dietary purine is degraded to a nonreutilizable form by the intestinal mucosa. Studies in other animal species have confirmed this, purine nucleotides, nucleosides, and bases absorbed from the gut lumen being largely converted to uric acid during passage across the mucosa and released as such in serosal secretions, prior to further degradation by urate oxidase (uricase) in the liver. Thus, in contrast to pyrimidines, humans have no apparent requirement for dietary purines. The intestine thus serves as an effective barrier through the activity of a battery of enzymes capable of rapidly degrading purines already partly processed by gut bacteria to the nonreutilizable metabolic waste, uric acid. Such rapid degradation of purines by the gut presumably reflects an important evolutionary development to protect the integrity of the human genome. The uric acid produced daily in humans thus derives from two sources: catabolism of exogenous as well as endogenous mono and polynucleotides (Figure 3).

Excess Dietary Levels of Nucleic Acids and their Clinical Consequences

As mentioned above, pyrimidines have no measurable end product. The potential toxicity of dietary nucleic acids thus relates predominantly to a single mutational event that has resulted in the fact that the insoluble uric acid, and not the much more soluble allantoin as in other mammalian species, is the only measurable end product of nucleic acid degradation in humans. Although it had long been accepted that the enzyme uricase had been lost in the course of human evolution, more recent studies have established that the absence of uricase activity results from a lack of gene transcription, rather than loss of the gene itself. However, other factors play an equally important role in determining the pathogenesis of nucleic acids ingested in the diet.

Role of Exogenous Purine in Determining Circulating Uric Acid Concentrations

The ingestion of food now known to be rich in purines has been noted for millennia to be high in subjects with what has been designated 'primary' gout, the gout affecting predominantly the middle-aged male. This type of gout is a disorder of affluent societies consuming diets rich in purines; it is rare in women or children. During times of hardship, uric acid concentrations in the population fell considerably, and 'primary' gout almost vanished. The fact that gout was extremely prevalent among wealthy Englishmen for more than three centuries up to World War I is not surprising when the dietary habits of the day are examined. These affluent gentlemen habitually consumed vast meals comprising many courses and frequently including 16 different meats, the majority of which were rich in nucleic acids and other purines.

Type of Nucleic Acid and Toxicity

Detailed studies of dietary nucleic acid absorption in humans were carried out by Zöllner and coworkers in the late twentieth century and confirmed that nucleic acids ingested in the diet exert their major

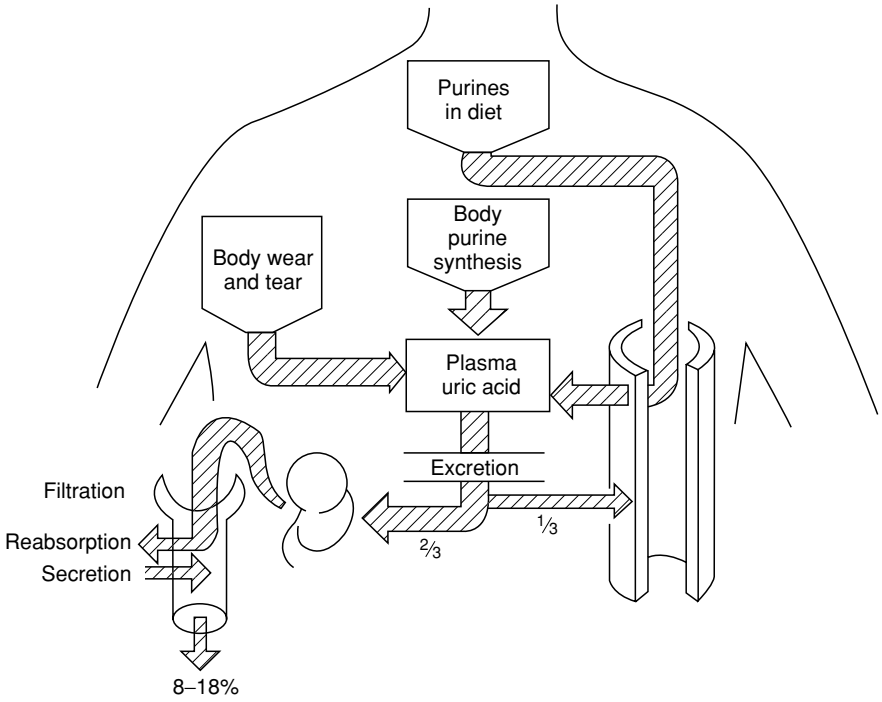

Figure 3 Schematic diagram showing the factors influencing the plasma uric acid, the end product of endogenous (body synthesis plus daily wear and tear) and exogenous (dietary) purine metabolism in humans. The different mechanisms by which this metabolic waste is eliminated (two-thirds by the kidney, one-third by the gut) in normal individuals are also shown. At the bottom left is a simplified version of the complex factors (involving filtration, reabsorption and secretion) interacting in the proximal tubule of the human kidney and resulting in the urinary excretion of only 8–18% of the filtered load depending on age and sex. Reproduced from Nucleic Acids: Physiology, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

effect on uric acid levels. These studies showed that the nature of the nucleic acid ingested is equally important, with the effect of RNA being more than twice that of DNA (Figure 4a). This effect is also evident whether the purine is ingested in the form of nucleic acids, mononucleotides, nucleosides, or bases. Moreover, some forms of purine, e.g., guanosine – the principal RNA degradation product in yeast-rich beverages such as beer (especially real ale) – are absorbed and catabolized more readily than others. A controlled study of diet in primary gout patients compared with control males of comparable age demonstrated that the average daily intake of most nutrients, including purine nitrogen, was similar. However, gouty patients drank significantly more alcohol, predominantly in the form of beer (60 g per day, equivalent to 2.5 l of beer) and had a significantly higher mean plasma uric acid (0.49 mmol l^{-1} compared with 0.39 mmol l^{-1}).

Role of the Kidney or Drugs in the Genesis of Toxicity

The pathological changes that result from uric acid being the exclusive end product of purine metabolism in humans are due entirely to the insolubility of this metabolic waste, coupled with the other peculiarity that primates display, i.e., the renal tubule reabsorbs around 90% of the filtered urate (Figure 3). Net reabsorption is slightly higher in normal males (92%) than in females (88%) and is lower in children of either sex (80–85%). This explains the higher plasma uric acid in adult males and makes them more vulnerable to situations of overproduction, or overingestion. Clearly, sex and age are equally important contributory factors.

It is noteworthy that when normal subjects are fed yeast RNA, the plasma urate rises little with increased intake, the increase in the excretion of urate being dramatic when the rise in plasma urate is modest (Figure 4b). Thus, neither overingestion nor overproduction (unless sudden and massive) is likely to raise the concentration of uric acid in the plasma considerably, if the renal response is normal. It is obviously not so in the majority of gouty males with primary gout, where the striking change is that, for any plasma urate concentration, the excretion of urate is consistently less than in normal subjects. This defect in handling by the kidneys relates to a greatly reduced

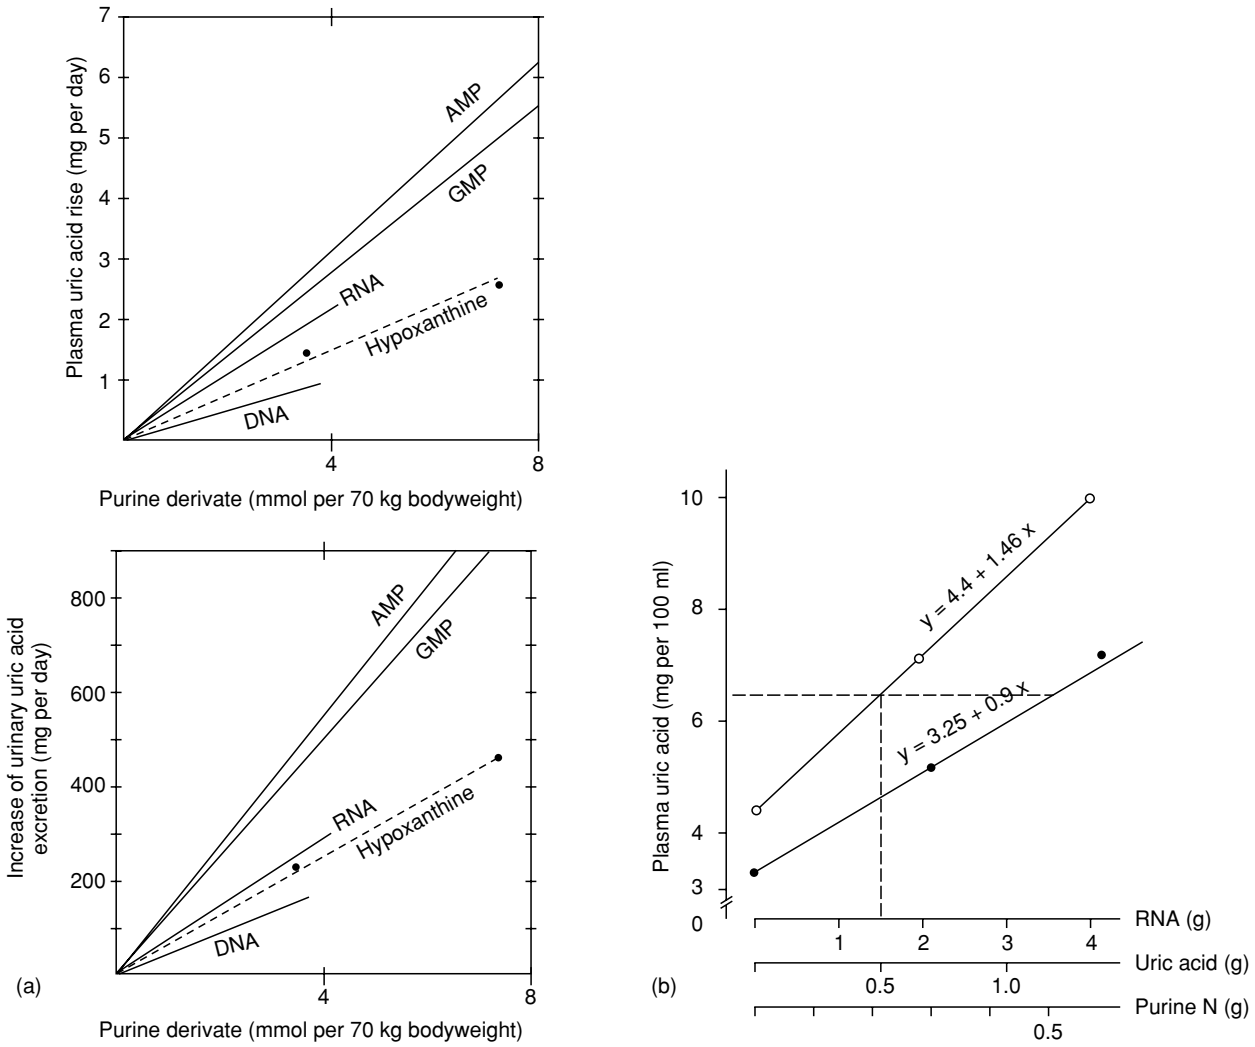

Figure 4 (a) Increase in plasma and urine uric acid (mg per day) in response to a purine load from the different sources indicated on a molar basis. (b) Influence of graded additions of RNA to a purine-free formula diet on plasma uric acid levels of either normouricemic (-•-) or hyperuricemic (-○-) individuals (some of whom had a positive family history of gout). Reproduced from Nucleic Acids: Physiology, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

clearance of uric acid relative to the glomerular filtration rate (FE_{UR}); FE_{UR} is the fractional excretion of uric acid. The mean is 5.4% in gouty males compared with 8.1% for healthy males of comparable mean age (52 years).

The exact nature of this difference is not yet clear, since studies must be reevaluated in the light of recent knowledge of how complex the renal tubular handling of urate is. However, there is no doubt that it involves the transport of uric acid, which occurs predominantly in the proximal tubule, is bidirectional, and has both a secretory and reabsorptive component (Figure 3). Current opinion suggests that the majority of gouty patients underexcrete urate because of a defect in tubular secretion. Confirmation must await identification at the molecular level of the different transporters involved in urate reabsorption and secretion. Clearly, a combination of events is needed to produce hyperuricemia and the clinical syndrome of gout. These are a large intake of readily absorbed purine coupled with a defect in the renal handling of uric acid at the kidney level, which means that the kidney cannot respond to a purine load without an abnormal rise in plasma urate concentration. (*See* **Renal Function and Disorders:** Kidney: Structure and Function.)

However, diet alone may not be the only culprit. Numerous other physiological and pathological agents such as lead are also capable of reducing urate excretion, and hence exacerbate the rise in

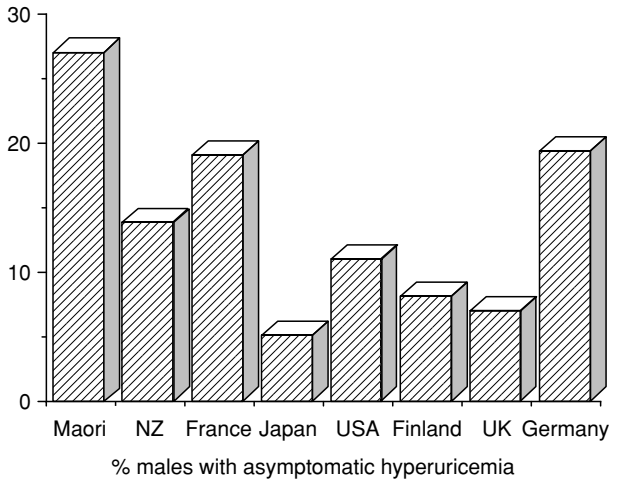

Figure 5 Percentage of Caucasian males, compared with a Polynesian race (the Maori), with asymptomatic hyperuricemia (defined as a plasma uric acid in excess of 0.42 mmol l^{-1}, or 7.0 mg dl^{-1}) in four EU countries, North America, Japan, and New Zealand (NZ).

plasma urate caused by diet. Any of these may lead to an acute attack of gout in a susceptible individual whose plasma urate is already elevated. The best known of the physiological substances are organic acids such as lactate; their overproduction may explain in part the hyperuricemia associated with excessive alcohol consumption coupled with inadequate food intake. Diuretics cause plasma volume contraction, and fractional urate reabsorption increases under these circumstances. The appearance of gout in patients treated with hypotensive agents over long periods currently accounts for over 50% of new presentations in gout clinics. Unusually, the number of elderly females in this group is high, and the mode of clinical presentation is frequently atypical.

Diet may also be important in drawing attention to an unusual subset of patients with juvenile onset of gout; a disorder affecting young males and, unusually, young females and children of either sex equally. Unlike primary gout, where renal function is normal for age, unrecognized, this dominantly inherited disorder is associated with progressive renal disease. Considerable variation in presentation has existed, and there has been no consensus as to whether the gout or the renal disease is the primary factor. However, it is now evident that there are two hallmarks for this disease: the first is hyperuricemia disproportionate to the degree of renal dysfunction; the second is that the degree of renal hypoexcretion of urate is generally extreme, which explains the associated tendency to gout. Moreover, the mean FE_{UR} in this group is only 5.1%, irrespective of age or sex: lower than that of the middle-aged gouty male (5.4%), and even more remarkable considering the high percentage of children and young women in this group. This universally low clearance explains the added susceptibility to dietary purine leading to the isolated attack of gout in children as well as young adults, which has drawn attention to families with 'familial renal disease,' hitherto leading to death in the 30s. Recognition of the correct nature of the familial disorder has underlined the need to measure urate clearance in all kindred members and enabled early diagnosis and treatment of 42% of seemingly healthy children.

This is important because long-term follow-up (>20 years) in these patients treated with plasma uric acid lowering agents has shown that early recognition and treatment ameliorates the progression of the renal disease. These studies implicate uric acid in the etiology of the renal disease, but this has been disputed by others. However, very recent studies suggest that a reappraisal of the pathogenesis and consequences of hyperuricemia in hypertension, cardiovascular disease, and renal disease is warranted, which adds credence to the above hypothesis.

Role of Dietary Nucleic Acid in the Genesis of Urolithiasis

Although overingestion of purines by subjects with a normal renal response does not precipitate gout, it can predispose to uric acid lithiasis. Uric acid stones are relatively common in Australasia and similar countries, where the consumption of purine-rich beverages and food (e.g., beer, seafood, and meat) is high, and in individuals addicted to health foods such as yeast tablets. Vitamin C is also uricosuric, and acute uric acid nephropathy and sometimes urolithiasis have also been reported following therapy with a variety of uricosuric drugs. Perhaps less well recognized is the uricosuric effect of a high-protein diet and the fact that the intake of purine-rich foods also predisposes to calcium stone formation.

Some foods rich in nucleic acid – vegetarian diets consisting of pulses and grains and yeast extracts – have a particularly high adenine content. Although this is not a problem in the normal population, such diets can be potentially lethal to a rare group of subjects with a genetic defect leading to the inability to recycle adenine, overexcretion of adenine, and the even more insoluble uric acid analog 2,8-dihydroxyadenine (2,8-DHA). Patients with this defect generally present in childhood with kidney stones composed of 2,8-dihydroxyadenine. One such case from a commune consuming a macrobiotic diet presented in acute renal failure with severe renal damage, progressing to dialysis and transplantation. Diet can thus be an important precipitating factor in the pathogenesis of inherited disorders associated

with the overexcretion of insoluble purines. (*See* **Macrobiotic Diets; Vegetarian Diets.**)

Reducing Dietary Levels of Nucleic Acids

Diet varies considerably in different countries and must be taken into account when investigating patients for suspected disorders of purine metabolism. Normal ranges for uric acid in plasma and urine differ greatly in the healthy population depending on the country (Figure 5). For example (and in contrast to the nineteenth century), until recently, the majority of subjects in the UK ingested a low purine diet consisting of one meat meal a day, and urinary uric acid excretion above 3.5 mmol per day was considered abnormal. By contrast, the upper limit of normal in Australia has been given as 7.00 mmol per day. However, the increasing affluence of some societies is now leading to an increase in gout, not only in adult Caucasian males, but also in countries such as Japan, where gout was once rare.

Turnover of Exogenous and Endogenous Uric Acid

A useful guide to the dietary purine consumption in different countries can be obtained from the percentage of males with asymptomatic hyperuricaemia. Using this yardstick, the highest consumption in the EU 20 years ago was in France (lovers of pâté and seafoods), the lowest in the UK (Figure 5). The statistics for Germany were from Bavaria where, as in New Zealand and Australia, beer consumption is high. Although similar statistics for diet-related differences are unavailable today, plasma uric acid will have risen along with the increase in obesity and blood pressure, especially in the UK. Race also plays a part, and Polynesians have a genetically low urate clearance compared with Caucasians, as exemplified by the New Zealand Maori (FE_{UR} 4.9% in normouricaemic males, 3.9% in asymptomatic hyperuricemic males).

As we have seen, the body pool of urate, and hence the plasma urate concentration, is the result of a balance between production, ingestion, and excretion. The method for assessing the contribution of diet is to evaluate *de-novo* production of purines by placing the subject on a purine-free diet for 5–7 days and measuring the urinary excretion of urate, which will equal endogenous production. In this way, less than 1–5% of subjects in any country have been found to excrete abnormally large amounts of urate (>3 mmol per day). In such rare cases, an underlying genetic metabolic defect can be generally demonstrated in which the normal feedback controls on *de-novo* nucleotide synthesis and thus endogenous purine production are overridden, resulting in gross uric acid overproduction. Two such defects – both of which are X-linked and generally present in childhood, or adolescence, but sometimes neonatally – have been identified.

Purine Content of Foods

A knowledge of the purine content of specific foods is essential if dietary effects are to be reduced to a minimum. Until recently, such data have been difficult to find but are now available on the web. Most tables give only purine nitrogen, which, as demonstrated by the purine loading studies mentioned earlier, is not always a good guide because of the variation in absorption. Pâté is a particular culprit, as is most offal and organ meat (liver, kidney, heart, brains, sweetbreads), game (venison, pheasant, partridge, grouse), and the nucleic-acid-rich fish and seafoods – herring, kippers, sardines, smelts, sprats, anchovies, salmon, trout, mackerel, crustaceans (crab, lobster, prawns), shellfish (scallops, mussels), and caviar or roe. Purine nitrogen varies and ranges from 50 mg per 100 g in beef steak to 234 mg per 100 g in sardines. Many fresh vegetables, e.g., spinach, peas, beans, lentils, mushrooms, asparagus, and cauliflower, also have a considerable purine content, as have soya and other pulses and grains (porridge and oats, wheat and rye cereals). All meat extracts (Bovril, Oxo) or yeast extracts (Barmene, Tastex) are very rich in purine.

However, many studies have established that humans addicted to diets rich in nucleic acids are generally very reluctant to alter their dietary habits despite the strongest advice to do so. Consequently, therapy to reduce the pathological effects of dietary nucleic acids, namely the elevated uric acid levels, becomes essential.

Therapeutic Approaches to Reducing Uric Acid Levels

Numerous plasma uric acid-lowering drugs are in current use. Some act by increasing the renal elimination of uric acid (uricosuric drugs, e.g., benzbromarone), or restrict its formation (e.g., allopurinol). Allopurinol reduces urine uric acid levels as well. As mentioned earlier, studies in both humans and animals have shown that allopurinol has an additional beneficial effect in reducing dietary purine absorption. Allopurinol is usually a safe drug, but in rare instances, mostly in renal disease, other factors must be considered. The active metabolite of allopurinol, oxypurinol, is handled by the kidney in a fashion akin to uric acid and thus, even normally, has a long half-life. Since excretion of oxipurinol is reduced in renal failure, the allopurinol dose must be reduced to lower the plasma oxipurinol and minimize the risk of bone marrow depression, or other undesirable side-effects, which include epidermal necrolysis and

hepatotoxicity. A recent study pinpointed the poor response to allopurinol in heavy drinkers and related this to the combined effect of ethanol in impairing urate excretion and increasing production. In rare instances, patients have had a severe allergic reaction to allopurinol. In such cases, the potent uricosuric drug, benzbromarone has proved beneficial, even in renal failure patients with kidney function as low as 25% of normal.

Allopurinol and Acute Renal Failure

It is important to note that in patients with genetic uric acid overproduction, allopurinol should be used with care. Its use to avert gout (or uric acid nephropathy) has precipitated acute or chronic renal failure due to xanthine nephropathy and sometimes xanthine stones instead. Xanthine is even more insoluble than uric acid, and as with uric acid, solubility cannot be improved by alkalinization of the urine. Xanthine nephropathy also may occur during massive endogenous nucleic acid breakdown in patients given allopurinol during aggressive therapy with cytotoxic drugs for malignant disorders. In such cases, much lower doses of allopurinol should be coupled with adequate hydration and alkalinization of the urine.

Role in Chemical Carcinogenesis

Substantial evidence from microorganisms and mammalian cells has implicated mutagenic events caused by damage to endogenous DNA as the initiating factor in carcinogenesis. Damage to critical regions of the genome of somatic cells can be produced by a variety of environmental mutagens. Examples of environmental factors affecting humans are cigarette smoke, asbestos, and ultraviolet (UV) irradiation. Recent putative additions to the list are radiation from microwaves and mobile phones.

A high correlation invariably exists between the mutagenic activity of different chemicals and their carcinogenic activity. Epidemiological evidence indicates a relationship between exposure to benzene and nonlymphocytic leukemia in humans, but the significance of DNA adduct formation in this is not clear. Normally, DNA possesses active repair systems to protect against such damage, which can be caused by a variety of chemical and physical agents, including ionizing, radiation, and UV light. Strands may become cross-linked, bases can be altered or lost, and phosphodiester bonds may be broken. UV light induces the formation of pyrimidine dimers, which are recognized and cleaved by specific endonucleases. Failure to repair the damage before DNA replication occurs results in the damaged region becoming the site of somatic mutations, chromosomal rearrangements or amplifications, and aberrant DNA methylation.

In this context, it is of interest that the P53 gene is altered in many human cancers. Recent studies using analogs that target specific enzymes of either purine or pyrimidine nucleotide biosynthesis have identified P53 as a cellular regulator of both nucleotide synthetic pathways (Figure 2). These studies have led to the proposal that P53 is not only a sensor of DNA damage, inducing apoptosis in response to DNA strand breaks, but rather a sensor of nucleotide depletion. Upregulation of P53 expression, activated by nucleotide depletion or related processes, prevents cells entering the S phase when precursor nucleotide pools are low, thus avoiding replication of damaged DNA through a prolonged, but reversible, G0/G1 arrest. The significance of these findings is that elongation of the S phase during nucleotide depletion is known to be associated with increased chromosome breakage. NUTRITION EDUCATION

S S Deshpande, Central Institute of Agricultural Engineering, Nabibagh, Bhopal, India

Background

Advances in nutrition research have provided means of prevention and control of some of the major crippling nutritional disorder with sever socioeconomic and health repercussions. The next logical step after the discovery of such solutions will be their propagation among the concerned community members. It is here that health and nutrition education has a role to play. The emphasis in these nutrition education programs ought to be on the proper use of natural dietary sources of nutrients and the need for full use of available health services and health and nutrition intervention program launched by government and other agencies.

Nutrition education programs, when properly implemented, have the potential to bring out desired behavior modifications among the communities. But for them to be successful, there are several obvious prerequisites such as the right approach suited to the community appropriately, motivated change agents, suitable educational strategies in terms of media, messages, etc. The ultimate impact of any nutritional education effort hinges on the extent to which the above criteria are satisfied.

Nutrition education has been defined as the process by which beliefs, attitudes, environmental influences, and understanding about food lead to practices that are scientifically sound, practical, and consistent with individual needs and available food resources; nutrition education should be available to all individuals and families. The fundamental philosophy of nutrition education is that efforts should focus on the establishment and protection of nutritional health rather than on crisis intervention. It is needed, regardless of income, location or cultural, social or economic practices, or level of education. Nutrition education must be a continuing process throughout the life cycle as new research brings additional knowledge.

Scope

Education means a change in behavior. It moves the individual from lack of interest and ignorance to increasing appreciation and knowledge and finally to action. Nutrition education offers a great opportunity to individuals to learn about the essentials of nutrition for health and to take steps to improve the quality of their diets and thus their well-being.

Nutrition education must continue throughout the individual's life in order to accommodate for developments in nutrition science and for changing economic circumstances, health requirements, and the new food products appearing in the nation's market. This requires a greatly expanded use of the mass media, and the involvement of governmental and private agencies and universities, as well as the food industries.

Concept

A concept is an idea around which the content of nutrition education curricula can be built.

What is Nutrition Education?

Nutrition education is the process of teaching the science of nutrition to an individual or group. Health professionals have a different role in educating an individual in the clinic, community, or long-term health-care facility. In these settings, the dietician, nutritionist, or nurse serves to assist or enable individuals to incorporate changes in eating patterns and behavior into their lives. The major focus of this type of nutrition is not knowledge and facts, but rather the development of permanent behavioral changes. This is the art of nutrition education – breaking down a large body of knowledge into small, individual components that are represented to a patient or client at a rate and level, at which they are able to absorb and use the information. Effective education is making nutrition information digestible and usable in an everyday setting.

Steps Involved in Nutrition Education

The development of an organized, coordinated nutrition education program requires a series of steps:

- Consumer research is needed to determine consumer use of existing information attitudes, knowledge, levels of awareness and concern, current

nutrition practices, and type of education to which they should be most receptive.
- Nutritional surveillance data are needed to determine the most important public information problems for determining reasonable objectives to be used in formulating the nutrition education.
- Most appropriate target populations for nutrition education are determined on the basis of awareness, nutritional status, current knowledge, and receptivity to nutritional information.
- A nutrition education message should be designed that is appropriate for the needs of the selected population groups.
- The curricula for the nutrition education program must be well thought out and planned. At every step, the learner and the educator should work together to develop goals, objectives, and appropriate activities and resources to meet the goal.
- Evaluation is crucial to any successful educational effort.

Why Nutrition Education?

A number of forces have emerged to stimulate increased recognition of the need for a stronger, more comprehensive and creative effort at nutrition education. These factors include:

- Many serious as well as less serious health problems are the result of lifestyles and personal habits, including habits of food consumption. Individual modifications in lifestyles may improve health status.
- Food Patterns. Differing forms of food vary in nutritive value as well as in taste appeal. The average consumer is often mystified and unaware of how to make the wisest food choices from such a variety. Thus, there is a great need for education to enable consumers to select wisely an appropriate diet from the vast supply of food available.
- Lifestyles are drastically different from those of the turn of the century. The public must be knowledgeable about how to meet nutritional needs without overindulgence in foods.
- Nutrition education is also necessary to aid the consumer to make economical food choices, that is, to save money while getting optimal nutrition. This is especially important for the low-income consumer.
- On a global basis, there is a real possibility of food shortages. Therefore, the consumer should know how to provide nutritional substitutes for unavailable food items.

What to Emphasize in Nutrition Education

It is very difficult to define the basic knowledge that should be conveyed to the public about nutrition. Much will depend upon what the learners already know, how they evaluate their present dietary habits and nutritional status, what their present eating habits actually are, how much they desire to know, and what changes they are willing or can afford to make.

Nutrition Education Strategies

In view of the multifactorial influences on food habits, there is no one way to persuade people to change their food choices. Thus, nutrition education must use a variety of techniques that must be a part of total family and community environments.

In other words, nutrition education involves information exchange as well as techniques to motivate and reinforce improved food habits. Successful nutrition education must include endeavors to make beliefs, attitudes, values, environmental factors, and individual ideas about food conducive to nutritionally sound, practical, and acceptable dietary habits. Nutritional education can be approached in various ways. What might be termed the rational–empirical curriculum design is the approach that is typically used by educators; it is logical and planned, and it involves behavioral objectives, activities that are designed to achieve objectives, and evaluation to determine the discrepancy between planned and achieved outcomes. The idea of self-responsibility for health suggests the basic notion that the individual possesses a dignity, worth, and responsibility to maximize these characteristics. Self-responsibility assumes that the individual has the potential and motivation to make wise judgments about factors that affect their health status. Another strategy has been termed the travel metaphor method. The idea is that there is a body of knowledge, facts, concepts, values and believes that are known and understood by the educator. It is the educator's responsibility to lead the learner through this body of knowledge and beliefs, and point out to the learner what is thought to be of importance. The educator is thus a travel guide whose job is to provide the student with a set of stimuli and the opportunity to take advantage and react positively. It then becomes the responsibility of the student to determine how they will make use of the contacts provided by the educator.

Another approach called the garden metaphor explains how humans grow, develop and flower naturally. The educator has the opportunity to nurture this environment so that the 'child' has the most opportunity to mature and to learn.

Another approach to health and nutrition education takes a strategy of social manipulation. The basic premise is that the matters affecting health are too urgent, too important, and beyond the individual's

power to control on their own. Thus, the role of the health educator is seen as one of attempting to control behavior and to shape the desired responses. This approach is often employed by the mass media.

The manipulative approach is more concerned with the behavior response patterns rather than the manner in which the individual reaches these patterns. The approach is an attempt to reach the desired behavior through a short-cut method and does not take time to prepare the individual to make fully informed, wise choices.

The most appropriate and effective strategy for stimulating improved food habits will depend upon the knowledge, background, personal characteristics, and motivation of the audience. It may also depend upon the size of the target group. Ideally, the approach should be individualized to the target audience's needs, goals, objectives, and other characteristics. A mix of various approaches may be necessary.

Systems Approach to Nutrition Education

The 'systems' approach to nutrition education provides a useful and practical tool to aid the nutrition educator in deciding what should be taught and how it should be taught. Simply defined, the systems approach is a flow of steps needed to achieve the desired objectives. The approach consists of input, process, and output.

A successful nutrition education effort must incorporate managerial elements that are crucial to the success of all program planning. These elements, which could be termed the input, are essential to an effective nutrition education process. They include needs assessment and identification of problems; study of available resources and alternative strategies of intervention; determination of objectives and goals; assignment of resources to implement program; staff development to implement program, and program monitoring and evaluation. Crucial to the entire process is a firm organization base and administrative and budgetary support for nutrition education efforts.

Follow-up and Evaluation

Nutritional counseling follow-up, in order to evaluate learning, is an essential factor, which needs to be included in the plan. After an initial interview, follow-up is usually planned for some time during the next 1–2 weeks or perhaps at a later time in the same week. As clients progress toward a goal, follow-up visits are generally spaced further and further apart. In a follow-up session, the client's progress needs to be measured against the objectives, and the client needs to receive positive feedback about their progress. In the event that no progress has been made or the client has slipped back into old habits, the counsellor needs to pursue the problem assertively. The problem needs to be identified and new goals or methods of achieving the goals established.

Summary

Nutrition education is a broad area; however, the nutritionists or nurses facilitating it are usually concentrated in the acute or long-term care facilities and community clinics. In all aspects of teaching and counseling, instructional objectives need to be established, the learner's knowledge assessed, behavioral objectives written, evaluation tools devised, information needs screened and organized, education materials selected, and instruction critiqued and revised. It is also essential to keep the learner's needs in the forefront and work to maintain a rapport with the client.

Education is not complete until the learning has been evaluated. Formal and informal tools may be used to measure learning against established objectives. Evaluation helps identify if further teaching or clarification of information is needed. To some degree, demonstrating successful learning at evaluation reinforces continuance of new behaviors, which is the goal of nutrition education.

NUTRITION POLICIES IN WHO EUROPEAN MEMBER STATES

A Robertson, WHO Regional Office for Europe, Copenhagen, Denmark

Introduction

In December 1992, after more than 2 years of preparatory work by the member states and the joint efforts of the World Health Organization (WHO) and the Food and Agriculture Organization (FAO), the International Conference on Nutrition (ICN) was convened in Rome to:

- increase public awareness of the extent and seriousness of nutrition- and diet-related problems worldwide
- promote effective strategies and actions to address these problems
- encourage the political commitment necessary to do so

Each of the 159 participating countries and the European Community reaffirmed their determination to insure sustained nutritional well-being for all people and committed themselves to achieve this goal by unanimously adopting the World Declaration and Plan of Action for Nutrition. The nine action-oriented strategies of the World Declaration and Plan of Action for Nutrition are summarized in Table 1. These provide a framework for national plans of action.

In 1996 a follow-up to ICN (Table 2) was held in the European region through a FAO/WHO consultation in Warsaw, Poland. Its aim was to assess implementation of the World Declaration. Representatives from European member states and Canada, the USA, the European Commission and the Holy See attended the meeting along with representatives from the United Nations Development Program (UNDP), the United Nations Children's Fund (UNICEF), nongovernmental organizations (NGOs) and the private sector.

Table 1 The nine action-oriented strategies of the plan of action for nutrition

Incorporating nutritional objectives, considerations, and components into development policies and programs
Improving household food security
Protecting consumers through improved food quality and safety
Promoting breast-feeding
Caring for the socioeconomically deprived and nutritionally vulnerable
Preventing and controlling specific micronutrient deficiencies
Promoting appropriate diets and healthy lifestyles
Assessing, analyzing, and monitoring nutrition situations
Preventing and managing infectious diseases (N.B. not included in this analysis, since not mentioned in any country reports)

Methods

Member states were requested to prepare a summary report of their progress for the 1996 follow-up meeting in Poland. Based on the 35 reports received (response rate of 70%) the WHO Nutrition Unit compiled an overview of the situation.

Member States were grouped into eight geographic regions: Balkan, Baltic, Central Asian Republics (CAR), countries of central and eastern European (CCEE), western Europe, southern Europe, Commonwealth of Independent States (CIS), excluding CAR, and Nordic countries (Table 3). The aim of this is to facilitate comparative analysis and interpretation and assist in drawing conclusions and recommendations.

Results

The country data are presented in tables under the headings of the strategies of the Plan of Action for Nutrition adopted at the ICN.

Discussion

Developing Food and Nutrition Policy

Around the time of ICN (1992), some member states in Central Asia, the former Soviet Union and the Balkan region were not fully independent and so were unlikely to have information about the ICN. Thus food and nutrition specialists in some parts of the WHO European region were probably unaware of the ICN and so it is hardly surprising that many countries had not developed national plans of action according to the ICN objectives.

Moreover a few WHO member states are not members of FAO (1998) and others have only recently joined. This probably explains why there were more health than agriculture representatives present – 66% compared with 27% – at the consultation in Poland in 1996.

One of the difficulties when attempting to develop intersectoral policies is the level of commitment that

each stakeholder has to public health versus their own possibly diverging interests (Figure 1). It is improbable that intersectoral policies will be implemented, unless all stakeholders are committed to the process. However, the long-term interests of the agriculture sector, the food industry, wholesale and retail representatives are dependent on policies which have been developed in collaboration with the voluntary sector and consumers. Consumers, the customers of the food industry, should be more involved in the process whereby food policy is developed.

Intrasectoral Collaboration within the Health Sector

Good collaboration between nutrition and food safety is essential because the public and consumers perceive food in a holistic way. Consumers do not compartmentalize food or distinguish between food safety and nutrition – consumers want good wholesome food they can enjoy without fear. There appears to be far more collaboration between the nutritionists and food safety specialists working in central and eastern Europe compared with those in western Europe.

There may be several reasons for the stronger collaboration in central and eastern Europe. Nutrition is a relatively new science and in eastern parts of Europe its evolution seems to be closely linked to 'hygiene' and the sanitary–epidemiology system. In eastern Europe nutrition and food hygiene have evolved from the same postgraduate specialization, usually as a specialization of medicine. In former socialist countries food safety is traditionally under ministries of health, whereas in some western European

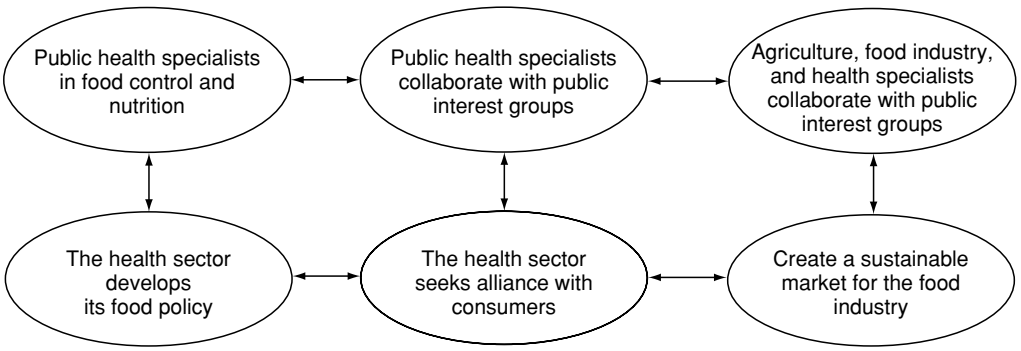

Figure 1 From intra- to intersectoral policy development food priorities for health.

countries only nutrition is under ministries of health and the responsibility for food legislation and enforcement may be with ministries of agriculture or trade in the west. However this is changing, especially in some European Union (EU) member states, where ministries of health are taking a much more proactive role in protecting consumers and their health.

Coordination between public health specialists working in food safety and nutrition is important for many other reasons. One is that from time to time food control authorities may issue warnings about food, e.g., chicken that contains *Salmonella*, or fish and vegetables which are contaminated. Meanwhile, as part of national campaigns, nutritionists promote the consumption of vegetables, fish, and poultry. Public health specialists must deliver consistent and reliable information to avoid public confusion. Closer cooperation between nutritionists and food safety specialists can prevent the promotion of conflicting messages.

Intersectoral Collaboration

Public health specialists dealing with food safety and nutrition should strengthen their collaboration with other sectors dealing with food, e.g., agriculture, food industry, wholesalers and retailers, voluntary sector and public interest groups representing consumer interests. Consumers have a vested interest in supporting the supply of safe food of good quality that is nutritionally healthy and the food industry has a vested interest in supplying healthy consumers. There is an opportunity for the health sector to strengthen health alliances with public interest groups working in the voluntary sector.

Surprisingly, in the country reports, there was very little mention about the importance of collaboration with consumer agencies except by Hungary, Norway, Poland, and Sweden. In these countries there is an understanding that the food industry can profitably increase the availability of vegetables and fruit, low-fat milk, and lean meat, on condition that it is assured a market.

Assessing the Nutrition Situation

Almost all countries reported a need to improve nutrition information systems. According to DAFNE (Network of the Pan-European Food Data Bank Based on Household Budget Surveys: countries participating are Belgium, Denmark, Greece, Germany, Hungary, Ireland, Poland, Portugal, Spain, and the UK), some had no information, while some use secondary data or access nutrition information from household budget surveys. Some had information from one-off surveys that were sponsored through international cooperation. The Nordic countries and the UK seem to have established the most comprehensive surveillance systems that provide information on food consumption and nutritional status on a routine basis. Clearly it will take time for some countries to achieve this level of sophistication but ultimately these data are essential to facilitate food and nutrition policy development.

It seems unlikely that, at least in the near future, nationally representative nutrition surveys will be carried out on a regular basis; therefore other strategies have to be found: members of DAFNE extract nutrition-related data from household budget surveys; in Italy secondary data sources were used to develop a national policy. Mortality data are available from the WHO Health For All database which is accessible through the internet from the WHO website. These data allow comparison of mortality statistics between different countries. FAO food balance sheets provide data such as the percentage energy coming from carbohydrate, fat, protein, and alcohol and the quantity of vegetables and fruits available nationally. These data are directly accessible from the FAO website.

In the future the EU may encourage its member states, and those wishing to join, to develop standard information systems. This will allow comparison of data on food intake, nutritional status, and diet-related behavior in different EU member states and so facilitate the development of cost-effective strategies that enable countries to save money on treating preventable diseases.

Improving Food Security

After the Second World War the main aim in Europe was to increase the supply of food, especially animal products, e.g., meat and milk. However the postwar policy was too successful (Table 4) and in the 1980s until the present time Europe has surplus stocks of butter, meat, and milk.

Since the Second World War, new scientific evidence has led to the level of recommended daily protein intake being reduced. For example the level of protein intake recommended by the FAO, WHO, and the United Nations University (UNU) in 1986 was $0.75\,g\,kg^{-1}\,day^{-1}$. This new level resulted in many countries reducing the level of their national recommended protein intakes for adults from 120 g to around 50 g per person per day. There is now some evidence suggesting that excess intake of some sources of protein, especially from red meat, could be associated with ill health.

Various hypotheses exist to explain how meat consumption may contribute to chronic diseases such as heart disease and certain cancers. Meat intake is associated with an increased intake of saturated fats

Table 4 Food policy in the twentieth century

1950s	*1960s*	*1970s*	*1980s*	*21st century*
Food insecurity and perceived nutrient deficiency, especially protein	Increased food production and consumption, especially of animal protein and fat	Surplus stocks of food, especially animal products	Links identified between mortality from NCDs and diets high in animal fats and low in vegetables and fruit	The opportunity to change food policy to meet health and environmental recommendations

NCDs, noncommunicable diseases.

which are linked to an increased risk of cardiovascular diseases and breast and colorectal cancer. Excessive protein intake may be associated with increased excretion of calcium and so possibly exacerbate the prevalence of osteoporosis. Excess intake of protein is associated with increased risk of renal disease, especially in infants, since the kidneys have to excrete excessive solute loads and so excess protein intake is perhaps linked to the risk of developing high blood pressure later in life. It is advisable that ministries of health review their national recommended intakes to insure that these are in line with current international recommendations.

Lessons learned over the past 50 years suggest future food policies should insure that:

- cereal and potato production should be geared to supply > 50% energy
- vegetables (excluding potatoes) and fruit production should be geared to supply a consumption of at least 400 g per day per person

Given the recommendations, contained in most dietary guidelines, 'to protect, promote and support the consumption of cereals, potatoes, vegetables and fruit,' it is surprising that there was no mention of the need to increase the production of these foods in the country reports. Without a food policy which guarantees food security in the form of cereals, potatoes, vegetables, and fruit, it is difficult to see how national targets for a healthy diet can be achieved.

One of the reasons why families living in countries undergoing economic transition (CEE and CIS) are not suffering from protein/energy deficiency is because many produce a large percentage of their own potatoes, vegetables, and fruit. In Russia, town dwellers produce 88% of their potatoes, 43% of their meat, 39% of their milk, and 28% of their eggs on urban household plots. This important share of production is generated on plots of 0.2–0.5 ha which together constitute only 4% of the total amount of agricultural land in Russia. In addition, imports from abroad have supplemented national food production and currently 50% of chickens and 30% of meat consumed in the Russian Federation is imported. In the short term, imports are essential during times of hardship and economic transition, but in the long term agricultural polices should promote sustainable production and protect local food production to insure national food and nutrition security.

In eastern Europe the agriculture sector forms a much higher percentage of national gross domestic product compared with western Europe. Almost 30% of the population in some CEE countries are employed in agriculture compared with only 1 or 2% in western Europe. Many economists are concerned about the impact when more countries join the EU because the Common Agriculture Policy (CAP) is not sustainable. The CAP receives almost half the EU budget and in 1995 it cost EU taxpayers 39 billion ECU. During the CAP reform process, health recommendations and dietary guidelines should influence the reformed policy in addition to concerns about national employment and the national food security of the EU accession countries.

Protecting Health Through Food Safety and Quality

In some reports there was no mention of the importance of food safety, especially in the countries of southern Europe. As mentioned in the introduction, it is vital to strengthen the collaboration between food control and nutrition agencies. Some western governments are already attempting to bring these two disciplines under one food authority and three-quarters (27 out of 35 countries) did include food safety in their ICN reports. Close collaboration becomes even more essential as the line between food safety and nutrition becomes more and more blurred with the introduction of precooked foods; functional, novel, and special dietary foods; and supplements. Moreover, with the introduction of food into global trade, the public's need for information will be immense. To provide reliable information, both food safety specialists and nutritionists need data on food intake patterns. More effective use could be made of resources if joint surveillance and risk management of food intake are carried out together.

Foodborne diseases are among the most widespread health problems in the contemporary world.

In rich and poor countries alike they impose substantial health burdens, ranging in severity from mild indispositions to fatal illnesses. The emergence of new foodborne diseases is an ominous trend. Epidemics due to newly identified pathogens such as *Campylobacter jejuni, Listeria monocytogenes, Escherichia coli 157:H7* and bovine spongiform encephalopathy (BSE) have hit industrialized countries. *Salmonella* outbreaks are one of the main causes of epidemics in Europe. Global trade will make it more difficult to contain foodborne diseases within national borders and enforce national food laws. In addition, chemical contamination, toxic materials, pesticides, veterinary drugs, and other agrochemicals require constant surveillance to insure their safe use. Similarly, the use of food additives can improve the quality of the food supply but appropriate controls are necessary to insure their proper use.

Most regions included in their country reports the need to harmonize their national food legislation with the EU and World Trade Organization (WTO). Many countries stated they are lining up to join either the EU or WTO (12 countries) and so intend to harmonize their national legislation with international directives set by the EU or Codex Alimentarius. It is essential that health professionals, especially those working in public health, become more informed about international agreements on global food trade and take a full part in the WTO Committee on Sanitary and Phytosanitary Measures (SPS Committee). Only if public health specialists, from both food safety and nutrition, participate can they hope to influence future food policies.

Promoting Breast-Feeding

Clearly there is a lot to be done in the European region to promote breast-feeding. More than one-third (13) of the 35 member states made no reference to breast-feeding in their country report. This does not necessarily mean that there are no active breast-feeding programs in the country (e.g., Romania) but it does mean that there is probably little coordination between those responsible for nutrition policy and those responsible for promoting breast-feeding. Perhaps this is because breast-feeding is regarded as a clinical issue dealt with by midwives and primary health care workers. However, public health nutritionists and hygienists in CCEE and the CIS do have an important role and should be active in the development of national policies to promote breast-feeding.

National breast-feeding initiatives will only be successful if policies are developed and enforced according to guidelines from the Baby-Friendly Hospital Initiative (BFHI) and the International Code for the marketing of breast milk substitutes. It is necessary to national and regional trends (marketing strategies and breast-feeding levels) to interpret the national situation and make recommendations to policy-makers.

The BFHI jointly launched in 1991 by WHO and UNICEF, aims to enable women to choose and practice breast-feeding as the primary source of nutrition up to about 6 months by minimizing obstacles which make it difficult or prevent women from exercising their right to breast-feed and to insure the cessation of free and low-cost infant formula supply to hospitals. The BFHI targets maternity services and hospitals, particularly health workers and those responsible for policies to help mothers succeed in breast-feeding. To become a baby-friendly hospital every facility providing maternity services and care for newborn infants should implement the Ten Steps to Successful Breastfeeding outlined in the joint WHO/UNICEF statement entitled *Protecting, Promoting and Supporting Breastfeeding: The Special Role of Maternity Services* and should end free and/or low cost supplies of breast milk substitutes.

There is clearly a vital need to increase the number of Baby-Friendly Hospitals in Europe and develop and enforce national legislation which is based on the International Code of Marketing of Breast Milk Substitutes.

In some countries there may be conflict between nutritionists, hygienists, and new breast-feeding policies. Some hygiene standards and decrees in the former Soviet countries, such as the recommendation that mothers should be separated from their babies after birth, contradict the current UNICEF and WHO recommendations to promote the 'rooming-in' of babies with their mothers. In addition, National Nutrition Institutes involved with research and development of breast milk substitutes and weaning foods may unintentionally interfere with breast-feeding promotion.

Complementary feeding (weaning) was not discussed in detail in any report and only mentioned very briefly in two country reports, those of Albania and Italy. Perhaps this is because the categories listed in the World Declaration of ICN do not specifically include complementary feeding, only breast-feeding. This was perhaps an oversight by the ICN committees since it is clearly important that all member states address their policies on infant and young child feeding. It is around the age of 6–24 months when mortality and morbidity levels are at their highest. It is likely that the high prevalence of anemia seen in some parts of the European region is due to poor feeding practices, such as the early introduction of foods and drinks, especially cows' milk and tea, before the age of 6 months.

Caring for the Deprived and Vulnerable

In the region around 70% of the population is suffering from physical and mental exhaustion as people cope with increasingly uncertain conditions related to very rapid economic and social change. This is especially true for the countries of the former Soviet Union where policy-makers are not used to developing safety nets for vulnerable groups. The transition to a market economy has resulted in soaring consumer prices due to a reduction in subsidies while salaries have remained low. In addition there is rising unemployment as a result of industrial restructuring and the new monetary polices have hit vulnerable groups in particular. Mechanisms must be developed to identify and protect the vulnerable groups in society.

Caring for vulnerable groups was mentioned in almost three-quarters (22) of the country reports. Many initiatives were related to the physiologically vulnerable, such as children, pregnant women, or the elderly. In addition, welfare safety nets, aimed at insuring a minimum family income by setting minimum wages, pensions, and unemployment benefits, were considered necessary for economically vulnerable groups such as the poor, low-income, unemployed, and refugees or immigrants and those with large or one-parent families.

The gap between the rich and poor is increasing in many countries in Europe, and as a phenomenon of the economic transition in central and eastern Europe, unemployment has appeared in many. If this trend continues, the food intake and nutritional status of vulnerable groups should be monitored closely in order to develop safety nets and prevent food insecurity. Among European industrialized nations the UK was exceptional in the pace and extent of the increase in inequality in the 1980s and by 1990 the level of inequality was almost back to 1930 levels.

Poverty is a growing concern in Europe, especially for those with incomes below societies' poverty lines. In 1994 it was estimated that 13.5% of the Polish population (about 5 million) had average monthly expenditures lower than the relative poverty line. In 1995, 4 million children in the UK lived in families with incomes below 50% of average earnings. Lack of food is associated with poverty, which can be measured by estimating the percentage of disposable income spent on food: in Romania the average figure is around 60%; and in Poland around 40%, compared with 22% in the EU.

Coping within a limited budget often means that healthier, safer foods are not affordable. In Lithuania increased food prices have caused socially deprived people to consume cheaper, less nutrient-dense foods which are more likely to be contaminated. In Poland the prevalence of nutrient deficiencies is highest amongst the unemployed and low-income families with many children. Poor people in the UK consume much lower quantities of vegetables and fruit.

There is growing evidence for the protective effect of vegetables and fruit against chronic diseases such as cancer and coronary heart disease. This suggests that the low intakes of vegetables by poor people may directly increase their risk of these diseases. Inadequate diets also have adverse consequences on a child's health, education, and future employability and there are demonstrable costs to society in each instance.

Micronutrient Deficiencies

There is no doubt that, in the European region of WHO, the most prevalent health problems related to diet are noncommunicable diseases such as cardiovascular diseases and cancers and not deficiency diseases. Nevertheless, micronutrient deficiency does exist in certain European countries under certain circumstances.

Iodine One of the most prevalent nutrient deficiencies is iodine. Iodine deficiency disorders (IDD) are prevalent throughout Europe and only six countries have no IDD (Finland, Iceland, Norway, Sweden, Switzerland, and the UK). Although this problem has been largely eliminated in some countries in western Europe, it is reemerging in some countries in CEE and the CIS. For example, in Albania and Tadjikistan iodine deficiency is severe and in some other countries the prevalence of IDD is increasing.

The main public health strategy recommended to solve this problem is universal salt iodization. This means insuring that all the salt used by the food-processing industry, the mass catering sector, and households is iodized. In some countries there is no universal iodization and only table salt is iodized (Italy, Poland). This could be a problem, especially in western Europe where most of the population get their salt from processed food products and not from home-cooked food to which salt is added during cooking or eating. Therefore nutritional epidemiologists should monitor the source of a population's salt, and so iodine.

In addition to insuring that iodized salt is used in food processing and mass catering, policy-makers should consider the need to include a recommendation to feed iodized salt to animals (cows). In the Nordic countries and the UK iodine is given to cows in the form of 'salt-lick' and so milk and milk products supply around 40–70% of the iodine intake in humans. In addition to insuring elimination of iodine

deficiency, this has the added benefit of limiting the amount of salt consumed by the population.

In CCEE and the CIS, cardiovascular diseases are responsible for 68% of all premature deaths, while in the rest of Europe this figure is only 43%. Moreover, proportionally, cerebrovascular diseases are markedly higher in CCEE and CIS. Because of the strong link between high salt intake and cerebrovascular disease, the WHO recommends a salt intake of no more than 6 g per capita per day. In Italy a campaign on the role of salt in the diet was launched. This campaign aims to eliminate IDD through the promotion of iodized salt, but at the same time preventing hypertension and vascular diseases through limitation of salt intake.

Iron The other main nutrient likely to be deficient in European countries is iron. Iron deficiency was mentioned as a problem by one fourth (9) of 35 member states. Prevalence studies show that anemia is widespread in central Asia and the Caucasus. For example, in Kazakhstan and Azerbaijan up to 70% of children younger than 2 years of age have low hemoglobin levels. In addition, 20–30% of women of childbearing age also have low hemoglobin levels. These problems may not be related solely to iron deficiency in the diet. For example, it has already been mentioned that early introduction of cows' milk is a major cause of iron deficiency in the young. Anemia in adults is associated with the presence of iron-absorption inhibitors in the diet, such as tea and coffee, which is frequently consumed in eastern European countries; or lack of absorption enhancers, such as vitamin C from vegetables and fruit.

Folate Folate deficiency is associated with neural tube defects. Denmark, Poland, and the UK mentioned national strategies related to solving this problem. Folate may also play an important role in the prevention of coronary heart disease by helping to reduce levels of homocysteine. The main food sources of folate are Brussels sprouts, asparagus, spinach, broccoli, cabbage, cauliflower, parsnip, iceberg lettuce, beans, peas, and beef and yeast extracts – yet another reason why national food and nutrition polices and dietary guidelines should promote vegetable production and consumption.

Other micronutrients There may be situations when the only solution to solve micronutrient deficiency is by food fortification of bread or salt, for example (such as for iodine deficiency), or, more rarely, by supplements (during emergencies). However, generally, where possible, WHO promotes primary prevention strategies such as increasing vegetable consumption rather than advocating consumption of nutraceuticals, food supplements, or multivitamin tablets. Population strategies advocating the use of vitamin supplements are not the solution to micronutrient deficiencies in Europe. Vitamin supplements may have many disadvantages: side-effects; nutrient imbalances; toxicity; malabsorption; long-term dependence and lack of confidence in locally produced foods, and, finally, supplements are an unnecessary expense.

Appropriate Diets and Lifestyles

Countries of the CARs and the CIS must pay more attention to the link between diet and noncommunicable diseases (NCD), such as cardiovascular diseases, certain cancers, diabetes, hypertension, and obesity. Some of the country reports focused too much on deficiency of protein and micronutrients. In focusing on deficiency the link between premature mortality from NCD and a diet high in fat, salt, fatty red meat, and fatty/sugary foods and simultaneously low in vegetables and fruit is neglected.

Some countries in the CIS and central Asia mentioned the need to increase the teaching of dietology/dietetics. There is still a tendency in some countries to prescribe many different types of diets for different disorders. Many of these dietary prescriptions have not been scientifically proven. In addition, many of the individuals referred for dietary treatment are suffering from obesity, diabetes, heart disease, high blood pressure, and other conditions related to unhealthy lifestyles. These cases should be treated using the healthy nutrition principles developed for the population. Dental caries is also widespread in many European countries and there can be little doubt that this is related to frequent high intakes of sugar as well as poor oral hygiene.

Some countries, such as Albania, Israel, Kazakhstan, Latvia, Romania, Slovakia, the Republic of Moldova, Ukraine, and Uzbekistan made no mention of the link between diet and NCDs. Moreover, only one-third (12) of 35 member states mentioned obesity (Austria, Azerbaijan, Czech Republic, Denmark, Estonia, Hungary, Lithuania, Luxembourg, Malta, Poland, Turkey, and the UK), despite the fact that the prevalence of obesity is high and appears to be increasing in every country in Europe. For example, the Russian Federation has one of the highest prevalences, where 55% of the female population is overweight. Little mention of obesity probably reflects the lack of data on body weight and height and illustrates the need for countries to collect anthropometric data as part of their health information system.

Physical activity and obesity Obesity is a chronic medical problem caused by a combination of an

energy-dense diet leading to excess energy intake and lack of physical activity. There is abundant evidence that obesity is associated with a high risk of coronary heart disease, hypertension, diabetes mellitus, and gastrointestinal disorders. The risk of cancers of a number of sites (endometrial, renal, colon, gallbladder, and postmenopausal breast cancer) is also linked to obesity. As treatment of obesity is difficult, the need to readjust dietary energy intakes and/or physical activity permanently is essential. Other health advantages of high levels of physical activity include improved mental and psychological health.

Only 17% (six of 35) of member states made reference to the importance of increasing physical activity (Armenia, Estonia, Malta, Poland, Sweden, and the UK). Environments which support improved eating habits and more active living are needed. It is recommended that prevention efforts are focused on population-based public health strategies.

Conclusion

Cooperation and collaboration are needed throughout Europe and there is a need to share information and build alliances. In western Europe there exists the European Academy of Nutritional Sciences (EANS), the Federation of European Nutritional Sciences (FENS), and the Arbeitsgemeinschaft Ernährungsverhalten/Working Association for Nutritional Behavior (AGEV) and many countries have their Nutrition Society. In CIS and CCEE there seems to be a lack of coordination, and nutrition networks or societies should be established to facilitate sharing of information and developments in the area of food and nutrition.

NUTRITIONAL ASSESSMENT

Contents

Importance of Measuring Nutritional Status

F Fidanza, Universita degli Studi di Perugia, Perugia, Italy

Aims of Nutritional Status Assessment

Nutrition has been more and more implicated in various health problems. Consequently, improving nutritional status can play an important role in solving or preventing these problems.

Malnutrition – both undernutrition and overnutrition – is widespread both in single patients as well as in population groups. Surgical patients, for example, often suffer from protein-energy malnutrition, and subclinical blood levels of vitamins and minerals are present even in population groups of developed countries. (*See* **Malnutrition**: The Problem of Malnutrition.)

But scientific interest is now moving from deficiencies to a new role for some micronutrients in the maintenance of health and the prevention of degenerative diseases.

Efforts to obtain reliable information about the nutritional status of both patients and population

groups encounter many difficulties. There are several reasons for these problems, the most important of which is the body's ability to adapt to adverse conditions, so that changes in biochemical or functional characteristics become evident only after substantial impairment has occurred. Methods of assessment must therefore be both highly specific and highly sensitive.

The complexity of the interactions between dietary inadequacy, disease, and personal and environmental variables also makes it particularly difficult to determine whether health impairment can be linked specifically to diet and whether or not any nutritional deficiency is secondary to some other defects. These problems can be solved only through continuing basic research to expand knowledge of the patterns of biochemical, physiological, pathological, and behavioral responses to deficiencies or excess of nutrients and to improve methods for applying this knowledge in practical situations.

Nutritional surveys can be cross-sectional (i.e., provide data on prevalence of malnutrition or deficiency) or longitudinal (i.e., provide data on incidence of malnutrition or deficiency and association with other factors). The serial collection of data at population level is a basic part of surveillance or of any intervention program.

A nutritional survey can be very general and comprehensive, in which case it includes the analysis not only of the prevailing nutritional problems of a given population but also of the responsible factors and the consequences. On the other hand, a survey can also be limited to some specific nutrients or selected population or patient groups. The selection is made according the objectives of the study and the funds, personnel, and time available. (*See* **Dietary Surveys: Surveys of Food Intakes in Groups and Individuals.**)

Malnutrition, whether under- or overnutrition, develops in various steps. In the prepathogenic period information on dietary inadequacy can be obtained from food balance sheets at national level and dietary surveys at individual or group level. These can provide an indication of potential nutritional problems of the population or group but do not assess the problems.

Late in the prepathogenic period some early changes in the body nutrient reserves can be present, but methods available are not sensitive enough to assess them.

In the pathogenic period, before the emergence of clear clinical signs, body tissue nutrient levels are modified to such a degree that metabolic and/or functional alterations appear. Biochemical and functional tests are then appropriate for status assessment and/or diagnosis.

Once the clinical horizon has been reached, nonspecific clinical signs and symptoms are present. Anthropometric measurements can be of some use early at this stage, as can biochemical and functional tests.

When symptoms are present clinical nutrition assessment and studies of morbidity data are of great help. The final stage of the nutritional problem can be assessed from analysis of mortality rates and data from postmortem examination, but in this way only information of retrospective conditions is obtained.

Sampling Procedure

In population studies if all the subjects cannot be examined, a very careful sampling procedure has to be chosen, considering first study design and then sample size. Sampling details most appropriate for each study design can be found in epidemiology textbooks. (*See* **Epidemiology.**)

Collecting and Storing Samples for Biochemical and Immunological Tests

Once the population sample is selected it is necessary to consider in great detail the collection and storage of samples for biochemical and immunological tests.

The instructions for sample collection and preparation vary according to the specific assays to be performed. Only general rules are provided here.

Body tissues and excretions can rapidly deteriorate and/or be easily contaminated. In general, to obtain whole blood, serum, or plasma, appropriate syringes or vacuum collection tubes are used. If handled carefully, hemolysis can be avoided.

For some minerals and trace elements, in order to avoid contamination, one must use new plastic (polystyrene or polypropylene) syringes and collection tubes, and wear powder-free latex gloves when collecting or working with specimens.

Urine samples must be acidified and chilled on ice in polypropylene or polyethylene bottles.

Specimens of adipose tissue can be obtained by microbiopsy or needle aspiration by vacuum tube assembly.

The plasma or serum for protein determinations can be stored for 1 month at 2–6 °C and for several months at −20 °C.

Lipid fractions immediately separated from serum or plasma are stable for 1 year or more at −70 °C, if properly handled. Adipose tissue specimens for fatty acid determination can be stored at −20 °C without any other precaution up to 18 months.

For most vitamin determinations, plasma or serum is used and it can be stored at −20 °C for several months or, in a few cases, even for years. Samples should be protected from light for fat-soluble

vitamins and riboflavin analysis. For the enzymatic assays of erythrocyte thiamin, riboflavin, and vitamin B_6 heparinized blood should be stabilized with proper ACD solution (ACD solution is a stabilizer made of citric acid, sodium citrate and D-glucose) for storage at 4–6 °C for 10 days. For the erythrocyte thiamin pyrophosphate (TPP) assay the determination should be carried out within 2 h of drawing blood because of TPP instability. For vitamin C determination, heparinized blood, after stabilization with metaphosphoric acid, can be stored frozen, preferably at −70 °C, for no more than 3 weeks. For vitamin C determination by high-performance liquid chromatography (HPLC), heparinized blood specimens can be stored for a few weeks at −80 °C after addition of reduced glutathione within 20 min of collection. The addition of dithiothreitol increases stability of plasma samples to more than 1 year at −70 °C.

Acidified urine specimens for thiamin, riboflavin, and vitamin B_6 determinations are stable at −20 °C for 3 months. The specimens should be protected from light. Longer storage is possible for biotin and pantothenic acid.

For mineral and trace element determination serum, plasma, whole blood, or blood cells are used with no great problems for storage, but glass containers should be avoided.

For cellular studies of immunocompetence the blood must be rapidly processed; in some cases the testing of frozen cells was successful.

Recommended Methods for Nutritional Status Assessment

Table 1 is a synopsis of some recommended methods. For a detailed description of them as well as for other methods, see the Further Reading section.

These methods can be used for the whole population as well as for single patients. In the clinical setting, nutritional assessment and support are best performed by a nutritional support team, including clinician, nutritionist, and clinical chemist. If needed, advanced methods for the assessment of body composition, nitrogen balance, and some prognostic indices are available to detect patient malnutrition and to predict outcome (sepsis, wound dehiscence, death).

Data Processing and Calculation

The most important stages of data processing are: coding (including a preliminary quality control); data input; quality control data; data bank; data analysis (using parametric and nonparametric techniques); and reporting. Specialized books describe in detail the above stages. For each type of variable, specific calculation methods may be used. Only general rules will be provided here.

For variables not normally distributed (some anthropometric data, ferritin, etc.), a logarithmic transformation can be applied. In some cases the use of nonparametric tests is preferred.

For the use and interpretation of anthropometric measurements an Expert Committee Report of the World Health Organization is highly recommended. Technical framework and detailed guidance on the use and interpretation of anthropometric measurements in pregnant and lactating women, newborn infants, infants and children, adolescents, overweight and thin adults, and adults aged 60 years and over are provided. An extensive series of reference data is included in an annex.

Computer programs are now commonly used to test specific hypotheses. Because of the highly specialized skills required for proper processing and analysis of data, it is recommended that specialists in these fields take part in the planning and execution of evaluation. To improve the quality of this work it is advisable that these specialists are also involved in the data recording – an essential preliminary step of data processing. This means that they must be involved in the design of the study and in the preparation and testing of various forms and/or questionnaires needed for the study.

For data analysis, a data stratification by age groups and sex or any other meaningful stratification like altitude (for hemoglobin), socioeconomic status, and health/disease data, must often be used. Results may be expressed in terms of means and standard deviations or standard errors or as percentages of values (prevalence) above or below an arbitrary cut-off point defining adequacy. Anthropometric indices can be expressed in terms of Z-score (or standard deviation score). If the sample size is large enough, the percentiles or the frequency distributions are very useful. This data presentation facilitates comparison between surveys in different countries; it permits at any time the selection of the percentile or the range of percentiles of reference, i.e., acceptability, and it can represent a combination of the descriptive and interpretative ways for analyzing and presenting collected data.

The final step is the interpretation of data. In general the prevalence of malnutrition or deficiency is obtained using cut-off from a reference population. This reference population and the population under study are often from different areas or the criteria used to specify the reference population are not carefully defined. However, since most reference values are population-specific, it is recommended that data from a clinically healthy reference population of the

same country or even of the same area, are collected. This is not necessary for nutritional surveillance, for which international references should be used.

In addition, for the interpretation of data, confounding factors must be taken into consideration, because they can alter the status and needs of some nutrients. Good examples are smoking habits, alcohol intake, drug use and abuse, physical activity, and consumption of toxic and antinutritive substances.

Use of Data

The main use of nutritional status data is to assess prevalence of malnutrition or deficiency in cross-sectional studies and/or the study of the association of malnutrition and its determinants in longitudinal studies.

An additional and important use of these data is for surveillance or intervention programs. In this case the data collection is often limited to the most relevant indicators of major risk for the population surveyed or the most vulnerable groups inside the population, such as pregnant and lactating women, children, adolescents, and the elderly. Nutrition-related risk factors of chronic disease have recently been included in the surveillance programs.

The assessment of nutritional status of single patients can be used for predicting outcome, and for establishing the need for, and monitoring the effect of, nutritional support. In this case the measurement of special biochemical markers of stress is highly recommended.

Limitations of Data

Most of the biochemical indices mentioned in Table 1 are static indices (measures of the concentration of a nutrient or its metabolites in a suitable biochemical matrix) that do not give information on the functions of the body. It would be desirable to measure organ functions instead (they depend on the adequate availability of a nutrient or the response to the regulatory process to maintain body stores). However, few sensitive and reliable functional tests are available and some of them are not specific for a single nutrient or not easily applicable in the field.

Other limiting factors are intraindividual variance and the lack of harmonization and standardization of methodology. As yet, there are no official methods for nutritional status assessment and there are too few quality controls and interlaboratory comparisons. There are currently few reference laboratories and official standards from international or national agencies. This makes comparison of data from different studies difficult.

The reliability and validity of the methods used are not always assessed. It is true that in some cases assessment of true validity is almost impossible. But concurrent or other types of validity are available. This is an area that needs much more consideration.

Also important factors which are not always assessed in nutritional epidemiology include sensitivity, specificity, and variability of indicators. The sensitivity can be diagnostic (the capacity to detect the earliest stages of deficiency) and biochemical (reflecting

every stage of the deficiency). The variability can be analytical (instrumental, preinstrumental), and biological (intraindividual, interindividual). The above items are limiting factors in data interpretation.

Anthropometry and Clinical Examination

J R Lustig and B J G Strauss, Monash Medical Centre, Clayton, Victoria, Australia

Introduction

A quick glance at a person will provide a gross estimation of nutritional status. Irrespective of training, we are all able to make these assessments: a Sumo wrestler is obese or overnourished, whilst a terminal AIDS patient is wasted and suffers from undernutrition. These assessments, however, are merely qualitative and contribute little to quantifying the nature and extent of these observations.

Table 1 Two-compartment model of body composition

Compartment	*Anthropometric technique used*
Fat mass/distribution	Body mass index
	Skinfold thicknesses
	Abdominal circumference
	Abdominal:gluteal ratio
Fat-free mass	Midarm circumference
	Midarm muscle circumference
	Midarm muscle area

Anthropometry comprises techniques that readily contribute to a more in-depth understanding of body composition and nutritional status, allowing the quantification of observations and the observation of changes with time.

Anthropometric methods are based on a model of body composition that consists of two distinct compartments: fat mass and fat-free mass (see **Table 1**). This two-compartment model of body composition defines the fat-free mass as a compartment consisting of body cells including skeletal muscle, extracellular water, the skeleton, and connective tissue, with the fat compartment consisting of the adipose tissue stores of the body, which has a very small cellular and water component. Anthropometric measurements can indirectly assess these two body compartments and thus provide an index of nutritional status. Alterations in body fat content generally are sensitive to changes in energy balance. Chronic malnutrition is reflected in changes to the protein stores found predominantly in skeletal muscle in the body.

Anthropometric techniques are rapid, portable, noninvasive, and inexpensive. The equipment required includes a tape measure, stadiometer (for measuring height), standardized weight scales, and skin-fold calipers. These techniques are frequently used in nutritional assessment and for monitoring changes in a diverse range of clinical settings. Such settings include tertiary referral centres, isolated rural practices, and population-based epidemiological studies. They are also used in gymnasia, infant welfare centers, schools, insurance assessments, sports clubs, and so on.

Anthropometric Assessment of Fat Mass

Body Mass Index (BMI)

$$\text{BMI} = \frac{\text{weight (kg)}}{\text{height (m}^2\text{)}}$$

Weight should be measured using standardized, good-quality weighing scales. The weight range of the scales should be known and should be appropriate for the subjects being weighed. This is particularly

important for the larger weights. Many instruments are not designed for weighing above 120 kg and are inaccurate when approaching higher weights.

Height is measured in the standing position using a stadiometer. Alternatively, a measuring stick attached to a vertical surface with some form of right-angled headboard can be used. Portable versions have been developed for field work. Shoes and socks should be removed and clothing kept to a minimum in order to allow assessment of posture. The subject should stand upright with the feet, buttocks, and shoulder blades in contact with the vertical surface or stadiometer. The head is positioned so that the Frankfurt plane (the line between the top of the pinna and the outer canthus of the eye) is horizontal. The subject is asked to take a deep breath, and the movable headboard is lowered until it is touching the crown of the head. The height is measured at maximum inspiration with the examiner's eyes level with the headboard to avoid any errors of parallax. The measurement is read to the nearest millimeter, the lower value being used if the level falls between two values.

Because of kyphosis or other postural problems, or, in the case of a patient being confined to bed, knee height has been used as a surrogate for estimating stature, and regression formulae have been developed to estimate height from knee height.

The BMI or Quetelet's index is the most commonly used weight/height ratio in adult populations. The BMI has a reasonable correlation with relative fat mass, as measured by body-density techniques. The correlation between BMI and relative fat mass, as measured by underwater weighing, was found to be 0.82 for a sample of women and 0.70 for a male sample. Another limitation on the usefulness of BMI in predicting body fatness in a given individual relates to the weight nominator. As weight is influenced by muscle, bone, and water as well as by fat, an individual with a well-developed musculo-skeletal system relative to height may have a BMI in the obese range but will not be overfat. BMI should thus be considered in the light of an individual's physical activity level.

Classifications of BMI have been developed, and these define relative levels of adiposity (see Table 2). Such a classification is based on surveys of Caucasian populations and may not apply to other ethnic groups. In addition, there is a good correlation between BMI and morbidity and mortality from obesity, e.g., heart failure, osteoarthritis, and hypertension.

The BMI can also be used as an index of wasting. Population studies have shown an increase in morbidity and mortality, and alterations in immune function as the BMI falls below 18.5, irrespective of the type of population, from undernourished groups, to those with clinical illnesses such as malignancies. The WHO has graded wasting on the basis of the BMI into mild (BMI, 18.5), moderate (BMI < 17.5) and severe (BMI < 16.5).

Table 2 Classifications for body mass index

Body mass index ($kg\,m^{-2}$)	*Health association*
< 16.0	Severe protein-energy malnutrition
16.0–16.9	Moderate protein-energy malnutrition
17.0–18.5	Mild protein-energy malnutrition
20.0–24.9	Apparently healthy, with low health risk
25.0–29.9	Overweight, with increased health risk
30.0–39.9	Obesity, increased macrovascular disease and diabetes mellitus
> 40.0	'Super obesity' with major morbidity

Abdominal:Gluteal Circumference Ratio

The ratio of the abdominal circumference to the maximal gluteal circumference defines the distribution of adipose tissue in the body. The waist is measured with the subject standing erect and undressed. The abdominal circumference is measured at the midpoint of the line between the rib or costal margin and the iliac crest in the midaxillary line. The maximal gluteal (buttock) circumference is also measured with the subject standing erect. It is important to define the sites measured and maintain consistency in these sites in order to compare sets of data.

A waist/hip ratio > 0.95 in males and > 0.85 females is consistent with abdominal obesity.

Abdominal fat distribution is associated with a range of adverse health consequences, including an increased risk of cardiovascular and cerebrovascular disease, impaired glucose tolerance, and hypertriglyceridemia, even when the BMI is in the 'healthy' range.

Skin-fold Thicknesses

Estimation of body fat content from skin-fold thicknesses assumes that measurements of subcutaneous fat represent total body fat. This assumption is not strictly true, as the thickness of subcutaneous fat does not necessarily reflect a constant proportion of total body fat. In addition, there are marked variations in the distribution of subcutaneous fat depending on age, sex, and race. None the less, this method provides useful information and is in routine use. Skin-fold thickness measurements may be taken at single or multiple sites. There is no universal agreement as to which skin-fold best represents total body fat. However, the triceps skin-fold is most frequently selected for a single-site assessment of body fat.

The measurement of the triceps skin-fold is taken at the midpoint of the upper arm. With the elbow bent to 90% the midpoint is located half-way between the acromium process of the shoulder and the olecranon process of the ulna. This point should be marked. The arm is then extended and allowed to hang loosely by the side. Using the thumb and forefinger, the skin-fold is grasped just above the midarm point. The calipers are applied at right angles to the skin at the midarm point and 1 cm in from the surface. The fold should remain held whilst the measurement is taken. Multiple skin-fold sites can be assessed and usually include both limb and trunk sites.

Body density can be estimated from skin-fold measurements. Using regression equations such as Durnin and Womersley's, skin-folds, sex, and age are used to derive body fat and fat-free mass. For example, for males aged 30–39 years:

1. $D\,(\mathrm{gm}^{-3}) = 1.1422 - (0 - 0544 \times \log_{10}$ (Skinfold sum [mm])), where D = density; skinfold sum = biceps + triceps + subscapular + iliac.
2. Percentage body fat or relative fat mass can then be calculated. Several equations have been derived. The Siri equation assumes that the density of fat is $0.900\,\mathrm{g\,cm}^{-3}$ and that the density of the fat-free mass is $1.100\,\mathrm{g\,cm}^{-3}$: % fat = $[(4.95/D) - 4.50] \times 100$.
3. Total body fat is derived as follows: total body fat (kg) = [body weight (kg) × % body fat]/100.
4. Fat-free mass (kg) = body weight (kg) − body fat (kg).

Both the skill of the operator and the character of the subcutaneous fat in an individual can influence the precision of skin-fold measurements. In general, the error of this method is approximately 5%. Depending on the equation used and the population studied, this may range from 3 to 9% body fat mass. Durnin and Womersley derived values for calculation of fat mass for all age groups in both men and women.

Anthropometric Assessment of Fat-Free Mass

Mid-arm Circumference

The upper arm contains both muscle and subcutaneous fat, so that measurement of the circumference of the midupper arm may be used as an index of nutritional status. In underdeveloped countries where the population is often malnourished and with little fat reserves, a change in this measurement can reflect total body protein stores. Serial measurement of the upper-arm circumference may be used to monitor nutritional intervention. Measurement of this circumference is described in the section on skin-fold thicknesses.

Midarm Muscle Circumference

In practice, midarm muscle circumference is used in preference to midarm circumference as a measurement which reflects total body protein stores. The upper-arm circumference comprises central bone surrounded by a layer of skeletal muscle and subcutaneous fat. The midarm muscle circumference, derived from the midarm circumference and the triceps skinfold thickness, takes into account an assessment of both fat and protein stores.

Small changes in muscle mass may not be detected by this technique. In addition, individual variations in the diameter of the humerus are not taken into account in this calculation. Midarm muscle circumference is derived using the following equation:

$$\text{Midarm muscle circumference} = \text{midupper arm circumference} - (\pi \times TSF),$$

where TSF = triceps skinfold thickness (in cm).

Midarm Muscle Area

Midarm muscle area provides a higher correlation with body protein stores than does either of the midarm circumferences. Because it takes into account a two-dimensional assessment, it reflects more accurately small changes in muscle mass. None the less, one appraisal of the equation suggests that it may underestimate significantly the degree of muscle wasting. Midarm muscle area may be calculated using the following equation:

$$\text{arm muscle area} = [C - (\pi \times TSF)]^2/4\pi,$$

where C = midupper arm circumference, and TSF triceps skinfold thickness (in cm).

The coefficient of variation for the measurement of midarm muscle area has been estimated as approximately 7% when made by trained operators. This is therefore not a sensitive enough method by which to detect small changes in muscle mass.

Conclusions

Anthropometry provides a rapid methodology for the indirect quantification of fat and fat-free mass and, thus, the body compositional aspects of nutritional status. The techniques require little in the way of equipment and are readily portable and inexpensive. Although they are insensitive to small changes in nutritional status, they have a useful role to play in assessment of nutritional status and for monitoring

progress over time. In addition, these techniques are useful in population-based field research of nutrition-related disorders.

Biochemical Tests for Vitamins and Minerals

A V Lakshmi and M S Bamji[a], National Institute of Nutrition, Hyderabad, AP, India

Introduction

Increasing attention is being given to the definition of marginal malnutrition since the elimination of clinical signs of deficiency *per se* is not sufficient for optimal health. Biochemical measurements on easily available body fluids represent the most objective assessment of nutritional status and often provide subclinical information. It also provides information on micronutrient toxicity. During the development of any deficiency disease, biochemical changes precede clinical symptoms and hence biochemical tests help to identify the disease at the subclinical stage. They also help to confirm the clinical diagnosis.

An ideal biochemical test should be specific, sensitive, and indicative of tissue depletion at an early stage but not immediate dietary intake. However, we do not have an ideal biochemical test for most nutrients and the method selected depends on the situation in which it is applied. Often, more than one test is required. Classification of an individual as severely deficient, marginally deficient, normal, or intoxicated may require different tests. In this chapter biochemical tests used for the nutritional status assessment of fat- and water-soluble vitamins and of a few minerals – sodium, potassium, calcium, iron, iodine, zinc, copper, and selenium are discussed.

Types of Laboratory Tests

Laboratory tests for the assessment of vitamin or mineral nutritional status can be placed in the following categories:

1. Measurement of excretion of nutrient or its metabolite in urine, without or after a bolus load (load return test)
2. Measurement of nutrient level and/or its active metabolites in blood
3. Assay of activity of a vitamin-dependent enzyme and its *in vitro* stimulation with corresponding coenzyme in the blood. (*See* **Coenzymes**.)
4. Measurement of rise in the concentration of a metabolite in the blood or urine (resulting from inadequate intake of the vitamin) after administering a load of the precursor

[a]Current address: Dangoria Charitable Trust, 1–7–1074, Hyderabad 500020, India.

Measurement of excretion of vitamin or its metabolite in urine can be carried out on a 24-h sample, random sample, or in the first voided morning sample of urine. Although a 24-h specimen provides the most accurate estimate, it is difficult to collect it in the free-living population. Measurements in random samples or a first voided urine sample, and expressing the value per gram of creatinine, may be useful for population studies but are not very reliable for individual assessment.

The limitation regarding the interpretation of urinary data is that it is influenced by immediate dietary intake and may not reflect tissue stores. Load return tests may yield better information regarding the state of tissues but they are seldom used now. Certain physiological and pathological conditions, as well as ingestion of drugs, influence urinary excretion of certain vitamins and minerals.

Either whole blood or different components such as plasma, erythrocytes, leukocytes, and platelets has been used for the assessment of vitamin and mineral status. The choice of the blood components is decided by the concentration of the nutrient and its sensitivity to vitamin or mineral depletion. High-performance liquid chromatography (HPLC) technique has revived interest in these measurements due to improved sensitivity. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Details regarding enzymatic tests and metabolite tests will be discussed while dealing with the individual vitamins.

Guidelines for Interpretation of Values

Availability of standard reference material (serum and erythrocyte hemolysates), use of standardized procedures, and strict quality control measures are necessary for arriving at interpretative guidelines. Since reference quality control samples are not available for many vitamins, and different laboratory procedures are adopted by various workers, only tentative guidelines based on the values obtained with apparently healthy, well-nourished controls are available at present for interpretation of data. (*See* **Vitamins**: Determination.)

Fat-soluble Vitamins

Vitamin A

Serum vitamin A level is not a sensitive indicator of vitamin A stores. The levels are however indicative of vitamin A status when the stores are either fully replete or totally deplete and in the absence of infection. Serum levels below 0.35 $\mu mol\,l^{-1}$ are usually associated with clinical signs of deficiency. Serum vitamin A levels above 0.70 $\mu mol\,l^{-1}$ are considered satisfactory and reflect adequate liver reserves (**Table 1**).

Table 1 Tentative guidelines for the interpretation of biochemical parameters of vitamin A status

Biochemical measurement	*Acceptable*	*Medium risk*	*High risk*
Serum ($\mu mol\,l^{-1}$)	> 70	35–70	< 35
Liver ($\mu mol\,g^{-1}$)	> 0.70	0.17–0.70	< 0.17
Relative dose–response (%)	< 20	> 20	
Modified relative dose–response (DR/R)	< 0.03	> 0.03	

DR, 3,4-didehydroretinol; R, retionol.

Marginal vitamin A status can be assessed by the relative dose–response (RDR) test or the modified relative dose–response (MRDR) test. The RDR test consists of determination of the plasma levels of vitamin A at baseline and 5 h after the administration of a small oral or intravenous dose of retinylpalmitate or retinyl acetate. An increase of more than 20% is indicative of inadequate hepatic reserves.

In the MRDR test, 3,4-didehydroretinol (vitamin A_2) is administered instead of retinol. This test requires only one blood sample for analysis. The ratio of dehydroretinol to retinol is used to assess liver vitamin A concentrations (Table 1).

Use of deuterated vitamin A for measuring the total body pool by means of isotope dilution is currently being refined.

Toxicity

High plasma levels of retinyl esters in the presence of high plasma levels of vitamin A is a sign of vitamin A toxicity. In conditions of normal vitamin A status, the plasma levels of retinyl esters is about 5%.

Spectrophotometric, HPLC fluorometric, and calorimetric techniques are used for measuring plasma vitamin A level. (*See* **Retinol**: Properties and Determination.)

Vitamin D

Measurement of serum 25-hydroxycholecalciferol, the major circulating metabolite of vitamin D, is the best indicator of vitamin D status. In healthy adults its concentration in serum varies from 20 to 130 $nmol\,l^{-1}$ and less than 12.5 $nmol\,l^{-1}$ is generally considered inadequate. It can be measured by HPLC or by competitive protein-binding assay. (*See* **Cholecalciferol**: Properties and Determination.)

Vitamin E

Vitamin E status is normally assessed by measuring levels of the vitamin in plasma or serum and other

tissues (red cells, platelets, adipocytes) by spectrophotometric, fluorometric, or HPLC methods. Since the levels of vitamin E and lipids in the serum are directly correlated, their ratio is a better measure of status than serum vitamin E alone (Table 2). The ratio of plasma vitamin E to cholesterol + triglyceride or vitamin E to cholesterol has also been reported to be as good as that of vitamin E to total lipids. (*See* **Tocopherols**: Properties and Determination.)

In vitro hemolysis of red blood cells in the presence of hydrogen peroxide, quantitating the formation of malondialdehyde from hydroperoxides generated by the *in vitro* peroxidation of polyunsaturated fatty acids or erythrocytes exposed to hydrogen peroxide is considered a functional test for assessing vitamin E status. The latter tests, based on quantitation of malondialdehyde formed, are considered to be more sensitive than the hemolysis test.

Vitamin K

In the past, vitamin K status has been assessed by measuring prothrombin time and other clotting times. These measures are however not sensitive to detect subclinical vitamin K deficiency since clotting time does not change until the concentration of prothrombin decreases by about 50%.

Vitamin K is needed for the γ-carboxylation of certain glutamic acid residues in proteins. During vitamin K deficiency, the vitamin K-dependent proteins occur in an undercarboxylated form. Milder forms of vitamin K deficiency can be assessed by measuring urinary γ-carboxyglutamic acid excretion or circulating levels of undercarboxylated prothrombin and osteocalcin. The last parameter is considered to be a very sensitive marker of vitamin K status. Plasma level of phyloquinone has also been used as a measure of vitamin K status. Plasma phyloquinone and urinary γ-carboxyglutamic acid can be determined by HPLC separation followed by fluorometric detection. Undercarboxylated prothrombin and osteocalcin can be determined by radioimmunoassay. (*See* **Immunoassays**: Radioimmunoassay and Enzyme Immunossay.)

Thiamin

The biochemical tests used for the assessment of thiamin nutritional status include measurement of: (1) erythrocyte transketolase activation coefficient (ETK-AC); (2) urinary excretion of thiamin; and (3) measurement of whole blood or erythrocyte thiamin pyrophosphate (TPP) concentration.

TPP is the coenzyme for transketolase and determination of ETK-AC is the most widely accepted procedure for assessing thiamin status. Activity of this enzyme is measured in erythrocyte hemolysate without (basal) and with a saturating amount of TPP added *in vitro* (stimulated). The ratio of stimulated to basal activity is called the activity coefficient (ETK-AC). Basal activity falls and ETK-AC increases in thiamin deficiency (Table 2). Activity can be measured by determining the rate of disappearance of pentose or appearance of hexose. However interpretation of the results is complicated under certain disease conditions (some cancers, uremia, neuropathy, and diabetes) and drug treatment (diuretics, antacids) since ETK activity is affected under these conditions. (*See* **Enzymes**: Uses in Analysis.)

Normal adults receiving adequate dietary thiamin excrete more than 0.3 μmol per 24 h. Urinary thiamin can be measured by fluorometric method. (*See* **Thiamin**: Properties and Determination.)

Measurement of blood or erythrocyte TPP by HPLC appears to be a more sensitive and promising indicator of thiamin status and needs further verification.

Riboflavin

Measurement of urinary excretion of riboflavin, red blood cell riboflavin, and erythrocyte glutathione reductase activation coefficient (EGR-AC) are used for the biochemical assessment of riboflavin nutritional status.

The urinary excretion method is useful for population surveys. On an adequate dietary intake of riboflavin, normal adults excrete more than 0.21 μmol g^{-1} of creatinine. Riboflavin concentration

Table 2 Tentative guidelines for interpretation of blood vitamin levels and enzyme tests

Parameter measured	*Acceptable*	*Medium risk*	*High risk*
Serum vitamin E (μmol l^{-1})	> 16.2	11.6–16.2	< 11.6
Serum vitamin E total lipid ratio	> 0.8		< 0.8
ETK-AC	< 1.15	1.15–1.25	> 1.25
EGR-AC	< 1.2	1.2–1.4	> 1.4
Serum folate (nmol l^{-1})	> 11.0	6.7–11.0	< 6.7
Erythrocyte folate (nmol l^{-1})	> 360	315–359	< 315
Plasma ascorbate (μmol l^{-1})	17–85	11–17	< 11
Leukocyte ascorbate (μmol 10^{-6} cells)	113–300		

ETK-AC, erythrocyte transketolase activation coefficient; EGR-AC, erythrocyte glutathione reductase activation coefficient.

in urine can be measured by fluorometric or microbiological assay or HPLC. (*See* **Riboflavin**: Properties and Determination.)

Red cell riboflavin level may be a better index of tissue status than urinary riboflavin. Fluorometric or HPLC technique can be used to estimate red cell riboflavin and the value can be expressed per gram hemoglobin or packed cell volume. However this test is not commonly used because tissue saturation is difficult to define and the value varies between individuals. Measurement of red cell flavin adenine dinucleotide (FAD) level using HPLC may improve the index.

At present, the EGR-AC test is the most accepted biochemical method for the assessment of riboflavin status. FAD, the coenzyme form of riboflavin, is necessary for the activity of glutathione reductase. The activity of this enzyme is measured in erythrocyte hemolysate or blood hemolysate without (basal) and with added FAD (stimulated). The ratio of stimulated to basal activity is called the activation coefficient (EGR-AC). This ratio increases in riboflavin deficiency (Table 2). EGR activity is assayed by rate reaction techniques. However the EGR-AC test fails to measure riboflavin status when glucose 6-phosphate dehydrogenase deficiency is also present.

During respiratory infections, urinary and blood levels of riboflavin are raised due to mobilization of the vitamin from the liver. There is a transient reduction in EGR-AC values also. Thus assessment of riboflavin status during such infection is difficult.

Niacin

Measurements of the urinary excretion of N^1-methylnicotinamide (NMN) and its oxidation product, N^1-myethyl-2-pyridone-5-carboxamide (2-pyridone) have been used to determine niacin status. Normal adults excrete more than 17 μmol NMN per day, whereas during deficiency its excretion is less than 5.8 μmol per day.

A more recent study suggested that erythrocyte nicotinamide adenine dinucleotide (NAD) concentration may serve as a sensitive indicator of niacin status and that a ratio of erythrocyte NAD to NAD phosphate (NADP) < 1.0 may suggest a risk of developing niacin deficiency. (*See* **Niacin**: Properties and Determination.)

Vitamin B_6

Several direct and indirect measures are used for the assessment of vitamin B_6 status.

Measurement of the plasma pyridoxal phosphate (PLP) level, the coenzyme form of the vitamin, is the most commonly used method and a concentration of 30 nmol l^{-1} is considered to be adequate. However, proper interpretation of plasma PLP data must take into account the factors which affect this value. High protein intake, pregnancy, age, smoking, and an increase in alkaline phosphatase activity are known to reduce PLP concentration. The measurement of both PLP and pyridoxal is suggested to be a better index of vitamin B_6 status during pregnancy. Pyridoxal phosphate levels in plasma can be measured by enzymatic or HPLC techniques.

The second direct measure is urinary excretion of 4-pyridoxic acid. It correlates well with dietary vitamin B_6 intake and this parameter is useful for population surveys. An excretion of > 3.0 μmol per day is considered to be associated with adequate vitamin B_6 status and it can be measured by fluorometric method. (*See* **Vitamin B_6**: Properties and Determination.)

Functional tests for assessing vitamin B_6 status include measurement of PLP-dependent transaminases, such as erythrocyte aspartate aminotransferase (EAST) and alanine aminotransferase (EALT) and their activation coefficient (AC), and tryptophan or methionine load test. They reflect tissue levels of PLP.

EAST or EALT activity is measured without and with added PLP to give an activation coefficient (EAST-AC or EALT-AC) – an enzymatic test analogous to that used for thiamin and riboflavin. Although widely used for assessing vitamin B_6 status, the interpretation of EAST-AC value is not standardized. Values ranging from 1.7 to 2.0 have been used to differentiate between adequacy and deficiency. The EALT-AC value suggested for adequacy of vitamin B_6 status is less than 1.25. These two enzymes can be assayed by colorimetric or rate reaction technique.

The tryptophan load test has been used in population surveys as a functional index of B_6 status. An inadequate status results in an increased excretion of tryptophan metabolites such as kynurenine and xanthurenic acid, since vitamin B_6-dependent enzyme kynureninase is required for their metabolism. This test is usually carried out after administering an oral load of 2–5 g tryptophan and measuring the urinary excretion of xanthurenic acid in a 6–9-h period. However excretion of tryptophan metabolites is influenced by factors like protein intake and pregnancy.

Folic Acid and Vitamin B_{12}

Serum as well as red blood cell folate reflect folate status. While serum folate reflects the dietary intake and readily available tissue reserves, red blood cell folate reflects long-term folate status. Microbiological or competitive protein-binding radioassay is used to measure folate levels in serum and red blood

cells. The guidelines for interpreting these values are given in Table 2. (*See* **Folic Acid**: Properties and Determination.)

The metabolism of histidine to glutamic acid is impaired in folate deficiency, leading to an increase in urinary excretion of formiminoglutamic acid (FIGLU). This occurs particularly after a loading dose of histidine. Normal adults excrete less than 35 mg FIGLU in 24 h after 5 g histidine load.

Deoxyuridine Suppression Test

In folic acid deficiency the activity of the enzyme thymidilate synthalase is impaired. This enzyme catalyzes the conversion of deoxyuridine to thymidine. In this test bone marrow cells or peripheral blood lymphocytes are preincubated with nonradioactive deoxyuridine and then with ^{3}H thymidine. The amount of radioactivity incorporated into the DNA of the cells is increased in folate as well as in vitamin B_{12} deficiency. These two deficiencies can be differentiated by *in vitro* incubation with respective vitamins.

Hypersegmentation of circulating neutrophils is a morphological change that occurs in folate deficiency due to slowed DNA synthesis. There are studies to suggest that this change occurs when plasma folate levels drop lower than 10 nmol l^{-1}.

Measurement of plasma homocysteine level may also indicate the adequacy of folate and, to a lesser extent, vitamin B_{12} status. Vitamin B_6 deficiency also raises plasma homocysteine concentration.

Vitamin B_{12} status is generally assessed by measuring its concentration in serum by microbiological or competitive protein-binding radioassay. Radioassay using pure intrinsic factor measures true vitamin B_{12}, whereas microbiological assay measures a few analogs of vitamin B_{12} as well. The lowest acceptable serum level using microbiological assay is 150 pmol l^{-1}, whereas for the radioassay specific for cobalamine, serum level < 75 pmol l^{-1} is considered deficient. Measurement of plasma vitamin B_{12} bound to transcobalamine II is considered to be more sensitive than total vitamin B_{12} for the assessment of marginal vitamin B_{12} deficiency.

The urinary or plasma methylmalonic acid level, preferably after an oral load of valine (its precursor), is a metabolic test for detecting vitamin B_{12} deficiency. Normal adults excrete less than 100 µmol in 24 h.

Pantothenic Acid

Urinary excretion of pantothenic acid or blood levels of the vitamin can be used to assess pantothenic acid status. Adults taking an adequate amount of dietary pantothenate excrete between 9 and 24 µmol of the vitamin per gram creatinine and the blood levels range between 1.2 and 1.8 µmol l^{-1}. Pantothenic acid levels in blood and urine can be measured by microbiological or radioimmunoassay. (*See* **Pantothenic Acid**: Properties and Determination.)

Biotin

Biotin nutritional status can be assessed by using the following sensitive biochemical parameters: (1) urinary excretion of organic acids such as 3-hydroxyisovaleric, 3-hydroxypropionic, and methylcitric acids, or of biotin and its metabolite bisnorbiotin; (2) assay of the activity of biotin-dependent enzyme propionyl coenzyme A carboxylase with and without *in vitro* addition of biotin in lymphocytes; and (3) measurement of plasma biotin level. Plasma biotin is a less sensitive indicator compared to the other two methods. The normal reported range for plasma biotin is 140–356 pmol l^{-1}. Biotin levels in blood and urine can be determined by microbiological or isotopic dilution assay. (*See* **Biotin**: Properties and Determination.)

Ascorbic Acid

Plasma and leukocyte ascorbate levels indicate ascorbic acid status. The simplicity and reliability of plasma ascorbic acid determination make it preferable for identifying individuals at risk of deficiency due to chronic low intake of the vitamin. However, plasma ascorbic acid levels may be less useful for defining the ascorbic acid status of individuals with adequate or high intake. Leukocyte ascorbic acid concentration reflects more accurately tissue stores of vitamin than plasma level.

Plasma and leukocyte ascorbic acid levels are determined by HPLC or colorimetric techniques. Thresholds for interpretation of ascorbic acid status are given in Table 2. (*See* **Ascorbic Acid**: Properties and Determination.)

Mineral Nutrition

In this section, biochemical methods used for the nutritional assessment of a few macro- and micromineral elements are given. However, the list is not comprehensive. Only those elements for which a laboratory test can give meaningful data from the nutritional point of view are included.

Sodium and Potassium

Dietary deficiency of sodium and potassium cations might occur after increased losses under certain conditions such as vomiting and diarrhea. Their status is generally assessed by measuring serum or plasma levels by atomic emission flame photometry or

atomic absorption spectrophotometry (Table 3). (*See* **Sodium**: Properties and Determination.)

Calcium

In blood, calcium is present almost entirely in the plasma. As ionized calcium in the plasma is under strict homeostatic control ($1.2\,mmol\,l^{-1}$), it cannot serve as a sensitive parameter to assess nutritional deficiency of calcium. (*See* **Calcium**: Properties and Determination.)

Bone density is an indirect measure of calcium status, since 99% of it is present in the bones. It can be measured by radiographic, single- or dual-photon absorptiometry techniques.

Iron

Iron status can be assessed by three types of biochemical tests, reflecting different stages of deficiency. First, bone marrow iron and serum ferritin concentrations indicate iron stores. Serum ferritin levels less than $12\,\mu g\,l^{-1}$ suggest depletion. As an acute-phase reactant, serum ferritin is elevated by acute and chronic infections, inflammatory diseases, malignancies, and liver disorders.

In the second stage of iron deficiency, referred to as iron-deficiency erythropoiesis, the supply of iron to the erythroid marrow is reduced. This can be assessed by the transferrin saturation index. An increase in red cell protoporphyrin level also indicates restricted iron supply to the developing red cell (Table 4).

Recent studies suggest that serum transferrin receptor is a sensitive and quantitative index of tissue iron status (Table 4). The levels are elevated in iron-deficiency anemia. Inflammation or liver disease does not affect serum transferrin receptor levels.

The third stage of iron deficiency is anemia, which can be assessed by hemoglobin level or hematocrit. Hemoglobin levels less than $13\,g\,dl^{-1}$ of blood for adult males and $12\,g\,dl^{-1}$ blood for adult females are considered deficient, whereas during pregnancy hemoglobin concentration less than $11\,g\,dl^{-1}$ is considered to be anemia. (*See* **Anemia (Anaemia)**: Iron-deficiency Anemia.)

Iodine

Urinary excretion of iodine reflects the dietary intake. An excretion of more than 100 μg per day suggests an adequate dietary intake of iodine. It can be measured by the kinetic method, based on iodide-catalyzed reduction of ceric to cerus by arsenic. (*See* **Iodine**: Properties and Determination.)

The only known requirement of iodine in humans is in the synthesis of thyroid hormones. Measurements of serum levels of thyrotropic hormone or triiodothyronine and thyroxine are sensitive functional tests for iodine status.

Zinc

Zinc levels in plasma, urine, hair and cellular compartments of blood, activity of zinc-dependent enzymes such as carbonic anhydrase in red cells and plasma levels of zinc-binding protein metallothionin have been used as indices of zinc nutrition status.

Plasma zinc appears to be the most widely used parameter. It decreases in cases of severe and moderate deficiency of zinc. Plasma zinc concentrations are susceptible to a number of pathophysiological influences. Since erythrocytes and hair have a longer half-life, their zinc content does not indicate acute zinc deficiency. Zinc levels in cells with rapid turnover (neutrophils and monocytes) can be used to detect mild zinc deficiency. Serum thymulin level without and with *in vitro* addition of zinc has been suggested as a sensitive method to assess mild zinc deficiency. Atomic absorption spectrometry is used for the analysis of zinc in urine and blood. Table 5 gives the normal range of tissue zinc. (*See* **Zinc**: Properties and Determination.)

Table 3 Normal ranges of sodium, potassium, copper, and selenium in blood

Parameter	*Range*
Plasma sodium ($mmol\,l^{-1}$)	136–145
Plasma potassium ($mmol\,l^{-1}$)	3.5–5.0
Plasma copper ($mg\,l^{-1}$)	0.8–1.75
Serum ceruloplasmin ($\mu mol\,l^{-1}$)	1.7–2.9
Plasma selenium ($\mu g\,l^{-1}$)	60–120
Erythrocyte selenium ($\mu g\,l^{-1}$)	90–190

Table 4 Assessment of iron status (commonly used cut-off values)

Parameter	*Value*
Serum ferritin ($\mu g\,l^{-1}$)	12
Transferrin saturation (%)	16
Red cell protoporphyrin ($\mu mol\,l^{-1}$)	1.24
Serum transferrin receptor ($mg\,l^{-1}$: normal range)	2.5–8.5
Hemoglobin ($g\,l^{-1}$)	
Men	130
Women	120

Table 5 Normal range of tissue zinc

Parameter	*Range*
Plasma ($mg\,l^{-1}$)	0.7–1.4
Erythrocyte ($mg\,l^{-1}$)	10–14
Urine (μg per day)	400–600
Leukocytes (μg per 10^{10} cells)	80–130
Hair ($\mu g\,g^{-1}$)	124–320

Copper

Copper status is commonly assessed by estimating serum copper concentration or by assaying the activity of the copper-dependent enzyme ceruloplasmin in serum (Table 3). Serum copper levels tend to be higher in women. The values are influenced by certain physiological and pathological conditions. About 95% of copper in serum is in ceruloplasmin, which is an acute-phase reactant protein. Erythrocyte copper-zinc superoxide dismutase has been suggested to be a better index of copper status than serum copper or ceruloplasmin.

Serum copper can be estimated by atomic absorption spectrometry. (*See* **Copper**: Properties and Determination.)

Selenium

Selenium status can be assessed by measuring its levels in urine, plasma, erythrocytes, and blood or by assaying the selenium-dependent enzyme glutathione peroxidase in erythrocytes or platelets.

Plasma selenium is a sensitive index of short-term changes until the plasma level reaches a plateau. Erythrocyte selenium and glutathione peroxidase activity indicates long-term changes because of the long life span of these cells.

The commonly used techniques for measuring selenium in biological fluids include fluorimetry, atomic absorption spectrometry, and mass spectrometry. Table 3 gives the frequently reported normal ranges in plasma and erythrocytes. (*See* **Selenium**: Properties and Determination.)

Selenium is an integral part of glutathione peroxidase and measurement of the activity of this enzyme is a functional test for the assessment of selenium status. The minimal erythrocyte selenium level required to reach a plateau of glutathione peroxidase activity has been estimated to be about 141 $\mu g\,l^{-1}$.

Conclusions

The value of biochemical tests can be improved with a better understanding of their limitation and their relationship to functional consequences. What level of biochemical insult can an individual accommodate without any ill effects? Can generalized interpretative guidelines be applied to all population groups or are there substantial variations? Despite these dilemmas, biochemical tests have an important place in nutritional diagnosis.

Functional Tests

N W Solomons, CeSSIAM, Guatemala City, Guatemala

Background

Reasons abound for assessing human nutritional status, ranging from the population level (epidemiology, public health) to assess risk of nutrient deficiency and excess, and to monitor changes and impacts of interventions to the clinical level, where a practitioner is interested in the patient's nutriture for routine maintenance, as a clue to disease, and in titrating nutritional and disease-specific therapies. (*See* **Epidemiology**.)

One of the options for assessing nutritional status is the approach of *functional assessment*. The purpose of this chapter is to discuss the history, origins, concepts, applications, advantages and disadvantages,

and modern advances in the arena of functional tests of human nutriture.

Historical Perspective

Clinical assessment of nutritional status by examining signs and symptoms is the most venerable approach; in fact, the syndromes of scurvy, beriberi, pellagra, rickets, and anemia had been recognized clinically long before the chemical nature and etiological roles of ascorbic acid, thiamin, nicotinic acid, cholecalciferol, and the hematinic nutrients (iron, folic acid, vitamin B_{12}) were discovered. (*See* **Anemia (Anaemia)**: Iron-deficiency Anemia; **Scurvy**; refer to individual nutrients.)

As *sensitivity* (the ability of a test to find all affected individuals) and *specificity* (the ability of a test to reject all unaffected individuals) of a diagnostic approach must always be considered, clinical examination has its limitations. In terms of sensitivity, clinical examination is a poor index of nutritional deficiency, as clinical manifestations emerge late in the process and only in those most deficient. They represent the tip of the iceberg. The specificity of clinical diagnosis is variable. Whereas scurvy and rickets are unmistakable, anemia has multiple nutritional bases and a host of causes unrelated to nutrition.

The twentieth century saw the chemical identification of the essential nutrients, producing reliable assays to measure nutrients or their metabolites in biological fluids and tissues. The first-line approach for the detection of deficiencies and excess of nutrients shifted from clinical examination to laboratory tests, with the realization that changes in body reserves and tissue content of nutrients decrease before the clinical manifestations of deficiency are expressed. Similarly, in terms of excessive accumulation, an increased burden of a nutrient occurs before overt toxic signs and symptoms develop. Most, but not all, biochemical procedures generate *static* indices of nutritional status. Assessment of individual status is pursued by constructing a normative reference distribution for a healthy, well-nourished population as the standard, and assigning cut-off criteria on the high and low ends that represent excess and deficiency, respectively. For a population assessment, the deviation of its biochemical distribution from that of the reference population is gauged, or the prevalence of individuals with values outside the criteria levels is tabulated.

The concept of *functional* assessment was added to the lexicon of nutritional status evaluation in the 1970s, although its origins go much further back to the Hess tourniquet test for capillary fragility for incipient scurvy of the early twentieth century, dark-adaptation tests for vitamin A status, and prothrombin- and coagulation-time tests for vitamin K adequacy of the middle of the century. However, in 1978 Study Team IX of the Committee on International Nutrition Programs of the National Academy of Sciences of the USA, chaired by the late Professor Doris Howes Calloway, issued a report arguing that the intactness of the physiological and behavioral functions that depended on nutrients was of more interest to policy-makers in governments and development assistant agencies than were the levels of nutrients in the body. In 1983, Noel Solomons and Lindsay Allen produced a *systematic* classification of tests of nutritional status based on measures of physiological performance or behavioral responses.

Definitions

This article compares and contrasts two types of indices that seek to determine the nutriture of individuals: *static* and *functional* indices.

Static Indices

Static indices are tests directed at assessing the *quantitative* content of a nutrient in the organism, either as whole-body reserves or as tissue concentrations. They represent chemically measurements of the nutrient itself, some active or inactive metabolite, or a complex, such as hemoglobin, that contains the nutrient. In the instance of iron status, for example, hemoglobin is a surrogate for iron in target tissues, whereas ferritin reflects its presence in body iron stores. Serum iron, transform saturation, and iron in hair or nails are all examples of static indices of iron status. (*See* **Anemia (Anaemia)**: Iron-deficiency Anemia.)

Functional Indices

Functional indices of nutritional status are those behavioral, physiological, or biochemical functions of the organism dependent on the adequate availability of a nutrient or resulting from the homeostatic regulatory processes that maintain body stores and harmonic internal distribution of some nutrients.

As mentioned, perhaps the first example of a functional test of nutritional status was the capillary fragility test of Hess, followed in the 1930s by dark adaptation tests based on Wald's elucidation of the dependence of retinal cone function on vitamin A. With the advent of isolated radioisotopes and whole-body counting, tests of the absorption, retention, and distribution of several nutrients have been developed. With the molecular biology, genomic, and proteonomic revolutions, new and unexplored

opportunities for functional tests have emerged. (*See* **Ascorbic Acid**: Physiology; **Retinol**: Physiology.)

Classification of Functional Indices

Classification by System

Functional tests can be conveniently classified according to the body system. The categories are as follows: (1) structure and structural integrity; (2) immunity and host defense; (3) transport; (4) hemostasis; (5) reproductive biology; (6) nervous system function; (7) hemodynamics and physical capacity. Some functional tests cannot be classified into any of these, and reside in a 'miscellaneous' catchment category.

Structure and structural integrity Under 'structure and structural integrity' are classified all of those tests that relate to growth and development of children and adolescents. At the level of specific tissues, tests of the integrity of somatic membranes, red cell membranes, capillary walls, and collagen and osseous structures also pertain to this category. The destruction (lipid peroxidation) of membranes is presumably related to the adequacy of vitamin E and of other putative antioxidant nutrients such as selenium, zinc, and copper. (*See* **Growth and Development**; refer to individual nutrients.)

Immunity and host defense In the category of immunity and host defense are included the multitude of tests of phagocytic, humoral, and cellular immunity,as well as the newer tests of messenger (hormonal) function of the cytokine mediators of the inflammatory response and of autoimmunity and autoimmune surveillance. Almost all macronutrients, and most of the micronutrients that relate to cellular proliferation or metabolism, influence the function at some level of host immunity. (*See* **Immunology of Food**.)

Transport Tests of transport function begin at the intestinal level, specifically with its homeostatic regulation of the body reserves. Additionally, at the level of transmembrane movement of nutrients, we have different uptake potentials based on the nutrient status of the organism. In both cases, deficiency should enhance a net inward flux, and sufficiency should balance inward and outward movement. Among the nutrients with regulated uptake at the gut are iron and zinc. Cobalt ion can be used as a surrogate for iron in an isotopic absorption test. The conversion of carotene to vitamin A by the gut is also regulated by the level of body vitamin A stores, and theoretically could be measured by a clinical test that measures the outcome of its uptake and intestinal metabolism. Isotopic turnover studies also fall into the category of tests of nutrient transport, as do the specific tests of mobilization from stores to the periphery, such as the relative dose–response and the modified relative dose–response for vitamin A status assessment. (*See* **Cobalt**.)

Hemostasis Nutrition with respect to vitamin C, vitamin K, and all micronutrients that influence platelet aggregation can be reflected in tests of hemostasis related to capillary structure, bleeding time, or clotting capacity. It should be noted that capillary integrity can be classified under 'structural integrity' or under 'hemostasis.'

Reproductive biology Spermatogenesis and gonadal–pituitary hormone axis function, as well as lactation and reproduction performance in the individual women and, at the population level, fertility and fecundity of the community, birthweights, and peripartum hemorrhage rates constitute functional tests of reproductive biology. (*See* **Menstrual Cycle: Nutritional Aspects**; **Premenstrual Syndrome: Nutritional Aspects**; **Lactation**: Physiology; **Lactic Acid Bacteria**.)

Nervous system function From cognitive performance, social competence, scholastic performance, through sleep pattern to peripheral nerve transmission and, finally, to the specific sensory reception in eyes, ears, nose, and tongue, functional tests in the nervous system cover a ganut of nervous functions. Both macro- and micronutrient deficiencies have been associated with impairment of higher cerebral functions. Micronutrients, such as thiamin with respect to the sixth cranial nerve function, vitamin A, zinc, and vitamin E for retinal function, and zinc and vitamin A for olfactory acuity, are some of the nutrients that can be evaluated in tests of the special senses.

Hemodynamics and physical capacity Functional tests of hemodynamics and physical capacity are based on techniques of noninvasive and work performance physiology. Doubly labeled water ($^2H_2{}^{18}O$) can be used as a long-term marker of energy expenditure. Protein, energy, and iron are the nutrients most regularly thought to be determinant of the performance of the individual in efforts of physical exertion. (*See* **Exercise**: Metabolic Requirements.)

Classification by Type of Test

The alternative form of classification of functional test of nutritional status is by type of test, i.e., by the manner in which the function is approached. These include four levels: *in vitro* tests of *in vivo* functions;

induced responses and load tests *in vivo*; spontaneous *in vivo* activities and responses of organs and tissues; and responses at the level of the individual or population. A selected array of functional tests are listed under the respective classifications described in the following four sections.

In vitro tests of *in vivo* functions

- erythrocyte transketolase activity coefficient;
- erythrocyte glutathione reductase activity coefficient;
- erythrocyte transaminase activity coefficient;
- circulating homocysteine concentration;
- granulocyte chemotactic response;
- lymphocyte chemotactic response;
- bactericidal capacity of granulocytes;
- leucocyte glycolysis;
- granulocyte reduction of nitroblue tetrazolium;
- serum opsonin activity;
- T-cell blastogenesis;
- monocyte interferon production;
- monocyte monokine (interleukin-1; tumor necrosis factor) production;
- erythrocyte fragility;
- ^{75}Se uptake by erythrocytes;
- ^{65}Zn uptake by erythrocytes;
- thymulin activity reconstitution by zinc *in vitro*;
- prothrombin time;
- descarboxy prothrombin levels;
- platelet aggregation;
- D(−)-uridine suppression test;
- ^{14}C-formate conversion in lymphocytes;
- tensile strength of skin strips.

This group of functional tests requires some form of biological sample, either blood to separate the various cellular elements or a skin biopsy. Where specific cellular elements such as platelets, lymphocytes, and granulocytes are concerned, the volumes of blood to be extracted can be considerable. The samples required for erythrocytes are usually small.

In vivo induced responses and load tests

- capillary fragility (Hess) test;
- experimental wound healing;
- collagen accumulation in subcutaneous sponge implant;
- mobilization of inflammatory cells (Rebuck skin window);
- delayed cutaneous hypersensitivity;
- *de novo* antibody formation;
- vasopressor response;
- total-body energy expenditure with $^{2}H_{2}{}^{18}$ metabolism;
- isotopic turnover studies with whole-body counting;
- radioiron absorption;
- radiocobalt absorption;
- zinc absorption tests;
- intravenous magnesium infusion tolerance (urinary excretion) test;
- retinol relative dose–response;
- dihydroxyretinol modified relative dose–response;
- β-carotene bioconversion to retinyl ester challenge
- thyroid radioiodine uptake;
- glucose tolerance test;
- postglucose plasma chromium response;
- postglucose urine chromium response;
- glucose load with exercise for lactate and pyruvate;
- urinary malonaldehyde excretion;
- mixed-function oxidase ($^{14}CO_2$) breath test;
- ^{14}C-histidine ($^{14}CO_2$) breath test;
- ^{14}C-serine ($^{14}CO_2$) breath test;
- histidine load for urinary formimino glutamic acid;
- histidine load test for urinary hydantoin propionic acid;
- purine load test for urinary xanthine;
- sulfur amino acid load test for abnormal sulfur metabolites;
- sodium bisulfite load test for abnormal sulfur metabolites;
- tryptophan load test for urinary xanthurenic acid;
- leucine load test for urinary 3-hydroxyisovaleric acid.

In this class of test, some form of substrate, either natural or artificial, and unlabeled, labeled with a stable isotope, or labeled with a radioisotope, is administered, and its metabolism is monitored. The metabolism is either governed by a nutrient-dependent function of the nutrient in question or related to the body's homeostatic regulation of nutrient reserves.

Spontaneous *in vivo* activities and responses of organs and tissues

- capillary bleeding tendency;
- dark adaptation;
- visual recovery time;
- central scotoma size;
- color discrimination;
- taste acuity;
- olfactory acuity;
- auditory acuity;
- abducens (sixth cranial nerve) function;
- nerve conduction time;
- skin conductivity;
- electroencephalography;
- sleep pattern;

- grip strength;
- weight gain as lean tissue;
- weight gain as fat tissue;
- maximal oxidative capacity;
- maximal work capacity;
- urinary malonaldehyde excretion;
- methyl selenol/methyl trimethyl selenomium ratio in urine;
- pulmonary excretion of volatile hydrocarbons (ethane or pentane);
- peripartum hemorrhage;
- sperm count.

The spontaneous function of organs and tissues, without provoking special handling of substrates or external stimuli, such as taste acuity and dark adaptation, constitute the least invasive and complex, and the most acceptable (to the person examined) of the range of functional tests of nutritional status.

Responses at the level of the whole individual or population

- linear growth velocity;
- total weight gain velocity;
- work productivity and spontaneous play activity;
- birthweight;
- Apgar score at birth;
- infant developmental scale performance;
- infant temperament;
- cognitive performance;
- scholastic performance;
- athletic performance;
- social competence;
- development of secondary sex characteristics;
- lactation performance;
- fertility rate;
- fecundity rate;
- infant mortality rate;
- disease resistance or susceptibility.

Finally, a series of functions of the whole individual or the average statistics for a community population can be used to assess nutritional status, as well as the impact of improvement or deterioration of health and dietary conditions on individual or collective nutriture. However, the more complex and integral the function, the greater is the number of factors – both nutritional and nonnutritional – that influence, mediate, and determine the performance. The quality of educational materials, the skill and motivation of teachers, and the state of civil tranquility are among the covariables that might influence the scholastic performance of children, in addition to the nutrition of the school population. If the first limiting factor in scholastic performance lies among these variables, it is doubtful that any limitation to maximal output from malnutrition could be demonstrated or exposed.

Newer *In vitro* Approaches to Functional Assessment of Nutritional Status Based on Molecular Biological (Genomics, Proteomics) Techniques

The decade since the publication of the first edition of this volume has been marked by dramatic advances in the molecular biology of characterizing and expressing the genetic potential and regulation of the cell at the level of the genetic code information (genomics) and the expression of messenger RNA for specific protein (proteomics). Because nutrients can become limiting in the basic mechanisms, and can induce or repress genetic expression, genomics and proteomics protend a series of approaches to functional assessment:

- nutritional expression of nutrient-dependent or nutrient-containing enzymes or proteins;
- nutritional expression of homeostatic regulatory protein;
- nutritional modification of regulatory elements;
- nutritional pattern of upregulation (or downregulation) of gene expression.

In fact, several laboratories have begun to exploit the second of these methods, in tests for human zinc status based on the expression of mRNA for metallothionein, the intracellular binding protein of divalent metals, in peripheral nucleated blood cells.

Advantages and Disadvantages of Functional Assessment

Advantages

In terms of screening tests in epidemiology and clinical nutrition, functional indices of nutritional status have potential advantages of noninvasiveness, individual accuracy of diagnosis, timeliness and interpretability of nutritional interventions, and policy relevance.

Noninvasiveness Almost by definition, static indices involve the sampling of blood or tissue. Many of the tests of performance are noninvasive in so far as no skin punctures or scrapings are involved. This factor may account for more compliance and cooperation on the part of potential clients or subjects. In an era of hepatitis B and human immunodeficiency virus viral endemicity, nonpenetrating procedures are also welcomed by investigators and laboratory personnel.

Individual accuracy of diagnosis The supreme advantage of functional tests is their potential to provide an accurate diagnosis of status for the *individual* patient, client, or subject. However, this can be accomplished only through *serial* testing before and after a trial of physiological or therapeutic doses of the nutrient in question. Whereas static indices, or functional indices measured in a cross-sectional fashion, must be interpreted as normal or abnormal in a normative fashion, in relation to the distribution in a standard reference population, functional tests repeated in the same individual can be assessed with respect to the degree of incremental change. Thus, an accurate assessment of status in an individual is possible. Those with a nutrient-responsive improvement or normalization in a function are truly deficient. For example, consider two persons with the same dark adaptation threshold, in the highest 10th percentile of the reference population; both receive a course of vitamin A therapy, but only one subject improves. If there is no intrinsic retinal disease in the latter, we can conclude that the threshold is a normal variant. In the former, it is a manifestation of vitamin A deficiency.

Temporal sensitivity in detecting nutritional deficits Another advantage of the functional test is the temporal sensitivity in detecting nutritional deficits. We generally recognize a hierarchy of *sequence* in the stage development of depletion. The earliest changes are those in nutrient-dependent function at the peripheral tissue level, often detectable before the nutrient levels in the tissues themselves have declined. Thus, between a functional deficit or a tissue-concentration decline, conventional wisdom favors the former as the earliest detectable alteration during nutritional depletion. As noted earlier, the signs and symptoms of the clinical deficiency syndrome appear much later in the course of depletion.

Interpretability of nutritional intervention Demonstrating the efficacy and effectiveness, that is whether or not a nutritional intervention, such as the fortification of a food, the distribution of a supplement, or the application of a nutrient-sparing program such as deparasitization or immunizations, is actually having an impact, has been the bane of public health nutrition. Even when normative references are used to determine 'abnormals,' in a baseline survey, a marked shift in the distribution of a population toward a normal distribution after the implementation of an intervention can allow success to be interpreted. The failure to observe any change can be taken as tentative evidence for a null effect. However, in serial testing, one must account for any 'learning effect' or spontaneous improvement that would be expected from prior exposure to, or experience with, the test procedure.

Policy relevance The policy relevance of functional assessment derives, in part, from the consequence of the foregoing discussion. For policy-makers, the demonstration that some aspect of *performance* was improved by a public health intervention generates more conviction and sustainability than simply showing that the level of the nutrient had increased in blood, hair, or urine. It provides a ready answer to the 'so what?' questions that those in charge of legislation or expenditures for health will ask.

Disadvantages

Functional assessment of nutritional status, however, is not a panacea; there are also notable disadvantages in their application. These include poor interpretability in cross-sectional studies, lack of specificity for nutritional status, and specific considerations in young children.

Poor interpretability in cross-sectional studies Status and functional indices share a common limitation when the issue is the nutritional interpretation of a result from a single clinical examination or a cross-sectional study. This limitation is the difficulty in accurately separating those with suboptimal nutritional status from those with adequate status by simple reference to an arbitrary cut-off level. It is a *probabilistic* issue in which only a certain level of *risk* of pertaining to a truly deficient or truly sufficient population can be concluded from a single point-in-time evaluation.

Lack of specificity for nutritional status Almost all of the functions that are measured to assess nutritional status can also be impaired by other (nonnutritional) causes. Thus, in a cross-sectional or single measurement assessment using a functional index of nutritional status, it is impossible to be sure that an impaired or abnormal function is related to nutritional deficiency or to some other pathology or a genetic abnormality. Moreover, even if a longitudinal study with supplementation is employed with a functional index, if the person has *multiple* nutrient deficiencies, and only a single nutrient is supplemented, the remaining deficits may impair a full recovery of the functional abnormality.

Considerations in young children For obvious reasons, tests related to reproductive biology are not applicable to children. Moreover, the use of radioisotopes *in vivo* is relatively or absolutely

contraindicated in young children. Stressful stimuli, such as vasopressors or electrical conductivity electrodes, or stressful performance challenges, such as maximal oxidative capacity, should be proscribed from the assessment of children.

Separating pharmacological from nutritional effects Even when serial or comparative measurements of a functional outcome are coupled to a nutrient-intervention format, the interpretation of the preexisting or prevalent nutritional state must be made with caution and judgment. What is a 'nutrient-responsive' situation, and what is a 'nutrient-deficient' condition? By way of analogy to personal esthetics, the application of make-up to a physically unattractive individual can make them 'presentable.' The appearance of a person already attractive by consensus standards can be enhanced with cosmetics to a state of 'ravishing,' however. Where are the valid boundaries to define an 'esthetic deficit'? Similarly, in household economy, what constitutes a 'deficient' income: when one cannot afford a Mercedes-Benz car? When one cannot afford any vehicle? Or when the funds do not allow for purchase of the basic necessities of food, clothes, shelter, and care? Additional wisdom and a grounded philosophical perspective are needed to differentiate enhancement (nutrient-responsive) from reversal of true deficits (nutrient-deficiency).

Important Applications of Functional Status Assessment

Assessment of Risk from Surgery and Other Major Therapies

Recently, grip strength, i.e., the development of contractive force by the hand musculature, has been shown to have some bearing on the prediction of survival or mortality, or the risks of complications in recovery from surgery or radiation or chemotherapy in association with static indices of anthropometry, immune status, and protein concentrations. Tests of active internal lipid peroxidation, such as the ethane or pentane breath tests, have theoretical promise as complementary indices for the prediction of risk of major therapy of precariously nourished patients.

Evaluation of Public Health Impact of Interventions

Faithful to the spirit of Study Team IX, the 1990s saw an increasing incorporation of functional assessment into the evaluation of public health interventions. Child growth in height and weight is the most commonly used variable. Other indicators of interest in public health nutrition are infection resistance, lactation performance, fertility, work output, and mortality. (*See* **Infection, Fever, and Nutrition**; **Children**: Nutritional Requirements.)

Functional assessment can also be used to gain inferences for improving the balance of nutrients in traditional regional diets. As field intervention studies with supplements of protein and energy failed to show major functional improvements, but the association with animal protein did, the *quality* of the diet in terms of micronutrient (vitamin, mineral) malnutrition was focused on in the 1980s.

Assessment of Dietary Nutrient Intake Requirements

Functional assessment is gaining a place in the continued fine-tuning of our knowledge of human nutritional requirements and dietary recommendations. The dominant concept of where to set the recommendation for the daily intake of a nutrient is at the amount that will prevent the development of signs and symptoms of deficiency in the majority or a population. When possible, the concept of the amount that supports a specific pool size of total-body nutrient content has been introduced. Given that functional alterations are generally the earliest detectable changes with the onset of depletion, the logical approach to defining intake requirements of a nutrient is that level which prevents functional changes in the majority of a population. As experience is gained with interpreting and avoiding pitfalls in the application of functional tests, they will be used increasingly to refine our present understanding of what nutrient intakes to recommend to maintain adequate nutriture. (*See* **Dietary Requirements of Adults**.)

New Frontiers for Functional Assessment

Functional indicators of adverse interactions from excesses or toxicity associated with high doses of intakes of nutrients for use in nutritional toxicology have lagged behind the progress in diagnosis of deficient and marginal states. More thought and research need to go into this domain.

The late James Olson has made a pithy distinction between the functions and actions of constituents in the diet. The former relate to the *essential* functions that define a nutrient. However, at higher doses, these nutrients begin to have actions to favor health or prevent disease that go beyond their capacities to nourish. Bioactive (nutriceuticals, phytochemicals) compounds in foods such as flavonoids, carotenoids, etc. have assumed growing interest. Since the chemical nature of the active substances is often unknown, functional markers seem to be the only variables with which to assess the status of consumers.

Conclusions

The clinician, epidemiologist, investigator, and public health professional – all those involved with nutritional status diagnosis – should be aware of functional assessment, its potential, and its limitations. Any approach to nutritional assessment has its advantages, disadvantages, and limitations. The use of functional indices of nutritional status tends to be less invasive, and more client-friendly, than static assessment tests that seek to measure nutrients directly in body fluid or tissues.

Impairment of a peripheral nutrient-dependent function or the body's response to regulation often occurs before nutrient levels decline in blood and tissues, and well before clinical manifestations of deficiency emerge. When coupled to a trial of nutrient supplementation, the functional approach, unlike the static approach, can provide a definitive, retrospective assessment of the original nutritional status of the host. Functional tests can be classified by the physiological or anatomical system that is measured, or by the level of investigation of the test. As the nature of the metabolism and physiological and biochemical functions of nutrients becomes better understood, newer strategies to exploit the functional assessment of nutritional status will be suggested.

NUTRITIONAL SURVEILLANCE

In Industrialized Countries

K F A M Hulshof, M R H Löwik and D C Welten,
TNO Nutrition and Food Research, The Netherlands

Introduction

Especially during the last two decades, evidence has accumulated that prevailing dietary patterns have adverse health effects. Nutritional assessment has become an important topic on the health-policy agenda. This article describes the aim of nutritional surveillance, the availability and usefulness of nutritional surveillance indicators (especially food consumption), and some trends, risk groups, and risk areas. Nutrition-related health problems and surveillance systems differ among countries, in particular between developed and developing countries. This article deals only with industrialized countries in Europe, Canada, Japan, Australia, and the USA. This paper reports the situation in the early 2000s.

Aim of Nutritional Surveillance

As stated by a Joint FAO/UNICEF/WHO Expert Committee, the objectives of nutritional surveillance are as follows: to describe the nutritional status of the population, with particular reference to groups at risk, to contribute to the analysis of causes for changes and differences, to promote decisions by governments on food and nutrition policy issues, to predict future trends, and to evaluate the effects of nutritional programs.

The international conference on Nutrition held in Rome in 1992, adopted a 'World declaration on Nutrition' and a 'Plan of actions for Nutrition.' In this plan, one of the nine action-oriented themes was 'Assessing, analysing and monitoring nutrition situations.' According to these themes, governments should, among other things: identify the priority of nutritional problems in their country, analyze their causes, plan and implement appropriate remedial situations, and monitor and evaluate efforts to improve the situation. Moreover, as a consequence of recent adopted directives of the European Union, the member states have to create systems that will monitor the use and intake of additives.

As illustrated in Figure 1, nutritional surveillance ideally provides information on a wide range of variables, from food availability, distribution and consumption and nutrient utilization (as reflected in nutritional status) to, ultimately, health status and mortality. This results in identification of public health problems that call for specific action and lead to nutrition research priorities (both applied and more fundamental). The data can be obtained from either existing sources, including administrative data, or surveys undertaken specifically for surveillance purposes.

Sources of Dietary Information

Insight into dietary patterns is a core target of nutritional surveillance, since this provides a comprehensive basis for nutritional risk assessment. In principle, three different types of data can be used: food supply data, data from household consumption surveys, and data from dietary surveys among individuals. Each type of data corresponds with a different stage in the food chain and is obtained by different methods.

Food-supply Data

Food-supply data provide information on the type and amount of food available for human consumption, to the country as a whole. The supply is calculated in food balance sheets (FBSs), which are accounts, on a national level, of annual production of food, changes in stocks, imports and exports, and agricultural use and industrial use. Food supply is usually expressed per head of the population in kilograms per year, or grams per day. The per-capita consumption of energy and some additional nutrients is calculated using food composition tables.

Food-supply data refer to food availability, which gives only a crude (overestimated) impression of potential consumption. Food and nutrient losses prior to consumption, owing to processing, spoilage, trimming and waste, may not be adequately accounted for. Furthermore, these data provide no information about the distribution of food among population groups or districts.

International FBSs are prepared and published by the FAO, the Organization for Economic Cooperation and Development (OECD) and the statistical office of the Commission of the European Union (EUROSTAT). The FAO has published FBSs since 1949, also covering the period 1934–1948. Since 1949, FBSs have been compiled on an annual basis from data supplied by about 200 countries. Information is available for all European countries, Australia,

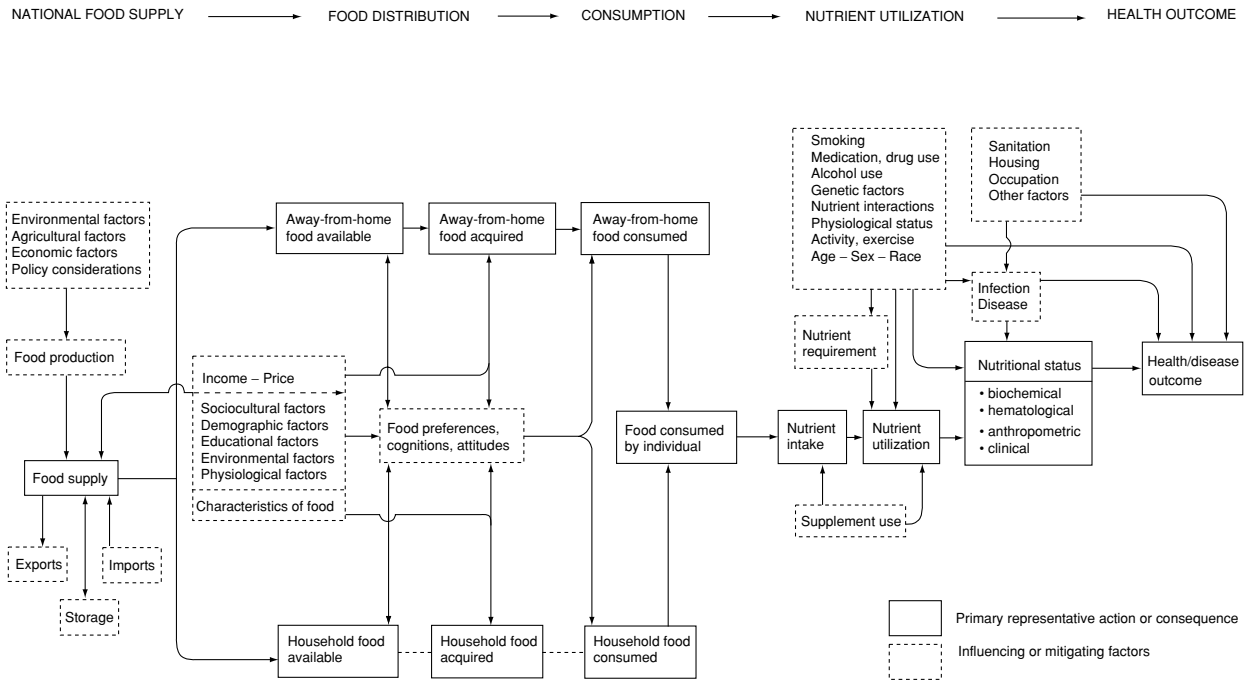

Figure 1 General conceptual model for food choice, food and nutrient intake, and nutritional and health status. Washington, US Government Printing Office, September 1989.

Canada, Japan, New Zealand, and the USA. Since 1971, the FAO has included its FBS data in the Interlinked Computer Storage and Processing System of Food and Agricultural Commodity Data (ICS). EUROSTAT publishes FBSs for the 15 member countries of the European Union. The OECD FBSs cover, besides several European countries, Australia, Canada, Japan, New Zealand, and the USA. Although FBSs are compiled in a similar way, they differ in coverage, food grouping and level of processing of commodities (e.g., FAO lists 300 food items classified into 17 food group categories; OECD 70 items in 13 categories) and in nutrient conversion. The FAO and OECD usually publish summaries of FBSs every 3–5 years, with a lag time of 3–4 years between data collection and publication. The ICS supplies figures on magnetic tape, on floppy disk and on Internet (http://apps.fao.org). EUROSTAT publishes supply balance sheets in the Agricultural Statistical Yearbook.

In addition to the international FBSs, many countries publish national FBSs, mostly in statistical yearbooks or special statistical publications. For example, US food-supply statistics are available from 1909 onwards. National FBSs tend to be more up to date. Owing to different methodologies underlying their compilation and presentation, these data can differ from international FBSs.

Despite their limitations, FBSs are useful in that they indicate the (in)adequate aspects of food supply, provide material for planning food supply (production, imports and exports) and give crude indications of (un)desirable changes in terms of potential (adverse) expected health impact. As a result of their long history, FBSs are especially used for assessing trends over time. In contrast to national FBSs, the international FBSs can be used for comparative studies, provided that the FAO and OECD data sets are used separately. Figure 2 illustrates the use of FBS data (FAO) for comparison across countries and for trends over time. This table shows the consumption of meat in five selected countries. Only in the UK has the consumption of meat and meat products remained remarkably steady since 1965. In the other countries, the total consumption of meat has increased considerably, especially in Spain. The same tendency has been observed in other southern European countries and reflects one of the important changes in the Mediterranean diet over the past decades. Such comparisons implicitly assume that the demographic changes across the countries are similar.

Household Surveys

Food available at the household level may be estimated by budget surveys and by consumption surveys. The first type of survey gives information on the purchases of food in terms of expenditure and is used for economic policy. For example, weights for the construction of consumer price indices can be calculated. In household-consumption surveys, the amounts of foods and drinks brought into the household are also recorded. For the most part, only the expenditures of meals taken outdoors are noted. Some household surveys may even measure changes in food stocks, in addition to acquisition.

In general, household surveys do not provide information on how food is handled within the household, or on actual consumption by its members. Sometimes, the consumption data are converted to individual intake levels. The methods vary from simply dividing the total consumption by the number of people in the households, to assigning factors (consumer units) to persons weighed according to age and sex. In contrast to FBSs, household surveys can supply information on food (and nutrient) patterns in subgroups of households. These groups may be classified by economic, demographic, and other factors, which provide the opportunity for risk group identification.

In most countries, household surveys started in the 1940s or 1950s. Only few countries have a continuous system, some repeat surveys every 3–4 years, and others repeat surveys only every 5–10 years. In The Netherlands, the household budget surveys started in 1951, and since 1978, they have been conducted annually. In Europe, the best-known study is the specialized and ongoing household food consumption survey of the UK. Australia, Canada, and Japan have regularly conducted household consumption surveys. In the USA, the first national household consumption survey was conducted in 1936–1937. Between 1942 and 1965, four nation-wide studies on household consumption were carried out. Since 1965, US household food-consumption surveys have also provided information on food intake at the individual level of household members. At present, a wide range of data on household surveys are available, as shown in the FAO Food and Nutrition Policy Papers and WHO publications. Since the dietary data are based on a variety of methods, the surveys are not very suitable for comparisons among countries. Differences exist in sampling procedures, food grouping, conversion to nutrients and period, frequency, and technique of data collection. Snacks, sweets, soft drinks, and alcoholic beverages are excluded from some studies. Data on the quantity of and/or expenditure on food may be collected by record keeping, by interviews or by both methods. Household accounts for nonfood items can cover a period of 4 weeks, but for foodstuffs, 2 weeks is more usual. The results of household surveys play an important role in nutritional surveillance at the national level, particularly when surveys are carried out annually, which reveals trends in food consumption.

To improve the possibilities for international comparison of these data in Europe, since 1993, an ongoing project of the European Union (DAFNE, DAta Food NEtworking) is harmonizing at the international level dietary exposure data from household budget surveys. DAFNE aims to create a pan-European food databank based on national household budget surveys by the development of the most appropriate way of using food and related data from these surveys. Methods were designed to calculate, for instance, the overall average availability per person per day of comparable food items or groups among DAFNE countries as well as average availability by degree of urbanization and educational level of household head. Distribution and cumulative distri-

bution functions of the availability of food items were estimated. Table 1 shows the differences in availability of fruit and vegetables (fresh and processed) in Greece, Ireland, Luxembourg, Norway, Spain, and the UK.

Individual Dietary Surveys

In contrast to FBSs and household surveys, data from individual surveys provide information on average food and nutrient intake and their distribution over various well-defined groups of individuals. Data more closely reflect actual consumption and can provide additional information on meal patterns, etc.

To collect dietary intake data on an individual level, several methods can be used. Briefly, the methods can be divided into two categories: record and recall methods. Record methods collect information on current intake, keeping a record of all foods and drinks based on menu, household measures and/or weighing, over one or more days. Recall methods reflect past consumption, varying from intake over the previous day (24-h recall) to usual food intake (dietary history or food frequency). Each form has its own strengths and weaknesses, and there is no single ideal method. Details of the available methods for assessing food consumption of individuals are given in numerous reviews and manuals.

To characterize the average intake of food and nutrients and their distribution over various groups of individuals one 24-h recall or 1-day food record is appropriate, provided that the sample is representative of the population under study, and day-of-the-week and seasonal variations are taken into account. To determine the proportion 'at risk' of inadequate intake, the food consumption of each subject must be measured over more than one day, or retrospective information on intake over a longer period may be used (e.g., dietary history method). The appropriate period depends on the purpose of making an estimate, the precision desired, the food component(s) of interest, the intra- and interindividual variation components, and the period over which an intake has to be low or high before health risks are introduced.

Probably all (industrialized) countries, if not all, have carried out small-scale dietary surveys. These surveys provide valuable information, but owing to samples of convenience and different food consumption methods, their usage in national nutrition policy and nutritional surveillance is often limited. Since the mid-1980s, the number of countries that have conducted individual dietary surveys is growing. The USA has one of the most comprehensive nutrition monitoring programs in the world and already has a longer tradition in the field of nutritional surveillance. The National Nutrition Monitoring and Related Research Program (NNMRRP) provides information about the dietary and nutritional status of the US population, conditions existing in the United States that affect the dietary and nutritional status of individuals, and relationships between diet and health. The Continuing Survey of Food Intakes by Individuals (CSFII) conducted by the US Department of Agriculture (USDA), and the National Health and Nutrition Examination Survey (NHANES) conducted by the Health and Human Services (HHS) are the two cornerstones of the NNMRRP surveys. They provide national estimates of food and nutrient intakes in the general US population and in subgroups. The CSFII emphasizes the food and nutrient intake defined by various socio-economic factors. In NHANES, information on dietary intake and health status in the same individuals is available. These surveys also provide the potential for assessing consumption of additives and pesticides in the diet.

Also Australia and several European countries have performed individual surveys on a national basis. Table 2 presents examples from studies conducted since 1985. The surveys differ in coverage of population, methods used to collect dietary data, nutrition-related health indices, etc. In several countries, dietary data were collected using a record method, but the number of record days varied from 1 to 7. A 7-day weighed record is thought to be the most accurate method of dietary assessment. However, this method has a high respondent burden, which can have consequences for the response rate, representativeness of the sample and data quality. Response rates vary widely. Sometimes, weighing factors are used to adjust for sources of nonresponse. Some subgroups (such as ethnic minorities, pregnant or lactating women) do not occur in the population in sufficient numbers to appear in the survey with sufficient representation to allow for separate estimates of their diet and nutritional status that are reliable. Extra sampling can improve the precision of estimates in nutritional assessment in specific groups and is used in several studies, including those in the United States. Special (vulnerable) groups can also be examined in separate studies. For example, in 1998, in The Netherlands, a nation-wide survey was conducted among 8-year-old Turkish and Moroccan children and their

mothers, with a Dutch control group. Norway plans to carry out a survey among migrants in 2000–2001.

The presented national dietary surveys provide valuable information for usage in national policy and are central in nutritional surveillance, and, when repeated in a proper way, trends over time can be studied. However, for a detailed evaluation of dietary intake in Europe, there is a need for increasing comparability of sampling designs, dietary methods, and selected population descriptors. The establishment of a Health Monitoring Program in Europe should make it possible to measure health status, trends, and determinants throughout the Community; facilitate the planning, monitoring and evaluation of Community programmes and actions; provide Member States the appropriate health information to make comparisons; and support their national health policies. As part of this program, since the end of 1999, the project European Food Consumption Survey Method (EFCOSUM) has aimed to define a (minimum) set of dietary components that are relevant determinants of health. Moreover, the study aimed to define a method for the monitoring of food consumption in nationally representative samples of all age–sex categories in Europe in order to provide internationally comparable data. This method can be used alone, or as a calibration method for ongoing studies. The project made use of progress in relevant projects carried out until now, such as DAFNE and EPIC, and addressed the possibility for data fusion with other health monitoring studies. Fourteen EU Member States as well as eight other EU countries are participating in EFCOSUM.

Nutritional Status and Health Indices

The assessment of nutritional status includes, in addition to dietary intake, indicators of nutrition-related health status, such as anthropometric measurements, hematological and biochemical tests, clinical signs of deficiencies, and risk factors for diseases associated with diet (e.g., overweight). Furthermore, determinants of food and health-related behavior, such as nutritional knowledge and attitudes, may be studied as well. These indicators can be included in the surveys or studied in separate samples. Several national studies listed in Table 2 studied both dietary intake and nutrition-related health-status indicators. In most surveys, anthropometric data were collected (sometimes self-reported data on body weight and body height); in some countries, also, medical examination and/or biochemical and hematological tests (e.g., Germany, Hungary, UK) were carried out, and information on physical activity was included (e.g., Norway, Sweden).

A major advantage of collecting comprehensive (broad oriented) information at the individual level is that interrelationships can be studied. In studying correlations between diet and nutritional status indicators, one of the characteristics of a cross-sectional study is that mostly low correlations are found. This is attributable to, among other things, intraindividual variation and inaccurate assessment of intake and status indicators. In a cross-sectional design, the observation that a particular dietary factor is positively or inversely associated with relevant variable is meaningful, even when there is a low *P*-value, since this provides suggestive evidence for diet–health relationships which should be studied in more detail. To establish a causal link between diet and health, both intervention and (semi)-longitudinal studies are necessary. Endpoints, such as morbidity and mortality data, provide valuable additional information on the role of nutritional factors in diseases.

Risk Areas and Risk Groups

Nutritional assessment includes a normative evaluation of dietary intake and nutritional status indicators in order to estimate, for instance, the proportion of the population at risk. Nutritional-status indices can be evaluated by comparing them with reference values mostly obtained from healthy adults. Alternatively, predetermined cut-off points (based on consensus reports) can be used. In evaluating dietary intake, the reference values applied in recommended dietary allowances (RDAs) or dietary guidelines are often used. However, the usage of cut-off values is prone to some misclassification owing to (biological) variation within and among individuals. Despite the weaknesses of cut-off points, these criteria are commonly used and often needed to evaluate dietary intake as well as nutritional status parameters.

In most industrialized countries, the principal nutrition-related health problems are related to unbalanced (mostly overconsumption) of some nutrients, particularly energy, fat, and saturated fatty acids. Although the mean intake of energy among adults is mostly lower than the recommendations, the data available from nutritional surveillance indicate a high prevalence of overweight and obesity in several countries. Obesity, defined as a body mass index greater than $30\,kg\,m^{-2}$, is a common condition in Europe and also in the USA. Although Table 3 gives only a rough impression (age groups are not always comparable, the periods in which studies were conducted differ slightly, exclusion criteria might vary, etc.), the data show that the proportion of subjects classified as obese varies among countries. Despite the differences, however, in recent decades, the prevalence of obesity has increased in most

Table 3 Prevalence of obesity (BMI $\geq 30\,kg\,m^{-2}$) in some countries

Country	*Year*	*Age (years)*	*Men (%)*	*Women (%)*
Austria	1993	19–65	6	5
England	1994	16–64	15	16
Finland	1991	20–75	14	11
East Germany	1992	25–65	20.5	26.8
West Germany	1991	25–65	16.0	21.4
The Netherlands	1992	19–65	5.5	9.2
USA	1988–1994	20+	22.3	25.0

European countries as well as in the USA in the past decade. For instance, in The Netherlands, among subjects aged 19 years and over, the proportion of obese subjects has increased during the last 10 years from 6.0% (1987–1988) to 10.4% (1997–1998). At the same time, in The Netherlands, a decrease in energy intake and fat consumption was observed. Data from DNFCS-1 (1987–1988) and DNFCS-3 (1997–1998) suggested that energy intake decreased from 2308 kcal day (9677 kJ) to 2190 kcal day (9191 kJ). This reduction of about 120 kcal day (~485 kJ) was attributable to a decrease in fat consumption (protein intake increased, and carbohydrate intake and alcohol consumption remained constant). This may imply that daily energy expenditure has decreased during the same period and may include an increased sedentary behavior. Findings of the statistical office confirmed a decrease in physical activity in leisure time.

Obesity is associated with several specific health risks, including an increased incidence of hypertension, increased noninsulin-dependent diabetes and high levels of cholesterol and other lipids. Corrected for these factors, obesity in itself has been reported to be an independent factor for cardiovascular disease. In most industrialized countries, a higher prevalence of overweight and obesity is observed among subjects with a lower socio-economic status.

Higher rates of mortality and morbidity have been found among lower socio-economic groups, as compared with higher socio-economic groups. In several studies, food-consumption patterns and nutrient intakes have been more consistent with current dietary guidelines among people with a higher socio-economic status. Recent analyses of 33 studies in 15 European countries, conducted within the framework of the European Union's FAIR program (FAIR-97-3096), showed that, particularly in the north and west of Europe, people with a higher education tend to consume more vegetables and fruits and less fats and oils. Table 4 presents some selected results. Other studies also found that people with a higher socio-economic status have reported eating more wholemeal and brown bread and less whole milk, eggs, and meat. A higher socio-economic status has been associated with a lower intake of fat, saturated fatty acids, and refined sugars, and a higher intake of fiber, although mostly, differences in nutrient intake levels have been quite small. In general, food disparities in relation to consumption levels might possibly explain some of the higher rates of mortality and morbidity among lower socio-economic groups.

Table 4 Average difference (95% confidence intervals) in consumption of selected foods (grams per person per day) between the highest and lowest educational level in nine European countries

	Education (highest minus lowest level)	
	Men	*Women*
Fruit	+24 (+19.0; +29.0)	+26.7 (+21.7; +31.8)
Vegetables	+12.1 (+8.3; +15.8)	+17.5 (+13.7; +21.2)
Fats and oils (added)	−2.9 (−4.0; −1.9)	−3.1 (−3.9; −2.3)
Meat	−32.6 (−36.0; −29.1)	−24.3 (−26.9; −21.8)
Milk total	+46.9 (+38.0; +55.9)	+39.9 (+33.2; +46.6)
Cheese	+9.9 (+8.4; +11.4)	+10.6 (+9.3; +11.8)

Concerning micronutrients, in most countries, the average intake of most minerals and vitamins appears adequate for the population. In general, iron is an exception in that many subjects have a low iron intake in comparison with recommended values. In most countries, groups with a low intake are young children, adolescents and women of child bearing age. Moreover, the intake of vitamins (e.g., vitamin A and its precursors, vitamin B_6, vitamin C, folic acid), minerals, and/or trace elements (e.g., calcium, magnesium, zinc, iodine) might be not always adequate among certain population groups in several countries. However, it should be noted that the confirmation of nutritional risk obtained by biochemical data is essential for assessment of risk areas and risk groups.

Nutritional Surveillance in the Future

A growing awareness of potential relationships between diet (as part of lifestyle) and health is accompanied by an increasing demand for (comparable) data. Research in the field of molecular genetics and nutrient–gene interactions is promising. Monitoring systems may also provide more information on variations within the human genome. This will enable us increasingly to focus on the specific needs of the individual at potential risk.

Since it might be expected that in the coming years, bioactive components, additives, and contaminants will become increasingly a topic of interest, future food-consumption databases should allow also the

assessment of these nonnutrients. Therefore, there will be a need for more descriptive specificity, such as brand names and more information on the food composition. The use of computer technology and advanced statistical methods may facilitate wider applications of survey data and cost-effective data fusions.

To improve valid comparisons between diet and health at the international level, a better harmonization of data collection, methodology and standardization of data analysis will be needed. Since 1990, this concept has already been implemented in the National Nutrition Monitoring and Related Research Program (NNMRRP) in the USA; in Europe, an increasing number of initiatives as to Pan-European projects are coming up with results.

NUTS

R A Stephenson, Maroochy Research Station, Nambour, Queensland, Australia

Introduction

Human consumption of nuts has been recorded from the earliest times and nuts continue as an important component of many diets throughout the world. Despite this, relatively few nut crops have become major commodities on world markets. In fact, most of the lesser known nuts, particularly those from warm climates (**Table 1**), are restricted to traditional diets, usually within relatively narrow regional boundaries. Consequently, information on them, including their composition and nutritional value, tends to be superficial. Only two of the lesser-known nuts of warm climates – macadamia (*Macadamia integrifolia*) and pistachio (*Pistacia vera*) – have developed

Table 1 Some lesser-known edible nuts of warm climates

Name and origin of nut	*Features*
Almondettes (*Buchanania lanzan* Spreng., family Anacardiaceae) Southern Asia	Related to pistachio nut; medium-sized tree; black, single-seeded fruits; pear-shaped kernels, 1 cm, eaten raw or roasted, delicious (combination of almond and pistachio flavor); 51.8% oil, 12.1% protein, 21.6% starch, 5% sugars
Bunya nut (*Araucaria bidwillii*, family Araucariaceae) Australia	Large pine tree; large cones bear starchy nuts *c.* 5 × 3 cm, usually roasted, flavor resembling that of chestnuts
Candle (Tung) nut (*Aleurites* spp., family Euphorbiaceae) China, South-east Asia, Indonesia	Attractive tree; fleshy fruit, containing a single nut, globose, *c.* 3 cm; hard, thick shell; soft, oily white kernel (*c.* 5 g); must be cooked, moderately poisonous raw, often used for oil
Cut nut (*Barringtonia procera, B. edulis, B. novae-hiberniae*, family Lecythidaceae, Brazil nut family) Pacific region	Confusion with taxonomy until recently, variable nut characteristics, trees are easy to propagate from seed or cuttings, common in coastal villages, *B. procera* is a more prolific bearer than the other two species – the fruits are a bit smaller (61 cf. 99 g) but have a higher kernel recovery (9%) and hence higher kernel production per tree (up to 50 kg fruit, 5 kg kernel), irregular bearing up to three times a year, high moisture content when fresh so shelf-life is limited, tasty, nutritious kernels, good nutty taste and long shelf-life when processed, relatively low oil content
Elaeocarpus spp., including silver, blue or bush quandong *E. grandis*, blueberry ash or blue oliveberry, *E. cyaneus*, and *E. dentatus*, family Elaeocarpaceae) Australia, New Zealand, Solomon Islands	Over 200 species, often attractive flowering trees producing blue berries from 12 to 25 mm, usually cooked before eating
Finschia nut (*Finschia chloroxantha*, family Proteaceae) Solomon Islands	Relative of macadamia
Galip nut (*Canarium indicum* L., family Burseraceae, also including related Java almond, *C. commune* and pili nut, *C. ovatum* Engl., adoa/bush ngali found only on Bougainville Island, *C. salmonense*) and *C. harveyi* from the Solomon Islands, Vanuatu, and Fiji Philippines, Moluccas (Indonesia), Papua New Guinea, Solomon Islands, Vanuatu	Tall, buttressed tree; roundish, dehiscent fruit bearing a single 5.5 × 2 cm nut, yield up to 300 kg nut in shell, hard, nonperishable shell, triangular in cross-section, *c.* 3 g, delicious, sweet almond-like flavor; 70–80% oil, 13% protein, 7% starch; remove testa before eating, raw or roasted, oil used for cooking and cosmetics, oleoresin burnt for lighting and incense or used to caulk boats, commercial production in Western Melanesia *c.* 100 000 tonnes nut-in-shell (16 000 t kernel, kernel recovery at 16%) from 2 million trees
Galo nut (*Anacolosa frutescens* (Blume) Blume, family Olacacae) South-east Asia, Philippines	Erect shrub or tree, hard wood used for building, fruit is a drupe (up to 18 g); the green-colored pulp and kernel can be eaten fresh but boiling brings out the delicious taste of the fruit; kernel often roasted; dry pulp and kernel contain respectively 9.5% and 10.7% protein, 4.5 and 7.5% fat, 70.8 and 75.5% carbohydrates, 7.2 and 3.7% fiber, and 7.9 and 2.9% ash; kernel recovery is high (73–85%)
Gnetum nut (*Gnetum gnemon*) Papua New Guinea, Solomon Islands	Some cultivation
Heritiera littoralis Solomon Islands	Common on seashore; some records of being eaten
Kauri pine nut (*Agathis* spp., family Araucariaceae) Pacific region	Attractive rainforest tree; overexploited for timber; limited use as a food source in the Pacific region only
Lotus seeds (*Nelumbo nucifera* Gaertn., family Nymphaceae) Asia, Papua New Guinea	Water lily revered by Buddhists; white, single-seeded carpers embedded in flat-topped, fleshy receptacle which dries when mature so that l-cm seeds rattle in their cavity; bitter green embryos removed before eating; eaten raw before fully ripe; nutty flavor, roasted or boiled when mature; rich in vitamin C, 58% carbohydrate (starchy), 17% protein, 2.5% fat
Macadamia nut (*Macadamia integrifolia* Maiden and Betche, *M. tetraphylla*, family Proteaceae) Australia	Evergreen tree adapted to the fringes of subtropical rainforests; spherical kernel enclosed by a thick, stony shell in a fibrous single-sutured husk; high oil content (> 72%); distinctive, delicate flavor
Moreton Bay chestnut (*Castanospernum australe*, family Fabaceae) Australia Pacific region	Fine spreading tree, large glossy fern-like leaves, deep green but lighter underneath, thick pea-pods with 5-cm 'chestnut' seeds; must be soaked and cooked before eating
Neisosperma oppositifolia	Seashore habitats; small kernel

Continued

Table 1 Continued

Name and origin of nut	*Features*
Okari nut (*Terminalia kaembachii* Warb., family Combretaceae, also *T. catappa* L., the tropical, Indian or sea almond, and *T. impedians*) Papua New Guinea, Vanuatu, South-east Asia, India	Tall tree easy to propagate; leaves clustered at twig tips; yields up to 100 kg large (up to 200 g) flattened, ellipsoid fruit with up to 10% kernel recovery; yields once (March to August) but sea almond bears sporadically throughout the year in low latitudes; stony endocarp encloses white kernel (up to 15 g) consisting of a leaf-like coiled cotyledon, *c.* 8 × 2 cm, 1.5–10 g; delicate almond flavor; contain about 50% sweet, colorless, nondrying edible oil; eaten raw or roasted, dry for long-term storage
Omphalea queenslandiae Solomon Islands	Woody climber; kernel needs processing
Oyster nuts (*Telfairia pedata* (sm. ex Sims) Hook, family Cucubitaceae) Tropical East Africa	Woody stemmed climbing vine, dioecious; large (< 15 kg), deeply ridged, dehiscent gourds containing up to 140 pale yellow seeds (nuts) enclosed in a strong, bitter-tasting, fibrous husk; nuts are flat and circular (3–4 × 15 cm thick); washed, sun-dried and dehusked before eating; raw or roasted; palatable, flavor similar to Brazil nuts; nutritious, *c.* 62% fat, 27% protein, rich edible oil
Pandanus nuts (various species, *Pandanus jiulianettii* Martelli, family Pandanaceae) Papua New Guinea, Pacific region	Wide ecological adaptation from coastal areas up to 1800 m, dioecious 'screw' pine; large, dense multiple fruit (syncarp) up to 30 cm diameter and 16 kg; individual fruits (*c.* 50 or more) separate easily, up to 10 cm long, 1.5 cm in diameter; contain two to four sweet seeds with a coconut taste; oily endosperm; normally roasted, fruitlet flesh of some species can also be eaten; dry seeds for long-term storage; oil content from 10 to 60%; depending on species, hardy stems and leaves also used for handicraft, furniture, and building materials
Pangi, Sis (*Pangium* edule, family Flacourtiaceae) Papua New Guinea, Solomon Islands	Berry an important food source in parts of Papua New Guinea
Paradise (Sapucaia) nut (*Lecythis usitata* Miers., family Lecythidaceae) Brazil, Guyana	Tall Amazon rainforest tree, related to Brazil nut but with superior, sweet delicate flavor (N.B.: some species poisonous); large, dehiscent woody fruits containing 30–40 irregular, oblong nuts resembling Brazil nuts but more rounded with a thinner, softer shell; white, creamy textured kernels; highly nutritious, 62% fat, 20% protein; eaten raw or roasted; edible oil
Pistachio nut (*Pistacia vera* L., family Anacardiaceae) Central Asia, the Middle East and Mediterranean basin	Small, deciduous, dioecious tree; resin ducts through all tree organs; bunches of nuts near shoot tips; harvesting at the correct stage of maturity is critical; fleshy hull surrounds dehiscent, bony shell which encloses the kernel; high in carbohydrates, mainly sucrose (16%), oil, largely unsaturated (55%), and essential amino acids (25%)
PNG oak (*Castanopis acuminatissima*) Papua New Guinea	Of minor importance; sometimes cooked before eating
Quandong (*Santalum acuminatum* Sprague and Summerhayes, family Santalaceae) Australia	Small, semiparasitic trees of desert regions; globular, edible, fleshy fruits; kernel enclosed in pitted, stony shell; oily; harsh aromatic flavor; nutritious, 60% fat, 25% protein; generally roasted
Sago plum (*Cycas revoluta* and other *Cycas* spp., family Cycadaceae) Australia, Papua New Guinea, Pacific region and East Asia	Glossy, fern-leaved plant with sturdy trunk, slow-growing, primitive seed plant. A sago-like meal is made from large seeds; must be soaked for a long time before eating
Souari nut (*Caryocar nuciferum* L., family Caryocaraceae) Brazil, Guianas	Attractive, large tree; fruits round, soft-wooded capsules, *c.* 15 cm diameter, containing two to five large, brown, kidney-shaped nuts up to 5 cm long; edible yellow pulp surrounding nut; kernel enclosed in hard, woody, warty shell up to 1 cm thick, hard to crack; kernel has soft, white, sweet, almond-like flavor; eaten raw or roasted; edible oil
Tahiti (Polynesian) chestnut (*Inocarpus fagiferus* (Parkinson) Fosberg., family Fabiaceae) Pacific Islands	Moderate-sized tree; stout, large (10 × 10 cm) green/brown kidney-shaped, nondehiscent, single-seeded pods borne in terminal clusters; fleshy 'nuts,' boiled or roasted when nearly ripe, taste like chestnuts, palatable, sometimes hard to digest; staple food on some islands; moderately nutritious, 80% carbohydrates (starch), 10% protein, 7% fat

Continued

Table 1 Continued

Name and origin of nut	*Features*
Tallow nuts (*Ximenia americana* L., family Olacaceae) Widespread throughout Tropics	Densely branched shrub, usually deciduous; egg-shaped, juicy, fleshy fruits contain a large, oily seed; white kernels; palatability varies; nutritious, rich in protein and oil; eaten raw or roasted; cooking oil
Water chestnut, Chinese water chestnut (*Trapa* spp., family Trapaceae) Tropical Africa, Central Europe, eastern Asia	Aquatic plant; not a true nut; hard-shelled, woody fruit with four woody, spiny horns contains a single large white starchy kernel; eaten raw, roasted, or boiled; *c.* 16% starch, 3% protein; not particularly nutritious

as commercial crops and will be discussed in more detail. Some commercial processing and marketing of local *Canarium*, *Terminalia*, and *Barringtonia* species has been initiated in the Solomon Islands, Vanautu, and Papua New Guinea in recent years. The pistachio is a temperate crop but has been included because of its requirement for long, hot, and dry summer and autumn seasons for commercial yields of acceptable quality.

The Macadamia Nut

The macadamia is considered to be one of the world's finest gourmet nuts because of its unique, delicate flavor, its fine crunchy texture and rich, creamy color. These features, together with relatively low volumes of production, have led to the successful promotion of macadamia as a luxury dessert nut. Macadamia nuts account for about 2.2% of the world's total tree nut production – approximately 17 800 t of kernel in 1998–99.

Origin

The macadamia nut is the only commercial food crop indigenous to Australia, originating along the fringes of rainforests in south-east Queensland and north-east New South Wales, from 25 °S to 28 °S latitude and within 24 km of the Pacific coast. Of the three species of macadamia, only two are edible – the smooth-shelled *M. integrifolia* and the rough-shelled *M. tetraphylla*. Only the former has been developed commercially. The rough-shelled macadamia, although producing a raw kernel of excellent eating quality, often contains a higher percentage of sugars which may caramelize on roasting, thus detracting from its appearance. The wild *M. ternifolia* produces a small, unpalatable, bitter kernel.

Botanical features

The evergreen macadamia tree is medium to large, attaining a height of up to 18 m and a spread of up to 15 m. It produces a number of vegetative growth flushes per year, with peaks of flushing in late summer and spring in Australia. The oblong to oblanceolate leaves are arranged in whorls of three and often have spiny, dentate margins, and short (5–15 mm) petioles. Three buds are arranged longitudinally in the axil of each leaf. Multiple branches and inflorescences may therefore be produced from each node. The pendulous racemes, 10–15 cm long and bearing up to 200 creamy white flowers, are borne on older wood. Although floral induction occurs in autumn, cool temperatures induce a period of dormancy. Racemes commence growing slowly in late winter and anthesis occurs in early spring. Fewer than 5% of flowers set fruit and many of these abscise 5–6 weeks after anthesis, coinciding with the stage of endosperm development and the commencement of rapid nut growth. Nuts take 6 months to mature.

Nut set is enhanced by cross-pollination. It is therefore recommended that at least two varieties be grown in orchards, often in alternate rows. Activity of pollinating insects, mainly native and domestic bees, is encouraged.

The fruit is a globose follicle in which only one of two ovules develops. In some varieties, however, a small percentage of the nuts produced are twins, resulting from the development of both ovules. Twins are undesirable because of the difficulty of extracting whole kernels. Mature fruits usually, but not always, abscise when the fibrous husk is still green. As the husk dries, it splits along a single suture to release the nut, consisting of a hard, thick, rough, stony, light-tan shell that encloses the kernel.

The rough-shelled macadamia is readily distinguished from the smooth-shelled species. The leaf margins are more serrated, with up to 40 spines on each side, and whereas new leaf growth of *M. integrifolia is* pale green in colour, young *M. tetraphylla* leaves are an attractive pink to red color. Racemes are longer (up to 30 cm) and bear up to 500 reddish-pink flowers.

Ecology

The macadamia occurs naturally in the fringes of subtropical Australian rainforests. Temperature is the major climatic variable determining growth and productivity, the optimum being 25 °C. Although the

mature macadamia is capable of withstanding frosts as low as −6 °C for short periods, longer periods or lower temperatures may severely damage or kill mature trees. Developing inflorescences are particularly susceptible to frost damage. However, there is a low temperature requirement for flowering, the critical minimum above which flowering is suppressed being 20 °C. On the other hand, continuous and prolonged exposure to temperatures greater than 35 °C often produces chlorotic and sometimes distorted growth.

The macadamia tree has several features suggesting adaptation to relatively harsh environments, including sclerophyllous leaves and dense clusters of fine, proteoid roots which develop to enhance nutrient uptake from poor soils, particularly those low in phosphorus. The conditions required for optimum production, however, are quite different from those for survival. Macadamia can be grown in a wide range of soils but not on heavy, impermeable clays and saline or calcareous soils. The trees are most suited to deep, well-drained soils with good organic matter content (3–4% carbon), medium cation exchange capacity with pH of 5.0–6.0.

Production

The commercial development of macadamia occurred in Hawaii where most of the crop is sold locally to tourists as 'suitcase exports' and, to a lesser extent, exported to the mainland USA domestic market where they comprise fewer than 3% of all tree nuts consumed. Australia and Hawaii dominate the world market, with 42% and 33% of the world's total production respectively. Australia produced 7500 t kernel from 12 200 ha in 1998–99, followed by Hawaii (5900 t), South Africa (1700 t), Kenya (950 t), Malawi (700 t), Costa Rica (450 t), Guatemala (450 t), and Brazil (180 t).

Over the last decade, macadamia production has more than doubled and will continue to increase as young plantings throughout the world come into production. The already intense competition from established nut crops has highlighted the need to develop new markets and promote more widespread consumption.

Composition

The quality of the macadamia nut is related to its oil content and composition. Mature nuts contain at least 72% oil (specific gravity, or SG < 1.0) for optimum eating and processing quality. Kernels with SG of 1.0–1.025 are classed as second-grade but can be used for lower-grade products. Third-grade kernels (SG > 1.025) are commercially unacceptable. Oil accumulation does not commence until the nuts are fully grown and the shell hardens. It accumulates rapidly in the kernel during late summer when the reducing sugar content decreases.

The composition of mature, roasted, and salted macadamia nuts is shown in Table 2. As with many oil seeds, the protein is low in methionine. Fresh kernels contain up to 46% sugar, mostly nonreducing sugar. The oil consists of mainly unsaturated fatty acids and is similar in both species, although the proportion of unsaturated to saturated fatty acids appears to be slightly higher in *M. integrifolia* (62:1 compared with 48:1). Detailed fatty acid composition is shown in Table 3. The fatty acid composition and the absence of cholesterol may lead to the promotion of macadamias as a high-energy health food. The major volatile components in roasted macadamia kernels are apparently similar to those found in other roasted nuts, although little detailed information on these is available.

Table 2 Nutritive value per 100-g sample of macadamia nuts (roasted in oil and salted) and pistachio nuts (dried and shelled)

Palmitate	6.15
Eicosenate	1.74
Stearate	1.64
Arachidate	1.59
Linoleate	1.34
Myristate	0.75
Laurate	0.62

Data from Cavaletto CG, Dela Cruz A, Ross E, and Yamamoto HY (1966) Factors affecting the stability of macadamia nuts 1. Raw Kernels. *Food Technology*. 20:108–111.

Harvesting and Storage

Macadamia nuts fall from the tree naturally when they are mature. They are either hand-harvested or picked up by machines; efficient machine harvesting requires a smooth, clean orchard floor.

Freshly fallen mature nuts may contain 25% moisture. The husk must therefore be removed as soon as possible to prevent overheating, mold development, and deterioration in quality. The dehusked nuts are initially dried, either artificially or air-dried, to 10% moisture or less before delivery to processors. The nuts are then further dried in silos to 10–15% moisture for longer-term storage, for most efficient cracking of the shell and thus more completed recovery of whole kernels. Drying is performed in stages (at 52 °C down to 45% moisture and then at 77 °C down to 15% moisture) to avoid adverse effects on kernel quality. After cracking and separation of shell from kernel, the product can then be lightly roasted and salted, or packaged raw in bulk in vacuum-filled, foil-laminate bags that help to prevent development of rancidity. Traditionally, kernel has been roasted in coconut oil, although dry-roasting techniques are now more popular. The packaged product is then kept in cold storage to prolong shelf-life. Under these conditions, kernel can be safely stored for at least a year.

The Pistachio Nut

The pistachio has a unique flavor and is popular as a gourmet nut, particularly in the USA. The crop has exacting environmental and cultural requirements for commercial production and these probably limit industry expansion.

Origin

Although the popularity of the pistachio has been recorded from the earliest times, its place of origin is uncertain. The genus *Pistacia* consists of 11 edible species which are widely distributed, including the USA, Africa, and central and eastern Asia. *P. vera* produces the largest nut and is the only species which has a dehiscent shell.

The pistachio appears to have originated on the slopes and plateau country of Iran, Turkestan, and Afghanistan south of the central Asian desert but is found growing wild as far east as India and Pakistan. It is widely cultivated in the Mediterranean basin, and more recently in Asia, the USA and, to a lesser extent, in Australia.

Botanical Features

The pistachio tree is small, dioecious and deciduous. It seldom exceeds 5 m in height and 10 m in diameter. The tree is hardy and can withstand extreme temperatures.

The leathery leaves with raised veins consist of one, three, or five leaflets. Juvenile leaves and those in environments with inadequate chilling have single leaflets, whereas mature leaflets in environments with adequate chilling have five. Resin ducts occur throughout tree tissues, and resin is exuded from any damaged parts.

In spring, inflorescent buds break first and there is often a delay of up to 7 days before vegetative buds break. Flowering may continue through to the latter part of spring, sometimes extending over a 2-week period, depending on variety and season. The transfer of pollen from male to female trees is by wind. Male pollinizer trees must be selected to flower at the same time as female trees in commercial orchards. One male tree per 10 female trees is required. The branched inflorescences are produced in clumps from several nodes just below the shoot tips. Bunches of nuts develop rapidly after pollination, the outer shell often attaining full size within a few weeks. The kernel, however, continues to develop over a 3–4-month period.

The nuts are mature when the outer skin of the husk changes from translucent to opaque. At this stage the husk is readily separated from the shell. The shells of good-quality nuts split to expose the edible kernel which is green or yellow in color with a green or reddish testa. Maturity of different varieties occurs at different times, up to 5 weeks apart, and each must be harvested at optimum maturity. Staining detracts from the appearance and the quality of the nut, resulting in much lower prices. Staining of shells is particularly a problem in humid or showery weather that also predisposes the development of aflatoxin-producing fungi. (*See* **Mycotoxins**: Occurrence and Determination.)

Apart from differences in time of flowering, maturity, and yield, varieties vary in the size and shape of

nuts produced, the percentage of split, empty, and stained shells, and the proportion of shell to kernel.

Ecology

Although essentially a subtropical, semiarid Mediterranean species, the pistachio is grouped with warm climate nuts because of its requirement of long, hot, and dry summers and autumns with an average daily mean of 30 °C for 3 months for good commercial yields. It requires a frost-free period of about 200 days to insure that developing inflorescences are not damaged in spring or by very cold winters. It does, however, require chilling during winter for satisfactory flowering. A total of 1000 h per year below 7.5 °C is required.

Production

The world production of in-shell pistachios in 1998–99 was 232 000 t, of which 157 000 t were exported. The main producing countries are Iran, Turkey, and the USA. The pistachio tree commences bearing at 5 or 6 years and increases from only 1 or 2 kg per year to levels of up to 50 kg of fresh nuts at 15–20 years. There is a tendency for pistachio to be a biennial bearing crop. The pistachio is particularly popular in the USA where it accounts for 9% of total nut consumption. Pistachios are usually marketed in shell and less frequently as kernel, often lightly roasted and salted.

Composition

The pistachio has a similar energy value to many nutmeats such as almonds but is lower than that of macadamia (Table 2). It is high in carbohydrate, mainly sucrose (16%). The fatty acids are essentially monounsaturated, although its polyunsaturated fatty acid content is higher and its saturated fatty acid content lower than in macadamia nuts.

The pistachio is high in minerals, particularly in potassium. A 100-g portion of pistachio kernels provides 92% of the daily thiamin requirement. Refer to individual nutrients.

Harvesting, Handling, and Storage

Mature nuts hang on the tree well under normal conditions and may be left until most are ripe. Under some situations, however, if the harvest is delayed, the husk dries on to the nut. Consequently the nut is stained and quality is lowered. Ripe nuts are readily dislodged by light shaking. Young trees may be harvested by hand but mechanical harvesting is normally used in commercial orchards.

The nuts must be husked and dried as soon as possible after harvesting to maintain high quality and an unblemished appearance and to avoid spoilage. The husked nuts may be sun-dried but drying artificially in silos between 65 and 72 °C is preferred for large commercial orchards. Freshly harvested nuts can contain as much as 45% moisture. This is reduced to about 5% in 10 h.

Some cultivars produce up to 25% empty shells in which kernels have failed to develop. These blanks must be removed from sound nuts prior to drying by flotation separation.

The dried nuts are sorted to remove those with blemishes. They are graded according to size, roasted, salted, and packaged. Most pistachios are marketed in their shells in snack packs.

Future Prospects for Lesser-Known Nuts of Warm Climates

Both pistachio and macadamia nuts are expensive compared with the major nuts. Future expansion of these industries may result in reduced prices and perhaps on promotion of the health benefits of nuts which is now generating a lot of nutritional research activity. As the volume of these commodities entering world trade increases, greater emphasis will be needed on market development and promotion to insure that they can compete with other nut products. It is unlikely that any of the other lesser-known nuts will develop significantly beyond their present regional boundaries.

O

OATS

G A Hareland and F A Manthey, North Dakota State University, Fargo, ND, USA

Background

Oat is a multipurpose crop that has been grown throughout the world for centuries, generally in cool moist climates. Archeological discoveries have traced oat back to the Greeks, Romans, and Chinese from the first century, but the grain may have originated in areas surrounding the Mediterranean sea in countries of the Middle East. The world oat crop is diverse and includes thousands of commercial cultivars that are grown for multipurpose use. Oat has traditionally provided an inexpensive source of onfarm livestock feed, forage, and bedding. Approximately 70% of the world production of commercially grown oat is used for livestock feed, 20% for human food, and 5% for industrial usage. More than half of the oat crop never leaves the farm where it is produced. Oat is oftentimes grown as an alternate crop to break cycles of soilborne insects and crop diseases. Unlike most other cereal crops, oat has remained at a relatively low market cost and has been confined to growing on marginal soils associated with poor drainage and low fertility. Although oat production has decreased in recent years, high-quality oat is still in demand for human consumption. Studies have shown that oat is nutritious and contains physiologically active fiber components that aid the process of digestion. Oat bran has been reported to have positive effects on lowering serum cholesterol levels in humans. Compared with other cereal grains, however, the functional properties of oat have not been well defined. Breeders can now evaluate gene combinations by using genetic mapping methods to study the world oat collections from which the functional and nutritional merits of oat protein, oil, starch, and bran components will be better understood. This article presents an overview of oat production, breeding and genetics, anatomy, biochemical and nutritional quality, and utilization.

Oat Production

Oat is considered one of the major cereal grains that are grown throughout the world. Yet over the past 10 years there has been a substantial decline in worldwide oat production, primarily because of low price compared with other cereal grains. Between 1994 and 1999, the six-year average worldwide production was 29.5 million metric tonnes (Table 1) compared with an average of 42.8 million metric tonnes between 1986 and 1989. The Russian Federation recorded the highest percent, 40.7%, of the world total area harvested and the UK recorded the highest average yield of 5.81 t ha^{-1} between 1994 and 1999. The 20 countries listed in Table 1 accounted for approximately 92.7% of the area harvested and 90.9% of the world production between 1994 and 1999.

Oat Breeding and Genetics

Oat (*Avena* spp. L.) belongs to the grass family, Gramineae. *Avena sativa* L. (Figure 1), often referred to as common spring or white oat, is a hexaploid containing three distinct diploid genomes, AACCDD, where $2n = 6x = 42$ chromosomes. *A. sativa* is the principal cultivated species grown throughout the world. *A. byzantina* Koch. is a red-oat type adapted to warmer climates where it is grown as a winter oat.

A. fatua L. (Figure 2) is a closely related wild oat hexaploid species that has little or no economic value and is considered one of the worst and ubiquitous cereal weeds in the world. A derivative of a wild/hull-less oat genetic cross can make an attractive ornamental decoration (Figure 3). Other wild oat species of *Avena* include the tetraploids ($2n = 4x = 28$ chromosomes) and diploids ($2n = 14$ chromosomes). The genetic variation among the approximately 21 000 oat genotypes, wild oat species included, has been explored only to limited extents.

Naked (hull-less) oat, *A. nuda* (Figure 4), is an agronomic variant of *A. sativa* and threshes free from its hulls (lemma and palea) during harvest. Naked oat is a species that originated in China

and has been grown for centuries. A single dominant gene controls the naked trait but the degree of nakedness is affected by modifying genes and environmental factors. Naked oat is high in energy, protein, and nutrition. The metabolizable energy content of the groat is comparable to that of corn, which makes naked oat suitable for animal feed rations.

Oat-breeding efforts continue to focus on the production aspects of the crop, usually through hybridization, such as selecting for improved yield, winter hardiness, lodging and disease resistance, plant maturity, hull–groat relationships, seed size, test weight, plant height, and protein content. Breeders are characterizing the germplasm of the thousands of accessions of oat in attempts to enhance specific traits such as protein, oil, beta-glucans, and other nutritional qualities. Genetic maps are being developed to identify molecular markers that are linked to quality and disease resistance traits. The Genetic Resources Information Network (GRIN) database of the US Department of Agriculture disseminates information on oat accessions to breeders for improving the overall quality of oat. Future breeding objectives will likely focus more on oat as a food, as research reports tend to characterize the positive nutritional and physiological properties of oat and oat products in human diets. Future demands by

food processors will encourage breeders to develop cultivars with improved milling qualities. Oat cultivars are likely to be adapted to different levels of protein, starch, lipids, and gums, and to changing seed size and shape for easier processing. Oat contains protein of superior quality, highly digestible carbohydrates, and an abundant source of nondigestible fiber. As the functional properties of the biochemical components become more evident, breeders will be encouraged to evaluate other genotypes for their agronomic, nutritional, and quality traits.

Anatomy of Oat Kernel

The compound inflorescence of an oat plant, referred to as a panicle (Figures 1, 3 and 4), is a continuation of the stem, and terminates in a single spikelet. Development of spikelets involves the formation of several florets, of which primary and secondary kernels develop to maturity (Figure 5). Occasionally tertiary kernels develop, but are smaller than the primary and secondary kernels. The hull of an oat kernel is normally attached loosely to the caryopsis. The groat is that portion of the oat kernel after removal of the hull (Figure 6). The major anatomical features of the oat kernel are the hull and groat (Figure 7). The hull contains two tissue layers, a lemma and palea. The outer portion of the groat contains the bran layers, which consist of the pericarp, seed coat, and aleurone cells. The aleurone layer is developmentally and genetically part of the endosperm but adheres to the outer bran layers upon separation of bran from the endosperm during milling. The aleurone is usually a monolayer of cells that represent the thickest part of the bran fraction. Cells in the aleurone produce and secrete enzymes that degrade storage material in the endosperm. The embryo, also part of the groat, is made up of the scutellum and embryonic axis. The scutellum is located between the endosperm and embryo. Scutellum secretes enzymes during germination and is involved in food transfer from the endosperm to the embryo.

The proportional size of the hull and groat affects processing and impacts the economic value of oat. Oat kernels of uniform size and high groat percentages mill more efficiently and yield higher quantities of bran and endosperm than nonuniform and small kernels. Groat percentages range from 65% to 85% of the oat kernel and weigh from 10 to 40 mg in cultivated species. Groat weight of the primary kernel is higher than the groat weight of either secondary or tertiary kernels. Cultivated oat kernels are generally larger and have less hull content than kernels from wild oat species. Environmental growing conditions affect groat percentages. Thin kernels with high hull

Figure 4 (see color plate 113) Oat panicle of naked (hull-less) *Avena nuda*.

content and low test weight generally result from dry conditions after heading.

Oat hulls are cellulosic and fibrous materials that are high in crude fiber and low in caloric value. Hulls decrease bulk density during transportation, but function to keep the groat clean for processing purposes and to protect the groat from mechanical damage during thrashing. Hulls are removed during milling before processing groats into flour or rolled oats. Oat dehulling is accomplished by feeding whole kernels into the center of a high-speed rotor. The kernels are dehulled by the centrifugal force and impact against an abrasive rubber ring on the inside housing of the dehulling machine. The hulls are further separated from the groats by air aspiration based on differences in density. The efficiency of the dehulling process is affected by the quality of oat. Lightweight kernels that are thin or short, and double kernels in which the hull of the primary kernel envelops the secondary kernel, do not dehull as easily as larger and higher test-weight kernels. Whole oat is generally graded for size during the cleaning operation by separating thin and short kernels from larger kernels before dehulling.

The major fractions of the oat groat are the endosperm and bran layers. Their relative proportions are affected by both genotype and environment. Approximate proportions of kernel fractions from cultivated species have been estimated as follows: hull, 24–32%; groat, 65–85%; embryonic axis, 1–2%; bran layers, 27–41% with a total thickness of less than 0.1 mm; and starchy endosperm, 56–68%. The bran contains higher concentrations of vitamins, protein, lipid, minerals, and fiber while the endosperm contains higher concentrations of digestible carbohydrates. The ratio of bran to endosperm has an effect on the total chemical composition of the groat.

Biochemical and Nutritional Quality

Protein

Protein quantity varies within a single cultivar by 3–4% depending on environmental growing conditions and location. The approximate protein concentration in individual fractions of cultivated oat species is: groat, 12–25%; embryonic axis, 25–40%; scutellum, 24–32%, bran, 18–32% and starchy endosperm, 9–17%. Oat hulls contain less than 2% protein in cultivated species, but at higher concentrations in wild oat species. The embryonic axis and scutellum contain higher protein concentrations than other kernel fractions, but together make up only about 3% of the groat size. Thus, most of the protein is actually located in the bran and endosperm. The bran contains about twice the protein concentration as the endosperm, but only about half of the total groat protein because of the difference in relative size of bran and endosperm. Protein content in specific oat fractions varies among genotypes. This is most evident when comparing cultivated species with wild species, which normally have thicker hulls and smaller groats.

Oat groats contain protein of high quality. The amino acids of oat are important for their human nutritional quality; of special interest are the levels of essential amino acids, which the body cannot synthesize. Lysine, the first limiting amino acid in oat, averages about 4.2% of the groat protein, which is higher than other cereals but slightly below the

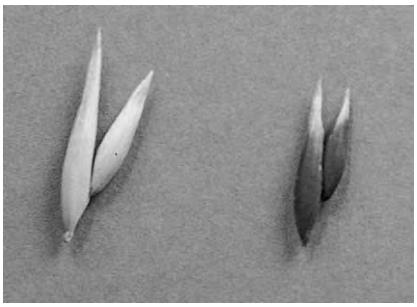

Figure 5 Kernels of cultivated white oat, *Avena sativa* (left), and a derivative of a wild *Avena* sp. (right). The primary (large) and secondary (small) kernels are attached.

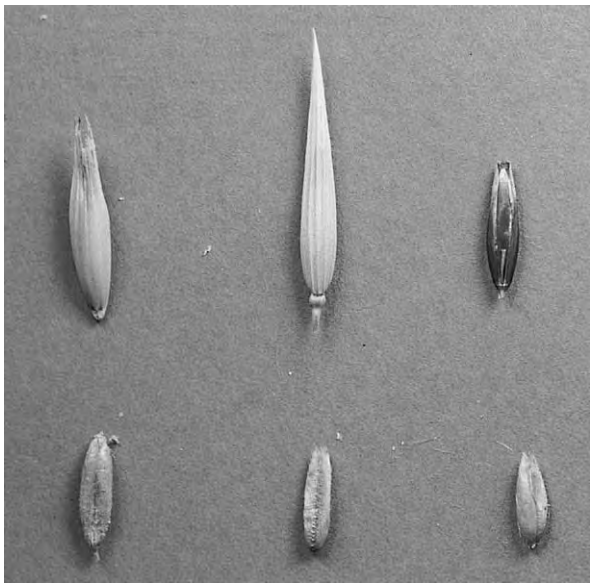

Figure 6 (see color plate 114) Kernels of cultivated white oat, *Avena sativa* (left), hull-less oat, *Avena nuda* (center), and a derivative of a wild *Avena* sp. (right). Whole oat kernels are pictured on the top row and the corresponding groats on the bottom row.

recommended Food and Agriculture Organization/World Health Organization reference standard of 5.5%. The embryo contains the greatest concentration of lysine. Oat ranks above other cereals in lysine content, including rice, because of the high protein concentration in the groat. Other essential amino acid concentrations associated within the groat are: methionine, 2.5%; valine, 6.4%; isoleucine, 3.9%; leucine, 7.4%; phenylalanine, 5.3%; and tryptophan, 1.7%.

Lipids

Oat contains relatively high lipid content compared with other cereal grains. Thus, oat serves as a unique source of energy as a livestock feed. Lipid concentration is genetically controlled and may vary from approximately 2% to 12% in cultivated species. Estimated percentages of free lipids in oat fractions are: hull, 2%; endosperm, 5.2%; aleurone and bran, 6.4%; scutellum, 20.4%; and embryonic axis, 10.6%. The embryonic axis and scutellum together contain the highest concentration of lipids in the oat kernel, but because of its relative size compared with other oat fractions, lipid quantity is low. The endosperm contains low lipid concentration, but contains over 50% of the lipids in the groat. The aleurone layer is very rich in lipid content and constitutes the major source of bran lipids.

Oat lipids are nutritionally important because of the high concentration of polyunsaturated fatty acids, especially linoleic acid. Linoleic acid, an essential fatty acid, is utilized in the synthesis of prostaglandins, which function to regulate smooth muscles like the heart. The approximate percentages of fatty acids in oat lipids are: myristic, 0.4–4.9%; palmitic, 15.6–25.8%; stearic, 0.8–3.9%; oleic, 25.8–47.5%; linoleic, 31.3–46.2%; and linolenic, 0.9–3.7%.

Oat and oat product quality may decrease upon storage because of possible chemical changes in the polyunsaturated fatty acids. Whole oat or undamaged groats that are stored below room temperature and at low moisture levels (less than 10%) show little change in quality. Conversely, damaged oat, groats, or ground oat that are stored for extended periods of time above room temperature and at high moisture have increased levels of enzymatic (lipase) activity. Lipase activity causes the release of free fatty acids from triacylglycerols, which are the major abundant class of oat lipids. Subsequently, unbound polyunsaturated free fatty acids such as linoleic acid undergo oxidation by action of lipoxygenase activity, leading to product rancidity. Lipase activity is highest in the bran because of its association with the aleurone layer, but can be minimized by thermally treating whole oat or groats during processing.

Carbohydrates

Starch is the major carbohydrate in oat and is found primarily in the endosperm. The amylose and amylopectin starch components are present in a ratio of about 1:3, respectively, which is similar to that of wheat and corn. High amylopectin, or waxy oat, and high amylose oat have not been reported in oat genotypes.

Oat contains an abundant source of nondigestible polysaccharides, which are carbohydrates that make up dietary fiber. The nondigestible polysaccharides are classified as either cellulosic or noncellulosic carbohydrates. Cellulose is a linear polymer of beta-1,4-linked glucose units, unlike the alpha-1,4-linked

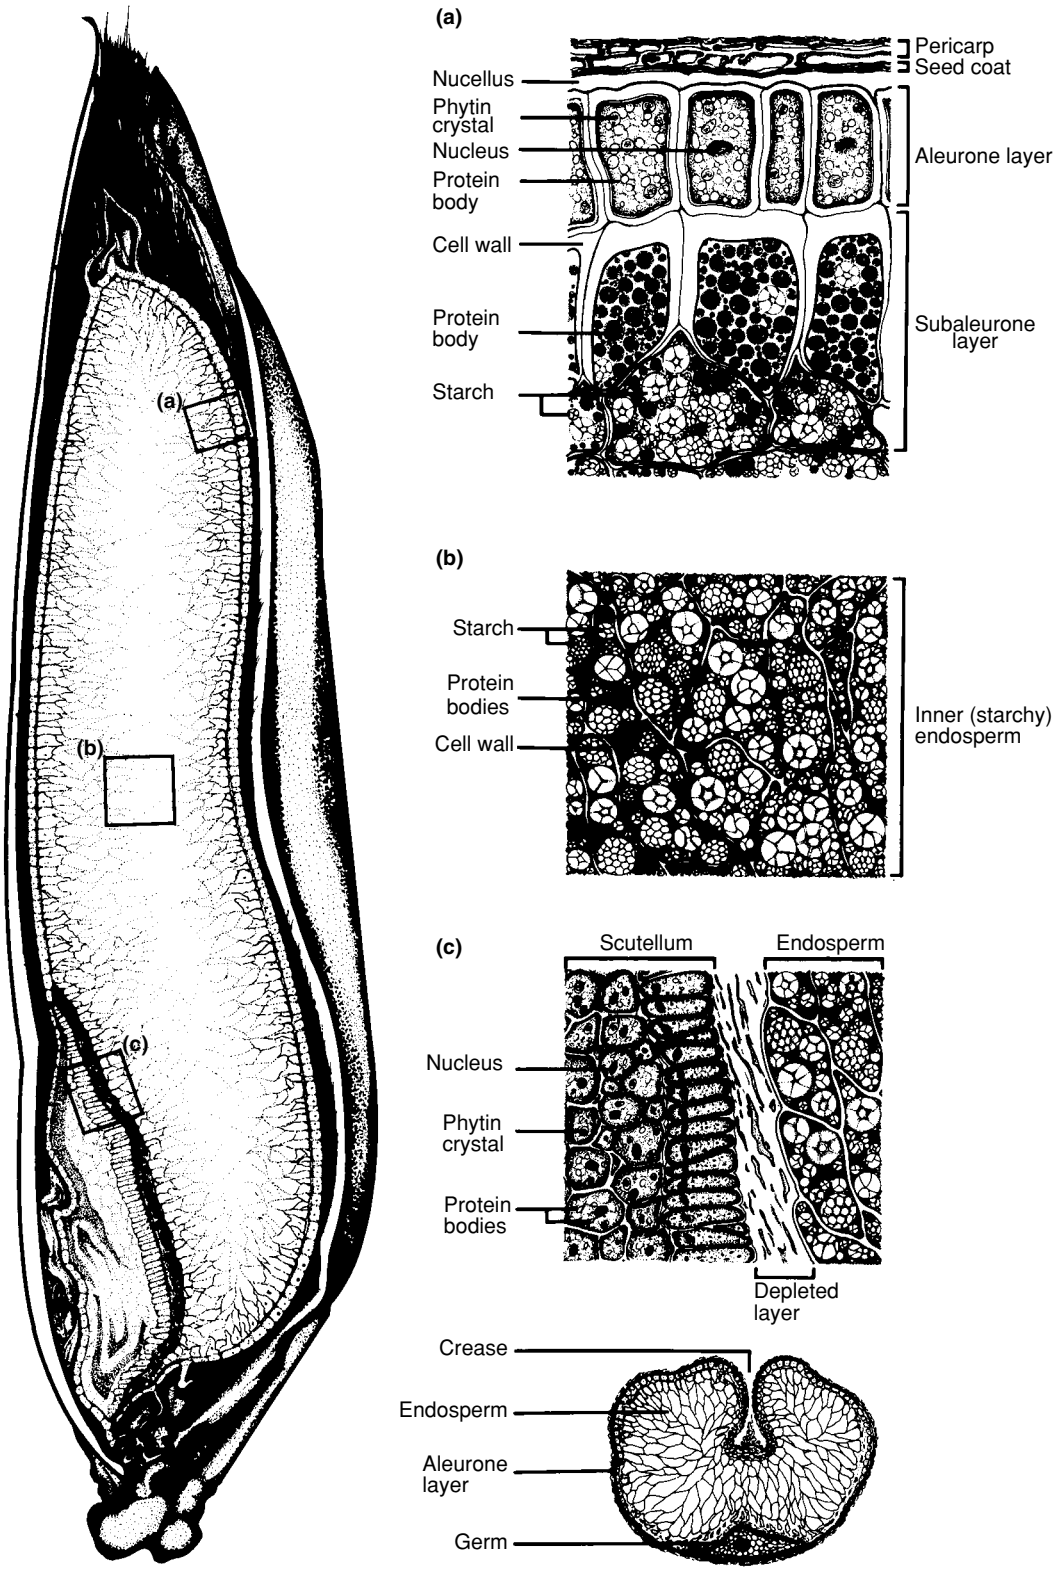

Figure 7 Major structural features of the oat kernel. Oat kernel on the left has been split longitudinally to reveal the approximate size and location of the major tissues. At the lower right is a cross-section view of the groat. (a), (b), and (c) are higher magnifications of portions of the bran, starchy endosperm, and germ. (Reproduced from Webster FH (ed.) (1986) *Oats: Chemistry and Technology*. St Paul, MN: American Association of Cereal Chemists, with permission.

glucose units that make up starch molecules. Noncellulosic polysaccharides include hemicelluloses, pectic substances, and gums and mucilage. Oat gum consists primarily of beta-glucans and pentosans. Beta-glucans are defined chemically as linear molecules of beta-1,3-and beta-1,4-linked D-glucopyranose units that are associated with cell wall structural components in both the bran and endosperm. Beta-glucans may be soluble or insoluble in water and contribute to the high viscosity of cooked rolled oats. Approximately 75% of oat beta-glucans are water-soluble. Pentosans are L-arabinofuranose residues linked as single-unit side chains to a backbone of beta-1,4-D-xylopyranose residues. Pentosans are present mostly in oat hulls and have been used in the commercial production of furfural. Upon acid hydrolysis of oat fiber, the polysaccharides yield sugars and sugar derivatives of D-xylose, L-arabinose, D-galactose, D-glucose, D-glucuronic acid, and 4-*O*-methyl-D-glucuronic acid.

Fiber-containing foods, upon ingestion, have a profound effect on food utilization from mouth to anus. Fiber directly affects gastric emptying time, rate of nutrient absorption from the intestine, fecal bulk, and frequency of bowel movements. Fiber indirectly affects pancreatic hormone secretions, hepatic glucose, and lipid metabolism. Under certain conditions, water-soluble beta-glucans have been reported to function in the small intestine as physiologically active, cholesterol-lowering ingredients. The hypocholesterolemic effects of beta-glucans tend to reduce the potential risk of ischemic heart disease. Oat hulls have little or no beta-glucan and are essentially water-insoluble fiber, which acts as fecal bulk in the large intestine. Total beta-glucan content in groats can vary from less than 2% to greater than 6%. Higher concentrations of beta-glucans are found in oat bran, which is obtained by separating endosperm and bran fractions by sieving. Beta-glucan content in oat bran is often higher than 7%.

Utilization of Oats

Oat is grown primarily for use as a forage crop and feed grain. Pliny, who reported on the human consumption of oat, stated in his *Natural History* that the Germanic tribes of the first century made 'their porridge of nothing else.' Oat later gained wide acceptance in Ireland and Scotland, where a variety of porridges were made. During the nineteenth century in America, oatmeal was sold almost exclusively in pharmacies and was suggested as a food for the infirm. In the late nineteenth century, Ferdinand Schumacher, a German immigrant, helped pioneer oatmeal into the largest selling cereal in the USA. His innovations included large-scale domestic milling, movement of oatmeal from the pharmacy to the grocery, and the development of packaging, brand names, and promotional literature.

Oat and oat products are used extensively in a variety of commercial food products. Thermal processing of oat enhances a unique flavor and aroma that contribute to utilization in cereals and baked-food products. Whole groats and steel-cut (sectioned) groats are processed into flakes. The traditional rolled oats made from whole groats are thick flakes requiring long cooking times, whereas flakes made from steel-cut groats are thinner and require shorter cooking times. Steam applied to sectioned groats produces variations of quick and instant flakes, with cooking times of less than 3–5 min. Oat flour is utilized as an ingredient in a variety of food products, and contains antioxidant activity in products likely to undergo fat oxidation during storage. Oat bran, obtained by sieving coarsely ground groats, is utilized as an ingredient in a variety of hot and cold cereals, and in baked products as breads, cookies, and muffins. The high viscosity of oatmeal makes it useful as a thickener in soups, gravies, and sauces, and a meat extender in meat loaves and patties. Processed oat hulls are used in the production of low-calorie, high-fiber baked products. Studies have shown that oat can be included in diets of celiac patients. The prolamin storage proteins, which cause the chronic condition in the intestine of celiac patients, are denatured by thermally processing the groats. In Sweden, Mill Milk Oat Drink was developed as a supplement for people who lack the ability to produce the lactase enzyme for digesting lactose found in dairy milk. Nu-trim, a thermomechanically sheared product from oat fiber, was developed for its high soluble beta-glucan content and used as a fat substitute in certain low-calorie products.

Oat has numerous industrial applications and potential for other uses. Oat starch has adhesive properties as a glue extender. Oatmeal has been used for cosmetic purposes to absorb dirt and sebaceous secretions from the skin. Oat hulls have cariostatic properties to prevent dental caries. Oat hulls have been used in the production of furfural and other derivatives as components in petroleum extractions, resins, plasticizers, insecticides, and pharmaceuticals; they may be used as a brewery filter aid; a component for making linoleum; and a component for making antiskid tire treads.

OBESITY

Contents

Etiology and Diagnosis

H Pande, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA
L J Cheskin, Johns Hopkins University, Baltimore, MD, USA

Background

The prevalence of obesity world-wide is increasing rapidly. The WHO has designated obesity as a major health problem throughout the world. In 1995, there were an estimated 200 million adults classified as overweight and obese world-wide. By 2000, the number of overweight and obese adults had increased to over 300 million. The obesity epidemic is not restricted to industrialized societies. In developing countries, it is estimated that over 115 million people suffer from obesity-related problems.

In the USA, the incidence of obesity among adults increased by 50% from 1976 to 1994. The most recent data demonstrate a prevalence of overweight (BMI 25+) or obesity (BMI 30+) of 64% and of obesity (BMI 30+) of 30.5%. Nearly 80% of some groups, e.g. middle-aged black women, are overweight or obese.

In most countries of Western Europe, the prevalence of obesity in adults is 15–25%. In the UK, over 20% of women and 17% of men are obese. Obesity is also increasing in prevalence in Latin America and the Caribbean. In South-east Asia, the Middle East, China, Japan, and the Pacific region, a marked rise in obesity is being seen in all populations and is now being recognized as a major public-health problem.

Obesity is clearly associated with increased morbidity and mortality. It is estimated to cause between 280 000 and 325 000 deaths per year in the USA. In 1995, the direct obesity-related health care costs in the USA exceeded $50 billion – nearly 6% of the entire national expenditure for health care.

Etiology

A simple and straightforward definition of obesity is an excess of body fat. However, obesity is more than just an accumulation of excessive amount of fat and its cosmetic consequences. It is a chronic disease with serious health consequences, is a major cause of morbidity and mortality worldwide, and is now considered the most common disorder of nutrition in developed countries.

The etiology of obesity is complex, multifactorial, and incompletely understood, despite significant advances in recent decades. It is thought to result from a

complex interaction between genetic, environmental, metabolic, dietary, and behavioral factors.

The pathogenesis of obesity can be considered the sum of those biological factors, which increase the predisposition towards expansion of adipose tissue mass together with consequences of adaptation to an environment that promotes and possibly rewards increased food intake and decreased physical activity.

When daily energy intake is equal to daily energy expenditure, a state of energy balance exists, and the body weight stays constant. When energy intake exceeds energy expenditure, a state of positive energy balance exists, and body weight increases. Overweight and obesity are usually the result of months and years of positive energy balance, resulting in enlargement of fat cells.

Genetic Factors

It has long been appreciated that obesity runs in families. Familial studies confirm that BMI is highly correlated among first-degree relatives.

Twin studies have shown a similarity in BMI between twins, which is stronger in monozygotic than in dizygotic twins. This correlation was found to persist even when the twins were raised separately.

Adoption studies have shown a significant correlation between the BMI of biological parents and adoptees, but not between the BMI of adoptive parents and adoptees. These studies suggest that the heritability of obesity may be as low as 10% (adoption studies) to as high as 80% (twin studies).

Some of the most compelling evidence for the genetic basis of obesity comes from the discovery of five mutations that cause spontaneous obesity and diabetes in mice. The Agouti (*Ay*), obese (*ob*), fat, diabetes (*db*) and tubby (*tub*) genes have all been cloned. In 1994, the discovery of the *ob* gene and its product leptin in *ob/ob* mice was a significant advancement in our understanding of the genetics of body-weight regulation. Since then, substantial progress has been made in characterizing genes related to human obesity. Genes responsible for previously existing mouse obesity mutations, *Ay*, *db*, *ob*, *fat*, *tub*, have been identified and have led to an understanding of the physiological pathways underlying each mutation.

Leptin, for example, is a 16-kDa hormone produced by adipose tissue, which acts by binding to receptors in the hypothalamus, which in turn alters the expression of several neuropeptides that regulate neuroendocrine function, appetite, and energy expenditure. A decrease in body fat leads to a decreased level of this hormone, which in turn stimulates food intake. In addition, decreased leptin levels activate a hormonal response that is characteristic of the starved state, including reductions in the resting metabolic rate. Increased body fat is associated with increased levels of leptin, which act to reduce food intake. By this mechanism, weight is maintained within a relatively narrow range physiologically.

Mutation of the leptin gene, leading to deficiency of leptin, results in the development of hyperphagia, hypogonadotrophic hypogonadism, and severe obesity with childhood onset (functionally equivalent to the *ob mouse model*). So far, only two kindreds with defects in leptin have been reported. In humans, mutations have also been identified in the leptin receptor in the hypothalamus (equivalent of the *db mouse model*), in the melanocortin 4 receptor (MC4R) and proopiomelanocortin (POMC), which is a precursor for the natural ligand of MC4R (*Agouti model*). Mutation in the prohormone and neuropeptide processing enzyme carboxypeptidase E in the *fat* mouse model and its equivalent in human peptidase PC1 have also been described.

Although monogenic mouse models have played an important role in our understanding of the biology of weight control, these mutations are rare and do not explain the common genetic predisposition to obesity seen in most human populations. They help us in understanding why, within a relatively homogenous environment, some individuals are lean and others are obese. However, only a small fraction of human obesity is due to a deficiency of leptin; instead, human obesity is associated with increased plasma concentrations of leptin. Thus, human obesity is characterized by a central and/or peripheral resistance or decreased responsiveness to leptin. The biological effects of the daily peripheral administration of recombinant human leptin in obese humans are currently being determined in clinical trials but are not expected to be dramatic, considering the nonresponsiveness to the satiety effects of high physiologic levels of leptin in obese individuals.

So far, more than 30 syndromes with a Mendelian pattern of inheritance associated with obesity have been identified. Most of these are pleiotropic syndromes in which obesity is one of the several features.

Prader–Willi syndrome (PWS) is the most common and best-characterized human obesity syndrome with an estimated prevalence of 1:25 000 and autosomal dominant pattern of inheritance. In addition to obesity, it is characterized by hypotonia at birth, small hands and feet, hyperphagia that usually develops between 12 and 18 months of age, mental retardation, short stature, and hypogonadism. Although familial inheritance of PWS is sometimes described, the vast majority of cases are sporadic. It has been established that PWS is most often caused by

a deletion of the paternal 15q11.2–12-chromosome segment.

A second, less common disorder, Bardet–Biedl syndrome, which was previously incorrectly named Laurence–Moon–Bardet–Biedl syndrome, is an autosomal recessive disorder. It shares many characteristics with PWS, including an increased risk of obesity. Studies of affected families have identified several different chromosomal loci (chromosomes 16, 11, 3, and 5) responsible for the syndrome, suggesting that it is a heterogeneous condition, with obesity being one of the common features.

The more common forms of obesity are, however, polygenic, and do not display a Mendelian pattern of inheritance. It is a quantitative phenotype that is probably influenced by numerous susceptibility genes, accounting for variations in energy requirements, energy utilization and storage, and the metabolic characteristics of the muscles, as well as being strongly influenced by environmental factors.

The strong environmental pressure to consume calories in excess of the energy expended exceeds the capacity for homeostatic adaptation in genetically predisposed persons, leading to an energy imbalance favoring fat storage. Genetic determinants of inter-individual variation in obesity and related phenotypes are likely to be multiple and interacting, with most single variants producing only a modest effect. Genome wide linkage studies in obese families and in different ethnic groups have led to the establishment of the 'human obesity gene map,' which contains entries for more than 120 genes and 16 chromosomal regions in which published studies indicate a possible relationship to excess adiposity or related phenotypes.

Landmark discoveries of leptin, uncoupling proteins, and neuropeptides involved in body-weight regulation have highlighted the importance of molecular genetic factors in determining an individual's susceptibility to obesity. These factors alone, however, cannot explain the rapidly rising prevalence of obesity in the past few decades and the current obesity epidemic, as our genes have not changed substantially over this period. It is believed that our genes simply permit us to become obese; the environment, however, may determine whether or not we do, indeed, become obese.

Metabolic Rate

Metabolic rate is the function of genetic, medical and voluntarily modifiable factors. The total daily energy expenditure (TDEE) is the sum of resting metabolic rate (RMR), the thermic effect of food (TEF), and the energy expenditure in physical activity (EEact). EEact can be divided into in activities of daily living and energy expended in additional physical activity.

TDEE has been found to correlate with body weight. The contribution of TEF and RMR to TDEE is on average 10 and 60%, respectively. The available evidence suggests that there is no association, or at best a very small association, between RMR and TEF and a tendency to gain weight. Activity-related energy expenditure contributes to 30% of the TDEE, is the most variable component, and may be the component that predisposes to obesity and can be most readily modified during efforts in weight control. Recent evidence suggests that incidental physical activity, such as large muscle contractile activity, which is, unfortunately largely involuntary, is a significant predictor of TDEE.

Decreases in TDEE can lead to obesity only if energy intake is not reduced to match the new level of energy expenditure. Humans have an effective homeostatic system with the ability to finely match the energy intake to energy expenditure to avoid positive or negative energy balance and changes in body weight. The effectiveness of this system is illustrated by the fact that adults on average consume 1 million calories every year, and a persistent mismatch of even 1% (about 10 000 calories with energy intake more than expenditure) would lead to an accumulation of fat and an increase in body weight of about 30 pounds in a decade. However, usually the body weight of an adult human increases only slightly over the course of a decade, which means that the homeostatic system operates with a remarkable degree of precision.

Endocrine Causes

Endocrine disorders can upset the precise physiologic regulation of metabolic rate and intake normally operating to maintain a stable body weight. These disorders include hypothyroidism, growth-hormone deficiency, Cushing's syndrome, insulinoma, polycystic ovary disease, and primary empty sella syndrome: all can lead to increased body fat. With treatment, patients who are deficient, for example, in either testosterone or growth hormone show a reduction in visceral adiposity when their hormone levels are normalized.

Studies have shown that patients with nonendocrine precipitants of visceral obesity have increased cortisol and insulin secretion combined with low production of sex steroids, such as testosterone in men, and a low rate of secretion of growth hormone. However, these altered endocrine functions seem secondary to the obese state and at least partially

responsible for the development of complications related to the obesity. Weight reduction in general is followed by normalization of endocrine function.

Environmental Factors

Although genetic and metabolic-endocrine factors may explain some of the variability between individuals within a given environment, changes in the environment must be responsible for the increase in the prevalence of overweight and obesity in the population in the past few decades. The rapid increase in obesity that occurred from the 1970s through to the late 1990s suggests that the environment has changed to one that is now strikingly obesity-promoting.

An increase in body weight would occur only when environmental factors overwhelm the ability of the regulatory process to adjust energy intake to energy expenditure. Several changes in the environment have contributed directly to the inability to match energy intake to energy expenditure.

The availability and consumption of energy-dense, high-fat foods is one such factor. Numerous studies in laboratory animals and humans indicate that high-fat diets increase the risk of overeating and development of obesity, and reducing dietary fat results in reduced total caloric intake by reducing the probability of overeating. Moreover, the appetite-suppressant effect of leptin may be overridden by access to high-calorie foods. Body-fat storage also occurs at a greater rate when excess energy comes from fat than when it comes from carbohydrate or protein.

It is becoming clearer that, unlike total energy balance, fat balance is not as closely regulated. A positive energy balance most often results from disruptions in fat balance. It is known that the presence of excess dietary fat does not acutely increase the rate of oxidation of fat for energy. Also, unlike carbohydrates and protein, the capacity for fat storage in humans is virtually unlimited. Excess calories in the form of fat are readily stored as triglyceride in adipose tissue, with a very high efficiency.

However even with a high-fat diet, most, but not all, individuals will become obese. The ultimate amount of weight gained will depend upon the genetic makeup and nongenetic factors like voluntary physical activity.

Another environmental factor is the consumption of more total calories in food as a result of an essentially unlimited supply of convenient, high-energy-density, relatively inexpensive, highly palatable foods, along with an increase in the portion sizes. This increases the likelihood of overeating.

The fast-food and restaurant industry has played a major role in this by using enticing food advertisements, serving large portions of high-calorie foods, and encouraging social eating behaviors. Studies have demonstrated that many of the highly palatable food items that have been introduced into the market by the food companies are optimized to elicit a highly positive reinforcing response, ensuring their continued ingestion and incorporation into our menu of familiar foods.

The relationship between dietary fat consumption and obesity, though, is not universally accepted. The evidence for this association includes the close correlation across nations between the percentage of energy in the diet derived from fat and the prevalence of obesity in that country, as well as laboratory studies in animals and humans, which demonstrate that consumption of a high-fat diet *ad libitum* tends to cause excessive weight gain. However, the USDA nationwide food consumption surveys show that the average fat intake, and the average total calorie intake had decreased between 1977 and 1988. Similar surveys in UK from 1970 and 1990 and studies from France have shown that fat consumption has decreased, yet paradoxically, the prevalence of obesity in USA and other countries has increased.

By contrast, self-reported food intake surveys (National Health and Nutrition Examination Survey) suggests that while dietary fat intake in absolute terms has remained relatively constant over the period, since the total energy intake has increased, the proportional intake from fat has declined. It would therefore be misleading to conclude that dietary fat intake is not likely to play a role in the increase in prevalence of obesity. Obesity prevalence might have risen even faster, if not for the apparent dietary-fat restraint and availability of reduced-calorie food products.

Physical Activity

It is well recognized and appreciated that increased energy intake and decreased physical activity, independent of genetics, would inevitably promote the development of obesity in individuals.

Various studies have shown that there is, indeed, an inverse relationship between physical activity and obesity. Cross-sectional, population, and cohort studies have shown that a low level of physical activity predisposes to obesity, while a high level is protective. In addition, normal-weight, postobese women who report being nonexercisers gained more than twice as much weight over 4 years of follow-up as regular exercisers.

Our increasingly inactive lifestyle may play an important and perhaps dominating role in the increasing prevalence of obesity. There are data to support that

work-related physical activity and energy expended in activities of daily living has declined in the past few decades. In the USA, however, leisure-time physical activity has not changed much since 1985, with 60% of the adults reporting that they are not regularly active, and 25% reporting that they are not active at all.

The amount of energy required for daily living has also decreased, owing to an increase in sedentary activities such as watching television, VCR, remote control, computer interactions, listening to music, etc.

Data from the national personal transportation survey in the USA have shown that the number of annual walking trips has declined significantly, whereas the number of daily car trips has increased by nearly an identical amount.

Decreases in TDEE as a consequence of the above factors would lead to obesity if energy intake were not reduced to match the new level of energy expenditure, which seems to be happening in developed countries. Even additional bouts of exercise, if followed by a high-fat and high-energy diet, can totally negate the energy expenditure of the exercise.

An individual's predisposition to engage in physical activity may be influenced by their genotype. Variations in muscle metabolic characteristics, like oxidative capacity, may play a role in the pathogenesis of obesity. The increased proportion of fast-twitch (type II B) as opposed to slow (type 1) muscle fibers in obese individuals may be responsible for decreased exercise tolerance and increased perception of fatigue by some of these individuals, predisposing them to be less active and gain weight.

Social and Cultural Factors

Social and cultural factors also make important contributions to the pathogenesis of obesity. The range of BMI of a population varies significantly according to the stage of transition to market economy and associated industrialization of a country, urbanization, changing social structures, and socioeconomic status. In the initial stages of the transition, the wealthier sections of society show an increase in the proportion of people with a high BMI, whereas in the later phases of transition, a high BMI among the poor shows increasing prevalence. This is usually accompanied by an increase in childhood and adolescent obesity and obesity-related disorders.

Cultural factors like cuisine, entertaining, and food selection, fat content of diet, attitude toward health, energy intake, body image, and physical activity also play a role in influencing the range of BMI in a population.

Fetal Undernutrition

Maternal malnutrition causing undernutrition of the fetus during intrauterine development may determine the later onset of obesity, independent of genetic factors. In support of the hypothesis is the finding of an inverse relationship between birthweight and adult obesity, blood pressure, and type 2 diabetes, in both men and women, in later life, with the highest BMI, glucose concentrations, and systolic blood pressures being observed in those with the lowest birthweight. The mechanism of this is unclear.

Diagnosis

The diagnosis of obesity is generally not difficult, but is is important to both quantify its degree and determine the relative risk of complications based on body-fat distribution, and other risk modifiers such as personal or family history of complicating conditions.

Body Mass Index

The body mass index (BMI) is accepted as the standard measure of relative body weight, i.e., weight adjusted for height. The BMI was found to correlate significantly with total fat content in the body. It can be used to assess overweight and obesity and to monitor changes in body weight and determine the efficacy of a treatment program.

BMI is calculated as weight in kilograms divided by height in meters squared.

$$\mathrm{BMI} = \mathrm{weight(kg)}/\mathrm{height(m)}^2.$$

The formula using nonmetric measurements is

$$\mathrm{BMI} = 703 \times (\mathrm{weight\ (lb.)}/\mathrm{height\ (in)}^2).$$

These values are independent of age and sex. Calculating BMI is simple, rapid, and inexpensive, and can be applied generally to adults. Although there are a number of accurate methods by which to assess body fat (e.g., total body water, total body potassium, bioelectrical impedance, and dual-energy X-ray absorptiometry), the measurement of BMI is the most practical approach in a clinical setting. This is especially true because no trial data exist to indicate that one measure of fatness is better than any other for monitoring overweight and obese patients during treatment.

Based on BMI, a standard classification of the degree of overweight and obesity has been established (Table 1). A BMI of >25 confers increased risk for a number of health conditions. There is strong evidence that weight loss in overweight and obese individuals reduces risk factors for diabetes, coronary

Table 1 Classification of obesity according to the BMI

Classification	*BMI (kg m^{-2})*
Underweight	< 18.5
Normal	18.5–24.9
Overweight	25–29.9
Obesity	
Class 1	30–34.9
Class 2	35–39.9
Class 3	> 40

artery disease, strokes etc. While the risk of medical complications generally increases with obesity class, an important modifier is the distribution of excess adipose tissue, as estimated most conveniently by the waist circumference.

Waist Circumference

Body fat may be preferentially located in the abdomen (android obesity pattern) or surrounding the hips and thighs (gynoid obesity pattern). The android pattern often reflects an accumulation of fat surrounding the abdominal visceral organs. The presence of excess fat in the abdomen out of proportion to total body fat is an independent predictor of morbidity. Waist circumference is a clinically acceptable measurement for assessing an individual's abdominal fat content, and they positively correlate with each other. The sex-specific cut-off associated with increased relative risk for the development of obesity-associated risk factors, when the BMI is 24.9–34.9, is shown in Table 2. When the BMI is more than 35, the waist circumference is usually more than the cut-off and thus does not have any additional predictive value. The waist circumference is a better marker of abdominal fat content than the waist-to-hip ratio and is the most practical anthropometric measurement for estimating a patient's abdominal fat content before and during weight-loss treatment.

Weight-for-Height Tables

Historically, weight-for-height tables like the Metropolitan Life Insurance Company table were used to define the normal weight range. However, such tables have major limitations, such as a reliance on primarily white reference populations, use of unvalidated estimates of frame size, and derivation of the table from insurance company mortality data.

Assessment of Risk Status

Adults with a BMI of 30 or more have a 1.5–2.0 times relative risk of death from all causes compared with individuals with a BMI of 20–25, with most of the increase being due to cardiovascular causes. It is therefore reasonable to assess an individual's absolute risk status by looking for the presence of the following conditions:

Table 2 Relationship between waist circumference and the risk of obesity-related complications

		Risk		
	Waist circumference	*Low*	*Moderate*	*High*
Men	(in)	< 37	37–40	> 40
	(cm)	< 94	94–102	> 102
Women	(in)	< 32	32–35	> 35
	(cm)	< 80	80–88	> 88

The high-risk cut off for men is a waist circumference of > 102 cm (40 in), and the high-risk cut off for women is a waist circumference of > 88 cm (35 in).

Coronary heart disease Obesity is associated with coronary heart disease (CHD), primarily via its impact on the CHD risk factors of hypertension, dyslipidemia, and type 2 diabetes mellitus. Obesity may also directly confer some increased risk of coronary artery disease (CAD) though. Besides BMI, excessive abdominal fat has also been shown to have a positive correlation with morbidity and mortality from CAD. Body weight, independent of risk factors, is also directly related to the development of left ventricular hypertrophy and congestive cardiac failure, perhaps via increased cardiac workload, and changes in vascular resistance and blood return. Obese individuals should also be evaluated for other cardiovascular risk factors, especially smoking and family history of CAD, as these may magnify the obesity-associated risk.

Type 2 diabetes mellitus Excess body fat is associated with increased insulin resistance and risk of developing type 2 diabetes mellitus. This correlation is strengthened by the fact that a significant majority of people with type 2 diabetes mellitus are obese. Moreover, the dramatic increase in obesity during the past decade has been accompanied by a dramatic increase in the prevalence of type 2 diabetes mellitus. In fact, overweight and obesity, especially in those with a more central body fat distribution, are the major risk factors for the development of type 2 diabetes mellitus.

Obstructive sleep apnea Obstructive sleep apnea syndrome (OSA) is characterized by occlusion of the upper airways and cessation of airflow for at least 10 s during sleep. Obesity is believed to change upper-airway anatomy through increased deposition of periluminal fat. This leads to apnea, arterial hypoxemia, recurrent arousals from sleep, excessive daytime somnolence, and snoring. OSA is more common among the obese, with those having a BMI 30 or more being

at greatest risk. Patients with OSA can develop complications like neuropsychiatric and behavioral disturbances, systemic and pulmonary hypertension, right heart failure, myocardial infarction and stroke. There are data indicating that the symptoms of sleep apnea improve with weight loss.

Hypertension Obesity may influence the blood pressure and predispose to hypertension. There is strong and consistent evidence that weight loss produced by lifestyle modifications reduces blood-pressure levels.

Dyslipidemia Obesity is associated with increased total and low-density lipoprotein cholesterols, increased serum triglycerides, and reduced levels of protective high-density lipoprotein cholesterol. All these lipid abnormalities are associated with an increased risk of developing CAD.

Other disease conditions associated with obesity Other conditions include ischemic stroke, nonalcoholic steatohepatitis, gallstones and cholecystectomy, osteoarthritis, menstrual irregularities, and infertility. Increased body weight is associated with an increased risk for certain forms of cancer, including colon cancer, endometrial cancer, and postmenopausal (but not premenopausal) breast cancer. Maternal obesity is a significant risk factor for the development of gestational diabetes mellitus, and neural tube defects.

Physical examination and laboratory evaluation

The physical exam should include, in addition to anthropometry, a pulse and blood pressure measurement, examination of the thyroid, auscultation of heart and lungs, palpation of the liver and examination of weight-bearing joints. A laboratory evaluation will help further in quantifying the risk of obesity-related complications and in monitoring weight loss. It should include serum chemistry, lipid profile and thyroid-function tests. In certain high-risk individuals, an electrocardiogram, stress test, chest X-ray, sleep study, pulmonary-function tests, ultrasound of gallbladder, liver, and ovaries, etc., may also be appropriate.

Conclusion

The etiology of obesity has been discussed from several perspectives. The concept of a genetic predisposition to weight gain, the biological mechanisms involved in the regulation of body weight, and its individual variation have been discussed. This was followed by a review of our current appreciation of the regulation of energy balance, presented from the point of view that small daily errors in positive energy balance integrated over months and years increasingly lead people to obesity. The complexity of the interaction between genetics, behavior, and the environment was also outlined.

Most available evidence indicates that higher levels of body weight and body fat are associated with an increased risk for the development of numerous adverse health consequences. Medical history should evaluate etiological factors that may have played a role in the development of obesity. Physical examination and laboratory tests should extend this evaluation to risk factors associated with obesity.

Fat Distribution

F Deeb, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA
L J Cheskin, Johns Hopkins University, Baltimore, MD, USA

Background

While obesity is easily diagnosed in most cases, and is well known to increase the risk of a variety of disease conditions, less well appreciated is the basic physiology of adipose tissue deposition and the effects of different distributions of adipose tissue on heath risks.

Types of Human Obesity

Obesity is defined as an excess of body weight as a result of an excessive accumulation of fat and results from interaction between the environment and genes. A historically high-fat diet, in concert with decreasing levels of physical activity, has recently resulted in an epidemic of obesity and overweight in much of the world, which now affects at least 64% of Americans. Human adipose tissue can be classified by site into four types: subcutaneous, yellow marrow, interstitial, and visceral. Subcutaneous adipose tissue lies directly under the dermis of the skin and superficial to the fascia overlying the skeletal muscles. More than half of total body fat is generally found in this site. Subcutaneous adipose tissue can be further divided into a deep layer and a superficial layer. One clinical study found that during weight loss, the deep layer decreased to a greater extent than the superficial layer; the significance of this finding is unknown.

Interstitial adipose tissue is found between cells and usually accounts for only a small proportion of total body fat. Yellow marrow is the fat within the bone marrow and is not normally subject to much increase with weight gain.

Variation in the amount visceral adipose tissue (VAT) has the greatest impact on health risks. VAT can be subdivided into retroperitoneal and intraperitoneal adipose tissue. The intraperitoneal adipose tissue can be further divided into mesenteric and omental depots, whose veins drain into the portal vascular system. The liver, too, may accumulate fat, primarily within the hepatocytes. This may occur as a benign result of weight gain (hepatic steatosis or benign fatty liver) or as a manifestation of the often-progressive disease known as nonalcoholic steatohepatitis (NASH), which is often accompanied by obesity and/or type 2 diabetes.

A variety of terms have been used to define differences in adipose tissue accumulation patterns including android/gynoid, apple/pear, central/peripheral, and upper body/lower body. Of note, typical body-fat distribution differs between men and women. Women tend to accumulate more lower-body fat during weight gain, whereas men tend to have upper-body abdominal accumulation of fat, as well as variable lower-body fat accumulation. Purely lower-body weight gain is not generally seen in non-castrated males, though the typical male pattern of predominantly upper-body weight gain is not infrequent in women.

The metabolic consequences of obesity are determined to some extent by the distribution of fat. A number of animal and human studies have found that central obesity poses a greater risk of, among other conditions, cardiovascular disease, type-2 diabetes mellitus, hypertension, gallstones, and gout compared with the risk associated with peripheral obesity. The amount of abdominal visceral fat appears to be the most important corollary of health risk for the individual with obesity. In fact, even in the absence of overall obesity, an excess of VAT appears to be associated with excess health risks.

Regulation of Adipose Tissue Distribution in Humans

In view of the close epidemiologic and metabolic associations between central obesity and disease, the regulation of adipose tissue growth and distribution is important to understand. Age and gender are two important, nonmodifiable determinants of the size of the VAT depot compared to subcutaneous fat. Increasing age and male gender tend to increase VAT magnitude at a given level of total body fat. That is, weight gain in general increases VAT, but to a lesser degree in younger people and in women. However, genetic factors account for a good deal of variability in the amount of fat deposited in VAT or other sites. In addition, some environmental (modifiable) factors appear

important, and include smoking and lack of exercise. A number of endocrine abnormalities have been variably detected in association with central obesity, including low testosterone secretion in men, elevated cortisol and androgens in women, and low levels of growth hormone in men and women. Hypersensitivity of the hypothalamo–pituitary–adrenal (HPA) axis may be the mechanism underlying these abnormalities. Insulin resistance in peripheral tissues, leading to hyperinsulinemia, also plays a key role. All of these hormonal changes have important influences on adipose tissue metabolism and distribution.

At the adipocyte level, insulin and cortisol contribute to lipid accumulation by decreasing lipoprotein lipase (LPL) activity. Growth hormone (GH) and testosterone increase LPL activity, so that the decrease in these hormones often seen in central obesity would also tend to decrease LPL activity and favor further adipose tissue deposition. Because of the higher blood flow, cellularity, and innervation in visceral compared with subcutaneous adipose tissues, the consequences of the hormonal abnormalities described above are believed to be expressed more in visceral adipose tissue. Another factor accounting for the disproportionate health effects of VAT is that the number of androgen and cortisol receptors is higher in VAT than other adipose tissue deposits. Thus, endocrine abnormalities in VAT, e.g., elevated levels of insulin and cortisol, which favor accumulation of fat, and decreased levels of GH and sex hormones, which mobilize fat, are magnified by the higher receptor density, leading to further accumulation of fat in VAT. In various physiological conditions associated with increased visceral fat mass, the balance between the lipid accumulation hormones (cortisol and insulin) and the hormones that prevent lipid accumulation and instead activate lipid mobilization (sex hormones and GH) is shifted to favor the lipid-enhancing hormones. Such conditions include polycystic ovary syndrome, Cushing's syndrome, menopause, aging, GH deficiency, HIV lipodystrophy, and excess alcohol intake. Finally, local synthesis of steroid hormones in adipose tissue may play a role in regulating deposition of fat. Regional measurement of fat turnover reveals higher rates of lipid mobilization in upper-body (visceral) adipose tissue than in lower-body adipose tissue. The order in men is as follows: omental visceral = retroperitoneal > subcutaneous abdominal > subcutaneous femoral adipose tissue.

Effects of Fat Distribution on Health

As noted, body fat distribution is now recognized as an important predictor and modifier of many of the adverse health consequences of obesity. Upper-body obesity and abdominal visceral fat are associated with a variety of metabolic complications, including hypertension, insulin resistance, type-2 diabetes mellitus, dyslipidemia, gout, and premature coronary death.

Evidence suggests that abnormally high adipose tissue turnover in VAT, mediated by high levels of LPL and/or increased sensitivity to catecholamines or decreased sensitivity to insulin's effect on inhibiting lipolysis, results in elevated free fatty acid availability and may explain some aspects of the metabolic consequences of upper-body obesity. Overall, though, the precise mechanism(s) by which excess VAT lead to adverse health consequences is poorly understood.

Heart Disease

Obesity is an independent risk factor for the development of coronary artery disease (CAD). Obesity also increases the risk of CAD indirectly through its adverse effects on insulin resistance, lipid metabolism, and blood pressure. Central obesity is the pattern most highly correlated with an adverse coronary risk profile. Treatment of obesity results in an improved coronary risk profile. Despite the high prevalence of obesity in coronary populations, the effect of weight loss on hard cardiovascular outcomes such as myocardial infarction and death has received relatively little attention.

Endocrine Abnormalities

The endocrine and metabolic complications most frequently seen in obesity are insulin resistance, type 2 diabetes mellitus, dyslipidemia, menstrual abnormalities, and infertility.

Insulin resistance is quite common in severe obesity, and occurs especially with central obesity. Insulin resistance is a central pathophysiologic feature of multiple conditions, the conglomeration of which is referred to as 'Syndrome X.' Syndrome X includes hyperglycemia, hyperinsulinemia, dyslipidemia, and hypertension, which are associated with an increased risk of CAD and stroke. HPA axis hypersensitivity, as evidenced by an increased response to challenges at all levels of the HPA axis, from the adrenals to the central regulatory centers, appears to be associated with obesity, in particular, central obesity. Sex steroid and GH secretions are blunted, despite heightened HPA reactivity. The hyperandrogenicity frequently seen in obese women may be related to increased testosterone production in the ovaries and adrenals.

Obesity in girls is associated with early menarche and puberty. The effect of childhood obesity on boys is more variable; obesity can lead to either early or

delayed puberty. Pubertal gynecomastia is a common problem in obese boys.

Gastrointestinal Conditions

A gastrointestinal disorder for which obesity is a classical risk factor is cholelithiasis. The magnitude of risk is directly related to the severity of obesity but probably not to fat distribution. Since, for each kilogram of fat gained, an additional 20 mg of cholesterol is synthesized and excreted in the bile, this increased cholesterol turnover is the probable mechanism by which obesity increases the likelihood of precipitation of cholesterol gallstones. The risk for gallbladder stones increases during weight loss because of unfavorable changes in bile composition (lithogenicity), increases in the flux of cholesterol through the bile ducts as fat is mobilized, and decreased gallbladder contractility. New gallstone formation especially occurs in subjects who experience rapid weight loss after gastric surgery for obesity or after dieting with a very-low-calorie (< 800 kcal per day) and low-fat diet (as many as 25–35% of patients in some studies develop usually asymptomatic gallstones). The risk for gallstones appears to be lower in patients consuming a low calorie diet (800 kcal per day) containing 15–25 g of fat per day (4% after 10 weeks of dieting).

NASH, a liver disease with frequent sequelae of fibrosis and cirrhosis, occurs most commonly among obese patients and those with type 2 diabetes, and thus is likely to be more common in central obesity. Alanine and aspartate aminotransferase and alkaline phosphatase are the most commonly elevated liver enzyme levels in NASH but are usually no more than twice the upper limit of normal and do not correlate well with histological abnormities. The pathogenesis of liver injury in obese individuals with NASH is in part secondary to the proinflammatory cytokine, tumor necrosis factor α (TNF-α), which has emerged as a key factor in various forms of liver disease. Data from animal and clinical studies suggest that TNF-α mediates not only the early stage of fatty liver but also the transition to more advanced stages of liver damage. A modest weight loss (> 10% of body weight) can normalize liver tests, decrease liver fat content, and decrease liver size.

Another common gastrointestinal condition associated with obesity is gastroesophageal reflux disease (GERD). Abdominal obesity (and pregnancy) are especially associated with GERD, as these conditions result in increased intra-abdominal pressure, which is a central mechanism for reflux of gastric contents into the acid-sensitive esophagus. Abdominal hernias are also associated in particular with central obesity.

Pulmonary Conditions

Pulmonary conditions associated with obesity include obstructive sleep apnea (OSA) and obesity-hypoventilation syndrome (OHS). In OSA, patients suffer from repeated attacks of upper-airway obstruction during sleep. OSA is fat distribution-sensitive because it is believed to be associated with increased fat deposition in the tongue, uvula, pharynx, and hypopharynx. OHS is a condition associated with serious obesity in which an awake patient suffers from hypercarbia and hypoxemia. Abdominal obesity is a mechanical factor in the etiology of OHS, since increased abdominal fat tends to raise the diaphragm, as well as increase fat deposition within the diaphragm and intercostal muscles, and also increase chest-wall weight. Leptin, a protein produced by adipose cells, serves as a pulmonary growth factor and as a modulator of the central respiratory control center. Leptin deficiency or, more likely, leptin resistance is believed to play a role in OHS and OSA.

Assessment of Human Obesity

In order to assess an individual's body fat content and fat topography, a comparison of measures obtained in the individual with age- and gender-specific norms is necessary. This procedure has proved to be challenging in both clinical and research settings. At least three body-fat measures (total body fat content, upper-body fat, abdominal visceral fat) are very important, and must be evaluated not just in a laboratory environment but also in the physician's office and in large-scale population studies. Table 1 lists the current methods available to obtain a direct or predicted measure of total body fat content.

Anthropometry is the cheapest, most widely used method of assessing human-body composition. Anthropometry measurements can be used both clinically and in epidemiological studies to grade the degree of adiposity in either individuals or groups. The measurements are also used to describe the anatomic distribution of adipose tissue and thus classify individuals and groups with regard to the type of obesity (central or peripheral). The anthropometric measures considered most useful in assessing obesity include weight, stature, skinfold thickness, and circumference of the trunk and limbs.

Weight

Body weight is best measured to the nearest $\pm$ 0.1 kg using a beam-balanced scale. Despite the requirement of frequent and careful calibration, spring scales or electronic scales may be used instead. Patients should

Table 1 Methods of estimating body fat and its distribution

be measured either nude or wearing light clothing of known weight.

Stature

The preferred method of measuring stature is by using a wall-mounted stadiometer, measuring to the nearest $\pm$ 1 cm. Plastic stadiometers are available for clinical use that have acceptable accuracy. The position of the patient is very important and should be standardized, the patient standing erect with the head, shoulders, and buttocks against the stadiometer wall. Body weight and stature can be used to calculate the body-mass index (BMI) (or Quetelet's index) or weight corrected for height and to compare this value to percentiles for the distribution of this index by sex, age, and race tabulated from large surveys conducted by the National Center for Health Statistics. The BMI is calculated as the weight (in kilograms) divided by the square of height (in meters) or as the weight (in pounds) multiplied by 704 and divided by the square of the height (in inches). It is important to remember that age and body proportion (leg/trunk length ratio) influence the correlation of BMI with height and that BMI is correlated with lean as well as fat mass. This means that a very muscular individual will have a measured BMI that puts them in the obese category, although they do not necessarily have an abnormal percentage of body weight composed of fat.

Skinfold Thickness

This is a measurement of a double thickness or 'fold' of skin, including the underlying fascia and subcutaneous adipose tissue, which is taken using calipers at standard locations on the body. It is performed by pinching and elevating a skinfold at a specific anatomical site using the thumb and forefingers, and measuring the thickness of the fold with a specially designed caliper. The anatomic sites commonly measured are the triceps (midway between the shoulder and the elbow), the subscapular, suprailiac and paraumbilical area, and the medial thigh and calf. These measurements correlate with, but do not accurately measure, the actual mean thickness of the subcutaneous adipose tissue. This has been illustrated by comparisons of caliper skinfold thickness measurements with radiographic and ultrasound measurements of the true subcutaneous adipose tissue thickness at different anatomic sites. Reproducible skinfold measurement requires training. A major criticism of skinfold thickness methods is that they ignore variations in the amounts of internal adipose tissues, especially the visceral adipose tissue that is associated with so many of the increased health risks of obesity.

Circumferences

Body circumferences can be measured more easily in severely obese patients than skinfold thickness. Circumferences have an additional advantage over skinfold thicknesses in that they can measure internal as well as subcutaneous adipose tissue. However, unlike skinfold measures, circumferences are influenced by variation in the size of underlying muscles and bone. The most useful circumferences for grading or predicting body fat and for describing adipose tissue distribution are the upper arm, chest, waist or abdomen, hip or buttocks, and the thigh (proximal or midthigh). In men, the waist circumference is highly correlated with total body fat. In women, the hip or thigh circumference is more predictive of total body fat. Many circumference indices have been devised in an effort to capture the association between

fatty-tissue distribution and morbidity and mortality. The most popular circumference index is the 'waist/hip ratio' (WHR), followed by the 'waist/thigh ratio' (WTR). The WHR is an independent predictor of metabolic disturbance including insulin resistance, hyperlipidemia, hypertension, and arteriosclerosis. Similar associations have been reported for WTR, as well as for skinfold thickness indices. Recent evidence suggests, however, that the waist circumference alone is as reliable as the WHR in predicting VAT and its associated health risks.

Ultrasound

Ultrasound has the advantages of measuring subcutaneous adipose tissue thickness more accurately than skinfold measures and of being able to measure otherwise inaccessible sites. The two major disadvantages of ultrasound are that an experienced technician is usually required and that the costs are high.

Hydrodensitometry

An obese person floats higher in water than a non-obese person. This is because the density of fat mass is lower than that of fat-free mass (FFM). Underwater weighing is one of the oldest *in vivo* methods of analyzing human-body composition as a two-compartment (fat and fat-free body mass) model. It held the status of being the 'gold standard' for body-fat composition analysis for many years but is both inconvenient and not as precise a measure of body composition as other methods.

Bioimpedance and Conductivity

Total body electrical conductivity and bioelectrical impedance are techniques for predicting body composition based on the measurement of the electrical resistance in the body to a tiny current. This electrical resistance is proportional to body shape and the volume of conductive tissue (body components with high water concentrations such as the FFM and skeletal-muscle mass). As a result, these methods do not estimate body fatness but instead predict FFM; fat must be derived secondarily as the difference between the predicted FFM and the body weight. These tests have the advantage of being simple, quick, and inexpensive, and can be readily used in population studies. Their disadvantages are the variability in the measurement and its dependence on the hydration level of the patient.

Absorptiometry

Dual-energy X-ray absorptiometry (DEXA) was primarily designed to measure the amount of mineral within bone, but can also be used to estimate the amount of fat in soft tissues. DEXA is an outgrowth of dual-photon absorptiometric systems, having been introduced in the early 1990s as faster and more accurate. DEXA is quick and simple to carry out, yields information about regional adipose tissue distribution, because it is a whole body scan, but is costly.

Imaging

Imaging studies, such as computed tomography and magnetic resonance imaging (MRI), are widely considered the most accurate means currently available for assessing body-fat distribution, but the limitations are the high cost, expertise needed, radiation exposure, and limited utility in a research setting. These are the only methods available for precise, accurate quantification of visceral and other internal depots of adipose tissue. MRI is now the method of choice for calibration of field methods of measuring body fat and skeletal muscles *in vivo*.

Isotope Dilution

Dilutional methods include a group of specialized research techniques for measuring body composition of fluid compartments (e.g., total body water (TBW), extracellular fluid, and plasma volume) and the electrolytes within those compartments, such as exchangeable potassium, sodium, and chlorine. They are costly, require specialized training, and are not widely available. Examples are heavy water and neutron activation measures.

Heavy Water

Water labeled with either two isotopes of hydrogen (deuterium, $2H_2O$; tritium, $3H_2O$) or oxygen ($H_2^{18}O$) has been used to quantitate TBW by a dilution method in healthy and diseased individuals.

Neutron Activation

Whole-body counting/*in vivo* neutron activation analysis can be used to estimate adiposity components. This method enables all main anatomic elements to be quantified at the anatomic level *in vivo*. Once the elements have been measured, the proportion of fat, protein, water, and mineral can be calculated by applying simultaneous equations. These techniques are not widely available but are precise.

In summary, an increasingly well-recognized and understood modifier of health risk in obesity is regional fat distribution. While the ideal method of measuring fat distribution has not been defined, efforts should be made to identify those individuals who are at high risk because of an unfavorably high VAT mass. As a marker of health risk, regional

distribution of fat is arguably more important than obesity *per se*, and should be afforded the prominence it warrants in the evaluation and treatment of obesity.

Treatment

L F Donze and L J Cheskin, Johns Hopkins University, Baltimore, MD, USA

Introduction

The purpose of this chapter is to review critically the current state of knowledge about the treatment of obesity. We will discuss various treatment approaches, including the recommended multidisciplinary assessment and treatment; popular, commercial, and self-help approaches; and more aggressive methods such as very-low-calorie-diets (VLCDs), pharmacologic treatment, and surgery. We conclude with recommendations for improving the likelihood of long-term maintenance after weight loss.

Multidisciplinary Assessment and Treatment

Components of a comprehensive or multidisciplinary approach to weight loss typically include medical management, behavior modification, dietary modification, exercise modification, and long-term follow-up. All too often, only one or two elements of a comprehensive approach are considered or implemented in practice. Ideally, all five treatment components will be present in one program, so that overweight individuals will not need to coordinate their own care. True multidisciplinary treatment is most likely to occur in university- or hospital-based programs, with a treatment team consisting of physicians, psychologists, dietitians, and exercise physiologists. A typical treatment process is described below.

Multidisciplinary Assessment

Before treatment can begin, it is important for the treatment team to gain a good understanding of the patient's situation, both in regards to the weight problem and the individual as a whole. Such understanding is typically accomplished via comprehensive evaluations with the patient, including medical, behavioral, nutritional, and exercise/fitness assessments.

Medical assessment Medical evaluation is strongly recommended for obese patients with a body mass index (BMI) of 30 or more, those who have medical comorbidities, and/or individuals who have not seen a medical care provider in a year or longer. This assessment is critical for understanding the etiology of the disorder in each patient and for establishing a reference point for response to therapy. Medical assessment usually consists of a focused medical history, a careful physical examination, and appropriate laboratory tests.

The medical history should include an assessment of patient and family medical history, including obesity, cardiovascular disease (CVD), hypertension, cancer, diabetes, thyroid and other endocrine diseases, and dyslipidemia. Patient history should

include a detailed weight history (lowest and peak adult weight, weight changes and their precipitants, and current weight); history of previous weight-loss attempts; use of tobacco, alcohol, drugs, and medications; and level of motivation. Patients should also be screened for conditions that contraindicate or compromise participation in an exercise program, such as recent myocardial infarction, angina pectoris, disabling osteoarthritis (especially of the knees), severe obesity with restricted mobility, pulmonary disease, or traumatic injury.

The medical care provider should conduct a comprehensive physical examination, with special attention paid to signs of potential comorbidities such as type 2 diabetes mellitus, hypertension, dyslipidemia, and sleep apnea, as well as to possible causes of weight gain such as hypothyroidism, polycystic ovarian syndrome (PCOS), and other endocrine conditions. Blood pressure should be measured with a sufficiently large cuff to give an accurate reading, with the patient in a relaxed state.

Laboratory evaluations can serve as screening tests for certain complications associated with obesity. Blood chemistries should include fasting serum glucose, cholesterol, triglycerides, and liver profile tests. An electrocardiogram (ECG) and complete blood count and urinalysis should be performed to establish a baseline prior to treatment. Thyroid-stimulating hormone (TSH) levels should be checked if there is any suspicion of thyroid dysfunction. Other endocrine and metabolic tests can be performed, if indicated.

Behavioral assessment A clinical psychologist typically conducts the initial behavioral assessment of the patient. This indepth interview covers the patient's psychosocial history, including childhood experience; any trauma, abuse, or unusual events as a child or adult; perceived reasons for weight gain; educational, occupational, and relationship history; and any current stressors that may interfere with the patient's ability to prioritize or adhere to treatment. The patient's diet and weight history are also assessed, including periods of weight gain and losses, the patient's experience on previously attempted diets, patterns of weight maintenance or relapse, and motivation for weight loss. The patient's current eating behavior is assessed by discussing a 'typical day' with regard to eating (such as time of day, foods eaten, and reported hunger or other motivations for eating). Binge-eating behavior and other symptoms of clinical eating disorders are also assessed. Finally, the patient's psychiatric history and current mental status, including history of depression or other disorders, previous and current treatment with psychotherapy or medication, and current depressive (or other) symptoms, are explored.

Dietary assessment A formal dietary assessment is best done by a registered dietitian with training and experience in weight management. An initial nutrition evaluation may consist of a 24-h recall of food intake, a food frequency to determine adequacy and composition of the diet, anthropometric assessment (i.e., waist and hip measurements), and an interview assessing meal patterns, beverage consumption, food preferences, grocery shopping/cooking pattern, restaurant dining, and any religious or cultural customs that may affect the patient's diet. The nutrition assessment is necessary to evaluate the initial nutritional status of the patient and to make appropriate nutritional and treatment recommendations. Although many aspects of diet may be characterized as behaviors, understanding patients' taste preferences and the macronutrient composition of their usual array of food choices is useful in suggesting dietary and behavioral changes that are consistent with the patient's preferences and lifestyle.

The results of the dietary assessment should be interpreted cautiously, because both underreporting and restrained eating (while under observation) are common. Despite these shortcomings, the information gathered can be quite valuable. For example, if an individual reports drinking almost 1000 calories per day in juice and soda, simply switching to noncaloric beverages will likely promote a significant weight loss.

Exercise assessment The exercise/fitness assessment should be performed by a trained exercise physiologist and should explore the patient's usual degree of physical activity, any limiting factors such as joint disease or injuries, preferred types of activity, and measurement of the patient's current level of fitness. A fitness test may consist of a Harvard step test and a test of flexibility, and bioelectrical impedance testing may be used to assess body composition. A formal stress test is not required unless active cardiovascular disease is suspected. The exercise physiologist may also explore lifestyle factors such as usual work hours, social support, and nearby facilities or other resources that could promote increased activity level.

Metabolic testing Metabolic testing of the patient's resting metabolic rate (RMR) via a metabolic cart (indirect calorimetry) is recommended if the necessary equipment and staffing are available. A metabolic test may be performed by an exercise physiologist, dietitian, nurse, or technician. Resting metabolic rate (also called resting energy expenditure,

REE), obtained either by metabolic cart or estimation formulas, is then used to determine daily caloric needs by multiplying RMR by an activity factor ranging from 1.3 (for very sedentary) to 2.0 or more (for very physically active individuals). This estimate of total daily energy expenditure is used by the dietitian to determine the patient's initial caloric requirements and an estimated rate of weight loss, given a specific reduction in energy intake in the diet.

Summary The entire multidisciplinary assessment can be an emotional and draining experience for the patient, who may not have previously talked about (or even thought about) his or her life in such an indepth way, and to a team of clinicians. We have found, however, that only after a comprehensive evaluation by the multidisciplinary treatment team can an optimized and individualized treatment plan be recommended.

Multidisciplinary Treatment

After multidisciplinary evaluations are complete, treatment can begin. The patient may participate in individual and/or group sessions with members of the treatment team. Weekly treatment sessions are recommended initially (for at least the first month of treatment), to provide the support and education necessary for the patient to stabilize his/her eating behavior and implement the suggested dietary and physical activity changes. Once weight loss is under way, less frequent appointments may suffice.

Medical monitoring Ongoing medical management, including vital signs, brief review of systems, discussion of any adverse effects of the diet or weight loss, and periodic repeated blood tests, is recommended for patients on low-calorie diets (< 1200 calories per day) and/or those with serious medical comorbidities. Medication dosage or scheduling (for example, of orally administered glucose-lowering agents or insulin) may need to be adjusted as a result of energy restriction and weight loss.

Behavior modification and psychological treatment Behavior modification in the treatment of obesity is a methodology for systematically modifying a patient's eating, exercise, or other behaviors that may be contributing to the obesity. It is typically the psychologist on the treatment team who suggests or implements behavioral techniques, although these tools may be useful in all components of treatment. The six principles used in behavior modification typically include self-monitoring, stimulus control, contingency management, stress management, cognitive restructuring, and social support.

Self-monitoring is the detailed, daily recording of food intake (or other behaviors) and the circumstances under which the behavior occurs. Food and exercise diaries (**Figure 1**) are used to assess the patient's eating and activity habits, to increase the patient's awareness of his or her own behavior, and to promote positive behavior change. Patients may be encouraged to record time of eating episodes, type and amount of food eaten, feelings of hunger and satiety, place, context, and/or comments (such as, 'Out with friends at happy hour' or 'Not hungry but feeling deprived'). These records are reviewed in treatment sessions, so that specific feedback can be provided to the patient. Research has consistently demonstrated that self-monitoring is associated with improved treatment outcomes, and patients often report that it is one of the most helpful obesity management tools.

Stimulus control involves identifying the environmental cues associated with unhealthy eating and inactivity. Modifying these cues involves strategies such as only eating at the kitchen table and not in front of the television; keeping tempting, high-calorie foods out of the house (or at least, out of sight); and laying out exercise clothes the night before as a reminder to exercise in the morning. Research has suggested that obese individuals are more strongly influenced by external cues to eating than are nonobese people. Therefore, modifying or eliminating these external cues can reduce eating in response to them. For this reason, patients are encouraged to 'turn off all distractions' while eating, in order to reduce environmental and behavioral cues to eating, such as watching television, reading the newspaper, or driving.

Contingency management is the use of rewards for appropriate behavior changes, such as increasing frequency of exercise or reducing intake of fast foods. The rewards can be granted by the patient, the patient's family, and/or the weight management center; however, rewards must be of value and reinforcing to the patient in order to be effective. At some weight-loss programs, patients can earn monetary 'vouchers' towards treatment sessions and products for regular attendance and compliance with treatment recommendations.

Stress management involves the use of problem-solving strategies to reduce or cope with stressful events. Meditation, relaxation procedures, and regular exercise are effective techniques to reduce feelings of stress. However, stress management also involves helping the patient understand the cause(s) of his/her stress in order to make the necessary life or environmental changes to prevent ongoing, chronic stress, which can interfere with weight-loss efforts or exacerbate the weight problem.

SELF-MONITORING RECORD

Daily Fat Intake = _____

Physical Activity

Time	Activity	Duration
	no time today!	

Figure 1 Example of a self-monitoring record.

Cognitive restructuring techniques are used to identify and modify a patient's dysfunctional attitudes and beliefs about weight regulation and body image. Examples include the use of affirmations (such as positive self-statements) and visual imagery (such as seeing oneself eating and exercising appropriately or visualizing a realistic body size). Many overweight patients adopt 'all or none' or dichotomous thinking patterns, which need to be combated with more flexible thoughts such as, 'Even though I ate two donuts this morning, the day is not ruined, and I will recommit to sticking to my diet plan, starting now!'

The final behavioral principle is social support. Such support, usually from the patient's family or a support group, is used to maintain motivation and provide reinforcement for appropriate behavior changes. Facilitated support groups are often an integral part of comprehensive weight-loss treatment for these reasons, and they further serve to 'normalize' the ups and downs of the treatment process.

These six behavioral principles are immensely useful in helping patients adhere to a healthy diet and exercise program. However, behavior modification alone may not be enough to address all of the psychological complexities of obesity and associated eating problems. Many patients seeking weight-loss treatment are clinically depressed in addition to being obese. For patients who are introspective and amenable to therapy, psychotherapy may be

recommended, either as part of their weight-loss program or with a therapist outside the program. Depressed patients who are not interested in psychotherapy, cannot afford it, or are severely depressed may be prescribed an antidepressant by the physician on the treatment team or referred to a psychiatrist. Although depressive symptoms often improve with weight loss, adherence to treatment may be easier if the patient is not actively depressed. Individual or group psychotherapy may also be beneficial to address other issues related to obesity, such as low self-esteem, body image, and relationship problems. Binge eating or other eating disorders often coexist with obesity and may require separate treatment by a specialist.

Nutritional management Nutritional management of obesity entails an individualized approach, based on the dietary assessment, within a multidisciplinary setting whenever possible. Diet prescription for weight management involves a caloric deficit to promote weight reduction. For patients with mild to moderate obesity, a caloric deficit of at most 500–750 calories per day is recommended to promote a 0.5–0.7 kg weight loss per week. A low-calorie, individualized food-based diet that is either balance-deficit (reducing the total number of calories while keeping proportions from carbohydrate, fat, and protein basically the same as before) or a fat-deficit diet, with most of the caloric reduction resulting from restriction of fat, can be prescribed. The latter approach is preferable for Americans, whose typical diet is too high in fat. Also, a greater volume of food can be eaten on a diet that emphasizes complex carbohydrates and reduces fat intake to 20–25% of calories consumed. In either case, the focus of a calorie- reduced food-based plan should be on nutritional balance, with calories distributed appropriately among carbohydrates, protein, and fat, based on recommendations outlined in the US Department of Agriculture Dietary Guidelines for Americans or similar World Health Organization guidelines.

The diet must be realistic – that is, based on dietary modification and practical changes in eating habits. Nutritional recommendations should be determined by the patient's current eating habits, lifestyle, ethnicity and culture, other coexisting medical conditions, and potential nutrient–drug interactions. The patient should be advised to drink at least 1.5–2.0 l of water daily, unless contraindicated, e.g., by congestive heart failure, edema, or renal insufficiency. Patients should also be encouraged by the dietitian to self-monitor their food intake, which may include measuring portion sizes and recording and calculating calories, fat grams, and/or carbohydrate grams. If energy intake is prescribed below 1200 calories per day, daily supplementation is usually indicated to ensure adequate vitamin and mineral intake.

Suggesting gradual changes is helpful in altering diet composition. Depending on the initial quality of the patient's diet, the dietitian may focus on revamping one meal at a time, so as not to overwhelm the patient. For example, if a patient's usual breakfast consists of biscuits with gravy, bacon, and sausage from a fast-food restaurant, an alternative of home-prepared oatmeal, yogurt, and fruit may be suggested. Once the patient has incorporated this change, the dietitian may then move on to improving the lunch meal. It is better to recommend dietary changes that are feasible (and achievable) for a patient, rather than prescribing a diet that the patient will reject or not be able to follow. Similarly, reducing the fat content of milk or meats in stages (e.g., 2% to 1% to skim milk) gives the patient a chance to adjust to the new taste before further reducing to a lower-fat version.

Exercise treatment Although regular, moderate physical activity alone results in limited weight loss over the long term, it is an essential and high-priority component of any weight management program. Regular physical activity is thought to be the most important predictor of long-term weight maintenance. Research has shown that patients who diet and exercise regularly are much more likely to maintain weight loss than those treated with diet alone. When performed in conjunction with caloric restriction, regular, moderate physical activity achieves the following effects: increases 24-h energy expenditure; maintains (or minimizes loss of) lean body mass; reduces cardiovascular risk by producing beneficial changes in the lipid profile; has positive psychological effects; improves insulin sensitivity; and may provide other health benefits independent of weight loss.

In determining an appropriate, individualized exercise program, the exercise physiologist and the patient together should consider a plan that: (1) fitsinto the patient's schedule and lifestyle; (2) considers the patient's likes/dislikes; (3) makes use of the patient's resources; and (4) is based on the patient's current level of fitness. The exercise physiologist should ensure that, before beginning a fitness program, all patients can recognize and dealwith abnormal physical responses to physical activity.

Eventually, the exercise goal of any weight management program should be 30–60 min of continuous, moderate-intensity physical activity five to seven times per week. Until a patient can tolerate

30 min of continuous activity, several 10-min periods of physical activity throughout the day can help build the patient's endurance while still burning calories. Additionally, short exercise and rest intervals can be alternated. The intensity, duration, and frequency of activity should be progressively increased, according to the patient's increasing ability. Patients should be encouraged to self-monitor their daily physical activities, including type of activity, time performed, and duration, so that progress can be appreciated and the goal reset a bit higher from time to time. The exercise physiologist may serve as a personal exercise trainer for those who desire additional motivation and accountability.

Popular Weight-Loss Approaches

Many overweight and obese individuals do not seek or have access to the type of multidisciplinary treatment described above, so instead, they turn to popular or fad diets, commercial weight-loss programs, and/or self-help groups. These three types of approaches will be briefly reviewed in the following section.

Popular Diets

Numerous commercially advertised diets are available to consumers today that promise quick results and a 'magic bullet' approach to weight reduction. We believe that it is best to be skeptical, and instill such skepticism in overweight individuals, about diets that are not part of a comprehensive approach to weight management. Many popular diets are based on very limited menus, because monotony may help curtail consumption. Any severely reduced-calorie diet will initially cause diuresis, which makes the diet seem efficacious at first. This diuresis usually results in approximately 2–4% loss of body weight during the first 7–10 days, although most of this weight will be regained when the period of severe caloric restriction ends.

Many popular diets are based on the dieter counting and limiting calories or some other constituent (such as fat, sugar, carbohydrates), with the end result that energy intake is decreased. Another type of popular diet is a fixed-energy-level diet, which limits intake by controlling portion sizes, menu choice, and composition. Popular diets of this type include prepackaged and portion-controlled foods available in supermarkets or from commercial and nonprofit weight management programs. Other popular diets may use an energy-deficit approach (described previously) or prescribe moderate hypocaloric plans, such as 1800 calories per day for men and 1200 calories for women.

A current trend in the USA is that of high-protein, low-carbohydrate plans, such as the Atkins diet, Sugar Busters, and the Carbohydrate-Lover's diet (to name a few). These diets are not nutritionally balanced and have not been scientifically demonstrated to be effective or healthful in the long term. They promote the metabolic state of ketosis, resulting in a large initial diuresis, as described above, which will be reversed once carbohydrates are reintroduced into the diet.

Commercial and Self-Help Approaches

Self-help and commercial groups have the potential to offer the personal involvement and comprehensive approach needed to promote behavior changes in complex problems such as obesity. This potential, combined with the large numbers of people who can be reached, make these groups the most influential approaches to weight management currently available. On the negative side, these groups often generate expectations greater than can be reasonably achieved, sometimes through misleading advertising. In addition, evaluations and outcome statistics of these programs (if existing) have not been made public.

Commercial programs Many commercial (for-profit) programs provide information on dieting and nutrition and may include elements of physical activity, behavioral techniques, the provision of food, and group support. In the USA, we have seen the recent emergence of local, commercial weight-loss centers, run by physicians, in which the primary treatment is medication that is either prescribed or dispensed at the center. Often, preprinted diet plans are given to patients with limited, if any, nutritional or behavioral counseling.

Self-help groups Self-help groups gather people with weight and/or eating problems and operate at little or no cost, generally without professional intervention. These groups offer considerable social support but vary in their philosophy. A group such as TOPS (Take Off Pounds Sensibly) includes more behavioral principles, whereas Overeaters Anonymous is based on the 12-Step model used in addiction programs and focuses on 'compulsive overeating' as the core problem.

Lack of evaluation It is striking how little is known about the effectiveness of commercial and self-help approaches. A few scattered papers have been published on such groups, but the focus has been on attrition rates rather than on the weight

loss and maintenance of the participants. It is possible that the lack of evaluation is due to problems with confidentiality in the self-help groups and with protecting the financial interests of the commercial programs. The closed atmosphere that now surrounds these programs will probably remain so unless regulatory action forces a scrutiny of treatment results.

In light of the lack of evaluation of commercial and self-help programs, and the similar lack of research on the safety of many popular diets, we recommend that all self-initiated weight loss attempts be approved and monitored by the individual's primary physician or an expert in weight management, if the primary physician is not trained or experienced in this area.

Aggressive Approaches to Weight Loss

More aggressive weight management approaches are available under medical supervision and are appropriate for individuals who are severely overweight (generally BMI $\geq$ 35) and/or those with serious medical conditions related to their obesity. Obese patients who have failed multiple weight reduction attempts through traditional programs may also be considered for aggressive strategies. Examples of aggressive approaches include supervised VLCDs, pharmacologic treatment, and surgery.

Very-Low-Calorie-Diets

A medically supervised VLCD (fewer than 800 calories per day) may consist of food, commercially available liquid supplements, or a combination of the two. The first incarnation of these diets was in the form of egg- or milk-based protein combined with water. The use of these severely calorie-restricted diets in medically unsupervised individuals led to at least 58 highly publicized deaths, often resulting from electrolyte imbalances and sudden cardiac death. However, with experience and careful patient selection and monitoring, VLCDs have evolved into comparatively safe weight-loss techniques. It is recommended that patients being considered for VLCDs undergo a comprehensive medical examination and an ECG. Absolute contraindications include the presence of untreated or severe cardiac, hepatic, renal, or thromboembolic disease; type 1 diabetes; cancer; and eating disorders. Weekly medical supervision is recommended while on the VLCD. With full adherence, weight loss averages 1.1–1.8 kg per week, depending on body mass and physical activity level. The initial diuretic phase may be pronounced and accompanied by symptoms such as lightheadedness, headache, or fatigue. Later symptoms may include constipation and cold intolerance. The diet period is followed by progressive refeeding. Throughout the course of dieting, education on nutrition, exercise, and behavior modification will help the patient maintain his/her weight loss during and beyond the refeeding phase. For this reason, multidisciplinary treatment is strongly recommended in combination with the VLCD. Without this education and support, weight gain will likely occur almost as rapidly as weight loss.

Pharmacologic Treatment

Adjuvant anorectic medications may be useful in select obese patients (BMI $\geq$ 30 or BMI = 27–29 with at least one major comorbidity) who have been unsuccessful in previous coordinated weight-loss efforts. Commonly used medications in the treatment of obesity are listed in Table 1. Among the safest and most effective medications currently available are phentermine and sibutramine, both centrally active appetite suppressants.

Phentermine is thought to increase the release and inhibit the reuptake of norepinephrine (noradrenaline) and dopamine from nerve terminals in the brain, thereby suppressing feelings of hunger. The Food and Drug Administration (FDA) has approved phentermine for short-term use (that is, a few weeks to 3 months). Sibutramine, a serotonin and norepinephrine reuptake inhibitor, appears to decrease food intake and may increase energy expenditure as well. Sibutramine has been approved for use for up to 1 year, to aid in weight loss or maintenance of weight loss.

An entirely different mechanism of action is employed by the recently FDA-approved agent, orlistat tetrahydrolipstatin. Orlistat is an inhibitor of pancreatic lipase; thus, it blocks absorption of fat, resulting in about 30% of ingested fat being

Table 1 Medications currently used for treatment of obesity and example trade names

Centrally acting anorexic agents
Phentermine (Fastin, Adipex-P, Ionamin)
Sibutramine (Meridia)
Mazindol (Mazanor, Sanorex)
Diethylpropion HCl (Tenuate)
Phenylpropanolamine (Dexatrim, Acutrim, decongestants)
Ephedrine (decongestants, herbal weight-loss supplements)
Locally acting agents
Orlistat tetrahydrolipstatin (Xenical)

HCl, hydrochloride.

excreted in the stools, with predictable side-effects. Its efficacy in weight loss is probably not only due to the decreased absorption of calories, but also to the Antabuse-like effect when a high-fat eating episode occurs. Orlistat is to be used in obese adults three times per day before meals and has been shown in studies of up to 2 years' duration to improve weight loss and maintenance. Because the malabsorption of fat induced by orlistat also causes malabsorption of fat-soluble vitamins, use of a vitamin supplement is recommended.

Incremental weight loss in controlled trials of anorexic agents tends to be in the range of 0.2 kg per week greater than placebo. This is a definite benefit, but the risks of drug therapy (as illustrated by the fen-phen controversy) must be carefully balanced against the benefits. There is the potential for medications to be prescribed inappropriately, to individuals who do not meet criteria for use or beyond the duration of continued efficacy. Physiologic or behavioral tolerance to these medications, resulting in decreased effects, may occur over time, and some are not recommended, and have not been studied, for longer than 3 months. At best, antiobesity agents may provide certain obese patients with a 'jump-start' to weight loss, or they may be used to improve dietary adherence during a particularly difficult time in the course of treatment.

Surgery

Surgical treatment of obesity may be considered only in carefully selected patients who meet the following criteria: (1) a very high medical risk exists (BMI ≥ 40 or BMI $= 35$–39 with life-threatening or disabling comorbidities); (2) obesity has been present for at least 5 years; (3) no history of or current untreated alcoholism, drug abuse, or major psychiatric disorder is noted; and (4) the patient is between 18 and 65 years of age. In addition, patients should have failed previous attempts at medically supervised weight reduction and should have realistic expectations about the long-term outcome achievable with surgery. A multidisciplinary team approach to screening patients preoperatively, including evaluation with the surgeon, a dietitian, a psychologist, and the patient's primary physician, is critical to the patient's long-term success.

Two proven surgical options are available for the treatment of morbid obesity: purely restrictive operations such as the vertical banded gastroplasty (gastric stapling), and gastric bypass operations such as the Roux-en-Y gastric bypass. These procedures primarily involve either the mechanical restriction of caloric intake by creating a small gastric reservoir, or the induction of malabsorption by bypassing variable lengths of the small intestine. The vertical banded gastroplasty (Figure 2) achieves weight loss by creating a small pouch with a narrowed outlet in the stomach by using a band of synthetic material. With the gastric bypass procedure (Figure 3), a small pouch is created of 20–30 ml, which limits oral intake, and a moderate degree of malabsorption is created by a Roux-en-Y loop of bowel anastomosed to this small gastric remnant.

The Roux-en-Y gastric bypass produces more substantial weight loss than vertical banded gastroplasty and may have longer-lasting effects. The gastric bypass results in weight loss averaging 50–60% of excess body weight, with good weight control documented for up to 10 years. This procedure is not without risks, including post surgical complications, food intolerance, nutritional deficiencies, extreme psychiatric distress, and even death. However, in the majority of patients, obesity-related comorbidities, such as diabetes and hypertension, are either reversed or prevented after obesity surgery, as long as weight loss is maintained.

Maintenance of Weight Loss

Maintaining weight loss seems to be inherently more difficult than losing weight, particularly for

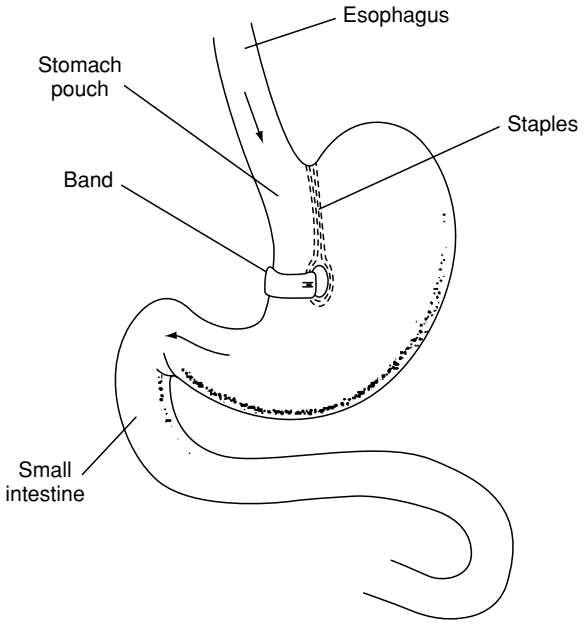

Figure 2 Vertical banded gastroplasty. A vertical staple line reduces the size and accommodation of the stomach. Mesh banding of the distal portion of the newly created gastric pouch slows the exit of food, leading to early satiety. individuals who used or were treated with caloric restriction. Unfortunately, the long-term success rate for all weight-loss methods (excluding surgery), defined as losing weight and keeping the majority of it off for at least 5 years, is low – perhaps 5–15%. Even after the most state-of-the-art, medically monitored comprehensive treatment, it is likely that patients will gradually return to their baseline weight within 3–5 years after treatment termination. Given this very high relapse rate, obesity can be considered a chronic condition, much like cigarette smoking or other substance abuse. As such, only the continuous-care model of management, which views obesity as a chronic disease requiring continuous support or contact after the end of formal treatment, has been found to produce significant maintenance of weight loss.

It is probable that some form of continuous or punctuated long-term care will be necessary for many (if not all) obese patients to maintain the dietary and lifestyle changes that produced their weight loss. With ongoing support from a physician or other health care providers, patients will be better able to maintain their changes in eating and activity behavior and the resultant weight loss. Regrettably, optimal strategies for weight maintenance are in a state of evolution and represent the key limitation of our current treatment of this highly prevalent, medically hazardous, and chronic condition. Research has identified continued program contact (e.g. monthly), regular physical activity, nutritional sophistication, and self-monitoring as four predictors of weight maintenance. It not surprising that the strategies helpful in promoting weight loss, such as self-monitoring, physical activity, regular weigh-ins, and attendance at a multidisciplinary program, will be the same strategies necessary for long-term maintenance of weight loss.

Epidemiology

N E Sherwood and M Story, University of Minnesota, Minneapolis, MN, USA

Introduction

Obesity is a major public health problem in the USA. The dramatic increase in the prevalence of obesity over the last few decades has raised concerns about associated health risks for children, adolescents, and adults. Obesity is considered the second leading cause of preventable death in the USA. Recent data suggest that the estimated number of annual deaths in the USA due to obesity approaches 300 000. A continuation of current trends could lead to further increases in the number of people affected by obesity-related health conditions and premature mortality. Prominent among the health risks associated with obesity are hypertension, type 2 diabetes mellitus, dyslipidemia, stroke, gallbladder disease, osteoarthritis, sleep apnea, respiratory problems, and certain cancers (e.g., endometrial, breast, prostate, and colon). Obesity is also associated with psychosocial problems such as binge-eating disorder and depression. Furthermore, individuals who are obese are adversely impacted by social bias and discrimination.

As the prevalence of obesity has been rising, the economic burden of obesity has been a topic of considerable discussion. The economic costs of obesity have been categorized into three areas, the cost to individuals because of the impact of obesity on health, costs to society due to lost productivity and premature mortality associated with obesity, and costs to individuals and service providers in treating obesity. Recent estimates suggest that obesity-related mortality may account for 7% of US health care costs. Medical care costs alone attributable to obesity in the US were estimated to toal almost $46 billion in 1990. Although no study to date has taken into account the entire range of costs associated with obesity, estimates of the economic burden are as high as $100 billion per year.

Monitoring the prevalence of obesity and associated health behaviors is critical for understanding and documenting the scope of the problem. The goal of this chapter is to review definitions of overweight and obesity in adults and children, present available data regarding the epidemiology of obesity and related risk factors, and discuss implications for future public health research and intervention.

Definitions of Overweight and Obesity

The terms obesity and overweight are often used interchangeably, but they are distinct conditions. Obesity refers to excess adipose tissue, whereas overweight refers to excess weight for height. Because it is difficult to obtain direct measures of obesity and since body weight tends to be highly correlated with adiposity, weight-for-height measures are generally used to classify overweight and obesity in adults and youths.

Adults

Definitions of obesity and overweight have varied over time and in different countries. In the USA, many studies have used the 1959 or 1983 Metropolitan Life Insurance tables of desirable weights for heights and defined overweight as a weight exceeding the midpoint of these standards by a certain percentage. In 1985, a NIH Consensus Conference endorsed the use of body mass index (BMI; $kg\,m^{-2}$) and adopted the 85th percentile of BMI from the second National Health and Nutrition Examination Survey (NHANES II) as the standard for defining overweight. The 85th percentile corresponded well to approximately 20% overweight according the 1983 Metropolitan Life tables. Using this standard, overweight was defined as BMI ≥ 27.8 for men and ≥ 27.3 for women. In 1995, a World Health Organization (WHO) expert committee recommended an alternative classification system for overweight and obesity; overweight was defined as a BMI of 25–29.9 $kg\,m^{-2}$ and obesity as a BMI $\geq 30\,kg\,m^{-2}$. Although the previous definition of overweight in the US used a cut-off of about 27 $kg\,m^{-2}$, epidemiological data show increases in mortality with BMIs above 25 $kg\,m^{-2}$. The category of obesity is further subdivided into three classes: obese class I (BMI 30–34.9), obese class II (BMI 35.0–39.9), and obese class III (BMI ≥ 40).

BMI has been accepted by numerous groups as the most practical and valid screening tool for assessing weight status in individuals and the most useful population-level measure of overweight and obesity. BMI provides meaningful prevalence estimates within and between populations and is useful for identifying individuals and groups at increased health risk and for evaluating the efficacy of obesity interventions. However, it is important to recognize that BMI does not provide information on body fat or body-fat distribution. Body-fat distribution has been identified as an independent predictor of health risk. Individuals with excess abdominal fat are at increased risk of negative health consequences of obesity. In adults,

the waist-to-hip ratio, or waist circumference, is often used as a marker of intraabdominal adipose tissue.

Children and Adolescents

Defining overweight or obesity in children and adolescents is complicated by the normal processes of growth, pubertal development, and body-composition changes. No standard definition exists for child or adolescent obesity. Classifications that have been used include weight-for-height percentiles, relative weight, percent of ideal body weight, skinfold measures, and BMI. BMI is currently the most accepted and widely used measure. For adults, BMI criteria have been based on mortality or mortality outcome research, but no risk-based criteria have been established for youths, as it is difficult to link youth weight status to chronic disease outcomes. Adult BMI criteria also utilize a single cut-off value for both sexes and all ages, which is inappropriate for children and adolescents who are experiencing growth and body-composition changes. Because BMI changes dramatically with age during childhood and adolescence, BMI needs to be assessed using age-specific reference curves. Gender-specific values are also needed for adolescents because of differences in body composition and timing of puberty. During puberty, males increase their lean body mass and decrease the amount of body fat, whereas girls experience rapid fat accretion.

The release of the revised National Center for Health Statistics (NCHS) and the Centers for Disease Control (CDC) growth charts incorporating smoothed gender- and age-specific BMI percentiles based on data from National Health Examination Survey (NHES) and NHANES will provide a useful reference for describing weight status in children and adolescents. It has been suggested by US expert panels that for clinical evaluation of obesity and epidemiologic application, overweight in youths should be defined as a BMI greater than the 95th percentile for age using national reference population data. Youths between the 85th and 95th percentile are considered at risk of becoming overweight.

Prevalence of Obesity: National Trends

Adults

Comprehensive data of trends in the prevalence of obesity provided by national surveys (NHES I (1960–1962); NHANES I (1971–1974); NHANES II (1976–1980); NHANES III (1988–1994)) show that the percentage of obese persons has increased over time. Although there was a small increase in the estimated prevalence of obesity across the first three periods (1960–1980), a much larger increase was observed between the third and the fourth surveys. The percentage of individuals classified as obese increased from 15% in NHANESII to 23% in NHANES III. An additional 33% of US adults in NHANES III were classified as overweight according to the BMI > 25.0 standard. According to these data, an estimated 97.1 million adults (55% of US adults) are classified as overweight.

Data from the Behavioral Risk Factor Surveillance System (BRFSS) also show that the prevalence of obesity has increased in recent years. The BRFSS is a cross-sectional telephone survey of noninstitutionalized adults aged 18 and older conducted by the Centers for Disease Control and Prevention and state health departments. Data from the BRFSS indicate that the prevalence of obesity increased from 12% in 1991 to 18% in 1998. The prevalence of obesity increased across both genders, all socio-demographic groups and in all states. These data are derived from self-reports of individuals; therefore, true rates of overweight and obesity are likely underestimated since individuals tend to underreport their body weight.

Children and Adolescents

Regardless of the method used to classify overweight or obesity, studies have shown high prevalence estimates among children and adolescents, and that rates have increased dramatically since the mid-1960s and continue to rise. NHANES data indicate that the prevalence of overweight (BMI at or above the 95th percentile) among youths doubled from 1976–1980 to 1988–1994, increasing from 8 to 14% for 6–11 year olds and from 6 to 12% for 12–17 year olds. Currently, about 11% of US children and adolescents are overweight, and an additional 14% have a BMI between the 85th and 95th percentiles, indicating that they are at risk for becoming overweight.

Gender Differences in Obesity

Data suggest that the prevalence of obesity is increasing across all populations in the USA, but epidemiological data show that certain subgroups of individuals are at a particularly high risk of obesity. Although the prevalence of obesity has increased over time in both men and women, the prevalence of overweight has remained relatively stable. Data show that men have higher rates of overweight compared with women, but women have higher rates of obesity than men. A major contributor to the high rates of obesity in US adults is weight gain with age. About two-thirds of obese adults became obese in adulthood. Between the ages of 20 and 50 years, weight gain tends to

occur at a rate of 0.45–0.91 kg per year, and major weight gain is most likely to occur between the ages of 25 and 34 among both men and women. Prospective epidemiological data also show that women in the US appear to be at twice the risk of major weight gain as men. The prevalence of overweight and obesity increases with age across both sexes, peaking around the 50–59-year-old age range. After age 70, the prevalence of obesity is lower in adult men and women. This lower prevalence may be due to both obesity-related mortality and decreases in BMI with age.

Among children and adolescents, national data show few gender differences in obesity rates. Males tend to have slightly higher rates of overweight compared with females (e.g., 15% for males compared with 14% for females).

Racial/Ethnic Differences in Obesity

Significant racial/ethnic differences in the prevalence of overweight and obesity have also been observed. The most recent NHANES III data show that among women, African American and Hispanic women are at highest risk, with about two-thirds of women in these ethnic groups meeting BMI criteria for overweight or obesity. Ethnic specific data from studies such as Hispanic HANES (HHANES), which includes Mexican Americans, Cuban Americans, and Puerto Rican Americans, and smaller studies of American Indians and Alaskan Natives, show high rates of overweight and obesity in these populations. In contrast, ethnic-specific data show that Asian American women have the lowest rates of overweight and obesity. Among men, fewer ethnic differences in overweight and obesity have been observed. According to NHANES III data, Hispanic men are at highest risk of overweight and obesity compared with non-Hispanic white men and African American men. According to data from the BRFSS, the prevalence of obesity in Hispanic men almost doubled over the last decade (10% in 1991; 18% in 1997). Data from smaller studies of American Indian and Alaskan Native men also show elevated rates of overweight and obesity compared with all-race data in US men.

As with adults, differences in overweight prevalence by race and ethnicity have been observed among children and adolescents. In NHANES III, the overweight prevalence among youths was considerably higher for male and female Hispanics, and African American girls compared with whites. For example, among 6–11 year olds, 16% of black girls, 14% of Hispanic girls, and 9% of white girls were overweight. Among males aged 6–11, 17% of Hispanic boys were overweight, compared with 10% of white and 12% of black boys. Other studies have shown excessively high prevalence estimates of obesity in American Indian youth. A recent survey of over 12 000 American Indian youths aged 5–17 years of age in the Northern Plains area found that 22% of the males and 18% of the females were overweight (BMI > 95th percentile).

Socio-economic Differences in Obesity

An inverse relationship between socio-economic status and obesity has been observed in the USA and is particularly pronounced for women. Data from NHANES III show that collapsing across all races, women with lower incomes are more likely to be overweight or obese compared with those with higher incomes. Examination of NHANES III all-race data for men shows that the prevalence of overweight does not vary across income groups. The relationship between socio-economic status and obesity, however, appears to vary across ethnic groups and according to gender. There is a strong inverse relationship between income and weight status among nonHispanic White women and a moderate inverse relationship between income and weight status among Hispanic American women. However, among African American women, weight status and income are only weakly associated. A similar trend has been observed in other studies. Although nonHispanic white men did not show any difference in weight status across income groups, examination of similar data in men shows that there is a positive relationship between income and obesity for Hispanic American and African American men.

Compared with adults, studies with children have shown a weak and less consistent relationship between SES and overweight. In NHANES III data, there was an inverse relationship between SES and overweight only for white adolescents. Overweight prevalence was not related to family income in African American or Hispanic youths.

Persistence of Childhood Obesity

Whether childhood-onset obesity leads to an increased likelihood of obesity in later life is an important issue with clinical implications. The likelihood of persistence of obesity from childhood to adulthood is related to the degree and duration of obesity, family adiposity, and age of the child. The likelihood of an overweight infant becoming an overweight adolescent or adult is small. Less than 15% of overweight infants and only about 25% of overweight preschool children will remain overweight into adulthood. Obesity is more likely to persist if it is present during the adolescent years. In general, the later into adolescence overweight persists, the severity of the obesity

and the presence of parental obesity increase the likelihood that obesity will persist in adulthood. A recent Washington state study tracked 850 infants over 21–29 years and found that among obese 6 years olds, about 50% remained obese. By the age of 10–14 years, 80% of obese children with at least one obese parent remained obese.

Global Trends in Obesity

Both childhood and adult obesity are becoming global concerns. Other industrialized countries such as England, Singapore, Japan, Canada, and Australia are also experiencing increasing rates of obesity in both adults and children. Similar to data from the US, women from other countries tend to have higher rates of obesity compared with men, although men may have higher rates of overweight. The WHO reports that the prevalence of obesity is also increasing in countries undergoing economic transition and in developing countries where obesity coexists with undernutrition.

Risk Factors for Obesity in Adults and Children

It is widely accepted that overweight and obesity are multidetermined chronic problems resulting from complex interactions between genes and environments characterized by energy imbalance due to sedentary lifestyles and ready access to a wide variety of foods. Research suggests obesity runs in families and that some individuals are more vulnerable than others to gaining weight and becoming obese. Researchers also agree that there is no single gene that causes obesity, but that multiple genes and gene mutations associated with weight gain are involved. Various mechanisms through which genetic susceptibility to weight gain have been proposed including a low resting metabolic rate, low level of lipid oxidation rate, low fat-free mass, and poor appetite control. Although genetic research is a promising approach for understanding the development of obesity and identifying those at risk for obesity, it should be noted that the rapid increases in rates of obesity and overweight that have been observed have occurred over too brief a time period for there to have been significant genetic changes in the population. Therefore, the following sections briefly review environmental factors associated with the obesity epidemic.

Environmental Influences: Dietary Intake

Increased population levels of energy intake is a likely contributor to the epidemic of obesity. However, research on trends in energy intake over the time period in which the prevalence of obesity has increased has not consistently supported this hypothesis. Data from national surveys show a decrease in energy intake over time, whereas, nutrient intake data from NHANES III show an increase in energy intake over time. A recent review of ecological data regarding the amounts and types of food available in the USA during the past two decades provides interesting data that may shed light on some of the discrepancies found in previous survey data. Specifically, although the availability and purchasing of reduced fat and reduced energy foods has increased over the past few decades, people are eating more meals away from home, eating larger portions, and consuming more convenience foods. These behaviors are more conducive to higher energy intakes and may be contributing to the increased prevalence of obesity.

Environmental Influences: Physical Activity

Low levels of energy expenditure are increasingly recognized as important contributors to obesity and related health conditions. An abundance of cross-sectional research shows that heavier individuals are less active than lighter individuals, and prospective research indicates that changes in physical activity level are associated with changes in body weight in the direction predicted by the energy balance equation. The past century has produced dramatic changes in physical activity patterns in the USA. Machines and labor-saving devices have become so commonplace that the energy expenditure now required for daily life is a fraction of what it was a generation or two ago. Voluntary or leisure-time physical activity has thus assumed central importance in meeting physical-activity requirements. Unfortunately, voluntary physical activity is not very popular. Less than 25% of all adults, adolescents, and children report that they engage in regular physical activity (i.e., a minimum of 30 min of moderate to vigorous activity on most days of the week), the activity level most recently recommended by health experts. The prevalence of regular physical activity also varies according to demographic characteristics. Decreases in physical activity are observed during adolescence, with the decline particularly pronounced among girls. Women are less physically active than men, older adults are less active than younger adults, and African American and Hispanic adults are less active than whites. A lower socio-economic status is also associated with lower levels of physical activity.

Although low levels of leisure-time physical activity likely contribute to the epidemic of obesity, it is

noteworthy that among adults, leisure-time activity has remained stable or increased since the mid-1980s, the time period during which the prevalence of obesity increased. Given this paradoxical finding, it is likely that increases in sedentary activities such as television watching and computer use and decreases in lifestyle, household, and occupational activity that have been less carefully measured have contributed to reductions in overall energy expenditure at the population level. Data from the Americans' Use of Time study show that the amount of free time spent watching television increased from about 4 h per week in 1965 to about 15 h in 1985. Documenting the prevalence of sedentary behavior among children and adults and targeting the reduction of sedentary activity as a health-behavior goal have received considerable attention in recent years.

Future Directions

Understanding and addressing the epidemic of obesity has become a global public-health priority. A recent 1997 WHO report on obesity, entitled 'Obesity: Preventing and Managing the global Epidemic,' noted that overweight and obesity represent a rapidly growing threat to the health of populations world-wide. Both children and adults in developing and developed countries are affected. The report concluded that the spectrum of problems seen across the world is of such magnitude that obesity should be regarded as the principally neglected public-health problem.

The recently released goals of Healthy People 2010 are to reduce the prevalence of obesity among adults from 23 to 15% and to reduce the prevalence of obesity among children and adolescents from 11 to 5%. The etiology of obesity is complex and encompasses a wide variety of social, behavioral, cultural, environmental, physiological, and genetic factors. To achieve these ambitious goals, considerable effort must be focused on helping individuals at the population level modify their diets and increase their physical activity levels, key behaviors involved in the regulation of body weight. A challenge to public-health professionals is to develop educational and environmental interventions that support diet and exercise patterns associated with a healthy body weight. Prevention of obesity should begin early in life and involve the development and maintenance of healthy eating and physical activity patterns. These patterns need to be reinforced at home, in schools, and throughout the community. Communities, government, health organizations, the media, and the food and health industry must form alliances if we are to combat obesity.

A coherent and standard international system for classifying overweight and obesity in children and adults is also needed. The WHO and US agencies recommend using BMI for adults, with BMI ≥ 25 denoting 'overweight' and BMI > 30 denoting 'obesity.' Criteria and methods for assessing and documenting obesity in children and adolescents need to be similarly developed. A common international standard would allow meaningful comparisons of obesity within and across populations and document obesity trends over time.

OFFAL

Types of Offal

W F Spooncer, CSIRO, University of Western Sydney, Richmond, NSW, Australia

Introduction

Offals are all the noncarcass parts of slaughtered animals with the exception of hide and skin. Most offals have the potential to be used as human food but this potential can only be realized if the offals are collected hygienically, inspected, and passed fit for human consumption, then cleaned and prepared in an appropriate manner. Offals which are not collected for human use, either because there is no demand for them, or because they are diseased or contaminated, are inedible offals. Inedible offals are either destroyed by burning or burying, rendered to produce tallow and meat meal or, if suitable, used as pet food. (*See* **Meat**: Slaughter.)

Definition of Offals

Because of the variety of different types of offals, both edible and inedible, some attempts have been made to group offals together in categories. Many texts refer to offal as being derived from the 'off fall' from carcass preparation. Some of this 'off fall' may be attractive as edible product while some of it may not be edible at all. To avoid the connotation that offals include unattractive and inedible material, the terms 'variety meats' and 'fancy meats' have been introduced as categories of offals which are edible and prepared and consumed in a recognizable form. Variety meats and fancy meats are items such as heart, tongue, kidney, sweetbread, liver, brain, tail, and tripe. In the USA, where the term variety meat is common, products which are not consumed in a recognizable form but could be used in processed meats are referred to as offal meat. Examples of offal meat are lungs, spleen, udders, and head meat. In this case the word 'offal' is reserved for inedible material.

Other ways in which offals are categorized include the distinction between white and red offals, and between organ offal and muscle offal.

The categories of white and red offal are used to distinguish stomach and intestinal offals from all other offals. This distinction is made because white offals require careful cleaning and preparation to remove intestinal and stomach contents before they can be used as edible material. Intestinal offal should be cleaned in an area separated from the preparation of other offals and carcass meat. Separate facilities for handling white and red offals minimize the chance of red offal being contaminated by intestinal contents.

The distinction between offals which are mainly organ tissue and those which are muscular tissue is made because of the difference in the potential keeping quality of the two types of offals. Organ offals, such as liver, kidney, lungs, spleen, and brain, are not as stable as muscular offals, such as tail, tongue, and diaphragm. In chilled storage, physiological activity in organ tissues can result in deterioration of the flavor and texture. (*See* **Meat**: Preservation.)

Specific Offals

Table 1 lists the items of offal available from slaughtered animals, alternative names, and possible

categorization of the offals. Table 2 lists typical weights of offals from different carcass types. (*See* **Beef**; **Pork**; **Poultry**: Chicken; Ducks and Geese; Turkey.)

According to American surveys, the more popular offals are liver, pigs' feet, oxtail, heart, tongue, pork maw (stomach), brains, sweetbread, tripe, and kidney. These offal items are described below. Other offals listed in Table 1 do not appeal to western tastes but are popular in other markets, particularly in Asian countries.

Liver

Liver is the largest organ in meat-producing species. Its color varies from light red to dark red brown and even black in old animals. The liver is attached by ligament to the anterior abdominal wall and to the stomach by the lesser omentum. During evisceration these attachments are torn or cut, and the liver is removed attached by ligament to the diaphragm and the rest of the pluck (heart, liver, lung, and diaphragm). The liver is separated from the pluck by cutting through the attachment to the diaphragm. The gallbladder and duct are then pulled or cut off the liver.

Liver is composed of specialized liver cells with a network of blood vessels and epithelia-lined ducts between the cells. The cells are held together by a network of connective tissue.

The texture and flavor of liver are affected by species and animal age. Livers from young animals are lighter in color, have more delicate flavor, and are more tender than those from older animals. Lamb and calf liver, and liver from young beef are more suitable for table dishes. Liver from mutton, older bulls, and cows are used in manufactured or processed meats. Pig livers have a strong flavor which is

Table 1 Summary of offal types

Offal type	*Alternative name*	*Category of offal*	
		Variety meat	*Red or white offal*
Organ or glandular offal			
Liver }	Lamb's fry	✓	Red
Heart } Pluck		✓	Red
Lung }	Lights		Red
Brain		✓	Red
Thymus	Sweetbread, heartbread, neckbread	✓	Red
Kidney		✓	Red

NA, not available.

appreciated in Asian countries, but in the west pig livers are used in processed meats rather than in table dishes.

To distinguish between the classes of bovine liver, they may be graded by weight. Livers in the range 1–3 kg are classed as calf livers. Larger livers from beef or ox may be graded into weight ranges of 3–4 kg, 4–5.5 kg, and over 5.5 kg. Ovine livers are not strictly graded but lamb liver should not exceed 700 g.

Heart

Hearts can be collected and trimmed in several styles. Whole hearts are removed from the pericardium and separated from the lungs and remainder of the pluck by cutting through the aorta and pulmonary vein. Whole hearts may be trimmed by cutting off the auricles along with the ossa cordis bones, aorta, and pulmonary vein. Even if the auricles remain in place, whole hearts are trimmed to remove remnants of the aorta, pulmonary vein, and the fibrous rings of the ossa cordis. Trimmed hearts comprise ventricles with associated fat, arteries, and veins, and may or may not include the auricles. They should be well washed to remove blood clots. Large hearts may be split open by cutting through the ventricle wall from the base to the apex.

The thick walls of the ventricles are composed of cardiac muscle, which is tough even in young animals. Cardiac muscle is supported by a network of connective tissue, which also contributes to the toughness of heart meat from older animals.

Tongue

Full tongues consist of the blade of the tongue with the roots attached, including the hyoid bones except the stylohyoid, the larynx, three tracheal rings, lymph nodes, salivary glands, and associated muscle and connective tissue. Short-cut tongues are a more common style of trim and are derived from full tongues by removing the larynx and roots by cutting behind the hyoid bones. Other trims of tongue are prepared with the hyoid bones removed.

The tongue blade is a core of skeletal muscle and connective tissue covered with an epithelial mucous membrane.

Brain

Brains include the cerebrum, cerebellum, and a portion of spinal cord. They are collected after opening the skull by splitting the occipital and maxillary bones. The brain is removed from the skull cavity, leaving the outer skin (the dura mater) in the skull but with a fine membrane (the pia mater and arachnoid meninges) covering the brain tissue. This membrane can be removed when the brain is cooked.

Brain tissue is not supported by a network of connective tissue and, consequently, has a soft, delicate texture.

Sweetbread

Sweetbread is the thymus gland and is only available from young animals. As animals mature, the gland

degenerates into a mass of connective tissue and fat. The sweetbread is collected in two separate portions, although it is a single gland. The main portion, also called neckbread, is found in the neck, either side of the trachea. The other portion is in the chest cavity, close to the heart, and may be called heartbread. After collection, fat and connective tissue is trimmed off the gland.

The thymus gland consists mainly of lymphocytes and is covered by a capsule of connective tissue. The capsule penetrates the gland and divides it into lobules. The texture of sweetbread is delicate but may be tough if sweetbreads are collected from older animals in which the thymus gland has started to degenerate. Sweetbreads are soaked in water to remove blood, blanched to firm the texture, and skinned to remove the capsule before they are prepared for the table.

Kidney

Kidneys are contained in a capsule of fat and remain in the carcass after evisceration. The common way to handle kidneys is to remove them from the capsule for inspection, trim off the ureter and renal blood vessels close to their entry to the kidney and, for beef kidneys, cut out the core of fat and connective tissue from the renal hilus.

Kidneys are made up of renal tubules and small veins and arteries. The structural components are the endothelial and epithelial cells of these vessels, and a network of connective tissue. There is a fibrous capsule of connective tissue around the kidney which is usually removed before kidneys are cooked.

Kidneys from sheep and pigs have the characteristic bean shape. Beef and calf kidneys are divided into lobules.

Pigs' Feet

Forefeet are collected from pig carcasses by cutting the foreleg between the carpal and metacarpal bones. Similarly, hindfeet are collected by cutting between the tarsal and metatarsal bones. Pigs' feet comprise the bones, tendons, skeletal muscle, connective tissue, fat and skin of the trotters, but toenails and all hair should be removed.

The edible part of pigs' feet is fat, muscle, and connective tissue. Prolonged moist cooking of the feet will soften and at least partially gelatinize the collagenous connective tissue and make the flesh tender.

Oxtail

Tails are collected from beef and veal carcasses by cutting off the tail at the sacrococcygeal junction. Tails consist of the coccygeal (tail) vertebrae with associated skeletal muscle, connective tissue, and fat. The last two or three vertebrae may be removed, and some or all of the subcutaneous fat at the anterior end of the tail may be trimmed off.

Tripe

Cattle and sheep stomachs have four compartments, all of which can be used to make tripe. Tripe from the rumen and reticulum is the most common. Rumen tripe is known as blanket tripe and reticulum tripe is known as the honeycomb. The internal surface of the rumen has densely packed papillae, while the reticulum has ridges in the shape of a honeycomb structure. In addition, there are thickened folds in the rumen wall. These folds contain a core of smooth muscle and are not covered by papillae. The fold can be trimmed out of the rumen to produce pillae tripe, known commercially as pillar or mountain chain.

The third compartment of the ruminant stomach is the omasum. The internal wall is in the form of deep, thin folds like the pages of a book. This appearance accounts for the popular name for the omasum, which is 'bible.' Although the omasum has a delicate flavor and texture, it is not commonly used as tripe because of the difficulty of cleaning the stomach contents from between the folds. The fourth part of the ruminant stomach is the abomasum, sometimes called the reed.

The four parts of the stomach are collected in one piece and the omental fat (caul fat) and spleen are removed. The neck of the omasum is cut to separate the rumen and reticulum from the omasum and abomasum. The rumen is cut open and the contents of the rumen and reticulum washed out. The rumen and reticulum are then trimmed into the different tripes, and external fat is trimmed off. Mountain chain tripe does not receive further processing, but blanket and honeycomb tripes may be further cleaned, scalded, and bleached with hydrogen peroxide.

The walls of ruminant stomachs are composed of smooth muscle and connective tissue. The papillae in the rumen are composed of collagen and elastin fibers covered with cornified epithelia, while the ridges and folds in the reticulum and omasum contain smooth muscle as well as connective tissue. There are small, cornified papillae on the folds of the omasum, and the surfaces of the folds are covered by a keratinized mucous membrane. The abomasum has a thick epithelial lining.

Tripes are generally tough because of the high connective tissue content. They contain about 35 g of collagen per 100 g of protein. They require prolonged, moist cooking to tenderize them. Bleached

tripe is treated with caustic soda and has a pH of about 7–9, which increases the water-holding capacity and helps to tenderize the tripe.

Maw

Pig's stomach or maw is a similar organ to the ruminant abomasum. The maw is separated from the rest of the viscera by pulling off the omental fat and spleen from their attachments to the stomach and cutting through the esophagus and duodenum. The maw is then split open and the contents washed out. After cleaning the maw, it is usually scalded in water at about 90 °C to remove the mucous membrane lining.

In common with the abomasum, the maw is composed of a wall of smooth muscle and connective tissue, with an inner lining of thick epithelia and mucous membrane.

Offal for Human Use

Offal consumption varies from about 1.7 kg per person per year in Canada to about 16 kg per person per year in Ireland. Table 3 shows per capita consumption of offal in western countries.

As shown in Table 1, almost all noncarcass parts can be used as food after the carcass and offal have been inspected and found fit for human consumption. (Exceptions are uteri from pregnant animals, and fetuses.) After collection, offals are trimmed and washed to remove contamination by blood, saliva, mucus, and ingesta. They may be distributed frozen, chilled, or vacuum-packed and chilled. Frozen offals held at −18 °C have a useful shelf-life of 6 months; chilled offals have a shelf-life of 2–3 days; and vacuum-packed tail, tongue, skirt, heart, kidney, and liver have a shelf-life of at least 3 weeks at 1 °C.

Table 3 Per capita consumption of offals by countries

	Consumption (kg per head per year)
Australia	4.7
Austria	4.5
Belgium and Luxembourg combined	8.0
Canada	1.7
Denmark	7.0
Republic of Ireland	16.7
Finland	8.1
France	6.6
Greece	6.0
Italy	3.8
Japan	2.5
The Netherlands	2.6
New Zealand	6.0
Norway	2.7
Portugal	5.0
Spain	4.0
Sweden	2.5
Switzerland	5.9
Turkey	2.1
UK	4.3
USA	4.1
Germany	5.7
Yugoslavia	2.9

Offals are consumed both as table dishes and in manufactured meat products such as sausages and pâté. There are many options for preparing and cooking offals, commensurate with the wide ranges of offal types. Some offals require initial treatment such as soaking and precooking. Brains, sweetbreads, and testicles are soaked in cold water to remove blood pigment and improve color. They are then blanched by brief immersion in hot water to firm the texture before they are cooked by other methods. Liver and kidney, particularly from older animals, may also be soaked to leach out the strong flavor associated with these offals. Stomachs and intestines are precooked by prolonged immersion in hot water to remove the mucosal membrane, and soften connective tissues. Tongues are also precooked, after which the thick skin of epithelia on the tongue blade can be peeled off. (*See* **Meat**: Sausages and Comminuted Products.)

Regulations may restrict the way in which offals are used in manufactured and comminuted meat products. In the EC and Australia, offals are considered to be meat but are distinguished from meat of skeletal muscle origin by using terms such as carcass meat and meat flesh, which exclude offal meat. In the USA, heart and tongue are considered to be meat, and other offals have the status of meat by products. The greatest restrictions on the use of offals is in uncooked meat products such as fresh sausages.

In Australia, no offals are permitted in fresh sausage and in the USA only tongue and heart can be used in fresh sausage. In the UK the designated list of permitted offals which can be used in uncooked products includes heart, kidney, liver, and tongue. In general, cooked meat products may contain offals. The Codex Alimentarius Commission has standards which restrict the use of offals in specific products. In summary, these standards are as follows:

1. Canned corned beef. Heart meat is the only offal permitted.
2. Luncheon meat. Luncheon meat with binder may contain offals, with the exception of lungs that have been collected from animals scalded by immersion in water. Only heart and tongue are permitted in luncheon meat without binder.
3. Cooked cured chopped meat. Only heart and tongue are permitted in products which do not contain binder. Offals (except udders, lungs, and

organs and glands from the genital system) may be used in products that contain binder.

Other Uses of Offals

Collection of offals for edible use requires – at least – inspection, washing, and trimming. The cost of these procedures may not be justified by the value of some offals. In this case the offals are disposed of or used in other ways. The main alternatives are to render offals to produce tallow and meat meal, or to use them as pet food. Inspected offal which is not edible because of contamination or disease status is rendered along with other offals which are not required for edible use or pet food, e.g., heads, hooves, and the residues of gut material after collecting sausage casing and tripe.

Offals collected for pet food may be subject to less rigorous inspection, preparation, and trimming than offals for human use and can be handled at a lower cost. The main use of offals is in canned pet foods. These products receive severe heat treatment, and offals which retain form and texture, such as lung and tripe, are most suitable. Liver, heart, and spleen are also used in canned pet food.

There are specialized uses for some offals. Pig and beef pancreas glands are used to produce insulin for the treatment of diabetes. However, insulin from pancreas glands is being replaced by insulin produced from bacterial fermentation.

The mucosa from the lining of lungs and intestines is used to produce the anticoagulant, heparin. A long-standing use of calf vells (abomasum) is in the production of rennet.

OLIVE OIL

M Tsimidou, G Blekas and D Boskou, Aristotle University of Thessaloniki, Thessaloniki, Greece

Introduction

Poseidon and Athena had a violent disagreement as to who should govern Attica (Greece). To settle this dispute, Zeus declared that he would give the country to whoever offered him the most useful present for mankind. Poseidon then presented a salty spring. Athena presented a twig. This twig would become a staunch tree, capable of living for untold centuries, whose fruit would be edible and from which an extraordinary liquid would be extracted for the preparation of man's food, alleviation of his wounds, strengthening of his system, and lighting his nights. Needless to say, Athena won, and the city, ever since, is named Athens (Figure 1).

The cultivation of the olive tree (Figure 2) dates back before recorded history. The origin of the tree is the area of Mesopotamia. The Minoans (2000–1450 BC) were quite advanced in the cultivation of the olive tree and the production of olive oil, which was also exported. One valuable source of information is the Linear B tablets from the royal archives of Knossos (Crete) and Pylos (Peloponnese) (see Figure 3). Greek mythology, the Old Testament, and Roman literature are full of information regarding the role of the olive tree and its products in religion and everyday life. The cultivation of the olive tree is an essential element of the civilizations developed in the Mediterranean Basin, closely related to their prosperity and cultural achievements.

Olive oil is obtained from the fruits of *Olea europaea* L. The evergreen tree has a life span of several centuries (300–600 years). Its longevity is partially

Figure 2 (see color plate 116) Olive tree in Rethimnon, Crete (Greece), courtesy of V. Zambounis, Athens.

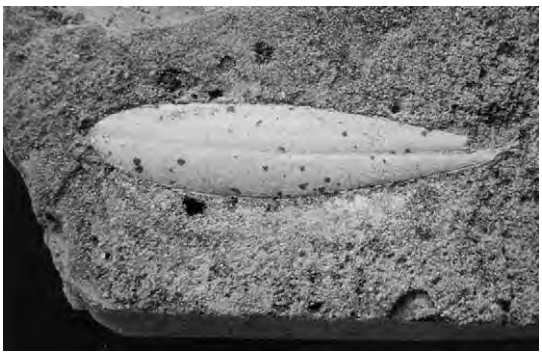

Figure 1 (see color plate 115) Picture of a fossilized olive leaf. Reproduced from Psillakis N and Kastanas E (1999) *The civilization of olive: olive oil*, 2nd edn. Greek Academy of Taste, Karmanor, Iraklion, Crete (Greece), with permission.

explained by the characteristic ability to send out shoots and roots from temporary buds at the lower part of the trunk. The height of an old tree may even be as much as 25 m, but trees in systematic plantations have an optimum height of 4–5 m to facilitate manual picking of fruits. The tree is resistant to unfavorable conditions (dryness, infertile soil, etc.) but requires a mild climate (not below −9 °C in winter – a moderate to high temperature in summer). Many species of olive tree are grown all over the world, some of them (>35) suitable for olive oil production. Cultivars used for oil production have a medium-sized fruit containing 17–30% oil when ripe. Among the most important oil-producing cultivars are: *Koroneiki, Megaritiki*, and *Tsounati* (Greece), *Leccino* and *Frantoio* (Italy), *Picual, Hojiblanca*, and *Lechin de Sevilla* (Spain). (*See* **Olives**.)

Olive Oil Trade and Consumption

Olive oil is an important component of the Mediterranean diet, which is now also gaining interest among consumers of northern Europe, USA, Canada, and other countries as a component of healthy eating. Olive oil is almost exclusively produced in Spain, Italy, Greece, Tunisia, Turkey, Morocco, and Portugal (*c.* 31, 31, 18, 4, 5, 2.5, and 2% of the world's production, respectively) (see also Table 1). More than 800 million trees, covering a total area of 25 million acres, yield approximately 2 000 000 tonnes of oil (Figure 4). Though olive oil production accounts for no more than 2% of the volume of edible oils traded world-wide, its market value has a significant share (15%) in international trade because of its high price.

Table 1 World olive oil production

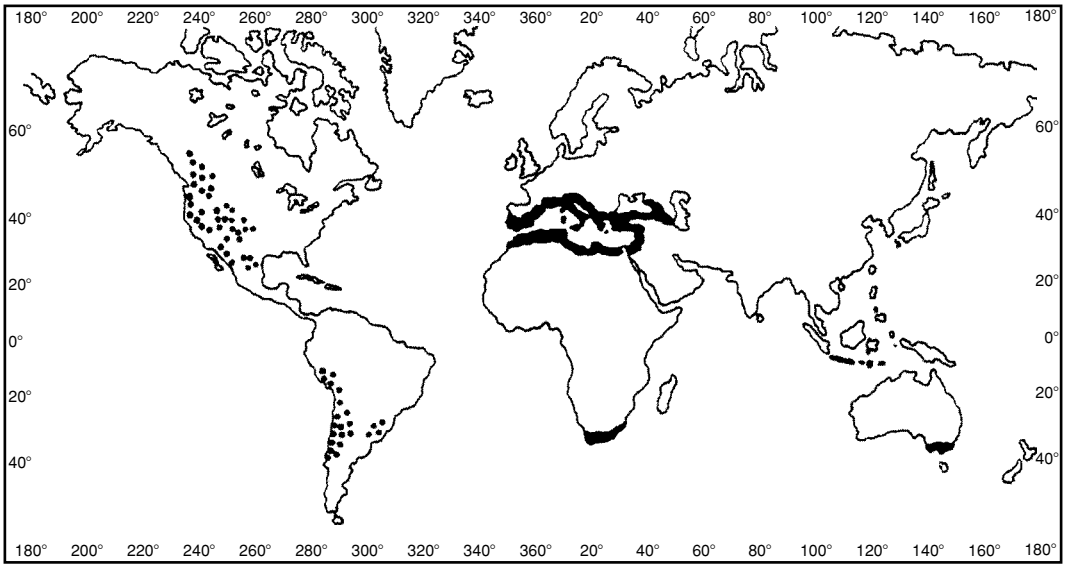

Figure 4 Olive tree growing areas of the world. From Kiritsakis KA (1998) *Olive Oil: From the Tree to the Table*, 2nd edn. Trumbull, CT: Food and Nutrition Press, with permission.

The International Olive Oil Council (IOOC), established in 1959, is the intergovernmental organization responsible for administering the International Agreement on Olive Oil and Table Olives. This agreement has been negotiated at the United Nations and lays down the policy that members should take for standardization of the market for olive oil, olive-pomace oil, and table olives. The Agreement is renewed regularly (for the time being, the 1986 Agreement has been prolonged until 31 December 2000). Principles and provisions set are compulsory in international trade, recommended in domestic trade, and incorporated in the trade standards for olive oil and olive-pomace oil.

According to recent IOOC reports, the increasing production of olive oil in Europe, as well as in the rest of the world, has led to a drop in prices and to a concomitant rise in consumption. Data concerning consumption in 1998/1999 and estimated consumption for 1999/2000 are given in Table 2. Similar trends stand for the year 2001/2002. Olive oil consumption is practically concentrated in the producing countries. The average annual per-capita consumption of olive oil reflects the economic policy and culinary traditions of each producing country. Thus, consumption that is reported for Greek consumers (19.5 kg) is twofold higher than that in Italy or Tunisia. In France and in the countries of central and northern Europe, consumption of olive oil is very low. In the last decade, there has been a significant increase in olive oil consumption. In countries such as Germany, Denmark, UK, and Ireland, the estimated per-capita per-year consumption in the last 2 years has been around 0.5–0.6 kg. In the USA and Canada, similar estimates are approximately 0.8 kg. The results of the 'Seven Countries Study' related the low rate of coronary heart disease among the Cretan population to the regular consumption of virgin olive oil. This was the first scientific evidence for the nutritional role of this 'high-in-monounsaturates' juice. Currently, the interest is focused on the role of olive oil in the prevention of bone and nervous-system functions, digestion, antiageing properties at cell and mitochondrial levels, diabetes, and breast tumors, and also in the preventive role of some of its minor constituents in the oxidation of low-density lipoprotein (LDL). (*See* **Coronary Heart Disease**: Etiology and Risk Factor; Antioxidant Status; Prevention.)

Commercial Types of Olive Oil

Olive oil is marketed in accordance with the designations of Table 3. Virgin olive oil is obtained by only mechanical or other physical means under conditions, particularly thermal, which do not lead to alterations in the oil. This oil has not undergone treatment other than washing, decantation, centrifugation, and filtration. *Extra, fine*, and *ordinary* virgin olive oils are different edible grades of virgin olive oil. *Lampante* is a nonedible grade of virgin olive oil suitable for refining or other technical uses. Refined olive oil is the oil refined by the methods used for other vegetable oils. These include neutralization, decolorization with bleaching earth, and deodorization. Olive oil is an edible blend of virgin olive oil and refined olive oil. Olive-pomace oil is obtained by solvent extraction of the cakes derived from olive milling. The triacylglycerol composition is similar to that of virgin olive oil, but some of the nonsaponifiable compounds differ significantly. Due to the high content of waxes, the oil has to be winterized before refining. *Olive-pomace oil* can be used as a mixture with virgin olive under the designation 'olive-pomace oil.' This oil cannot be called 'olive oil.' Virgin olive oils may also be traded as 'appelation d'origin' products in accordance with the existing legislation (e.g., EC Regulation 2081/92). (*See* **European Union**: European Food Law Harmonization.)

Olive-oil Extraction

There are three extraction procedures currently used to separate the oil from the other phases in the paste, liquid or solid. These are *pressure*, *centrifugation*, and *percolation*. Specialized manufacturers provide suitable machinery for the proper extraction of olive oil.

Pressure

This is the oldest method but is still in use. In this system, the paste is pressed to release an oily must (olive + vegetation water) (Figure 5). The liquid phase separates from the solid phase with the help of the drainage effect of the mats and the stone fragments. A cake is formed between the mats, while the two liquid phases (oil and vegetation water) are separated by centrifugation.

Figure 5 (see color plate 117) Hydraulic pressure unit (courtesy of ELAIS SA, Piraeus, Greece).

Centrifugation or Three-phase Systems

The crushed olives are mixed with water. A horizontal centrifuge (Figure 6) separates the mass into pomace and must, which is further separated into oil and vegetation water. In the 1970s and 1980s, three-phase centrifuges replaced pressure systems to a great extent to cut processing costs and to reduce olive storage time. A recent innovation to reduce polyphenol losses is the so-called two-phase system, which is able to separate the oily phase without the addition of water. The oily phase is separated from the paste to give oil and water plus husks.

Percolation

A steel plate is plunged into olive oil paste. When it is withdrawn, it will be coated with oil because of the different surface tensions of the liquid phases (the metal phase is coated with a skin of oil). The system

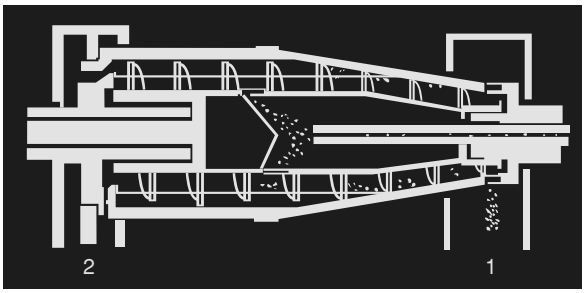

Figure 6 Horizontal centrifuge (decanter): 1, exit of solid phase. 2, exit of liquid phase (oil and water). From Kiritsakis KA (1998) *Olive Oil: From the Tree to the Table*, 2nd edn. Trumbull, CT: Food and Nutrition Press, with permission.

is combined with a continuous horizontal centrifuge to increase the capacity.

Cold Pressing

Cold pressing is the extraction process of olive oil from olive paste at a temperature of less than 25 °C.

Milling Conditions and Quality of Olive Oil

Traditional pressure-extraction systems yield good-quality oil when olives are in good condition and good manufacturing practice is applied. Percolation (selective filtration) also provides good-quality oil. Centrifugation plants have a larger hourly processing capacity and significant practical advantages. In such systems, however, the paste has to be thinned with warm water. This lowers the level of polar natural antioxidants, which have been associated with the storage stability of the oil and its beneficial health effects. Depending on the variety and stage of maturity of olives, different crushing systems are necessary to obtain the optimum polyphenol content and better aroma characteristics. Stone mills yield oils with a good aroma and less intense bitter taste than metal-disk crushers because of a lower polyphenol content. Hammer crushers usually yield oil with a characteristically high content of polyphenols. The malaxation time and temperatures are also critical for the aroma and quality.

Other methods to improve the quality and organoleptic scores during milling are based on the use of pectolytic and cellulolytic enzymes. The International Olive Oil Council, however, does not accept such techniques because olive oil is by definition obtained from the fruits of olive tree only by *'physical means.'*

Olive Oil Composition

The composition of olive oil is primarily triacylglycerols and secondarily free fatty acids, and some 0.5–1.5% of nonglyceridic constituents. The Codex Alimentarius Commission, the IOOC, and the Commission of the European Union provide identity and compositional characteristics for olive oil and olive-pomace oil.

EEC Regulation 2568/91 and subsequent amendments (EC 2632/94, EC 656/95, and EC 2472/97) set the limits for fatty acid composition and content in sterols, waxes, saturated fatty acids in position-2 of triacylglycerols, erythrodiol + uvaol, trilinolein and *trans* unsaturated fatty acids and also for specific absorption at various wavelengths. These limits are very strict and aim at protecting good-quality olive oil, and especially virgin olive oil, from adulteration. The same directives also define analytical methods. (*See* **Fatty Acids**: Properties; Analysis.)

Extended information for the composition of olive oil and other aspects of olive oil chemistry and technology are provided in reviews and books authored mainly by Spanish, Italian, and Greek authors.

Fatty Acids and Triacylglycerols

The fatty acid composition of olive oil ranges from 7.5 to 20.0% palmitic acid, 0.5 to 5.0% stearic acid, 0.3 to 3.5% palmitoleic acid, 55.0 to 83.0% oleic acid, 3.5 to 21.0% linoleic acid, 0.0 to 1.5% linolenic acid, 0.0 to 0.8% arachidic acid, 0.0 to 0.2% behenic acid, and 0.0 to 1.0% lignoceric acid. The olive oil composition may differ from sample to sample, depending on the zone of production, the latitude, the climate, the variety, and the stage of maturity of olives when collected. Olive oil has a fatty acid composition similar to that of hazelnut, almond and high-oleic sunflower oils. This composition differs significantly from any other type of edible oil and fat. (*See* **Nuts**; **Sunflower Oil**; **Vegetable Oils**: Types and Properties.)

The triacylglycerol profile of olive oil, as determined by reversed-phase liquid chromatography, is also different from the profiles of maize, cottonseed, sunflower soybean, and rapeseed oil, and resembles that of hazelnut oil. The main triacylglycerols found in olive oil are: OOO (40–59%), POO (12–20%), OOL (12.5–20%), POL (5.5–7%), SOO (3–7%) (O = oleic acid, P = palmitic acid, S = stearic acid, L = linoleic acid).

Tocopherols

The dietary benefits of olive oil are partly attributed to the presence of α-tocopherol and other natural antioxidants. α-Tocopherol acts not only as a free radical trapping agent but also as a singlet oxygen quencher. This protective effect against photooxidation is enhanced by the presence of β-carotene. The

main homolog of vitamin E forms present in olive oil is α-tocopherol, which makes up approximately 95% of total tocopherols. The other 5% are β- and γ-tocopherols. Good-quality, fresh virgin olive oils have a considerable content of α-tocopherol (200–300 mg kg^{-1}). Refined, bleached, and deodorized olive oils have markedly reduced contents because of the losses of tocopherols during processing. (*See* **Tocopherols**: Properties and Determination.)

Squalene

Squalene ($C_{30}H_{50}$), an intermediate in the biosynthesis of sterols in plant and animal world, is the major olive oil hydrocarbon. Squalene is found in olive oil at a concentration ranging from 0.7 to 12 g per kilogram of oil. The squalene content depends on the olive cultivar and oil-extraction technology, and it is dramatically reduced during the process of refining. There are claims that squalene can enhance the quality of life, if taken continuously, and that its consumption is beneficial for patients with heart disease, diabetes, arthritis, hepatitis, and other diseases. It has been claimed that the high squalene content of olive oil, as compared with that of other human foods, is a major factor in the cancer-risk-reducing effect of this oil.

Carotenoids

The main carotenoids present in olive oil are β-carotene and lutein. Trace amounts of neoxanthin, violaxanthin, cryptoxanthin, and other xanthophyls may be found. The total carotenoids content may range between 1 and 20 mg per kilogram of oil; normal values do not exceed 10 mg kg^{-1}. Oils have been reported that have a higher content of lutein than of β-carotene and *vice versa*. So far, studies have indicated an inverse correlation between β-carotene intake and incidence of cardiovascular disease, but no clear effect on low-density lipoprotein (LDL) oxidation has been demonstrated with β-carotene. (*See* **Carotenoids**: Occurrence, Properties, and Determination.)

Sterols

Phytosterols are functional ingredients. They have an absorption level 20 times lower than that of cholesterol. Phytosterols inhibit the absorption of cholesterol in the body during digestion. Four classes of sterols occur in olive oil, common sterols (4-desmethylsterols), 4-α-methylsterols, 4,4-dimethylsterols, and triterpene dialcohols (erythrodiol and uvaol) (Figure 7). The major class is 4-desmethylsterols. Usual values reported for these classes are 1000–2000 mg per kilogram of oil. Part of the total sterols is present as esters with fatty acids. β-Sitosterol makes up 60–90% of the total sterol fraction. Other sterols found in considerable amounts are δ^5-avenasterol (Figure 8; 5–36% of the total sterol fraction) and campesterol (approx. 3% of the total sterol fraction). The rest of the 4-desmethylsterols present in olive oil are found in trace or very small amounts. Certain sterols are probably responsible for the resistance of olive oil to rapid deterioration at elevated temperatures. (*See* **Functional Foods**.)

Phenolic Compounds

Virgin olive oil contains phenolic substances that affect its stability and flavor. Tyrosol (4-hydroxyphenethyl alcohol) and hydroxytyrosol (3,4-dihydroxyphenethyl alcohol) are usually mentioned as the major constituents. Other phenolic compounds are caffeic acid, *o*-coumaric acid, *p*-coumaric acid, ferulic acid, gallic acid, homovanillic acid, *p*-hydroxybenzoic acid, *p*-hydroxyphenylacetic acid, protocatechuic acid, sinapic acid, syringic acid, tyrosol glucoside, and vanillic acid. Aglycons of oleuropein and ligstroside, the esters of hydroxytyrosol and tyrosol with

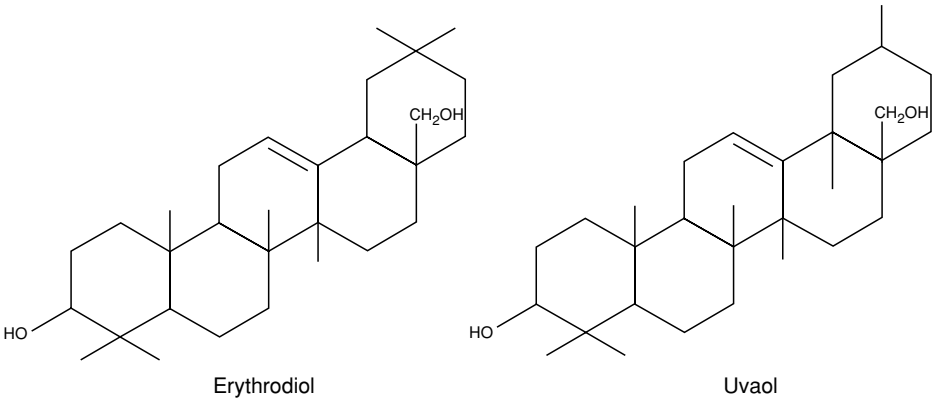

Figure 7 Two triterpene dialcohols used to check purity of virgin olive oil.

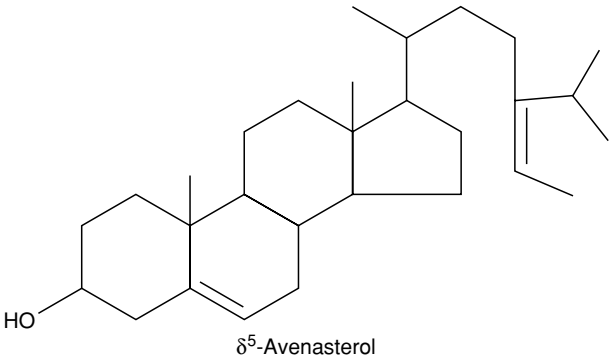

Figure 8 Chemical structure of Delta ^{5}-Avenasterol.

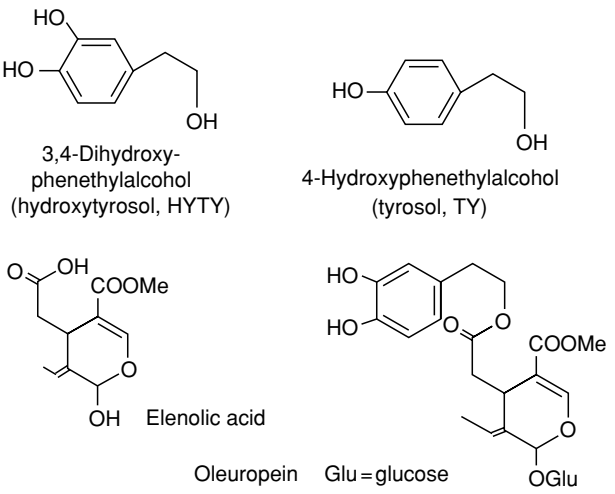

Figure 9 Major phenolic and related compounds in olive fruit and olive oil.

elenolic acid, diacetoxy and dialdehydic forms of these aglycons, elenolic acid, and flavonoids have been also reported to be present in the polar fraction of virgin olive oil (Figure 9).

The content in phenolic compounds differs from oil to oil (a few to more than 400 mg per kilogram of oil, expressed as caffeic acid). When the level exceeds 300 mg kg^{-1}, the oil may have a bitter taste. However, a high polyphenol content appears to be beneficial for the shelf-life of the oil, and there is a good correlation of stability and total phenol or *o*-diphenol content. Among the various phenolic compounds tested for their contribution to the stability, hydroxytyrosol and caffeic acid were found to be the most potent antioxidants.

Dietary antioxidants present in exra virgin olive oil were found to increase the resistance of low-density lipoproteins to *in-vitro* or *in-vivo* oxidation experiments. According to a large number of reports, hydroxytyrosol is the most important biophenol of olive oil similar to the phenolic compounds encountered in green tea and in red wine. Oleuropein also presents valuable functional properties, but it occurs in olive oil only in trace amounts. It is found in abundance in olives and olive leaves. (*See* **Phenolic Compounds**.)

Chlorophyls

The color of olive oil is mainly due to pheophytins α and b. Traces of chlorophyls α and b may be found only in fresh oils. The chlorophyl content in virgin olive oil ranges from trace amounts to more than 30 mg kg^{-1}. The level of chlorophyls (and carotenoids) depends on genetic factors, degree of fruit ripening, and extraction technology. The level decreases as the fruit ripens. In the absence of light, chlorophyls probably act as weak antioxidants. In the presence of light, it is accepted that chlorophyls act as strong oxidation promoters. Chlorophyls are responsible for the yellow/green hues of the oil. (*See* **Chlorophyl**.)

Volatile and Aroma Compounds

More than 100 constituents have been identified in virgin olive oil, mainly hydrocarbons, alcohols, aldehydes, esters, and ketones. However, only a few of these compounds contribute significantly to its aroma. The most important odorants are volatiles with six carbon atoms, arising from the enzymic oxidation of both linoleic and linolenic acids during olive crushing and malaxation. Genetic, agronomic, and technological parameters, such as olive variety, degree of fruit ripening, crushing, and malaxation conditions or extraction system affect the enzymic activity and alter the quality and intensity of the aroma. Certain compounds were found to be responsible for desirable flavor attributes, e.g., (Z)-3-hexenal for the 'green, apple-like' odor, hexanal for the 'grassy' odor, (E)-2-hexenal for the 'green, bitter almond-like' odor, ethyl 2-methylbutanoate for the 'fruity' odor. Other compounds such as octanal, nonenals, decadienals, 1-octen-3-one, acetic acid, 3-methylbutanol, 2-phenylethanol, etc., are responsible for some negative attributes. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Storage and Packing

The oxidative stability of virgin olive oil is mainly related to its characteristic pattern of triacylglycerols (low unsaturation, *iodine value* < 90) and also to the considerable levels of polar phenolic antioxidants and the presence of α-tocopherol. Since the early 1970s, it was found that there was a good correlation between polyphenols and the oxidative stability of the oil, and

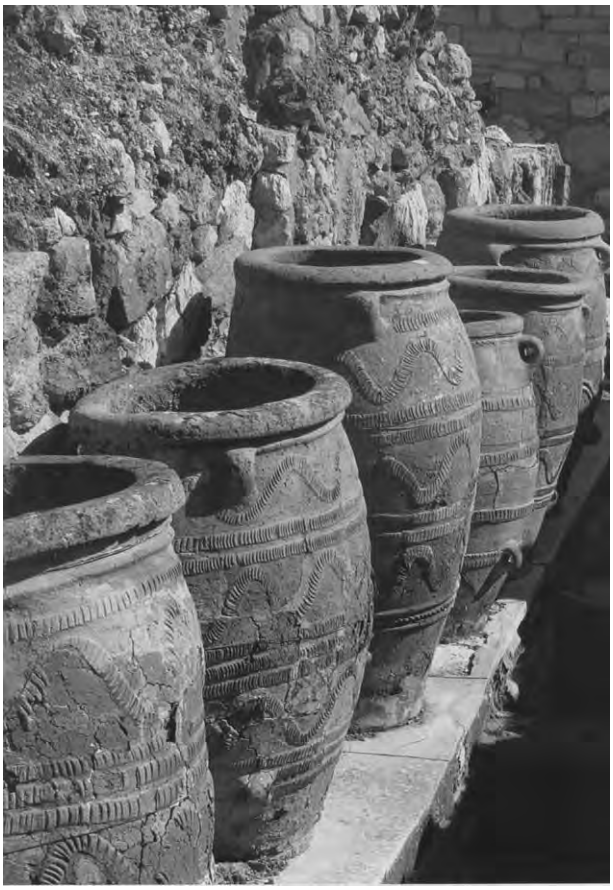

Figure 10 (see color plate 118) Pottery from Knossos Palace. Reproduced from Psillakis N and Kastanas E (1999) *The civilization of olive: olive oil*, 2nd edn. Greek Academy of Taste, Karmanor, Iraklion, Crete (Greece), with permission.

all the researchers agreed that the level of polyphenols or of specific phenols, e.g., tyrosol level, coincided well with the overall oil quality. Thus, oils with a high initial peroxide value may have an unexpectedly long shelf-life due to a high content of natural antioxidants. In the last decade, some researchers focused their interest on the contribution of individual phenols present in virgin olive oil to its oxidative stability. Recent publications indicate that there is an interest in all natural antioxidants of olive oil that are studied in parallel. The importance of polyphenols for olive oil stability explains the efforts of investigators to develop an appropriate technology to recover them from olive oil wastewater.

Bottled virgin olive oil has a shelf-life of around 18 months. This period is very long for a fat product. The resistance of the oil to oxidation may be supported by special storage and packing conditions (see Figure 10).

Storage in dark places is essential for the keepability of the product to prevent the prooxidant activity of chlorophyls in the presence of light. Storage in cool places protected from air access is suggested to prevent autoxidation. Therefore, stainless steel containers are ideal for storage. Glass bottles are resistant to fat and oxygen permeation, but only colored bottles offer light protection.

Traditional and Modern Use

Olive oil is part of a cuisine that is simple, light, and placid, with defined tastes and full of harmony, the so-called Mediterranean cuisine. Olive oil resistance to the development of rancidity is combined with a vast array of flavor and color hues and distinct features due to differences in cultivars of olives from which the oil is extracted. A good-quality olive oil blends perfectly with the greens. The exquisite taste of olive oil is very often complemented by the sharp taste of vinegar, lemon, or tomato. In salads or in cooking, olive oil is usually mixed with herbs and spices, which are also an important element of the Mediterranean diet. Olive oil shows a remarkable resistance during domestic deep-frying of potatoes or in other uses at frying temperatures due to its low unsaturation. It is, therefore, recommended not only as a salad oil but also for cooking and frying.

OLIVES

B L Raina, Regional Research Laboratory (CSIR), Jammu, India

Introduction

Olive (*Olea europaea*, family Oleaceae) is an evergreen xerophytic tree grown for its drupes, which yield oil and are also marketed as table or pickled olives. The olive seems to have been cultivated since prehistoric times in the eastern Mediterranean region, and has been closely associated with human religious, sociocultural, medicinal, and nutritional needs. Today, olive cultivation has attained commercial crop status in every country with a Mediterranean climate. Spain, Italy, and Greece are leading producers of olives. Other important olive-producing countries are Turkey, Tunisia, Portugal, France, Morocco, Algeria, Syria, Yugoslavia, Jordan, the USA, Cyprus, Israel, Argentina, and Libya.

Production and Trade

There are about 800 million olive trees in the world, covering about 9 million hectares (ha), with the annual olive fruit production being about 13.7 million metric tonnes (t). Approximately 720 000 t of the production are consumed as table olives, and the remaining 8 680 000 t are used for the extraction of oil (**Table 1**). Nearly 2.3 million t of olive oil and 230 000 t of olive residue oil is produced globally. About 260 000 t of olive oil and 200 000 t of table olives is traded in international markets. Olive oil is exported by 35 countries to more than 100 countries in five continents. Spain is the largest exporter and Italy buys nearly half of the entire quantity traded in the international market. Of the 300 000 t of olive oil produced in Greece, around 65% is consumed on the domestic market, whilst 100 000 t is exported, mostly to the European Union (EU). Seventy-five percent of all the olive oil produced in Greece is edible virgin olive oil, for which the global market is expanding. With its 4.2% share of world olive oil production and 8.7% share of world exports. Turkey ranks fourth and in some years fifth after Tunisia. The annual increase in olive oil production is 1.4% as compared to 4% in respect of other edible oils.

As the world's largest producer, Spain produces between 200 000 and 250 000 t of table olives per year. This is over 60% of EU production. Half is for the domestic market and half is for export. Greece is the second largest producer of table olives and exports of the typical table varieties are greater than

sales on the home market. The production of table olives in Italy is around 86 397 t per year. Table olives account for about 3.4% of the annual crop, and barely 10% of world production. Turkey is one of the world's biggest producers and consumers of table olives, and lies sixth in the export ranking. It is the world's top producer of black olives (29%) and their second biggest exporter (19%).

The crop is very labor-demanding, provides employment to millions, and accounts in many countries for a major share of agricultural income. Almost 25% of the farming income in the Mediterranean basin is from olive products. The olive products, which have been consumed by the Mediterranean people for generations, are increasingly becoming a luxury in countries with a high standard of living.

Botany

Olive is an evergreen tree 3–12 m or even more in height and, in some instances, bears fruit for 1000 years or even more; branches are numerous; leaves are opposite, leathery, lanceolate, dark green above, silvery beneath; flowers are small, white, dimorphic (male and perfect), appearing in early spring in loose axillary clusters. Fruit setting in olive is erratic in certain areas, especially where irrigation is insufficient, the plantation is dense, the pests and diseases are not controlled and, above all, a single cultivar is planted over a wide area, reducing the chances for cross-pollination.

The olive fruit is a globular, oblong, or sometimes crescent-shaped drupe. The pericarp is composed of epicarp or skin, the mesocarp or pulp, and the endocarp or stone (pit) which contains the seed. The fruit reaches its maximum weight 6–8 months after flowering late in spring, and passes through successive shades of straw, pink, and red, before finally turning purplish-black at full maturity. The ripe fruit weighs from 1.5 to 13 g. The pit with its hard shell makes up 13–30% of the fruit weight and the skin 1.5–3.5%. The seed does not exceed 3% of the weight of the fruit. At full maturity, the mesocarp contains 6–10% soluble solids and 15–40% or even more oil, depending on variety. The pericarp contains 96–98% of the total amount of oil, while the remaining 2–4% of the oil is in the kernel. The characteristic bitter glycoside, oleuropein, is more concentrated close to the peel.

Varieties

The principal varieties cultivated for oil have medium-sized fruits and are harvested when ripe. More important among these are Arauco, Bouquetier, Corfolia, Dafnolia, Fratoio, Koroneiki, Lechin, Manzanillo, Morcal, Nevadillo, Picual, Rozzola, Rougette, Smertolia, Taggiasea, Tsounati, and Zorzalena. The varieties preferred for table olive production, with less than 8% oil, include Ascolano, Calamata, Chalkidikis, Conservolea, Gordal, Hojiblanca, Manzanillo, Megariticci, Mission, Sevillano, Throumbolia, Verdale, and Volou.

Physiology and Biochemistry

Fruit Development and Ripening

Along with an increase in fruit weight, various changes in constituents occur during the development of the fruit. In the cultivar Gordal, there is a continuous increase in the oil content, a brief rise in reducing sugar content, followed by a decline till maturity, a sharp initial drop in crude fiber content and a gradual one afterwards, and a low protein and ash content. There are no qualitative changes in chlorophyl and carotenoid pigments in Hojiblanca and Manzanillo olives during growth and ripening. The pigment content in the virgin olive oil varies according to the degree of ripeness of the fruits. Initially the major component is pheophytin, while in oil obtained at the end of the season lutein is the most abundant. The loss of chlorophyl pigments in the fresh fruits and virgin oil is not due to activation of chlorophyllase during oil processing. The β-carotene content and its provitamin A value diminish with ripeness (13.2 μg β-carotene per g oil is reduced to 1.27 μg g^{-1} in Sevillano variety). The considerable range in the lutein/β-carotene ratio (between 1.3 and 5.1 depending on variety) makes this ratio a differentiator of single-variety oils. The amount of coumaric acid, syringic acid, and flavonol varies with maturity. The quantitative differences in the composition of flavonol and flavone glycosides during ripening may be useful in the biochemical characterization of olive cultivars. Cultivar and stage of maturity influence tocopherol and tocotrienol contents. The concentrations of the volatile compounds during three stages of ripeness in four different cultivars are reported to decline with increasing ripeness, although hexyl acetate is highest and hexan-1-ol lowest at the ripe stage. During maturation of the fruit, the size of oil droplets within the olive increases, raising the extractability of the oil from about 20% in the early stage to as much as 90% in fully mature fruit. Furthermore, small fruits are characterized by high oleuropein and low verbascoside contents. The gradual loss of firmness and of anhydrogalacturonic acid content of the pectic chain is associated with increasing enzyme activities. Pectinesterase activity appears

during ripening and polygalacturonase activity mainly during storage. The activity of cellulolytic enzymes increases with ripening of the fruit. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; **Ripening of Fruit**.)

Constituents of Olive Fruit

The moisture and oil content form 85–90% of the weight of pulp, while the rest comprises organic matter and minerals. The major monosaccharides in fruit pulp are glucose, mannose, xylose, galactose, and arabinose, accompanied by mannitol and rhamnose in certain cultivars. The pulp is rich in potassium. Small amounts of organic acids, such as citric, malic, oxalic, malonic, fumaric, tartaric, lactic, acetic, and tricarballylic (1,2,3 propanetricarboxylic acid) are present. (*See* **Acids**: Natural Acids and Acidulants; **Carbohydrates**: Classification and Properties.)

A variety of phenolic compounds are found in olive pulp; caffeic and ferulic acids are among the simpler of them. The major orthodiphenolic compound typical of olives is oleuropein, which is responsible for the bitter taste of immature olives. Two linear compounds are reported to be isolated from the ethyl acetate extract of residues resulting from Spanish olive oil processing. These compounds are identified as 3-(1-(hydroxymethyl)-(E)1-propenyl) glutaric acid and 3-(1-(formyl)-(E)1-propenyl) glutaric acid. These products are structural components of oleuropein. Oxidation products of oleuropein and other phenolics impart the black color to the fruit as a result of complex interactions between diphenol oxidase and oleuropein. Anthocyanins, specifically the glycosides of cyanidin and peonidin, are responsible for the purple and black color of ripe olives. The highest concentration of anthocyanin pigments has been observed in the epicarp ($0.55\,g\,kg^{-1}$); a complex mixture of flavonoids is found in the mesocarp; derivatives of luteolin and apigenin are found in the endocarp. (*See* **Phenolic Compounds**.)

The skin, pulp, and seed contain different lipid fractions and fatty acids, sterols, triterpene alcohols, dialcohols, and hydrocarbon fractions. Among the differences between the parts of the olive drupe are the presence of erythrodiol and traces of uvaol, oleanoic acid, traces of ursolic acid, and oleanoic aldehydes in the skin only. The distribution of unsaponifiable hydroxy compounds fractions within the drupe and their concentration in oils from various parts of Lingurian olives reveal the presence of sterols, 4-methylsterols, triterpene alcohols (TTA), triterpene dialcohols (TTDA), linear saturated alcohol (LSA), and phytol. Most of the sterols, 4-methylsterols, TTA, and phytol are found in the pulp, while LSA and TTDA are found in the peel. The main hydroxy components are LSA in the peel, TTA in the pulp, and sterols in stone and seed. The kernel oil is characterized by the presence of estrone ester (8 μg per 100 ml oil).

Fifty-six volatile compounds are reported to be present in the leaves, flowers, epicarp, and mesocarp of Lucca and Mission varieties, and 29 compounds, including 3-vinylpyridine, methylvinylpyridine, and *cis*-jasmone, have been identified in these varieties. Higher concentrations of hexanal and *trans*-2-hexanal are found in the Lucca variety, while numerous long-chain hydrocarbons are found in flowers of both varieties. The peroxidase activity and lipid peroxidation intensity in leaves may be of potential use in selecting olive cultivars for yield.

Soil and Climate

Olive does well on moderately saline soils not suitable for most other crops. The soil should be deep and well-drained, so that the roots penetrate deeply to take advantage of underground moisture even in relatively arid areas. The olives can also grow on calcareous slopes provided the fertility of the soil is built up.

Olive can be grown commercially in warm-temperate and subtropical countries located between latitudes 30° and 45°N and 30° and 45°S, at 300–400 m altitude in the north to 1000–1220 m above sea level in favorable sections of the south. The production of olives under dry conditions needs better resource management. This includes use of special tools and traditional water conservation measures. It cannot be grown where the winter temperature falls below −9°C, as this temperature will kill the trees. A certain degree of chilling, differing considerably among cultivars, is necessary for floral induction. The olive blooms relatively late in the spring. A long, relatively hot growing season is required for the fruit to develop to the appropriate size. A consistently clear and dry atmosphere is necessary for maximum yield of fruit. Adequate soil moisture must be present throughout the year to produce heavy yields of the required size of fruit.

Cultural Practices

Propagation

Olives are propagated by hardwood cuttings, or by small softwood cuttings rooted under mist sprays, or by 'ovule' protuberances formed at the base of the trunk. The treatment with IBA+ putrescine HCl and

placing the cuttings in the polyethylene tunnel improve the rooting ability. Although propagation by seeds provides a stronger root system and more fruitful trees, the seedlings produced require grafting and thus a longer time to reach fruiting. The variable nature of the rootstock may bring about variability in the growth and size of the trees. The nursery trees are planted 8–12 m apart in irrigated orchards or 12–22 m apart in unirrigated groves.

IRTA-i.18, a clone selection of the olive Arbequina, is superior to the cultivar for fruit color, fruit yield at a density of 300 trees h^{-1}, crown volume, fruit weight, flesh/stone ratio, and oil content, and identified as suitable for commercialization. The topical pollen application can be used instead of interplanting of pollinizer trees to reduce shotberry incidence in Manzanillo olive groves.

Irrigation and Drainage

For production of a good crop of large fruit size, the trees should have adequate soil moisture throughout the year, especially before flowering time in late winter and early spring and during the summer, when fruit growth takes place and new fruiting wood develops. In the Mediterranean region both oil and pickling olives are largely grown without irrigation. Under rain-fed conditions the olives require 40–50 years to reach full productivity, necessitating the use of many intercrops to provide income during the interim period. The yield of full-bearing olive trees in Spain is about 825 kg ha^{-1}, and water is the main limiting factor for low yield.

In California, the olive groves are grown under irrigated conditions. To insure adequate tree growth and profitable yields, supplementary summer irrigation is necessary. Olive is very sensitive to excessive soil moisture. Poor drainage at any time, if prolonged, will kill the tree.

Fertilizers

The olive tree can obtain the required amount of potassium and phosphorus from the soil. However, nitrogen is utilized by the plants more rapidly, necessitating the application of nitrogenous fertilizers. Under irrigated conditions in California, the growers apply 450 g nitrogen per tree per year just before onset of the winter season. In gravelly, shallow, foothill types of soil, the trees respond well to potassium and boron. In Greece, a fertilizer mixture containing nitrogen, phophorus, and potassium is used.

The organic method of cultivation using *Hedysarum coronarium* cover crop inoculated with a granular formulation of *Rhizobium hedysarii* to supply nitrogen to olive significantly increases the total and organic nitrogen in the soil and has an impact on olive productivity.

Pruning and Thinning

Pruning methods for the bearing trees vary greatly. In the Mediterranean region, heavy pruning is practiced. Heavy pruning under irrigated conditions leads to reduced yields owing to the removal of potential fruit-bearing surfaces, and results in fruit bearing in alternate years. A moderate amount of annual pruning, involving removal of injured, dead, or ill-placed branches, is all that is necessary to spread the fruiting surface uniformly, so that every part of the bearing wood is adequately exposed to light and air. The height of plants in regular plantation is generally maintained at up to 5 m. In some countries, thinning of fruits is achieved by spraying the young fruits with 150 p.p.m. naphthaleneacetic acid. Spray-thinned trees may be expected to bear fruit the following year. The girdling with GA3 plant regulator application (50 or 100 p.p.m.) increases the fruit yield.

Pests and Diseases

Olives have many pest problems, some of them affecting the tree or the fruit itself. Olive fruit fly (*Dacus oleae* Gmel.), olive kernel borer (*Prays oleae* Bern.), olive scale (*Parlatoria oleae* Colvee.), Oleander or ivy scale (*Aspidiotus hederae* (Vallot), greedy scale (*A. camelliae* Signoret), California red scale (*Aonidiella aurantii* (Maskell), and black scale (*Saissetia oleae* Bern.) are the important pests of olive. Two recent reports of beetles injurious to the olive tree involve *Nericonia nigra* and *Noemia semirufa*.

The olive fruitfiy (*Dacus oleae* Gmel.) is a major pest in the Mediterranean region. The insect attacks at early fruit maturity, causing fermentation and premature fruit dropping. Sometimes, owing to adverse climatic conditions, the production loss due to this fly can be as high as 30%. The infestation adversely affects the oil quality by increasing acidity, especially when infestation exceeds 30%. The pest is best controlled by proteinaceous attractant sprays. (E)-2-hexanal emitted by the crushed olives has repellent property to the fruitfly. Chrysopids are the most active and effective predators on olive kernel borer (*Prays oleae* Bern). The pesticides deltamethrin, fenthion, and formothion are also used to control *Dacus oleae*. The use of green immature olives for pickling has become popular in Spain as a means of escape from the olive fly.

The principal disease of the olive tree is 'olive-knot,' caused by *Bacterium savastanoi* Stevens, which leads to knots or tumors on the leaves, twigs, branches, and trunk. There is no proper control for

this disease, except to avoid olive varieties which are susceptible to cold injury and to this organism, or by quarantine. The root-knot, citrus and reniform nematodes can be suppressed by less irrigation frequency and predacious nematode in olive.

Peacock spot (*Cycloconium oleaginum*) and *Verticillium* rot (*Verticillium alboatrum*) are the fungal diseases of olive, occasionally causing heavy losses in production and fruit quality. The problem is serious in humid areas, but can be controlled by various fungicides such as Bordeaux mixture or lime sulfur. Soil solarization of individual diseased trees, when combined with chemical weed control, is effective in controlling *Verticillium* wilt in olive trees. (*See* **Fungicides**.)

Harvesting

Traditionally, the olives are harvested by hand into a receptacle in the autumn or early winter at the appropriate green-yellow stage. Olives for oil extraction are collected by beating the branches of the tree with long poles so that the fruit falls on to cloth sheets laid on the ground. This is done after the fruit has turned black. Beating of the trees tends to promote the spread of olive-knot disease through injury to the fruit and tree. In Greece and elsewhere, the scarcity of farm labor has resulted in the introduction of plastic nets for collection of naturally falling fruit. To obtain better-quality oil, the olives should not be left on the nets for more than 15 days. Chemical sprays to induce fruit abscission are used to aid the mechanical harvesting of olives. Mechanical shakers with stationary cloth, canvas-covered, or mechanized collecting frames are used to a limited extent, mostly for harvesting olives for oil. A 'beating-down' machine for mechanical picking of olives without damaging the trees has been tested in Italy. The machine is particularly suitable for high-yielding trees with well-developed foliage, and for old trees, for which vibrating picking machines are not recommended.

For high-quality table olives, where uniformly ripe fruit is a requisite, the fruit is handpicked using ladders. The finest and most highly prized oil is made from olives picked just before they begin to soften and darken. The time of maturity may vary within the cultivated area, among the trees within the same grove, or within the fruits on the same tree.

The measurement of Brix values allows for rapid, inexpensive estimation of the oil content of olive fruits at the harvest site and is useful in determining optimum harvest time. The respiration rate is another new ripening index for drupes and the harvesting of olives is suggested to be conducted during the climacteric phase of the fruits.

Postharvest Handling and Storage of Fruit

Ideally, the extraction of oil should follow the harvesting of the olives without delay. As this is impractical, the olives must be stored for a period before processing. During storage, several chemical and biochemical changes may occur that lead to the deterioration of the oil. The most serious damage is caused by enzymes indigenous to the olive tissue and those produced by the microflora on it. The pathogenic and saprophytic fungi isolated from stored olives, except *Saccharomyces* spp., increase the acidity of the extracted oil, and no aflatoxins are reported to be detected in samples infected by *Aspergillus flavus*. As the olive tissue respires, heat is produced, which, if not effectively dissipated, accelerates the enzymatic actions. Lipolysis, lipid oxidation, and other undesirable reactions occur, leading to a lowering of the oil quality.

To minimize the effect of these activities, the olives are stored in 25-cm-thick layers in cool buildings. The use of perforated trays for spreading and stacking saves space. The olives are better stored under water in tanks containing mild preservatives, such as 3% salt or 0.03% citric acid and 3% salt, or 2% metabisulfite. Aerobic storage with a low concentration of acetic acid gives stable color and texture even after 3 months; bulk storage can be done in 50% ethanol. Aerobic storage and the maintenance of a CO_2 concentration of 10–15 mg per 100 ml throughout the storage period eliminates shriveling. Fruit maturation is delayed by refrigeration compared with storage at room temperature and the firmness of the fruits stored at room temperature decreases much more rapidly. The sensory and chemical qualities of the oil produced from fruits stored at 5 °C can be maintained for fruit storage durations up to 45 days, but with storage at 8 °C, these qualities are maintained for storage durations up to 15 days. For fruits stored at room temperature, oil quality deteriorates after 7 days of fruit storage. The processing period of oil mills can be extended by freeze-storing of olives at −18 °C for 90 days. This also helps to increase oil extraction. (*See* **Preservation of Food**.)

Processing and Utilization

Oil is extracted traditionally by simple equipment involving crushing, pressing, and separation of oil from the liquor. It is now being replaced by modern mechanical equipment of widely varying designs, either as separate units or combined as a single-stage process. The olive oil recovery processes have been patented in many countries.

The oil obtained from sound fruit by pressing without further treatment is called virgin olive oil. After

the first pressing, the residual pulp is still rich in oil and is usually recrushed and repressed with or without the addition of warm water. Oil obtained from the second pressing tends to have a more intense color and higher acid content, as well as a weaker aroma. This latter oil, together with inferior virgin oil, is further subjected to refining treatments such as neutralization, deodorization, bleaching, and winterization; this helps in removing acid, color, and odor. The oil so obtained is called refined olive oil, which is largely used for mixing with the first extraction to produce edible grades. Refining procedures decontaminate oil containing fenthion residues. The remaining press cake still retains about 4–5% oil, but more than 50% of the total oil in the cake can be obtained in a single step by direct extraction in a continuous centrifugation system, after adding about I % Na_2CO_3 by weight of cake. It is then necessary to dry and further deoil the cake for better stability towards autoxidation. The dried cake is extracted with hexane and the resulting 'sulfur oil' is repeatedly rectified. The extraction with hexane results in an oil with higher acidity and moisture content, but a lower percentage of impurities.

Olive oil has been classified by the United Nations Conference on Olive Oil, held in Geneva in 1961, into four groups according to the method of preparation and acid content:

1. Virgin olive oil. Oil extracted by pressing, free of admixtures, called 'extra' when the oleic acid does not exceed 1 g per 100 g, and 'fine' if the acid content does not exceed 1.5 g per 100 g and the flavor is perfect; 'ordinary' olive oil may contain acid up to 3.0 g per 100 g and have a slight off-flavor; if the oil has a definite off-flavor it is classified as 'lampante.'
2. Refined olive oil. This oil may be called 'pure' when it is refined from virgin oil, and 'second-quality' when it is refined from solvent-extracted oil.
3. Blended olive oil. Blended oil can be called 'pure' when it consists of a blend of virgin and refined oil, and 'blended' when it contains a blend of virgin and second-quality refined oil.
4. Industrial oils. These oils are obtained by extraction of olive residue with solvents.

Storage and Packing of Oil

Olive oil undergoes deterioration during storage. It is important to store the oil extracted from olives of different varieties separately. The storage drums and tanks should be of inert material, impermeable to oil, and lined with epoxy resins, enameled tiles, or glass; and the oil should be stored at a constant temperature of about 15 °C.

Olive oil is packed in several types of retail containers including bottles made of glass, polyvinyl chloride (PVC) or polyethylene, tin-plated cans, and in tetrabriks. The containers should provide protection of the oil from light, and leave a minimum volume of head space. Packing of oil under vacuum and inert gases is also recommended.

Table Olives

Many different methods of converting olives into olive products exist in different olive-growing countries. The traditional method of preparing table olives by removing their bitterness through alkaline treatment, which grew up in the environs of Seville, Spain, is rapidly being replaced by technically advanced methods. Production has been increased and costs have been cut, and the industry has remained highly competitive. Sevillian green olives are the predominant type used (70%), followed by oxidation-darkened olives (25%), and untreated black olives (5%). The chief innovations in the last 25 years have been mass fermentation, development of conservation in an aerobic medium, development of automatic stoning and stuffing machines, developments of pastes, fixing of pack conditions and treatments, and general mechanization of all handling, packing, and storage of the end product.

The major commercial methods are as follows.

Green Fermented Olives (Spanish Method)

The fruits are picked when they are still firm and light green in color. The principal varieties processed in Spain are the Sevillano and Manzanillo. The fruit is covered in large containers with 1.8% lye solution and kept at 28 °C for 4–8 h. The treated olives are frequently washed with water for 24–36 h.

The washed fruits are then covered with brine in fermentation tanks. This changes the color of the olives from deep green to the typical 'olive-green' shade. The product, on attaining equilibrium, contains 6–8% NaCl. Spices may now be added to the fermented olives according to consumer preference. Closed containers help prevent the development of surface yeasts and molds.

The fermented olives, before marketing, are graded according to shape, size, and color. Sometimes the olives are pitted and stuffed with pimentos, onions, almonds, anchovies, or other products. The fermented brine is filtered (or replaced by fresh brine) for covering the olives in bottles or cans prior to pasteurization.

Olives at different stages of ripeness suffer major losses during the pitting process; green unripe olives are excessively firm, and the cell wall of changing-color

olives is too disorganized to give good industrial results. The treatment with high concentration of lye and its 100% penetration into the flesh, irrespective of fruit size, results in significant textural decline and changes in the composition of polysaccharides that are most important to the cell wall structure.

Among the major spoilage organisms, zapatera – a butyric acid producer – is important.

Canned Ripe Olives (American Style)

The principal commercial varieties packed are the Ascolano, Manzanillo, Mission, and Sevillano. Straw-yellow to cherry-red olives are graded according to color and size to insure uniform lye penetration. The fruits are placed in 5.8% brine for 6 weeks or longer in large wooden or concrete tanks, and the brine concentration is gradually raised to 10%. The fruit is then transferred into shallow vats and treated 4–8 times with gradually decreasing strength of lye (3.0–0.5% NaOH). Each treatment is followed by exposure to air for 1–5 days, either with frequent turning in the presence of air or by bubbling air through the immersed fruit. The olives are then leached by frequent changes of water for 5–7 days until all traces of NaOH are removed. (*See* **Canning**: Principles.)

The washed olives are pasteurized, cured in 2–3% NaCl for 2–6 days, graded, and packed into enameled cans covered with 2.5–3.5% NaCl solution, sealed and sterilized at 116 °C for 1 h. Pitting and stuffing of olives are often practiced.

Black (Naturally Ripe) Olives (Greek Method)

The Greek black olive industry uses naturally ripe, fully matured and dark-purple fruits of mainly Calamata, Conservolea, and Magaritici varieties. The fruits are covered with brine, and the concentration is gradually increased to prevent shriveling. The covering brine concentration is kept at 10% NaCl during winter and increased to 15–16% during summer to prevent spoilage. The bitterness is lost within 3–6 months, and the lactic acid formed during fermentation does not exceed 0.5%. The dark-purple anthocyanins of the olives turn light red during fermentation.

The olives, while being prepared for marketing, are exposed to air until the dark color is regained. The fruits are carefully sorted and graded according to international standards, and repacked in fresh brine containing about 8% NaCl and 0.5–0.75% acetic acid.

Antifungal treatment trials of 'Greek-style' black olives indicate that sorbic acid 0.075% is the most efficient preservative, followed by 0.075% benzoic acid and 0.032% calcium proprionate. In the olives inoculated with *Aspergillus parasiticus*, the preservatives totally inhibit aflatoxin formation, while the toxin can be detected at low concentrations in all controls.

The spoilage organisms encountered are zapatera, galazoma, and film-forming pectolytic organisms which disintegrate the 'meat' of the fruit. This last problem can be prevented by means of a thin layer of paraffin oil on the surface of the brine.

Utilization of Byproducts

Olive Cake or Meal

The press residue may be used as a fuel, manure, animal feed, soil conditioner, fiber (cellulose and lignin) for food use, or in single-cell protein production. Sludge obtained from olive-processing plants enriched with nitrogen fertilizer can be applied to olive orchards growing on alkaline alluvial soils and as manure for maize. The spent form of olive oil cake can be incorporated into the diets of rabbits at 30% level. Mixtures of organic acids of low molecular weight and fatty acids can be recovered from the waste gases produced during drying of cake. *Pleurotus eryngii* can be grown on a medium containing olive husks.

Olive Stones

The olive stones find use in molded products, plastics, and furfural manufacture. Activated carbon produced from olive stones has a high adsorption capacity against lead.

Olive Vegetation Water

Tocopherols, flavor compounds, antioxidants, and anthocyanins can be recovered from olive vegetation water. Olive oil deodorization distillate contains squalene in a concentration range of 10–30%. Squalene in high purity with 90% yield can be recovered by supercritical carbon dioxide extraction. The application of 100–200 m^3 waste waters from olive oil-processing plants per hectare, 45 days after sowing, markedly increased barley and sunflower yields and was reported to have no adverse effects on soil microorganisms. (*See* **Antioxidants**: Natural Antioxidants; **Flavor (Flavour) Compounds**: Structures and Characteristics; **Tocopherols**: Properties and Determination.)

Nutritional and Health Aspects

The use of olive oil, whether in medicine or as source of nutrition, has its roots in ancient history. During the last few decades, renewed interest has been generated in the nutritional and health aspects of the olive. The oil is used largely for culinary

purposes, in wool combing, the manufacture of toilet preparations, and in the pharmaceutical industry.

Besides its physiological advantage in being rapidly and completely digested, the oil also has clinical importance e.g., antiulcer activity, effectiveness in combating gallbladder disease, and in lowering plasma cholesterol level. Omega-6-polyunsaturated fatty acid in olive oil may exacerbate adjuvant-induced arthritis. Olive pollen extract can induce an asthmatic response. (*See* **Fatty Acids:** Dietary Importance.)

ONIONS AND RELATED CROPS

S Khokar, University of Leeds, Leeds, UK
G R Fenwick, Institute of Food Research, Norwich, UK

Introduction

The genus, *Allium* (family Alliaceae), is large and geographically diverse, comprising over 500 species, most of which have little commercial importance. Alliums are distributed across warm temperate and temperate regions and into the subArctic belt. The major centers of genetic diversity are Afghanistan, Iran, and Pakistan with the Mediterranean basin being regarded as a secondary center. In addition to the onion (*A. cepa* L.), cultivated vegetable Alliums include garlic (*A. sativum* L.), leek (*A. ampeloprasum* L.), Japanese bunching onion (*A. fistulosum* L.), rakkyo (*A. chinense* G. Don), Chinese chives (*A. tuberosum* Rottl. ex Spr.), chives (*A. schoenoprasum* L.), and shallot (*A. cepa* L.).

The onion is by far the most important of the cultivated Alliums. Production is mainly in the Northern Hemisphere, with relatively little in unfavorable tropical regions (where shallots are grown). Cultivation experience, cultural attitudes, social beliefs, and culinary practices have resulted in specific Alliums being prized in particular regions; for example, leek and shallots in Western and Northern Europe; kurrat in Egypt and the Eastern Mediterranean; rakkyo, Japanese bunching onion; and garlic in China and Japan. The dramatic increase in global travel, interest in exotic and ethnic foods, and associated culinary practices, allied to improvements in agronomic practices and varietal- and postharvest characteristics have combined to encourage demand for fresh and processed vegetable Alliums. This has been intensified by prevailing enthusiasms for both 'healthy' eating and naturally occurring health remedies and medicines.

Onions and other cultivated Alliums have long been prized for their culinary properties, flavor, and taste and for their use as natural medicines. More

recently, their nutritional and health-enhancing properties have attracted much scientific investigation and consumer interest, thereby encouraging primary production and stimulating postharvest activities and opportunities. This brief article addresses the composition, flavor, postharvest handling, and processing of Alliums, emphasizing their significance for human health and well-being. The focus is mainly, but not exclusively, on onion and garlic.

History

The onion has been cultivated for over 4000 years; the earliest records are found in Ancient Egypt, including carvings dated to the third and fourth dynasties (2700 BC). In addition to being eaten, onions had significance in funeral rituals and embalming. During their Exodus (1500 BC), the Israelites recalled the foods of Egypt, including onion, leek, and garlic; mention was made of onions in Indian manuscripts dating from the sixth century BC. Locally grown onions were among the fermented vegetables given to the builders of the Great Wall of China (third century BC). Greek and Roman authors, notably Theophrastus and Columella, described the botany and cultivation of the onion, whereas others, such as Hippocrates and Dioscorides, focused on its medicinal properties. These culminated in the writings of Pliny, which addressed the cultivation, uses, and history of onions, garlic, and leek, and, together with the work of the military physician Galen, these had a great influence on the practice and writings of herbalists in medieval times and later. More extensive information has been published in the reviews of Fenwick and Hanley.

Production

Onion production in Asia accounts for more than 60% of the global production; together, India and China account for more than a third; in comparison, European production is less than 10%. Asian production of garlic exceeds 80% of the global volume, with China alone producing almost two-thirds. The world production of dry onions and garlic in 1999 is summarized in Table 1.

Table 1 Production of dry bulb onions and garlic ($\times 10^3$ tonnes)

Country	*Onion*	*Garlic*
World	41 527	9 042
Asia	25 511	7 585
Africa	2 780	178
North and Central America	3 370	301
South America	2 796	286
Europe	3 454	266
People's Republic of China	11 290	5 990
India	4 429	451
USA	2 995	224

From FAO Production Data (1999).

Composition

Onions and garlic are found in kitchens all over the world, being used as cooked vegetables, in salads, and as a flavoring in meat, poultry, and vegetarian dishes. Onions additionally possess excellent processing characteristics and may be canned, pickled, frozen, and fried. Dehydrated onion and garlic powders and flavor extracts also serve to enhance the value of these Alliums in the home and in the food industry. The proximate composition of selected Alliums is listed in Table 2. The cultivar, agronomic and environmental conditions during growth, and postharvest conditions all affect the composition. Protein, fat, and fiber contents are low in comparison with other vegetables, and starch is absent. Carbohydrates include sucrose, glucose, fructose, and fructose polymers. Green onion tops have also been found to be rich in β-carotene and to contain significant amounts of vitamin C. Alliums are rich in amino acids and γ-glutamyl peptides (including precursors of the characteristic pungent flavoring compounds), as well as biologically active secondary metabolites such as anthocyanins, flavonols, and phenolics.

Flavor

Alliums are rich in sulfur-containing compounds that are broken down by endogenous enzymes to yield a number of more volatile, less stable chemical compounds. These are considered to be responsible for much of the biological activity found in Allium extracts and oils, as well as determining the particular flavor characteristics of individual members of the family. (*See* **Flavor (Flavour) Compounds**: Production Methods.)

Flavor Biochemistry

Intact alliums have no pungency, since the volatile products are only released following the interaction of the enzyme, alliinase, with the *S*-alk(en)ylcysteine sulfoxide (alliin, I) which occurs when tissue is damaged or disrupted (Figure 1). The initial products of this enzymic hydrolysis are ammonia, pyruvate, and

an alk(en)ylthiosulphinate (allicin, II). The latter, which possesses odor characteristics typical of the freshly cut tissue, can undergo further nonenzymic reactions to yield a variety of compounds, including thiosulfinate [III] and di- and trisulfides [IV]. These compounds have slightly differing flavors and odors, and may impart a cooked note to steam-distilled onion or leek oils.

Not all alliums contain the same substituted cysteine sulfoxides; onion contains primarily the *S*-(1-propenyl), *S*-propyl, and, to a lesser extent, *S*-methyl derivatives (Ia–c, respectively). Thus, the typical flavor of onion is due to the presence of propyl- and 1-propenylthiosulphinates and corresponding di- and tri-sulfides. In contrast, garlic contains predominantly *S*-(2-propenyl)cysteine sulfoxide (*S*-allylcysteine sulfoxide, Id) and, and none of the 1-propenyl isomer. Its flavor is consequently due to the presence of 2-propenylthiosulphinate and related di- and trisulfides. Hive and leek contain relatively more *S*-methylcysteine sulfoxide, which yields methylthiolsulfinate (possessing a 'cabbagy' note), dimethyldisulfide, and related compounds.

Since it is possible for both symmetrical (II, $R = R'$) and mixed (II, $R \neq R'$) thiolsulfinates to be formed during the enzymic breakdown of alliins, and since these can yield all of the breakdown products mentioned above and which can subsequently enter into secondary chemical reactions, the composition of the flavor volatiles of freshly chopped onion, leek, and garlic can become very complex. Almost 100 compounds have been identified in freshly cut onion and garlic, and processing – especially that involving thermal treatment – causes additional chemical reactions to occur. These give rise to thiphenes, polysulfides and the products of amino acid–sugar (Maillard) reactions.

Lachrymatory Factor

Alone amongst the common alliums, the onion contains large amounts of *S*-(1-propenyl) cysteine sulfoxide (Ia). This compound is unique because the action of alliinase does not give rise to allicin, but rather to a mixture of unstable isomers of thiopropanal-*S*-oxide (V), which comprise the lachrymatory principles of the onion. The mode of formation of these compounds and their properties suggests that the problems of peeling onions may be reduced if carried out under running water, or if the onion is first chilled.

Estimation of Flavor Strength

The development of simple and reliable methods for the assessment and comparison of strength of flavor in onions and garlic, which may be required to identify cultivars with advantageous processing characteristics, has been the subject of much investigation. Since the enzymic cleavage of flavor precursors by alliinase generates a range of breakdown products, these have been used to measure pungency. The lachrymatory principle has been measured colorimetrically and spectrophotometrically, but these determinations are necessarily confined to onions. A robust method for pyruvate employs the color reaction with 2,4-dinitrophenylhydrazine; however, this cannot be employed for dehydrated products due to the presence of interfering by-products formed during dehydration and storage. Gas-chromatographic methods, with initial flavor concentration, have also been used to measure the headspace volatiles. The

amount and composition of the volatile fraction is largely dependent upon the conditions (degree of tissue disruption, temperature, time), so that all of these variables must be kept constant if reliable comparisons are to be conducted. Alternative approaches involve measurement of alliinase or γ-glutamyltranspeptidase activity. It is possible to monitor the flavor precursors, including γ-glutamyl peptides and alliins; however, such methods provide an indication of *potential* flavor, since the presence of the appropriate enzymes is necessary to release the volatile compounds.

Factors Determining Flavor

Amongst the many factors that have been found to have an effect on flavor are genotype, physiological age and condition, storage, and agronomic and environmental conditions. Thus, the range of flavor intensity in onions may vary 10-fold, with the most pungent being selected for processing. Sprouting of onions during storage leads to an increase in flavor as a result of a rise in transpeptidase levels and the conversion of γ-glutamyl peptides to alliins. Alliums grown under dry or arid conditions are smaller and visually less attractive than those grown in an abundance of water, but generally possess stronger flavors. The application of sulfur to the soil during growth significantly increases flavor, pungency and (in onions) lachrymatory character. The available sulfur is used preferentially for plant growth; only when these growing requirements are met is the secondary metabolic pathway, leading to alliin and allicin, enhanced.

Nutritional and Health Aspects

Garlic bulb and onions, two members of the Allium family, have been widely reported to possess a significant antioxidant activity which has been ascribed to allicin, a known scavenger of peroxyl radicals. Recent studies have indicated that, in addition to this scavenger, other compounds could also be involved. The onion contains a number of quercitin, isorhamnetin, and kaempferol conjugates and, indeed, is one of the major sources of flavonols in European diet. A relatively small range in content of quercitin conjugates for red (110–295 $mg\,kg^{-1}$) and yellow (119–286 $mg\,kg^{-1}$) cultivars have been reported. Flavonoids have been shown to offer protection against degenerative conditions such as cardiovascular disease, cancer, and aging.

Many alliums, including noncultivated wild types, have been extensively used for their therapeutic and medicinal properties. Most traditional medical practices include references to onion, garlic, and other alliums in the form of extracts, decoctions, concoctions, and poultices. Onions and garlic oils have proved effective in the treatment of a number of conditions, including intestinal worms, stomach ulcers, eye disorders, gastrointestinal disturbances, hypertension, and malarial fevers. Beneficial antitumor, hypoglycemic, hypolipemic, antiatherosclerotic, antiplatelet aggregation effects have also been reported. The active principles in many cases have been shown to be the sulfur-containing alliin derivatives.

A number of 'odor-free' garlic products, including capsules, extracts, and tablets, are commercially available. Since the biologically active principles also possess pungency, some care is needed to ensure that the treatment employed to remove odor has not at the same time reduced or removed the medicinally active compounds. (*See* **Garlic**.)

Postharvest Storage

Postharvest losses of onions may range from 10 to 30%, with even higher losses being reported from tropical regions. A number of factors have been shown to contribute to these figures; as a result, cultivars have been selected for improved storage characteristics, methods for sprout control developed, and storage practices and technologies optimized. Postharvest losses may be minimized if damage and bruising are reduced during harvest, storage, and packing; adequate ventilation of storage areas is vital if moisture accumulation on tissue surfaces, and subsequent disease proliferation, is to be avoided.

Dormancy, Sprouting, and Storage

Bulb dormancy is controlled by a complex interaction of growth inhibitors and promoters. Natural dormancy commences with harvest maturity and continues for 4–9 weeks, during which period, the bulbs will neither sprout nor continue to grow due to the influence of inhibitors translocated from the green leaves. However, these inhibitors are gradually destroyed with time. Once dormancy has passed, roots may emerge and leaf shoots appear; sprouting is optimal at 10–15 °C. Onions may be stored without sprouting if maintained at 0–5 °C and 65–70% relative humidity (RH). Sprouting has also been inhibited by controlled-atmosphere storage atmosphere storage at reduced oxygen levels (for example, 5–10% CO_2, 3% O_2, 5 °C), γ-irradiation or preharvest foliar treatment with maleic anhydride (MH). Onions treated with MH and held between −2 and 0 °C and 65–70% RH can be stored for 6–7 months without any deterioration of quality.

Garlic bulbs intended for consumption are held at ambient temperatures and can remain in good condition for several months. However, for extended storage of up to 8 months, bulbs should be stored at −2 to 0 °C and 60% RH. Sprouting most readily occurs between 5 and 10 °C, and inhibition may be achieved, as described for onions. Unlike onions and garlic, leeks are in active growth when harvested; they can have a postharvest life of up to 8 weeks at 0 °C and 95% RH. Controlled atmosphere treatment (for example, 10% CO_2 + 1% O_2) can extend the storage period further. Leeks are stored upright to avoid curvature of the pseudostems.

Storage Diseases

Postharvest diseases of onions, which will reduce the quality and, thereby, the value of the crop, are largely determined by the growing and storage conditions. The major disease of stored onions in temperate regions is neck rot, caused by *Botrytis allii*. This may be controlled by seed and set treatment with benomyl/thiram and effective postharvest drying. Other soilborne diseases (notably, white rot, pink rot, basal rot and smudge) are best controlled by combinations of field treatment and good husbandry.

Processing

Dehydration

Onions were included in the first dehydration experiments carried out in the late eighteenth century. A major program of onion and garlic dehydration was conducted in California in the 1920s, and dehydrated onion was already extensively used in food processing by the end of the next decade. It was the onset of World War II that provided the necessary impetus for the development of commercial food dehydration techniques. Onions for dehydration are generally white or yellow and have a high solids content (18–20% and above) and strong pungency. After preliminary cleaning, peeling, and slicing/chopping, onions are dehydrated at 75–60 °C, the temperature being reduced as the moisture content decreases. The final moisture content of 4% is achieved through warm air circulation. Discoloration may be minimized by effective curing and conditioning whilst the application of fluidized-bed techniques may overcome problems of scorching and agglomeration. In general, 8–10 kg of raw onions produce 1 kg of dehydrated product. Garlic may be dehydrated under similar conditions, with 5 kg of fresh bulbs producing 1 kg of dried product. Experiences of hot-air drying of chives have revealed problems such as an undesirable flavor, texture, and color. Flash-freezing and drying have proved effective in overcoming these problems. Dehydrated leek products are available for use in soups and other products, and dry green onions have been used to replace more expensive shallots and chives. Onion and garlic powders are used in the manufacture of onion and garlic salt. Both dehydrated onion and garlic are prone to discoloration, a problem that can be minimized by optimizing the drying conditions or employing approved additives. (*See* **Drying**: Theory of Air-drying; Physical and Structural Changes.)

Onion and Garlic Oils

Onion oil is obtained by the distillation of minced onions. The oil, obtained in a 0.002–0.03% yield, depending upon the source and processing conditions, has a flavor enhancement 500 times that of the dehydrated product. Garlic oil comprises 0.1–0.25% of the fresh weight of the clove, 1 g being equivalent to 200 g of dried garlic. The intense pungency of these products makes them difficult to use directly, and they are usually diluted in vegetable oil, or encapsulated.

Onion and Garlic Juices

Onion and garlic juices contain both flavor and aroma-active compounds, their precursors and sugars. They may be blended with volatile oils to restore a 'rounder' flavor profile. The juices, viscous and dark brown in color, can be mixed with a support (such as propylene glycol, lecithin or glucose) to provide an oleoresin with a flavor intensity 10 times greater than that of the dehydrated powder.

Others

Canned and bottled onions are used by the catering industry, especially in North America. Onion rings, coated in batter, are widely used in fast food outlets; these are supplied frozen, usually being extruded rather than machine-cut. Pickled onions, popular in the UK, are prepared from both 'brown' and pearl/cocktail onions (28–45 mm and 10–28 mm, respectively). Typically, brown onions are steeped in brine (10%) for 1–4 days, and lactic acid is added to control fermentation. They are then washed, covered in vinegar, and pasteurized; bisulfite may be added to maintain the color. Silverskin onions tend not to be pasteurized since this adversely affects the texture and flavor. Fermentation of Alliums has been described for thousands of years; onions, garlic, and leek are included in a variety of fermented products such as kimchi, ragi, sauces, and pickles. Many varieties of salamis and sausages are also strongly flavored with garlic before drying.

ORGANICALLY FARMED FOOD

S Stolton, Elm Farm Research Centre, Berkshire, UK

Introduction

As our food system becomes ever more complex, foods become more highly processed, and the variety of foods available at any one time overcomes geographical and seasonal restraints, some consumers have been drawn towards alternative forms of production such as organically farmed food that are seen as more 'natural' and 'healthier' and perhaps of higher quality. The scientific evidence substantiating such claims remains limited, however, and is often the subject of intense debate. In practice, any analysis of the differences between organic and conventional food needs to encompass a wide range of different issues relating to health, environment, society, and the innate preferences of consumers.

What is Organic Farming?

Organic food is produced by farming methods that rely to a large extent on locally available resources and depend on maintaining ecological balances and optimizing the benefits from naturally occurring biological processes, rather than on manipulating the ecosystem through use of agrochemicals and fossil fuels. Organic agriculture aims to encompass agricultural systems that promote environmentally, socially, and economically sound production. By respecting the natural capacity of plants, animals, and the landscape, organic agriculture aims to maximize the quality of food whilst maintaining a sustainable agriculture and environment.

The principal aims of organic agriculture are summarized by the International Federation of Organic Agriculture Movements (IFOAM) in its *Basic Standards for Organic Agriculture and Food Processing*. These aims are:

- to produce food of high nutritional quality in sufficient quantity;
- to interact in a constructive and life-enhancing way with all natural systems and cycles;
- to encourage and enhance biological cycles within the farming system, involving microorganisms, soil flora and fauna, plants, and animals;
- to maintain and increase long-term fertility of soils;
- to use, as far as possible, renewable resources in locally organized agricultural systems;
- to work, as far as possible, within a closed system with regard to organic matter and nutrient elements;
- to work, as far as possible, with materials and substances which can be reused or recycled, either on the farm or elsewhere;
- to give all livestock life conditions which allow them to perform the basic aspects of their innate behavior;
- to minimize all forms of pollution that may result from agricultural practice;

- to maintain the genetic diversity of the agricultural system and its surroundings, including the protection of plant and wildlife habitats;
- to allow agricultural producers a life according to United Nation human rights, to cover their basic needs, and obtain an adequate return and satisfaction from their work, including a safe working environment;
- to consider the wider social and ecological impact of the farming system.

The IFOAM *Basic Standards* have provided a framework for almost all the national regulations and for the international World Health Organization/Food and Agriculture Organization Codex Alimentarius on organic agriculture. They are used by organic farmer organizations worldwide as a common platform. In many countries organic food and farming are regulated by legislation. In the European Union, for example, organic standards and certification procedures are enshrined in the European Community (EC) Regulation 2092/91, which provides a legal definition of organic production in Europe and for organic produce imported into Europe.

What Makes Organically Farmed Food Different?

There have been persistent calls from within the food industry for research that distinguishes clearly what, if anything, differs between organic and conventionally produced foods. Studies have been increasing in both number and scale, although results remain ambiguous. This is a highly political subject and there are regular well-publicised claims to 'prove' the issue one way or another. However, in reality many questions remain to be answered.

The majority of the scientific studies carried out to determine what, if any, special characteristics can be attributed to organically farmed food, as opposed to food produced under other production regimes, have been comparative, using one or two crops to determine general trends.

A comprehensive literature review of over 150 comparative studies of this sort was published in 1997. The review highlighted a number of inherent problems with comparative studies to date, including that there was no clear and consistent definition of 'conventional' agriculture (although primarily this term denotes a system where farming methods attempt to substitute natural processes – for instance, by using inorganic fertilizers or pesticides) and that sample sizes tended to be small – both of which make trend analysis difficult. Most studies reviewed are physicochemical evaluations of concentrations of desirable or undesirable elements in food. Other analytical methods used in comparative studies include electrochemical, plant physiological, and multivariable physicochemical methods, susceptibility to infection, and postharvest behavior. More 'alternative/holistic' methods to determine the quality of organic food have also been developed but these are not generally recognized by conventional scientists. Such methods include the ascending-imaging method, round filter chromatography, copper chloride crystallization, and the measurement of ultraweak photon emissions. The studies carried out using these methods claim to have shown a trend towards organic foods having more 'vital activity' than other food from other production systems.

Other researchers argue that focusing solely on physicochemical evaluations misses many of the wider issues relating to organic food and also misses the reasons why most consumers buy organic food. Just as the organic farming system cannot be fully understood by studying one crop in the rotation, the qualities of organic food cannot be determined by one or two comparative studies of individual food products or the effects of an organic diet on laboratory-reared animals. A more valid approach to understanding the characteristics that may make organic food different is to look at a wider range of attributes that together could be said to describe 'food quality.'

A new framework, or definition, of food quality, combining six distinct criteria was drawn up by a group of international experts involved in the food industry, at a colloquium organized by the UK-based organic research organization, Elm Farm Research Centre, in 1989. Like all such concepts, this can never hope to cover all aspects of quality. However, the definition does incorporate the many issues that have been the focus for research into the quality of organic food and is thus a useful tool for reviewing research findings. In many areas quality characteristics can be measured quantitatively and comparisons between organic and conventional practices can be made; however, our choice of food is often led more by the subjective non-quantifiable values, which can make the judging of quality more difficult, but no less valid.

The Six Aspects of Food Quality

The six criteria of food quality (authentic, functional, biological, nutritional, sensual, and ethical) identify the range of issues that consumers and producers recognize as important with respect to food production and composition. They thus provide a framework within which a more comprehensive analysis of what makes organic food different can be carried out. Each criterion is briefly examined below.

Authentic

> Food that is authentic, traditional or natural and has not been adulterated in production, processing or storage, including the use of genetically modified organisms or their derivatives.

Consistently, research into consumers' attitudes shows that the main perceptions of organic food are linked to phrases such as 'no chemicals/additives/pesticides,' 'natural' and 'healthy.' Although there is an increasing range of processed organic foods being produced, these processes are themselves bound by standards for organic production. According to the IFOAM *Basic Standards*, the general principles of organic food processing and handling are that: 'any handling and processing of organic products should be optimized to maintain the quality and integrity of the product.' Furthermore, the processing methods should ensure that: 'the vital quality of an organic ingredient should be maintained throughout each step of its processing.'

Measuring authenticity is almost impossible because it relates to such a large extent to individual consumer preferences. However, issues like the avoidance of most agrochemicals, the fact that organic food aspires to be locally produced, and the generally reduced processing appeals to a substantial part of the food market. The fact that organic food is also free of genetically modified (GM) food also meshes well with consumer preferences in Europe and beyond. More generally, the less processed nature of most organic food helps fulfill the needs of those consumers who are consciously trying to move away from the highly processed foods that became a dominant part of the industry in the 1980s and 1990s.

Functional

> How appropriate food is to its specific purpose – i.e., food that produces, stores, or cooks well. 'Functionality' is also used by food scientists and technologists to describe ingredients that blend well, or which have a good shelf-life.

Concern about the world's diminishing biological diversity (or biodiversity) has been growing in recent years. Although biodiversity loss tends to be linked in people's minds with threats to rainforests or to rare animals like giant pandas, genetic diversity is also being lost within food production. This loss inevitably affects our choice of the variety of food and the functionality of crops produced.

Loss of variety means loss of potential to adapt to different conditions. A distinction between organic and conventional agriculture is that in the former, encouragement of greater variety is an important part of the overall system, because reduced reliance on agrochemicals to change conditions in the soil means that the plants must themselves be better adapted to local conditions. Organic standards encourage the expansion of varieties grown to gain benefit from those suited to particular growing conditions. For example, conventional wheat grown in an organic system will show a distinct reduction in protein content, whereas selection of a variety suitable for the particular conditions on the farm can allow baking-quality wheat to be grown.

This encouragement of diverse species use is threatened by the general reduction in crop diversity. A survey of some 75 crop species, carried out by the Rural Advancement Fund International, found that about 97% of the varieties given on old US Department of Agriculture lists are now extinct (assuming that varieties that are not stored in US seed banks are probably extinct). This loss is not unique to the USA, for example, indigenous wheat, rice, and sorghum varieties have virtually disappeared from many centers of diversity in areas of Europe, the Middle East, Africa, and Asia. Of the 2500 or so apple varieties that have been grown in the UK, just nine now dominate the retail outlets. Within the EC, this erosion of diversity in crops has become legally obligatory with the introduction of a common catalogue. Varieties not listed are seen as inferior and cannot be legally sold by seed companies.

Organic growing conditions can also contribute to the functionality of food. A review of research on storage degradation by the Soil Association shows that organic crops can have better storage quality and postharvest behavior than nonorganically grown produce. Organic plant production is characterized by a relatively low level of nutrient supply compared to conventional crops. This leads to earlier completion of vegetative growth and an early onset of maturity, which may contribute to a longer shelf-life. Respiration rates and enzyme activity, which can also result in lower storage losses, also tend to be lower in organically farmed foods.

Biological

> How food interacts with the body's functioning. This includes both negative and positive interactions, such as the detrimental effects of some food additives on allergies and beneficial effects of foods in stimulating immunity to disease. The concept also refers to the pharmacological qualities of foods and herbs.

Many consumers feel that organic food can have positive effects on health and this is a major reason for purchase. A comprehensive review of over 400 published papers by the Soil Association of existing research on the differences between organically and

nonorganically grown foods has revealed significant differences to key areas of food quality important to the promotion of good health – food safety, nutritional content, and the observed health effects of organic food. The review notes that, while there has been little research carried out on humans, a number of feeding trials on animals have shown significant improvements in the growth, reproductive health, and recovery from illness of animals fed organically produced food.

Reproductive health is seen as a particularly sensitive indicator of environmental conditions and has been the focus of some research into the effects of organic food on health. It is known that occupational exposure to pesticides can impair reproductive health and it is hypothesized that long-term low-dose exposure to residues through food intake may also have adverse effects, so food with less pesticide residues might be expected to have beneficial results. In the mid-1990s, two small studies in Denmark indicated that semen quality was improved among consumers of organic food and this gained worldwide publicity – however, a larger study could not confirm these results. Several feeding experiments have also been carried out, but over a range of studies of mice, rats, pigeons, rabbits, and hens the reproductive effects of diet have shown no clear trend. In feed experiments with mice and rats the share of stillborn animals and animals that died shortly after birth was significantly higher in litters fed on conventionally produced feed.

The routine use of antibiotics in intensive farming has been linked to the development of 'superbugs' resistant to antibiotics used to combat human illness. As organic standards only allow the use of antibiotics in animals to cure specific problems, it is reasonable to suggest that an organic diet will reduce the build-up of antibiotic residues.

Nutritional

How food contributes to a balanced diet. This recognizes individual food values, such as vitamins, protein, and trace elements, and undesirable elements such as fats and sugar and nitrate and sodium, which in large amounts can be harmful.

Public concern about the presence of pesticide residues, additives, and nitrates in food is the reason many consumers purchase organically produced food. The organic sector has, however, been careful to stress to consumers that, given the state of the environment, and the presence of pesticide residues in soils, air pollution from spray drift, and industrial pollution, no food production method can guarantee a 100% chemical-free crop. There is however evidence that organic foods do have lower levels of pesticide residues than comparable conventional crops, although these results should not be overestimated given the small number of studies.

Concern has also been expressed over increasing nitrate intake from dietary sources, notably from the consumption of vegetables, although the possible health impacts of this remain the subject of debate. There is considerable variation in the levels of nitrate in foods, and in the consumption patterns of different foodstuffs amongst people; for example, the nitrate content of leafy vegetables is generally higher in winter. Comparative studies on farming systems and the related accumulation of nitrate in vegetables have been the subject of several research projects in recent years. In the UK, trials showed significantly lower levels of nitrate accumulation when using composted farmyard manure compared to the use of the soluble compound fertilizer – although fertilization with either type of material did lead to an increase in the level of nitrate in the plants. This trend is confirmed over a range of research studies (the Soil Association reviewed 16 studies, of which 14 showed a trend toward significantly lower nitrate contents in organically grown food), with nitrate content of conventional produce as opposed to organic production being particularly high in nitrophilic leaf, root, and tuber vegetables.

The presence or absence of harmful or potentially harmful substances in food only represents one aspect of the nutrition equation, as our food is made up of a range of nutrients such as vitamins and minerals. The Soil Association reviewed 99 papers that compared the nutritional quality of organically and conventionally grown crops. These studies were assessed for validity in terms of agricultural practice and scientific analysis. Of those studies deemed valid, the Soil Association concluded that vitamin C and dry-matter contents are higher, on average, in organically grown crops. Mineral contents were also higher, on average, in organically grown crops, although the small number and heterogeneous nature of the studies included mean that more research is needed to confirm this finding. Research also indicates a clear long-term decline in the trace mineral content of fruit and vegetables, but to understand the reason for this the influence of farming practices requires further investigation.

As well as having effects on individual elements of crops, the choice of an organic diet may also have an effect on overall dietary habits. A survey of the diet of UK organic consumers concluded that those committed to the consumption of organic food have a different diet from the average consumer – a diet that is more in line with the productive capacity of the organic system. By collecting detailed diet diaries and comparing them with data from the Office of

Population Censuses and Surveys, organic consumers showed a significant swing towards the consumption of fruit and vegetables, with a reduction in the protein food 'centerpieces.' Protein consumption was less dependent on meat, being derived from other sources. Staples showed a greater diversity, with a greater intake of pasta, grains, and cereals, with less concentration on potatoes. The survey data also showed an increased consumption of fibrous foods and a decreased consumption of animal-based as well as sweet and fatty foods.

Sensual

Food which appeals to the senses; the industry uses the term 'organoleptic' to refer to sensual quality of food, i.e. its look (esthetic appeal), taste, feel (as in mouth feel), smell, and sound.

The determination of whether organic food tastes better than food produced from other forms of production has been the subject of considerable research. Although it is widely believed by consumers that organically farmed food tastes better than the alternatives, there is no conclusive scientific evidence to prove this. Partly this is due to individual preferences in taste, which makes the determination of quality through taste alone totally subjective, and is complicated by a whole range of regional factors, such as soils and climate, which make direct comparisons between growing systems difficult (unless trial plots are extremely well matched). The Soil Association also suggests that other influences on taste could be the higher water content in conventionally grown food diluting its flavor, different choices of cultivars, and the fact that organic produce has sometimes been shown to have higher natural sugar content, which may be perceived as a better or worse taste, depending on the product.

Review of feeding experiments with animals has however drawn one unexpected, and so far unexplained, conclusion. When given the choice, animals almost always prefer organic produce to conventionally produced feed.

Ethical

This concept has four related but distinct meanings: environmental (the effects on our environment of food production methods); social (the conditions in which food producers are treated – on the farm, in the factory, on the shop floor); ethical (the morality of the way specific foods are produced – for example, the conditions of animals raised for meat); and political (the effects of the food industry on specific countries).

Research into consumer preferences suggests that there has been a shift in emphasis amongst purchasers of organic food in the last decade, away from people primarily driven by personal health concerns to those with a wider interest in the environmental and social impacts of the food that they buy.

There is a large literature describing the environmental problems of conventional agriculture and the benefits of organic agriculture. For example, long-term research projects have accumulated substantial evidence that organic systems are beneficial to biodiversity. An overview of research findings from 23 of these projects by the Soil Association concluded that in most studies there were important differences between the biodiversity on organic and conventional farms, with generally greater levels of both abundance and diversity of species on organic farms. On average, the research found five times as many wild plants in arable fields and 57% more species, 25% more birds at the field edge, and 44% more species in fields in the autumn and winter, and three times as many nonpest butterflies in crop areas.

In a review of the environmental impacts of organic farming in 18 European countries, an assessment of a series of environmental indicators found that organic farming has more floral and faunal diversity than conventional farms, tends to conserve soil fertility and system stability better and on a per-hectare scale has between 40 and 60% lower CO_2 emissions and is likely to have lower emissions of N_2O, CH_4, and NH_3.

Sociological data comparing organic and conventional farming systems are not so well advanced. The IFOAM began a project on data collection and farm system comparison in 1997 and has developed a methodology which collects data on 13 indicators that provide information on subjects such as production of main and byproducts, recycling, male and female hired and own labor, financial results, energy consumption and production, water use, family expenditure, and education. The methodology is now being tested in Guatemala, India, and Nicaragua. Results to date have shown that self-reliance, which is defined as a percentage of output value that is consumed on the farm, is higher in the organic farms.

Conclusions

Many of the issues described above are not limited to organic production: for example, fresh food is available at the farm gate from many conventional farms and there is a growing fair-trade movement that insures equitable returns for food produced in developing countries. However, organic farming is the only system where all such issues are addressed together and within a legal framework through the organic standards, insuring that consumers can be reasonably

confident that a 'package' of health, environmental, and social issues has been addressed in the production of the organic food that they purchase. When provided with the whole picture, across a range of issues such as those given above, there does seem to be sufficient research to conclude that organically farmed food does have some unique characteristics.

OSTEOPOROSIS

J J B Anderson, University of North Carolina, Chapel Hill, NC, USA

Background

Osteoporosis is considered a chronic multifactorial disease because many variables contribute to the development of low bone mass and low bone mineral density accompanied by an increased risk of fracture. This disease usually occurs in late adulthood, following the menopause in women, and a decade or so later in men, but it may appear rarely earlier in life depending on the status of reproductive steroid hormones.

Both hereditary and environmental factors contribute to the multifactorial nature of this disease. Individual differences in constitutional factors as well as lifestyle/environmental determinants influence bone. In terms of lifestyle, both regular physical activities and a healthy diet remain two of the more important contributors to bone health and the maintenance of its functions into late life. The major function, sound ambulation, needs to be preserved as long as possible through exercise and diet. When calcium intake is not adequate, the adaptational role of the calcium regulatory system operates in an attempt to preserve skeletal structure for its functional uses. If the adaptation is not sufficient, bone deterioration, i.e., loss of both mass and density, will lead to fragility fractures. These and related topics are covered in this paper. (Although drugs that help conserve bone are widely used today, this review focuses on dietary risk factors and nutritional therapies.)

Bone Structure

Bone tissue consists of two types within the same specific bone, e.g., a vertebra of the spinal column: trabecular (cancellous) and cortical (compact). Trabecular tissue is the more metabolically active because it has about eight to 10 times more total surface area than cortical tissue, and these surfaces are all largely covered by bone cells that are responsible for new bone formation and old bone resorption (degradation). In the body of a vertebra most of the bone tissue is trabecular, but near the surfaces of the entire vertebra, cortical bone predominates. Therefore, each specific bone or organ contains both types of bone tissue but typically in different locations within the bone. For example, long bones, such as the femur, contain much more trabecular tissue at either end near the hip joint or knee joint and a much greater proportion of cortical bone in the shaft that connects the two ends. This distinction is important because most of the fractures of the bones (organs) occur where more metabolically active trabecular bone tissue exists.

Bone Gain and Bone Loss through the Life Cycle

In early life, during the growth periods of the skeleton, bone acquisition through bone formation dominates. This phase represents the making of the skeletal model, i.e., modeling, and it typically ends by 16–18 years in females and 18–22 years in males. Modeling is characterized by greater formation than resorption and results in a net gain of bone mass or bone mineral content (BMC) by the end of the growth phase. Modeling is completed at the end of linear growth. In remodeling of the skeleton, resorption of bone equals formation; so, the net amount of bone mass remains fairly constant, though some modest gain may still occur until the mid-20s or beyond. During the beginning of the remodeling, the increase in pubertal hormones is responsible for the cessation of growth in length, or height increase. At this time, bone mineral density (BMD) attains a maximum value that becomes the 'healthy norm' for an individual for the rest of their life. (In the definitions of osteopenia and osteoporosis, the healthy means of a population of 20–29-year-old males or females are taken as the standard values for determining osteoporosis late in life (see below.)

In late life, i.e., after the menopause in women and a decade or so later in men, imbalances in the remodeling of the skeleton result in bone losses, so that reductions in both BMC and BMD occur. The loss of estrogens after the menopause and probably the later decline of androgens by men contribute to the increase in resorption, the reduction of formation, or both. The increase in resorption is triggered by increased activity of osteoclasts, and the decline in formation is directly related to decreased activity of osteoblasts. An increase in bone turnover, i.e., increased rates of resorption and formation with resorption dominating formation, greatly accelerates the rate of bone loss. Most individuals are slow or moderate losers of bone, whereas only a small fraction are 'fast losers.' Bone turnover is assessed by measurement of chemical markers of degraded matrix proteins, such as collagen, resulting from

bone resorption and of hormones, especially parathyroid hormone, involved in calcium homeostasis.

The changes in the skeleton over the life cycle reflect early-life gains and late-life losses. When the losses become sufficient to deteriorate to the state of osteoporosis, an individual becomes at risk of fragility fractures of bones such as the vertebrae and proximal femurs (hips). The hip fractures are the most severe and debilitating, and many individuals never recover.

Measurement of BMC and BMD

BMC and BMD are measured today using a technique called dual energy X-radiographic analysis (DXA). Osteopenia, or too little bone, is followed by osteoporosis, or even greater bone loss, which places an individual at great risk of a fracture. Quantitative definitions of osteopenia and osteoporosis have been established by the World Health Organization as follows: osteopenia is between minus 1 and 2.5 standard deviations (SDs) below the 20–29-year-old mean values for women or men; and osteoporosis is greater than −2.5 SDs below the 20–29-year-old means. (These values of individuals at any adult age compared with means of healthy young adults are known as *T*-scores.) According to this definition, a postmenopausal 60-year-old woman with −3.0 SDs below the mean at different skeletal measurement sites does not necessarily have any clinically diagnosed fracture, but she is likely to have one over the next few years without any drug (or drug and diet) therapy.

In addition to the DXA determination of bone status, biochemical markers may also be used to assess the severity of bone turnover and the potential risk of fracture. Therefore, both clinical observations, e.g., loss of height and pain in the lower back, and biochemical marker data may increase the diagnostic significance of DXA measurements that classify an individual in the osteoporotic range or >2.5 SDs below the healthy means.

Types of Osteoporosis

Type I osteoporosis uses the postmenopausal woman as the prototype, although men also rarely may suffer from the abrupt loss of sex steroids that impact greatly on the retention of bone tissue. Type II osteoporosis is age-related and typically occurs in both genders in the later decades of life; the causation of Type II is poorly understood, but it accelerates when the musculoskeletal system functions decline.

Although, for simplicity, only two types of osteoporosis are defined here, other variants clearly exist. One that is of increasing importance is corticosteroid-induced osteoporosis because of the widespread use of prednisone and related drugs in therapy of diseases other than osteoporosis. This type of osteoporosis is called secondary. Other drugs may also induce secondary osteoporosis.

Nondietary Risk Factors for Osteoporosis

Several nondietary risk factors – all potentially adverse or harmful – have been identified that promote the loss of bone and the onset of fractures. Seven environmental/lifestyle factors are listed here:

- thinness with low LBM;
- cigarette smoking;
- excessive alcohol consumption;
- insufficient physical activity;
- drugs – over-the-counter and prescription;
- decline of sensory perceptions;
- falls.

Each of these factors has a risk associated with it, but when two or three exist together at the same time, the risk of an osteoporotic fracture may increase exponentially rather than additively. For example, the small-framed older postmenopausal woman who smokes a pack of cigarettes a day, drinks two or three servings of alcohol a day, and who has little physical activity in her daily life will typically be at great risk of an early hip fracture, i.e., by age 70 years or younger. When the old-old, i.e., greater than 80, suffer declines of acuity of their senses, such as vision and equilibrium, or take medications that result in the same effects, they are much more likely to fall and break their hip.

The most important of these adverse factors, in general, may be the decline in regular physical activity that results in the loss of lean body mass (LBM), characterized by declines in muscle strength and tone, because bone loss follows closely the loss of LBM.

Many elderly take several drugs, i.e., polypharmacy, and some of them become confused or have difficulty maintaining equilibrium. Each of these factors may contribute to falls and consequent hip fractures.

Dietary Risk Factors

In addition to adverse environmental/lifestyle factors, numerous dietary factors may also have adverse effects on skeletal tissue. These deleterious factors are thought to operate throughout the life cycle, not just during late life. The major variables are given here, but this list is not exhaustive:

- low calcium;
- high phosphorus;
- low vitamin D;
- high-animal protein and acid load;
- high-sodium snacks;
- vegetarian diet;
- poor diet in general.

The most common dietary problem associated with the development of osteoporosis has been an inadequate consumption of calcium, at least among Caucasians in Western nations, including pediatric populations. Low calcium intakes in these nations are typically accompanied by high phosphate consumption because of both the ingestion of naturally occurring phosphorus in foods, especially animal proteins, and phosphorus from food fortification. Phosphorus fortification is fairly common in Western nations because of the widespread use of processed foods – foods modified with the many applications that utilize phosphate salts of one type or another. Cola-type soft drink beverages also fit in this category, although, technically, they are not foods. The net result of consuming phosphate-rich foods may be a low calcium (Ca) to high phosphate (P) intake that is worsened when individuals consume little milk or cheese in their usual diets.

If the Ca:P ratio declines to approximately 1 to 4, the serum parathyroid hormone (PTH) concentration becomes elevated (but remains within the normal range). A constantly elevated PTH leads to bone loss and a gradual decline in BMD that eventually becomes osteoporosis. How many years bone takes to get into the osteoporotic range, according to WHO definitions, is not clear, but a long-term dietary pattern of low calcium–high phosphate may even contribute to low bone mass in females before they reach 20 years of age, if fractures among girls and pubertal females are a valid index of low bone mass.

Coupled with limited skin exposure to vitamin D-promoting sunlight, a low intake of vitamin D from foods, especially fortified dairy products in the USA and various deep-sea fish species in much of the world, is now considered a risk factor for low bone mass. The mechanism for this condition is not entirely clear, but a low circulating concentration of 25-hydroxyvitamin D is linked with both a decline in intestinal calcium absorption and an increase in bone turnover with a resultant loss of bone.

A usual high-animal protein intake has been reported by some investigators to contribute to bone loss and an increase in risk for osteoporosis. The mechanism is considered to reside in the increased production of acids, i.e., phosphoric and sulfuric, from the degradation of phosphorus- and sulfur-containing amino acids that are considerably greater in animal than plant proteins, such as those derived from soy. The net effect is an increased loss of calcium ions in urine. This loss has been shown acutely and in short-term experiments, but it has not been established in long-term studies.

High-sodium snack foods have become very popular in Western nations, and they contribute additional sodium to an already high intake that derives from so many foods processed with sodium or salt. Calcium renal losses increase on high-sodium intakes because the kidneys favor sodium reabsorption at the expense of calcium ions. The net loss of calcium comes from bone, and therefore a loss of bone mass may be associated with excessive consumption of sodium-rich snack foods.

Vegetarian diets may also compromise bone health through a number of possible mechanisms, but the low calcium and vitamin D intakes from a vegan dietary pattern may be largely responsible for lower bone mass among vegetarians.

Finally, a poor diet, especially one based on a limited intake of fruits and vegetables, may be deficient in other bone-essential nutrients, such as magnesium, vitamin K, zinc, antioxidant nutrients, and probably a dozen others. Any one or a combination of these deficits may inhibit efficient bone formation. Adverse effects include loss of protection against oxidants, and poor regulation of acid–base balance, thus impacting bone as a major buffering store. Whatever the mechanisms may be, bone health requires a wide variety of nutrients that are best supplied by a varied diet consisting of the recommended numbers of servings of foods each day.

Adaptation to Low Calcium Intakes

Several adaptations to dietary intakes occur after each meal in healthy individuals; a number of these adaptations directly affect calcium homeostasis by impacting on serum PTH and 1,25-dihydroxyvitamin D concentrations. For example, a low calcium intake, especially when coupled with a high phosphate consumption pattern, stimulates PTH secretion via a calcium sensor on the membranes of parathyroid gland cells. Elevated PTH, in turn, stimulates the removal of calcium from bone (see above).

In addition, a low calcium intake stimulates the vitamin D regulatory mechanism by increasing the renal production of the hormonal form of vitamin D, i.e., 1,25-dihydroxyvitamin D, which leads to an increase in intestinal calcium absorption and bone utilization of calcium. The potential problem in older women, and perhaps men, is that the intestinal

adaptation declines, and less calcium can be absorbed with the hormonal stimulus.

Finally, excessive, continuous PTH secretion that may develop late in life with a low Ca:high P ratio diet and low circulating 25-hydroxyvitamin D concentration contributes to bone loss almost across the 24 h of a day. It is now recognized that a persistent and continuous treatment with PTH causes significant bone loss, whereas a discontinuous treatment with PTH, i.e., once daily or once weekly, increases bone mass and density by stimulating osteoblasts to make new bone tissue. Thus, any type of low calcium intake that generates a continuous secretion and elevation of PTH in blood will have serious negative consequences on the maintenance of bone, especially of trabecular bone tissue.

Dietary Prevention and Treatment – Foods and Supplements

The principles of both primary and secondary prevention of osteoporosis are similar: increase calcium in the diet through foods and supplements to 1000 mg or more per day in order to suppress PTH secretion (see above), and assure that individuals obtain sufficient amounts of vitamin D through both foods and supplements: a dosage of 800 IU or more is recommended. Sunshine exposure is also encouraged, depending on geographic latitude and time of the year. Finally, a healthy diet containing virtually all nutrients from foods makes sense from a nutritional perspective. For the elderly, a daily supplement that contains a wide range of nutrients at recommended intake levels is both safe and inexpensive. The current dietary reference intakes should be used to guide consumers in maintaining appropriate amounts of nutrients each day (1997–2001).

Public Health Implications and Conclusions

Since the incidence and prevalence of osteoporosis are increasing as our populations are aging, greater expenditures are anticipated for direct care of hip fracture patients and then their subsequent rehabilitation. Many victims will not survive the first post-fracture year. Preventive strategies, either primary or secondary, that are cheap and effective, must be identified and implemented. Improving the diet may be one of the most easily modifiable approaches for the prevention of osteoporosis, but of course, if individuals cannot ambulate, the dietary changes will have little impact with regard to osteoporosis. Walking and maintaining activities of daily living by the elderly are critical for the prevention of osteoporosis. Any type of minimal exercise program should also yield some benefit to the retention of musculoskeletal function.

OXALATES

S C Morrison, New Zealand Institute for Crop and Food Research, Lincoln, Canterbury, New Zealand
G P Savage, Lincoln University, Canterbury, New Zealand

Introduction

Oxalic acid and its salts occur as end products of metabolism in a number of plant tissues. When these plants are eaten they may have an adverse effect on mineral bioavailability because oxalates bind calcium and other minerals. While oxalic acid is a normal end product of mammalian metabolism, the consumption of additional oxalic acid may cause stone formation in the urinary tract when it is excreted in the urine. The mean daily intake of oxalate in the diet in the UK has been calculated to be 70–150 mg; tea, rhubarb, spinach, and beet are common high oxalate-containing foods. Soaking and cooking foodstuffs high in oxalate will reduce the oxalate content by leaching.

The consumption of high-oxalate foods is more likely to pose health problems in those who have an unbalanced diet or those with intestinal malfunction. A diet high in oxalate and low in essential minerals, such as calcium and iron, is not recommended. Vegans and lactose-intolerant persons may have a high-oxalate and low-calcium diet unless their diet is supplemented. Vegetarians who consume greater amounts of vegetables will have a higher intake of oxalates, which may reduce calcium availability. This may be an increased risk factor for women, who require greater amounts of calcium in the diet. Persons with an increased absorption rate of oxalate are advised to avoid or eat fewer high-oxalate foods to prevent kidney stone formation. In healthy individuals, the occasional consumption of high-oxalate foods as part of a balanced diet does not pose any particular problem.

Oxalates in Plants

Oxalate can be found in small amounts in many plants. Oxalate-rich foods are usually minor components in human diets but are present in higher quantities in seasonal diets in certain areas of the world (particularly in the tropics) as a component of grains, tubers, nuts, vegetables, and fruits. The highest levels of oxalates are found in the foods listed in Table 1.

In general, oxalate content is highest in the leaves, then in the seeds, and lowest in the stems. Reports show that the stems or stalks of plants, such as amaranth, rhubarb, spinach, and beet, contain significantly lower levels of oxalates than the leaves. In the buckwheat family (e.g., rhubarb, sorrel), there is almost twice as much oxalic acid in the leaves as in the stalk. However, in the goosefoot family (e.g., beet, spinach), oxalic acid is more abundant in the stalk than in the petiole of the leaf. It must be noted that the leaves of rhubarb are rarely eaten and therefore the oxalate content of its leaves is of no concern in human nutrition.

Oxalic acid concentration tends to be higher in plants than in meats, which may be considered oxalate-free when planning low-oxalate diets. Meats, fats, and dairy products contain very low levels of oxalates.

The levels of oxalates in fungi are low when compared to the levels found in spinach and rhubarb. The giant mushroom (*Tricholoma giganteum*), a large, edible fungi, is reported to contain 89 mg $100\,g^{-1}$ dry weight (DW) oxalic acid while tropical species of mushrooms, including termite and ear mushrooms, contain between 80 and 220 mg oxalate $100\,g^{-1}$ DW.

High oxalate levels in tropical plants are of some concern. Taro (*Colocasia esculenta*) and sweet potato (*Ipomoea batatas*) were reported to contain 278–574 mg $100\,g^{-1}$ fresh weight (FW) and 470 mg $100\,g^{-1}$, respectively. Total oxalate levels in yam (*Dioscorea alata*) tubers were reported in the range 486–781 mg $100\,g^{-1}$ DW, but may not be of nutritional concern since 50–75% of the oxalates were present in the water-soluble form and therefore may leach out during cooking. Oca or New Zealand yam (*Oxalis tuberosa* Mol.) contains 80–221 mg $100\,g^{-1}$ FW soluble oxalate. Higher levels of oxalates are usually found in the leaves and highest concentrations of oxalate have been found in the skin of these tropical root crops. Peanut greens, commonly consumed in tropical climates, are reported to contain 407 mg $100\,g^{-1}$. Coriander leaf (*Coriandrum sativum*) contains 1268 mg $100\,g^{-1}$; horsegram (*Macrotyloma uniflorum*) and santhi (*Boernavia diffusa*) contain 508 mg $100\,g^{-1}$ and 3800 mg $100\,g^{-1}$ respectively. Nuts such as peanuts, pecans, and cashews are relatively high in oxalates. Sesame seeds have been reported to contain high quantities of oxalate, ranging from 350 to 1750 mg $100\,g^{-1}$ FW.

Beverages with a high-oxalate concentration include Indian black tea, cocoa drinks, Ovaltine, cola, and certain types of beer.

The oxalic acid content is variable within some species; some cultivars of spinach (Universal, Winter

Table 1 Common foods exhibiting high levels of oxalates

Spinach	Beet	Rhubarb
Swiss chard	Yam, oca, sweet potato	Gooseberries, strawberries
Kale	Peanuts, pecans	Black tea
Purslane	Soybean	Cocoa, chocolate, Ovaltine
Collards	Wheat germ, wheat bran	Cola
Mustard and turnip greens	Sorrel, parsley, amaranth	Beer

Giant) contain 400–600 mg $100\,g^{-1}$, while others range from 700 to 900 mg $100\,g^{-1}$. Oxalic acid accumulates in plants, especially during dry conditions. A study comparing two cultivars of spinach, Magic (cv. summer) and Lead (cv. autumn), revealed that the summer cultivar contained greater amounts of oxalate (740 mg $100\,g^{-1}$ FW) than the autumn cultivar (560 mg $100\,g^{-1}$ FW). Oxalate content has been reported to increase as the plant ages and becomes overripe. The proportion of oxalic acid in the leaves of the goosefoot family can double during ripening. However, in tomatoes, oxalic acid content has been reported to decrease during ripening.

Absorption and Metabolism in Mammals

Calcium can combine with oxalate to form calcium oxalate in the intestinal lumen, making the calcium unavailable for absorption; calcium oxalate is then excreted in the feces. Free or soluble oxalate is absorbed by passive diffusion in the colon in humans; comparative studies between healthy individuals and those with ileostomies indicate that the colon is the principal site for oxalate absorption. However, it is suggested that the small intestine may be the major absorptive site rather than the colon. The absorption of oxalates from individual foods varies depending on their dietary conditions and source; in general, the absorption is quite limited. It has been estimated that 2–5% of administered oxalate is absorbed in humans. Experiments have shown that more oxalate is absorbed when consumed while fasting (12%) compared to only 7% oxalate absorption when consumed with a normal diet. The percentage of oxalate absorption varied markedly from 1% for rhubarb and spinach to 22% from tea, but generally absorption was higher at low doses.

Oxalate is an end product of ascorbate, glyoxylate, and glycine metabolism in mammals. Thirty-three to fifty percent of urinary oxalate is derived from ascorbate, 40% from glycine and 6–33% from minor metabolic pathways and dietary oxalate; dietary oxalate appears to account for only 10–15% of excreted oxalates.

Chemical Properties and Toxic Effects

Oxalic acid forms water-soluble salts with Na^+, K^+, and NH_4^+ ions; it also binds with Ca^{2+}, Fe^{2+}, and Mg^{2+}, rendering these minerals unavailable to animals. However, Zn^{2+} appears to be relatively unaffected. Calcium oxalate ($Ca(COO)_2$) is insoluble at a neutral or alkaline pH, but freely dissolves in acid.

Ingestion of 4–5 g of oxalate is the minimum dose capable of causing death in an adult, but reports have shown that 10–15 g is the usual amount required to cause fatalities. Oxalic acid ingestion results in corrosion of the mouth and gastrointestinal tract, gastric hemorrhage, renal failure, and hematuria. Other associated problems include low plasma calcium, which may cause convulsions and high plasma oxalates. Most fatalities from oxalate poisoning are apparently due to the removal of calcium ions from the serum by precipitation. High levels of oxalate may interfere with carbohydrate metabolism, particularly by succinic dehydrogenase inhibition; this may be a significant factor in death from oxalate toxicity induced in animals grazing pastures containing high levels of *Halogeton glomeratus*. Halogeton (*H. glomeratus*) and wood sorrel (*Oxalis cernua*) are high in oxalates and are known to cause injury to grazing cattle and sheep.

Although garden sorrel is a herb and not normally consumed in large quantities, there has been one report of fatal oxalate poisoning after a man consumed an estimated 6–8 g oxalate in vegetable soup containing 500 g sorrel. Both fatal and nonfatal poisoning by rhubarb leaves is thought to be caused by toxic anthraquinone glycosides rather than oxalates. Experiments involving the consumption of more than 30–35 g day^{-1} of cocoa, a high-oxalate foodstuff, by eight women provoked symptoms of intoxication including loss of appetite, nausea, and headaches. However, cocoa contains theobromine (1500–2500 mg $100\,g^{-1}$) and tannic acid (4000–6000 mg $100\,g^{-1}$), both of which are more toxic than the oxalic acid present (500–700 mg $100\,g^{-1}$). There appears to be a great deal of confusion as to what was responsible for these poisonings and it would be unwise to assume that only one factor was responsible.

Effect on Bioavailability of Minerals

High-oxalate foods have been known to inhibit calcium and iron absorption. Even though vegetables such as spinach, rhubarb, and Swiss chard are high in calcium, the calcium cannot be absorbed due to the presence of oxalates in these vegetables. When calcium absorption from spinach, a high-oxalate and high-calcium food, was compared with calcium absorption from milk, a high-calcium food, the results showed that the calcium from spinach is not readily available (only 5.1% absorbed), probably due to the high content of oxalates. The adverse effect of oxalates is greater if the oxalate-to-calcium ratio exceeds 9:4 (or approximately 2). The oxalate-to-calcium ratio in a food varies widely and can be classified into three groups, as summarized in Table 2.

Oxalate and calcium levels and the oxalate-to-calcium ratio of specific foods are detailed in Table 3.

Foods that have a ratio greater than two, as well as containing no utilizable calcium, have excess oxalate, which can bind calcium in other foods eaten at the same time. Foodstuffs with a ratio of about one do not encroach on the utilization of calcium provided by other products and therefore do not exert any demineralizing effects. However, these foods are not good sources of calcium. Although parsley (*Petroselinum sativum*) contains average levels of oxalate (140–200 mg $100\,g^{-1}$), its high calcium levels (180–290 mg $100\,g^{-1}$) reduce the oxalate-to-calcium ratio to a low level.

Oxalate appears to interfere only slightly with zinc absorption. A counteracting or protective mechanism may prevent the precipitation of zinc by oxalates. Increasing the proportion of magnesium ions in solution was reported to inhibit the binding of calcium and zinc oxalates. This observation explains the minor effect oxalates have on zinc absorption from some leafy vegetables, such as spinach, which has high levels of calcium and zinc, and relatively high levels of magnesium.

Oxalic acid may cause greater decreases in mineral availability if consumed with a high-fiber diet but the decrease may be only temporary. Negative calcium, magnesium, zinc, and copper balances were detected in males consuming a diet containing fiber and oxalates. When spinach was replaced by cauliflower, a low-oxalate vegetable, fiber had no effect on the minerals studied, indicating that the apparent negative balances obtained were due to the presence of oxalic acid.

Adverse Effects of Oxalates

Acute

A number of plants contain calcium oxalate crystals (measured as insoluble oxalate). When ingested, they are not absorbed into the blood stream and remain largely undissolved within the digestive tract, so they have no systemic toxicity, but the sharp raphide crystals can penetrate the tissues of the mouth and the tongue, causing considerable discomfort. Most of the plants that contain calcium oxalate crystals are members of the arum family. It has been suggested that calcium oxalate crystals are responsible for the irritating sensation in kiwi fruit (*Actinidia* sp.) and soluble oxalates are thought to account for the bitter taste present in some oca (*O. tuberosa* Mol.). Conophor seeds (*Tetracarpidium conophorum*) are a popular Nigerian snack, which have a bitter taste when raw but are palatable when cooked. This observation was correlated with a 73% decrease in total oxalate concentration after cooking.

Chronic

Oxalate is poorly absorbed under nonfasting conditions. Once absorbed free oxalate binds to calcium ions to form insoluble calcium oxalate, it remains in the insoluble form.

Free oxalate and calcium can precipitate in the urine and may form kidney stones. These stones consist mainly of calcium oxalate (80%), which is relatively insoluble in urine, and calcium phosphate (5%). Oxalate crystallizes with calcium in the renal vasculature and infiltrates vessel walls causing renal tubular obstruction, vascular necrosis, and hemorrhage, which lead to anuria, uremia, electrolyte disturbances, or even rupture. Kidney stones are becoming more common in men between the ages 30 and 50 years in industrialized countries. The risk factors involved in stone formation are a low volume of urine, increased urinary excretion of oxalate, calcium, or uric acid, a persistently low or high urinary

Table 2 Examples of plants with varying oxalate to calcium ratios

Oxalate-to-calcium ratio	*Examples*
Group 1: Plants with a ratio greater than 2	Spinach, rhubarb, beet, sorrel, cocoa
Group 2: Plants with a ratio of approx. 1	Potatoes, amaranth, gooseberries, currants
Group 3: Plants with a ratio less than 1	Lettuce, cabbage, cauliflower, green beans, peas

Table 3 Oxalate, calcium, and oxalate-to-calcium ratio (Ox:Ca) of some common foods

Foodstuff	*Oxalate (mg 100 g^{-1} FW)*		*Calcium (mg 100 g^{-1} FW)*		*Ox:Ca ratio*

Basel: S Karger; Meena BA, Umapathy KP, Pankaja N and Prakash J (1987) Soluble and insoluble oxalates in selected foods. *Journal of Food Science and Technology* 24: 43–44; Noonan SC and Savage GP (1999) Oxalates and its effects on humans. *Asia Pacific Journal of Clinical Nutrition* 8: 64–74 with permission.

pH, and a low concentration of urinary inhibitors, such as magnesium, citrate, and high-molecular-weight polyanions. Normal urine is usually supersaturated with calcium oxalate. The normal urinary excretion of oxalate is less than 40–50 mg day^{-1} with less than 10% coming from the diet. Intakes of oxalate exceeding 180 mg day^{-1} lead to a marked increase in the amount excreted. Small increases in oxalate excretion have pronounced effects on the production of calcium oxalate in the urine, implying that foods high in oxalate can promote hyperoxaluria (high oxalate excretion) and increase the risk of stone formation. Rhubarb, spinach, beet, nuts, chocolate, tea, coffee, parsley, celery, and wheat bran cause significant increases in urinary oxalate excretion in healthy individuals and have been identified as the main dietary sources in the risk of kidney stone formation. It has been reported that black tea increased oxalate excretion by only 7.9%, compared with increases of 300% and 400% for spinach and rhubarb, respectively. Therefore 2–3 cups a day of black tea would have little effect on the risk of urinary stone formation when compared to spinach and rhubarb. It appears that tea is a significant source of oxalate intake in UK diets.

The main reason for the strong relationship between the risk of calcium stones and urinary oxalate excretion appears to be the effect that the latter has on the supersaturation of urine with calcium oxalate. The amount of oxalate excreted in the urine was higher in individuals with kidney stones than in healthy individuals, suggesting that those with kidney stones absorb more oxalate, consume more oxalate or oxalate-producing substances such as ascorbate, or metabolize more oxalate precursors. Excessive or

increased absorption of oxalate from normal diets is the result of intestinal abnormalities or malfunction. This is termed 'enteric hyperoxaluria' and is the commonest cause of increased renal oxalate excretion. It has been indicated that people with abnormal gastrointestinal absorption are at greater risk for hyperoxaluria and, as a result, kidney stone formation, than healthy individuals and should reduce their intake of oxalate and its precursors, such as ascorbate. A low-oxalate diet has prevented stone formation in some cases involving gastrointestinal disorders associated with hyperoxaluria.

An increase in calcium intake should be accompanied by a lower oxalate consumption, because a low-calcium and high-oxalate diet enhances oxalate absorption and excretion, which carries an even greater risk of stone formation than high calcium excretion. An increase in calcium intake may reduce urinary oxalate excretion by binding to more oxalate in the gut, thus reducing the risk of stone formation. Varying the amounts of calcium does not significantly alter levels of urinary calcium. From experimental work, it has been concluded that hypercalciuria plays, at most, a secondary role in the formation of calcium stones compared with mild hyperoxaluria.

Excessive ascorbic acid (vitamin C) intake may increase urinary oxalate output with an increased risk of forming kidney stones. An excess dose is considered to be 2000 mg of vitamin C per day. However, ascorbic acid doses greater than 500 mg day^{-1} were reported to induce a significant increase in urinary oxalate, and doses of 1000 mg day^{-1} would increase urinary oxalate excretion by 6–13 mg day^{-1}. The recommended daily intake in many countries is in the region of 80 mg.

Effects of Processing

Oxalates may be removed from food by leaching in water but this is not the most effective method as it removes only the soluble oxalate. Although the amount of oxalate in raw soybean (*Glycine max*) is relatively low, soaking and germination of the seed reduced the oxalate concentration. Cooking germinated soybeans reduced oxalate concentration below that in uncooked germinated soybeans. Soaking followed by cooking also proved to be effective, although not as effective as germination. Oxalate content in horsegram seeds (*M. uniflorum*) decreased by 38% when seeds were dehulled (508 and 315 mg 100 g^{-1}, for seed and dehulled seed, respectively). Roasting was found to be the least effective method. Roasting chicory roots was reported to increase oxalate content. Roasting oca (New Zealand yam, *O. tuberosa* Mol.) also increased oxalate levels by 10–26%. This may be caused by the decrease in moisture content, a hypothesis supported by reports of dry tropical leafy vegetables having higher oxalate concentrations than fresh vegetables.

A 40–50% loss of total oxalates by leaching was reported when yam tubers (*D. alata* and *D. esculenta*) were boiled, compared to steaming (20–25%) and baking (12–15%). Cooking proved most effective in reducing total oxalates. However, it must be noted that water-soluble minerals also leach out at the same time. Mineral leaching appears to vary between plant species. Blanching has been reported to decrease the oxalic acid content in spinach. However blanching, by conventional and microwave methods, reduced the oxalic acid content of sweet potato, peanut, and collard leaves only slightly whereas other antinutritional factors such as tannic and phytic acid were reduced significantly. Spinach, orach, and silverbeet are generally eaten after being boiled. However, rhubarb, cocoa, and common and garden sorrel may be consumed in the raw state and therefore should be eaten in smaller quantities.

Fermentation, frequently used in Asian countries, has been reported to decrease the oxalate content of foods. A marked decrease in oxalic acid content was reported in *Icacinia manni* (a starch tuber) after fermentation. Oxalic acid was observed to decrease by 37% (86 to 54 mg 100 g^{-1} FW) during souring of poi (a cooked taro paste) at 20 °C.

Recommendations

Foods high in oxalates should be consumed in moderation to insure optimum intake of minerals from the diet. Although some foods are reported to be high in calcium and other essential minerals, the amount available may be limited due to the presence of oxalates. For instance, spinach is a high-calcium food, yet because of its high oxalate content, the calcium availability is almost negligible. The availability of magnesium, iron, sodium, potassium, and phosphorus may also be restricted.

High-oxalate foods should be cooked to reduce the oxalate content. Soaking raw foods will also reduce the oxalate content but other useful nutrients such as water-soluble vitamins and minerals may also be lost at the same time. Oxalates tend to occur in higher concentrations in the leafy parts of vegetables rather than in roots or stalks.

For the general population, the occasional consumption of high-oxalate foods as part of a balanced diet does not pose any health problems. However, there are some groups of people who may be at risk from oxalate-induced side-effects.

Vegans and vegetarians should be aware that some foods contain high levels of oxalates. The diets of vegans and those persons with lactose intolerance may be low in calcium as a result of the exclusion of dairy products, unless their diet is supplemented by some other high-calcium food products. It is recommended that high-oxalate foods should be accompanied by calcium-rich foods such as dairy products and shellfish. If high-oxalate foods are consumed in conjunction with a low-calcium diet, then the consumer may be at risk of hyperoxaluria, which may lead to kidney stone formation.

Women tend to be more susceptible to calcium and iron deficiencies than men. Osteoporosis is a concern amongst females, especially after menopause. People suffering from fractures should also be aware of the potential effects of oxalates on mineral availability, as high calcium levels are required for bone repair. Once again, consumption of high-oxalate foods with an adequate-to-high calcium intake should pose no health problems. It must also be noted that calcium is only absorbed and used when there are adequate levels of vitamin D in the body, either obtained via the diet or synthesized by the body when exposed to sunlight. Women should eat red meats, which are low in oxalate, to satisfy their iron intake. Adequate levels of vitamin C are required for the absorption of iron, but excess amounts are not advised because ascorbic acid is converted into oxalate.

The risk of stone formation is three times greater in males and they should avoid eating excess amounts of high-oxalate foods. Sufferers of hyperoxaluria and kidney stones are advised to restrict their diet to foods containing low or medium levels of oxalates, as although urinary oxalate arises predominantly from endogenous sources, it can be influenced by dietary intake. Excess vitamin C intake is not recommended in these patients.

Inhabitants of tropical countries should be aware that leafy tropical plants and tropical root crops tend to contain higher levels of oxalates than plants from temperate climates. People living in these areas are at possible risk of stone formation due to hyperoxaluria, and mineral deficiencies if sufficient minerals are not consumed.

OXIDATION OF FOOD COMPONENTS

K L Parkin and S Damodaran, University of Wisconsin-Madison, Madison, WI, USA

Scope

Antoine Lavoisier (1743–94) recognized oxidation as a chemical process, concluding that oxygen was the element responsible for the formation of acidic residues, or oxides, upon combustion of certain substances. A contemporary definition of oxidation is the process by which oxygen is added, or hydrogen or electrons are withdrawn. For a component to be oxidized, another has to be reduced, and reduction can be defined as the withdrawal of oxygen, or the addition of hydrogen or electrons. The component that is oxidized and loses electrons is the reductant and the component that is reduced and gains electrons is the oxidant. Oxidation is distinct from oxygenation; the latter is a noncovalent coordination of oxygen with a component, as in the case where hemoglobin and myoglobin bind oxygen to facilitate oxygen transport in blood and muscle, respectively. In food systems, oxygen is the most common oxidant, although other endogenous and added chemicals can also serve as oxidants. The principal negative effect of oxidation in foods is that flavor quality is lost, giving rise to the defect often referred to as oxidative rancidity. In addition, functional, color, and nutritional qualities of food components can be lost as a consequence of oxidation in foods. However, there are also some oxidative processes in foods that have beneficial effects on quality.

The Basic Process of Oxidation

Oxidation–Reduction Potentials

The potential or thermodynamic favorability for two components to be involved in an oxidation–reduction (redox) reaction can be predicted from the corresponding half-reactions of oxidation and reduction. Table 1 provides a selective list of some standard reduction half-reactions, using the hydrogen half-cell at pH 7.0 as a standard. As the reduction potential (voltage) becomes more positive, the tendency for that half-reaction to take place increases. Thus, the most powerful oxidants in Table 1 are hydrogen peroxide and oxygen. For each component, oxidation half-reactions take place in the reverse direction of what appears in Table 1 and have voltages of the opposite sign of the same magnitude.

The redox potential (E_h) of food systems is dependent on the concentration and redox states of the components of that system. One of the most important components is oxygen and, at limited dissolved oxygen components, E_h is strongly dependent on the oxygen content. 'Reducing' conditions or a very negative E_h (e.g., −400 mV) exist when dissolved oxygen is poised at near-anaerobic levels.

Transition metals such as copper and iron are believed to be involved in oxidation in foods via a redox cycling mechanism. Since there is very little 'free' iron and copper in biological systems, the types and concentrations of chelators present have a marked effect on the redox behavior and thus oxidative activity of these transition metals.

Oxidation in foods is often caused by free radical reactions. There are three stages of free radical oxidation, also referred to as autoxidation when the oxidant is oxygen. The first step, or 'initiation,' involves the formation of a free radical species ($X^{\cdot}$) from a biological component (XH), usually by the abstraction of a hydrogen atom ($H^{\cdot}$) by active oxygen or high-energy irradiation (eqn (1)). 'Propagation' of free radical oxidation processes occurs by chain reactions that consume oxygen and yield new free radical species (peroxy radicals, $XOO^{\cdot}$) or peroxides (XOOH), as in eqns (2) and (3). The products ($X^{\cdot}$ and XOOH, see also eqn (6)) can further propagate free radical reactions. 'Termination' of free radical oxidative reactions occurs when two radical species react with each other to form a nonradical adduct, as in eqn (4).

$$XH \rightarrow X^{\cdot} + H^{\cdot} \quad (1)$$

$$X^{\cdot} + {}^3O_2 \rightarrow XOO^{\cdot} \quad (2)$$

Table 1 Standard electrode potentials of selected reduction half-reactions

Reaction	*Volts*
$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O$	1.77
$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$	1.23
$Cu^{2+} + e^- \rightarrow Cu^+$	0.15
$Fe^{3+} + e^- \rightarrow Fe_2^+$	0.11
Dehydroascorbate + $H^+ + 2e^- \rightarrow$ Ascorbate	0.054
$2H^+ + 2e^- \rightarrow H_2$	0.00
$RSSR + 2H^+ + 2e^- \rightarrow 2RSH$	−0.39[a]

[a]Estimated value for oxidized disulfide (RSSR) conversion to reduced thiol (RSH) such as for oxidized/reduced glutathione and cystine/cysteine couples.
Standard Conditions: pH 7.0, 1 mol l^{-1} for each component.

$$XOO^{\cdot} + XH \rightarrow XOOH + X^{\cdot} \quad (3)$$

$$X^{\cdot} + X^{\cdot} \rightarrow X - X \quad (4)$$

Activation of Oxygen

In food systems, molecular oxygen (dioxygen; O_2) is generally the source of oxidizing power. Other strong oxidants include the food additives hydrogen peroxide (H_2O_2), calcium and benzoyl peroxides, and bromates ($KBrO_3$). All of these compounds are conjugates of oxygen. However, not all strong oxidants are composed of oxygen, as fluorine and bromine are also strong oxidants.

Although the reaction of ground state oxygen ($^3O_2$, triplet oxygen) with organic compounds is thermodynamically favorable, it is kinetically slow due to the high energy of activation required for oxygen to react. The electron configuration of $^3O_2$ includes two unpaired electrons in the outer shell, yielding a triplet signal in a magnetic field. All known organic compounds are in a singlet state, having all electrons paired with another. Consequently, facile reaction between $^3O_2$ and organic molecules is forbidden due to the incompatibility of their electron 'spin' states.

'Activation' of $^3O_2$ overcomes much of the energy barrier to its reactivity as an oxidant. One means of activation is the excitation of $^3O_2$ to yield singlet molecular oxygen ($^1O_2$); the latter has the two outer electrons paired in a single orbital. Other forms of 'activated' or 'reactive' oxygen result from the first three one-electron reductions to $^3O_2$ in the process of reducing $^3O_2$ to water. These reactive species of oxygen include the superoxide anion radical (O_2^-) and its conjugate acid (HO_2), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($\cdot OH$). The standard reduction potentials of each of these steps is provided in Table 2. The electronic structure of these activated forms of oxygen facilitate their reactivity with biological compounds. The strongest electrophiles (electron seekers), $\cdot OH$ and $^1O_2$ are the most reactive forms of 'active' oxygen, followed in reactivity by O_2^- and then H_2O_2.

Table 2 Standard electrode potentials for univalent reductions of O_2 to H_2O

Reaction	*Volts*
$O_2 + e^- \rightarrow O_2^-$	−0.16 (−0.33)
$O_2^- + e^- + 2H^+ \rightarrow H_2O_2$	0.89
$H_2O_2 + e^- + H^+ \rightarrow \cdot OH + H_2O$	0.38
$\cdot OH + e^- + H^+ \rightarrow H_2O$	2.32

Standard conditions: pH 7.0, 1 mol l^{-1} for each component. For O_2, electrode potential also provided, in parentheses, at 10^5 Pa (0.987 atm).

Some of these active oxygen species can be interconverted, and these processes can be facilitated by the presence of specific catalysts. Activated forms of oxygen can also be formed by γ irradiation and by photosensitization of pigments in foods.

Catalysts of Oxidation Reactions

Catalysts of oxidation reactions can be enzymatic (protein) or nonenzymatic. Transition metals (M^n, reduced form; M^{n+1}, oxidized form) can participate in redox reactions with $^3O_2$ to yield O_2^-/HO_2, as in eqn. (5). The resulting O_2^- can initiate oxidation reactions. Another manner by which transition metals can cause oxidation reactions is by breaking down lipid hydroperoxides (LOOH) (eqn (6)), and the alkoxy radical ($LO^{\cdot}$) so formed can cause further oxidative reactions. Since there are often small quantities of LOOH in food systems this process is probably important. Transition metals can also take part in the interconversion of active oxygen species, as in the Haber–Weiss reaction (eqn (7)). This reaction can be mediated by three partial reactions (eqns (8)–(10)). In the first reaction (eqn (8)), O_2^- acts as a reductant and donates an electron to an oxidized transition metal (e.g., iron). In the second step (eqn (9)), O_2^-, acting as both an oxidant and reductant, undergoes dismutation to form H_2O_2 and $^3O_2$. In the third step (eqn (10)), also called the Fenton reaction, the reduced transition metal donates an electron to H_2O_2 to form the extremely reactive $\cdot OH$, and the transition metal reverts back to its oxidized state to allow another cycle. In food systems, several endogenous components, such as ascorbic acid and thiol compounds, can replace O_2^- as a reductant. This set of reactions also illustrates the participation in oxidative reactions of all activated oxygen species generated by univalent electron reductions of $^3O_2$.

$$M^n + {}^3O_2 \rightarrow M^{n+1} + O_2^- \quad (5)$$

$$M^n + LOOH \rightarrow M^{n+1} + LO^{\cdot} + OH^- \quad (6)$$

$$O_2^- + H_2O_2 \rightarrow {}^3O_2 + OH^- + \cdot OH \quad (7)$$

$$O_2^- + M^{n+1} \rightarrow {}^3O_2 + M^n \quad (8)$$

$$2O_2^- + 2H^+ \rightarrow {}^3O_2 + H_2O_2 \quad (9)$$

$$H_2O_2 + M^n \rightarrow M^{n+1} + \cdot OH + OH^- \quad (10)$$

Other nonenzymatic catalysts include photosensitive pigments in foods. Photosensitive pigments become elevated to an excited triplet state upon the absorption of light energy, and can transfer that energy to $^3O_2$ or other biological components. Some pigments favor transmission of energy to organic

compounds (type I process) which ultimately yield O_2^- and H_2O_2 from $^3O_2$. Other pigments favor transmission of energy directly to $^3O_2$ to yield $^1O_2$ (type II process). Examples of photosensitizers of each of these types in foods are riboflavin and chlorophyll, respectively. (*See* **Chlorophyl**; **Riboflavin**: Properties and Determination.)

Enzymatic catalysts of oxidative reactions usually cause oxidations of specific biological compounds. For example, the enzymes lipoxygenase, polyphenoloxidase, sulfhydryl oxidase and xanthine oxidase are common to foods and cause the specific oxidation of unsaturated fatty acids, mono- and diphenolic acids, protein thiol (cysteine) residues, and xanthine, respectively. Glucose oxidase converts glucose to gluconic acid and also produces H_2O_2. Xanthine oxidase and peroxidase can produce H_2O_2 and O_2^- and $^1O_2$, respectively, and this is dependent on which substrates are being utilized and the level of oxygen present. These active oxygen species may cause the oxidation of other biological compounds, leading to losses in food quality.

Oxidation of Food Components

Lipids

Polyunsaturated fatty acids with 1,4-pentadiene functional units are particularly sensitive to oxidative reactions. Using linoleic acid as an example, oxidation can be initiated by two basic mechanisms, abstraction (autoxidation) and 'ene' addition (Figure 1). Abstraction is when an electron (or hydrogen atom) is removed from the fatty acid by reaction with an electrophilic species such as $^{\cdot}OH$ or $X^{\cdot}$, or by interaction with high-energy radiation. The initial abstraction step yields a fatty acid free radical (initiation step) which can then undergo addition of $^3O_2$ (propagation step) and then abstract an electron from another biological compound. The methylene or 'allylic' hydrogen atoms of the pentadiene structure are most readily abstracted. The resulting free radical ($L^{\cdot}$) can be stabilized by resonance along the original pentadiene structure, and the fatty acid radical tends to undergo addition of $^3O_2$ when the unpaired electron is most 'delocalized' or located at the terminal sites, or C9 and C13, resulting in the formation of first the linoleic acid 9- and 13-hydroperoxyl radicals, and then the 9- and 13-OOH (hydroperoxides) isomers. Further oxidative processes can be initiated by interaction of these hydroperoxides with transition metals as previously described in eqn (6). (*See* **Fatty Acids**: Properties.)

The 'ene' addition reaction that can initiate lipid oxidation is caused by the highly electrophilic $^1O_2$, which will add directly to the double bond since this is where the highest electron density can be found. Thus, a mixture of 9-, 10-, 12-, and 13-OOH isomers are produced by $^1O_2$ reaction with linoleic acid.

Once the fatty acid hydroperoxides and hydroperoxyl radicals are formed, additional initiation reactions can take place for these initial products, being unstable, can be subject to secondary reactions, as shown for linolenic acid oxidation (Figure 2). Oxidation of any remaining double bonds can take place, and in some cases the fatty acid radicals can attack adjacent intramolecular double bonds, forming cyclic structures. Alternatively, hydroperoxyl fatty acids can react with adjacent fatty acids to yield polymerized oxidation products. 'Scission' reactions lead to fracture of the fatty acid chain and result in the emanation of reduced molecular weight ketones and aldehydes. These latter secondary products, being fairly volatile, give rise to the off-flavors and odors that are associated with oxidized foods or oxidative rancidity. One product that can be formed by secondary reactions of oxidizing lipids is malondialdehyde (MDA). MDA is often used by food scientists as an indicator of the degree of oxidation of lipids in foods. In cases where specific secondary products are formed by enzyme reactions, such as by lipid hydroperoxide lyases in freshly cut cucumber and tomato fruits, the resulting volatile compounds are pleasant and contribute desirable aromatic qualities.

Thermally induced oxidation reactions can occur in both saturated and unsaturated lipids at temperatures encountered during processes such as deep-fat frying. Oxidation generally proceeds via the initial formation of hydroperoxides. The high temperatures can cause many isomerization and scission reactions to take place, producing a myriad of secondary or breakdown products such as epoxides, dihydroperoxides, cyclized fatty acids, dimers, and aldehydes and ketones resulting from scission reactions.

Proteins

Proteins, peptides, and amino acids in foods undergo several oxidative changes during food processing. The amino acids that are most susceptible to oxidative degradation are methionine, cysteine (cystine), histidine, and tryptophan. Under severe oxidizing conditions tyrosine, serine, and threonine are also oxidized to some extent. Oxidation of proteins and amino acids is caused by several agents, such as light, γ irradiation, peroxidizing lipids, metal ions, the products of enzymatic and nonenzymatic browning reactions, and food additives such as hydrogen peroxide, benzoyl peroxide, bromates ($KBrO_3$) and azodicarbonamide. (*See* **Amino Acids:** Properties and Occurrence; **Protein**: Chemistry.)

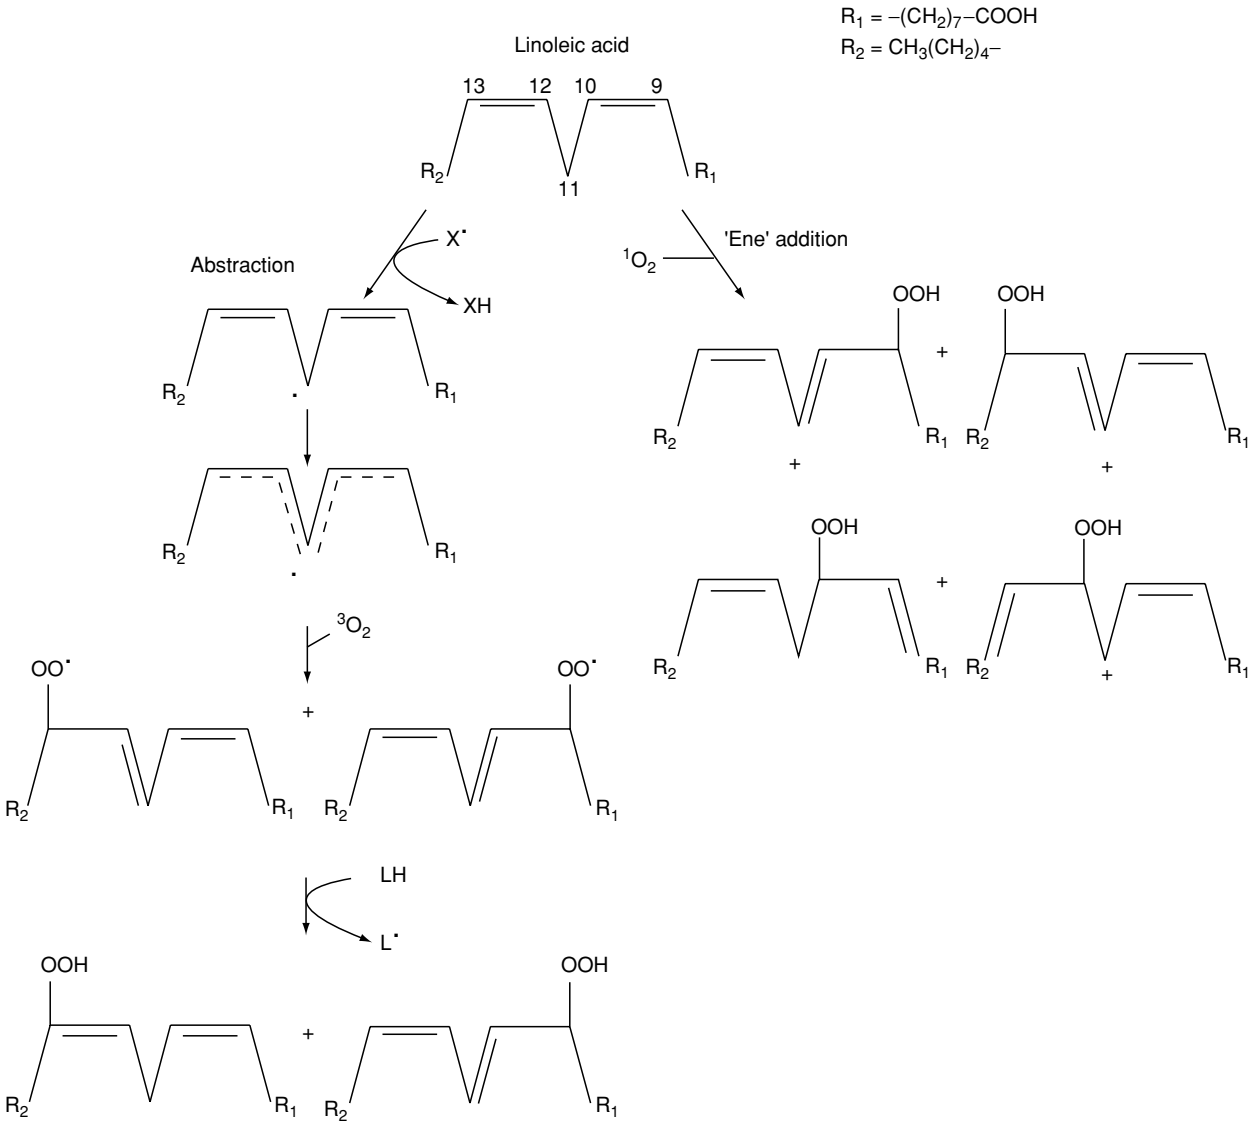

Figure 1 Initiation reactions for the oxidation of linoleic acid. Reproduced from Oxidation of Food Components, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Treatment of proteins with hydrogen peroxide or calcium peroxide causes oxidation of methionine sulfoxide (reversible), which can be further oxidized to methionine sulfones (irreversible) (eqn (11)). Cysteine residues can be oxidized by peroxides or other forms of activated oxygen to yield the sulfenic (Cy-SOH), sulfinic (Cy—SO_2H) and sulfonic (Cy—SO_3H), acid derivatives. Oxidation of cystine residues in proteins results in the formation of mono-, di-, tri-, and tetrasulfoxides.

Free thiol groups in proteins are readily oxidized by atmospheric oxygen to form disulfide cross-links. Free thiol groups also catalyze thiol-disulfide interchange reactions, which often lead to polymerization of proteins. Oxidizing agents such as $KBrO_3$ and azodicarbonamide are often used as additives in wheat flour in order to improve dough formation. These additives are believed to oxidize and block the free thiol groups of protein and nonprotein constituents, and thus prevent the occurrence of thiol–disulfide interchange reactions in the dough. The modulation of oxidation–reduction behavior in dough systems may also be controlled by ascorbic acid, dehydroascorbic acid, and glutathione.

When foods containing photosensitive substances, such as riboflavin and chlorophyl, are exposed to light, the amino acids histidine, cysteine, methionine, tryptophan, and tyrosine are oxidized by the activated oxygen species O_2^-, H_2O_2 and $^1O_2$. γ Irradiation of foods results in the formation of H_2O_2

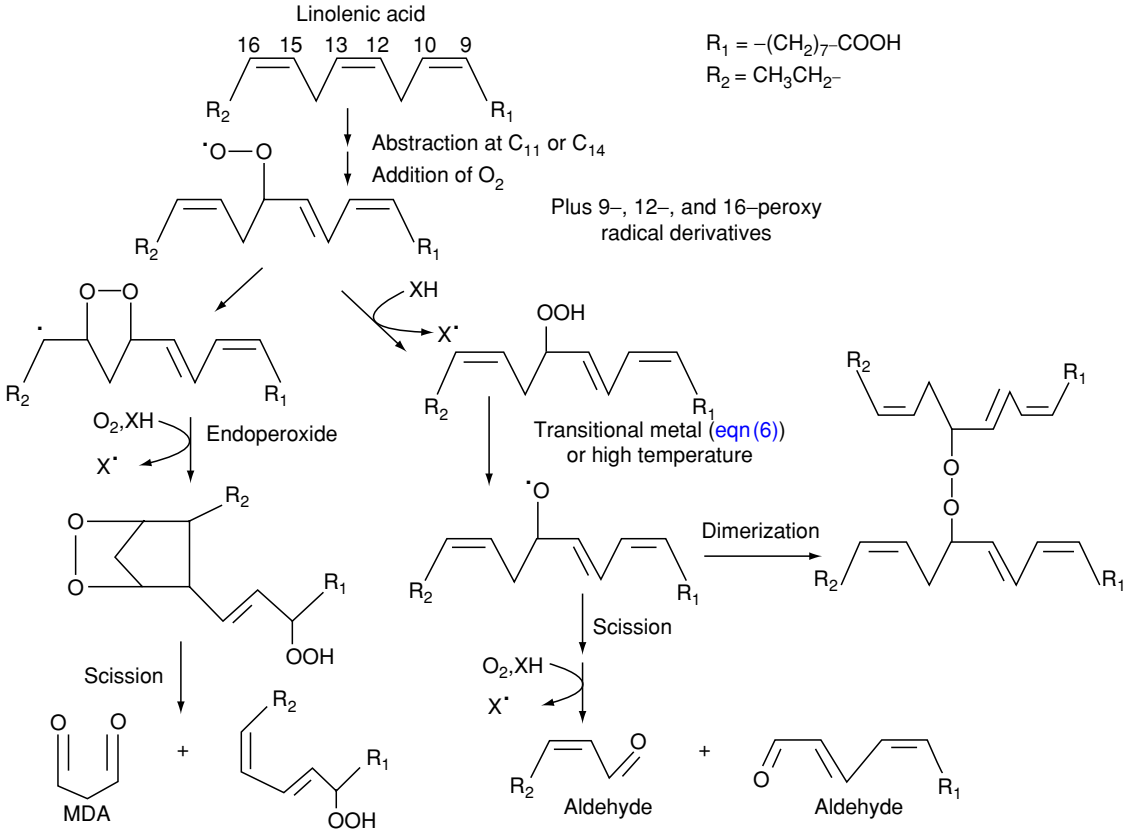

Figure 2 Initiation and secondary reactions for the oxidation of linolenic acid. Reproduced from Oxidation of Food Components, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

$$-CH_2-CH_2-S-CH_3 \rightleftharpoons -CH_2-CH_2-\overset{\overset{O}{\|}}{S}-CH_3 \rightarrow -CH_2-CH_2-\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}-CH_3 \qquad (11)$$

through radiolysis of water in the presence of oxygen, which in turn causes oxidative changes in proteins. Tryptophan residues can also be oxidized upon exposure of proteins to acidic conditions.

Substantial oxidation of free amino acids and amino acid residues in proteins occurs in the presence of peroxidizing lipids. Methionine, cysteine, histidine, and lysine are the most susceptible amino acids/residues. Two types of mechanisms, one involving the alkoxy ($LO^{\cdot}$) and peroxy ($LOO^{\cdot}$) free radicals, and the other involving malondialdehyde and other carbonyl compounds, are believed to be involved in the oxidation of proteins by peroxidizing lipids. In the first case, the lipid free radicals react with proteins (P) and induce formation of protein free radicals ($P^{\cdot}$), followed by polymerization of protein molecules (eqns (12)–(16)). In addition to the free radical-induced polymerization of protein molecules, the lipid peroxides formed during the reactions oxidize methionine, cysteine, histidine, and tryptophan residues. The highly reactive malondialdehyde formed in peroxidizing lipids reacts with amino groups of lysyl residues, resulting in intermolecular cross-links.

$$LOO^{\cdot} + P \rightarrow {}^{\cdot}LOOP \underset{O_2}{\rightarrow} {}^{\cdot}OOLOOP \underset{P}{\rightarrow} POOLOOP \qquad (12)$$

or

$$LO^{\cdot} + P \rightarrow LOH + P^{\cdot} \qquad (13)$$

$$LOO^{\cdot} + P \rightarrow LOOH + P^{\cdot} \qquad (14)$$

$$P^{\cdot} + P \rightarrow P - P^{\cdot} \qquad (15)$$

$$P - P^{\cdot} + P \rightarrow P - P - P^{\cdot} \qquad (16)$$

Heat treatment of proteinaceous foods causes several oxidative changes in proteins. While mild heat treatment results in protein denaturation and loss of functionality, severe heat treatment often causes undesirable chemical changes in amino acid residues and complex reactions of proteins with

other food components, such as carbohydrates and lipids. (*See* **Browning**: Nonenzymatic.)

When protein is heated at temperatures above 300 °C, as commonly encountered during broiling and grilling, several amino acid residues undergo thermal decomposition and pyrolysis. Several of these pyrolysis products have been isolated, identified, and shown to be highly mutagenic. The most carcinogenic/mutagenic products are formed from the decomposition of tryptophan, glutamate and lysyl residues. (*See* **Carcinogens**: Carcinogenic Substances in Food: Mechanisms; **Mutagens**.)

Carbohydrates

Carbohydrates are not as sensitive to oxidation reactions as are lipids and proteins. In addition, since many oxidation products are not volatile, the practical consequences of carbohydrate oxidations in foods are limited. Oxidation of food carbohydrates can take place, especially at high temperatures, resulting in caramelization reactions. (*See* **Caramel**: Methods of Manufacture; **Carbohydrates**: Interactions with Other Food Components.)

Some industrial processes employ oxidation reactions to prepare functional derivatives of monosaccharides for the chemical industries. However, the carbohydrate oxidations of most relevance to foods involve enzymatic reactions. Glucose oxidase oxidizes glucose to gluconic acid while simultaneously reducing O_2 to H_2O_2. The enzyme is added to foods to reduce glucose levels (to prevent nonenzymatic browning in eggs to be dried) or oxygen tension (to stabilize beverages and salad dressings from oxidative deterioration).

Carbohydrates can be oxidized by the same free radical mechanisms as described for lipids. Low-molecular-weight carbohydrates such as glucose, mannitol, and deoxyribose are known to react with $^{\cdot}OH$ and produce oxidized derivatives. Again, these derivatives, when present, have little impact on food quality and are thus of little practical significance.

Minor Food Components

Oxidation of minor food components can also influence food quality. Oxidation of ascorbic acid by enzymatic (ascorbic acid oxidase) or nonenzymatic means can compromise nutritional quality. Ascorbic acid, and other organic acids, can be degraded by active oxygen species and by reactions initiated by transition metals. Polyphenol oxidase and tyrosinase are enzymes found in plant and crustacean foods that oxidize phenolic acids and initiate secondary nonenzymatic reactions that are responsible for darkening and often loss of color quality. (*See* **Ascorbic Acid**: Properties and Determination.)

Environmental Factors

Temperature

Generally, as the temperature increases, the rate of oxidation reactions also increases. Rate increases usually follow a $Q_{10} = 2$ relationship, or a doubling in rate for every rise of 10 °C, provided no change in the mechanism of reaction occurs with a corresponding change in temperature and as long as competing reactions have little impact on the reactants. For oxidative reactions caused by enzymes, an optimum temperature exists. This is because enzymes, being proteins, are denatured above a characteristic temperature and will lose biological activity. Another factor is that, as temperature increases, oxygen solubility in water decreases and this could attenuate the temperature activation of oxidative reactions if oxygen was a limiting component in the process.

Moisture

Lipid oxidation reactions generally have rate minima at intermediate water activities (a_w) of about 0.3. As a_w increases above 0.3, rates of oxidation increase, probably due to increased mobility and activity of catalysts. At a_w below 0.3, rates of oxidation increase, perhaps due to solvation and removal of catalysts and reaction intermediates from lipids and into the aqueous phase. (*See* **Water Activity**: Effect on Food Stability.)

Chemical Composition of Food

The relative concentrations of various prooxidants and antioxidants in the food, and their identities and relative reactivities, will greatly influence the rate of oxidation reactions. Antioxidants, such as butylated hydroxytoluene, butylated hydroxyanisole, propyl gallate, ascorbic acid, and sodium bisulfite can be added to impede oxidative reactions. On the other hand, the inadvertent addition of transition metals, such as iron and copper, from processing equipment can hasten oxidative reactions in foods. In addition, the nature of the substrate sensitive to oxidative reactions is important. For example, foods rich in polyunsaturated fatty acids (vegetable and fish oils) are more sensitive to oxidation than those rich in monounsaturated fatty acids (animal depot fats). (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

Exogenous Factors

Packaging materials and strategies can have an influence on rates of oxidation. Foods containing photosensitive pigments are often packed in opaque or translucent containers to minimize photooxidative

processes by preventing the activation of oxygen by these pigments. The head space of products in containers can also be controlled to inhibit oxidative processes. For example, foods can be sealed in containers after the head space has been flushed with an inert gas such as nitrogen or under vacuum. Both approaches serve to minimize the oxygen available to support oxidative reactions. Products may also be coated, such as with sugar syrups on fruits to be frozen, to minimize the availability of oxygen for oxidative reactions.

Examples in Foods

Many foods are susceptible to oxidative reactions. Plant and fish oils, due to their high levels of unsaturation, can deteriorate in flavor very rapidly if oxidation is allowed to take place. Lipid oxidation gives rise to the 'fishy' flavor and aroma in frozen fish and this limits acceptable storage life. Refining procedures for vegetable and seed oils are partly designed to remove chlorophyl which can cause flavor deterioration by initiating photooxidative reactions. Another light-sensitive food is milk. The endogenous riboflavin can cause photooxidation of lipids and proteins and yield the undesirable 'light-activated flavor.' Early recognition of this problem gave rise to the domestic delivery of milk in opaque containers, in many countries, to prevent its exposure to light. (*See* **Fish Oils**: Composition and Properties; **Milk**: Processing of Liquid Milk; **Vegetable Oils**: Dietary Importance.)

Nuts and high-fat products, such as potato crisps, can be packaged in containers having a modified atmosphere or head space. Nitrogen flushing of containers and packing under vacuum are processes designed to limit the amount of oxygen available for oxidation reactions. (*See* **Chilled Storage**: Use of Modified-atmosphere Packaging.)

Most plant tissues, particularly fresh fruits, brown excessively upon cutting or bruising. This is often due to the presence of polyphenol oxidase, which acts on phenolic acids in these foods. After the initial enzymatic oxidations, a series of subsequent nonenzymatic oxidations convert these phenolic acids into polymers that are responsible for the brown color. (*See* **Phenolic Compounds**.)

Not all oxidative reactions in foods are undesirable. In the extrusion processing of foods at alkaline pH, the oxidative polymerization of proteins results in the desirable texturization in simulated meat products. Protein and lipid oxidation are also recognized for their beneficial effects on dough strengthening in the baking industries. A third example is the emanation of characteristic flavors and aromas upon slicing of fresh cucumbers and tomatoes. The sources of these flavors are unsaturated fatty acids which have been initially oxidized by endogenous lipoxygenase activity and have been transformed further by other enzymes. The chemical 'fermentation' of tea leaves and the 'ripening' of olives are achieved by potentiating polyphenol oxidase enzyme activity on endogenous phenolic acids, causing the development of desirable coloration in these products.

Generally, oxidative reactions that can be controlled can be manipulated to yield beneficial effects, whereas those that cannot often yield detrimental effects on food quality.

OXIDATIVE PHOSPHORYLATION

D A Bender, University College London, London, UK

Background

The total body content of ATP is of the order of 10 g, whereas the daily turnover of ATP is equal to the body weight, some 70 kg. A small number of metabolic reactions involve direct transfer of phosphate from a phosphorylated substrate on to ADP, forming ATP – substrate-level phosphorylation. Under normal conditions, almost all of the phosphorylation of ADP to ATP occurs in the mitochondria, by the process of oxidative phosphorylation – the oxidation of reduced coenzymes linked to the reduction of oxygen to water and (under normal conditions) obligatorily linked to phosphorylation of ADP → ATP. This obligatory linkage of substrate oxidation, reoxidation of reduced coenzymes, and reduction of oxygen to water with the phosphorylation of ADP mean that the availability of ADP controls the rate at which substrates are oxidized. In turn, the availability of ADP to be phosphorylated is dependent on the rate of utilization of ATP in performing physical and chemical work. Thus, energy expenditure in physical and chemical work controls the rate at which metabolic fuels are oxidized, rather than being used to form reserves of (mainly) adipose tissue triacylglycerol.

With the exception of glycolysis and the pentose phosphate pathway, most of the reactions in the oxidation of metabolic fuels occur inside the mitochondria and lead to the reduction of nicotinamide nucleotide and flavin coenzymes. Within the inner membrane of the mitochondrion, there is a series of coenzymes that are able to undergo reduction and oxidation. The first coenzyme in the chain is reduced by reaction with NADH, and is then reoxidized by reducing the next coenzyme. In turn, each coenzyme in the chain is reduced by the preceding coenzyme, and then reoxidized by reducing the next coenzyme. The final step is the oxidation of a reduced coenzyme by oxygen, resulting in the formation of water. Figure 1 shows an overview of this mitochondrial electron transport chain.

Experimentally, the electron transport chain can be dissected into four complexes of coenzymes, which catalyze:

1. Oxidation of NADH leading to the reduction of ubiquinone to ubiquinol. This complex is associated with the phosphorylation of ADP → ATP.
2. Oxidation of reduced flavoproteins and reduction of ubiquinone to ubiquinol. This complex is not associated with phosphorylation of ADP.
3. Oxidation of ubiquinol, leading to reduction of cytochrome c. This complex is associated with the phosphorylation of ADP → ATP.
4. Oxidation of reduced cytochrome c leading to the reduction of oxygen to water. This complex is associated with the phosphorylation of ADP → ATP.

This means that there are three sites in the electron transport chain between NADH and oxygen that are linked to the phosphorylation of ADP → ATP, but only two between reduced flavoproteins and oxygen. Experimentally, this is seen as a ratio of phosphate esterified:oxygen consumed (the P:O ratio) of approximately 3 when substrates that reduce NAD^+ are oxidized, and approximately 2 when substrates that reduce flavoproteins are oxidized.

Experimentally, mitochondrial metabolism is measured using the oxygen electrode, in which the percentage saturation of the buffer with oxygen is measured electrochemically as the mitochondria oxidize substrates and reduce oxygen to water. Figure 2 shows the oxygen electrode traces for oxidation of malate (which is linked to reduction of NAD^+) and succinate (which is linked to reduction of a flavoprotein). The greater consumption of oxygen for oxidation of succinate compared with the same amount of malate reflects the lower P:O ratio for succinate oxidation.

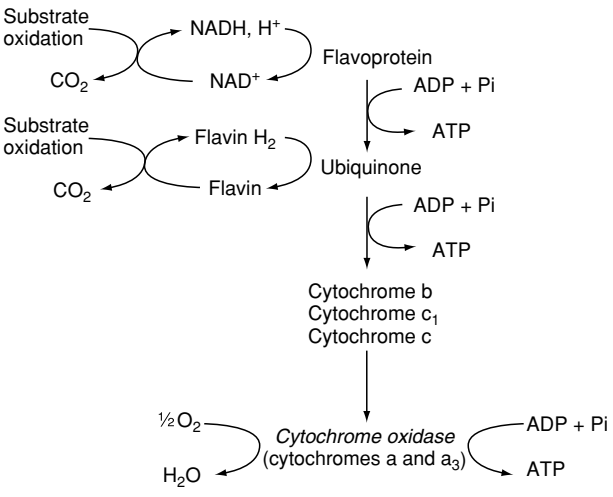

Figure 1 Overview of the mitochondrial electron transport chain.

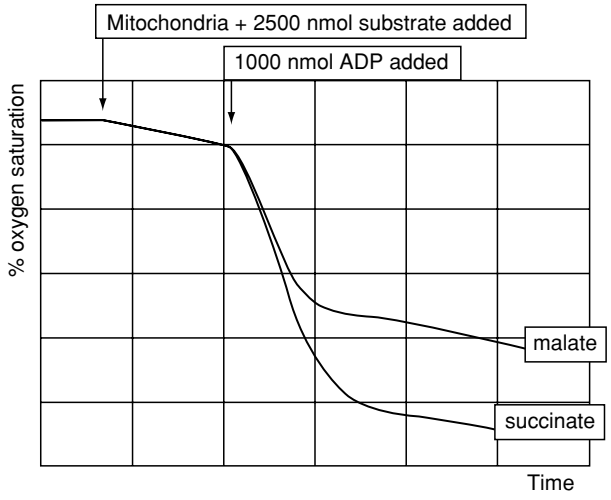

Figure 2 Oxygen electrode traces for mitochondria oxidizing malate and succinate.

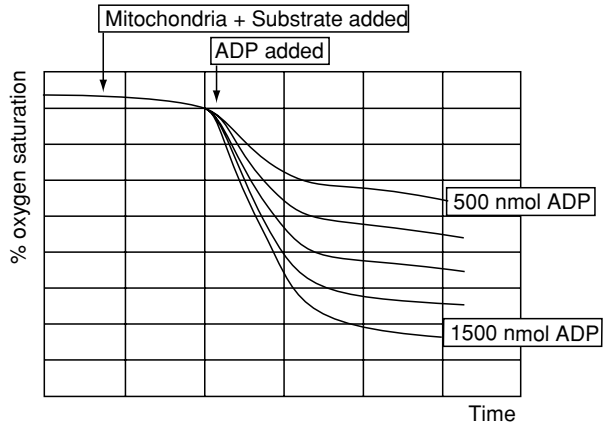

Figure 3 Oxygen electrode traces for mitochondria oxidizing malate with varying amounts of ADP.

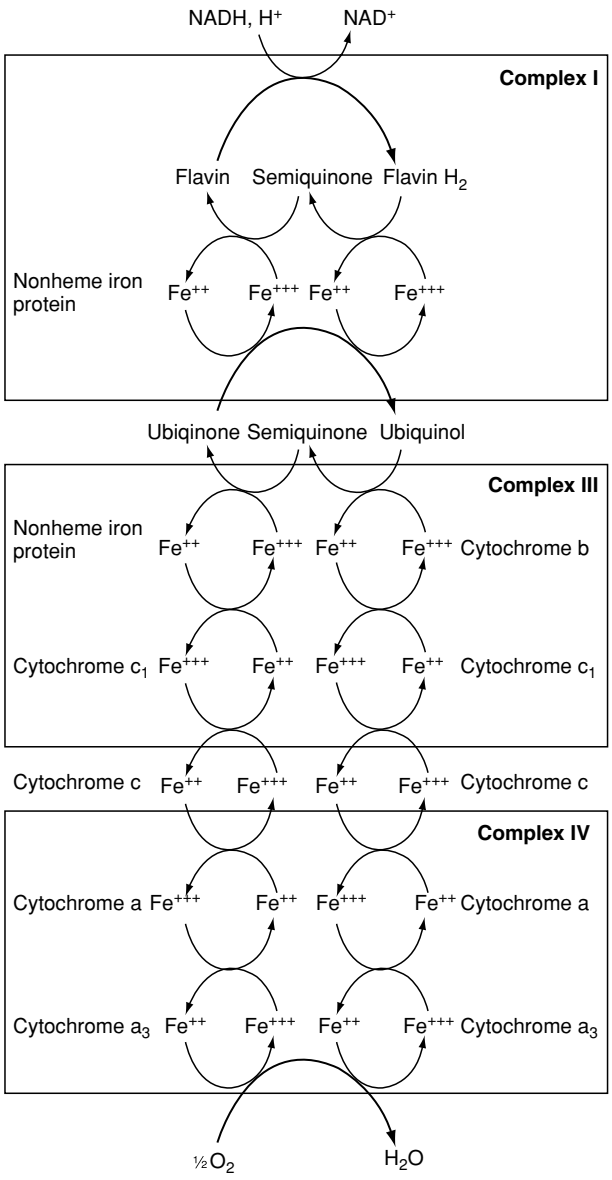

Figure 4 Mitochondrial electron transport chain.

Figure 3 shows the oxygen electrode traces for mitochondria incubated with varying amounts of ADP, and a super-abundant amount of malate. As more ADP is provided, so there is more oxidation of substrate, and hence more consumption of oxygen. This illustrates the tight coupling between the oxidation of metabolic fuels and the availability of ADP to be phosphorylated.

Mitochondrial Electron Transport Chain

The mitochondrial electron transport chain is a series of enzymes and coenzymes in the crista membrane, each of which is reduced by the preceding coenzyme, and in turn reduces the next, until finally the protons and electrons that have entered the chain from either NADH or reduced flavin reduce oxygen to water. The sequence of the electron carriers shown in Figures 1 and 4 has been determined in two ways:

- By consideration of their electrochemical redox potentials, which permits determination of which carrier is likely to reduce another, and which is likely to be reduced.
- By incubation of mitochondria with substrates, in the absence of oxygen, when all of the carriers become reduced, then introducing a limited amount of oxygen, and following the sequence in which the carriers become oxidized. The oxidation state of the carriers is determined by following changes in their absorption spectra.

In order to understand how the transfer of electrons through the electron transport chain can be linked to the phosphorylation of ADP to ATP, it is necessary to consider the chemistry of the various electron carriers. They can be classified into two groups:

Hydrogen carriers, which undergo reduction and oxidation reactions involving both protons and electrons – these are NAD, flavins, and ubiquinone. As shown in Figure 5, NAD undergoes a two-electron oxidation/reduction reaction, while both the flavins and ubiquinone undergo two single electron reactions to form a half-reduced radical, then the fully reduced coenzyme. Flavins can also undergo a two electron reaction in a single step.

Electron carriers, which contain iron (and, in the case of cytochrome oxidase, also copper) undergo oxidation and reduction by electron transfer alone. These are the cytochromes, in which the iron is present in a heme molecule, and nonheme iron proteins, sometimes called iron–sulfur proteins, because the iron is bound to the protein through the sulfur of the amino acid cysteine. Figure 6 shows the arrangement of the iron in nonheme iron proteins, and the three different types of heme that occur in cytochromes:

- heme (protoporphyrin IX), which is tightly but noncovalently bound to proteins, including cytochromes b and b_1, as well as enzymes such as catalase, and the oxygen transport proteins hemoglobin and myoglobin;
- heme C, which is covalently bound to protein in cytochromes c and c_1;
- heme A, which is anchored in the membrane by its hydrophobic side chain, in cytochromes a and a_3 (which together form cytochrome oxidase).

The hydrogen and electron carriers of the electron transport chain are arranged in sequence in the crista membrane, as shown in Figure 4. Some carriers are entirely within the membrane, whereas others are located on the inner or outer face of the membrane. Each of the three complexes in which phosphorylation of ADP → ADP is linked to electron transport forms a membrane-spanning unit.

There are two steps in which a hydrogen carrier reduces an electron carrier: the reaction between the flavin and nonheme iron protein in complex I, and the reaction between ubiquinol and cytochrome b plus a nonheme iron protein in complex III. The reaction between nonheme iron protein and ubiquinone in complex I is the reverse – a hydrogen carrier is reduced by an electron carrier.

When a hydrogen carrier reduces an electron carrier, there is a proton that is not transferred onto the electron carrier, but is extruded from the membrane, into the crista space, as shown in Figure 7. When an electron carrier reduces a hydrogen carrier, there is a need for a proton to accompany the electron that is transferred. This is acquired from the mitochondrial matrix, thus shifting the equilibrium between H_2O and $H^+ + OH^-$, resulting in an accumulation of hydroxyl ions in the matrix.

Similar pumping of protons across the crista membrane occurs in complexes III and IV, although it is less obvious than in complex I. Thus, each complex that is associated with phosphorylation of ADP → ATP pumps protons into the crista space as it transports electrons.

Phosphorylation of ADP Linked to Electron Transport

The result of electron transport through the sequence of carriers shown in Figure 4 is a separation of protons and hydroxyl ions across the crista membrane, with an accumulation of protons in the crista space, and an accumulation of hydroxyl ions in the matrix, i.e., creation of a pH gradient across the crista membrane.

This proton gradient provides the 'driving force' for the phosphorylation of ADP → ATP – a highly endothermic reaction. Protons reenter the mitochondrial matrix, down the proton gradient, through transport pores in the membrane that are an integral part of the mitochondrial primary particles that contain the ATP synthase, and form the transmembrane stalk of the primary particles.

ATP synthase acts as a molecular motor, driven by the flow of protons down the concentration gradient from the crista space into the matrix, through the transmembrane stalk of the primary particle. As protons flow through the stalk, they cause rotation of the core of the multienzyme complex that makes up the primary particle containing ATP synthase.

As shown in Figure 8, there are three ATP synthase catalytic sites in the primary particle, and each one-third turn of the central core causes a conformational change at each active site:

- at one site, the conformational change permits binding of ADP and phosphate;
- at the next site, the conformational change brings ADP and phosphate close enough together to undergo condensation and expel water;
- at the third site, the conformational change causes expulsion of ATP from the site, leaving it free to accept ADP and phosphate at the next part turn.

At any time, one site is binding ADP and phosphate, one is undergoing condensation, and one is expelling

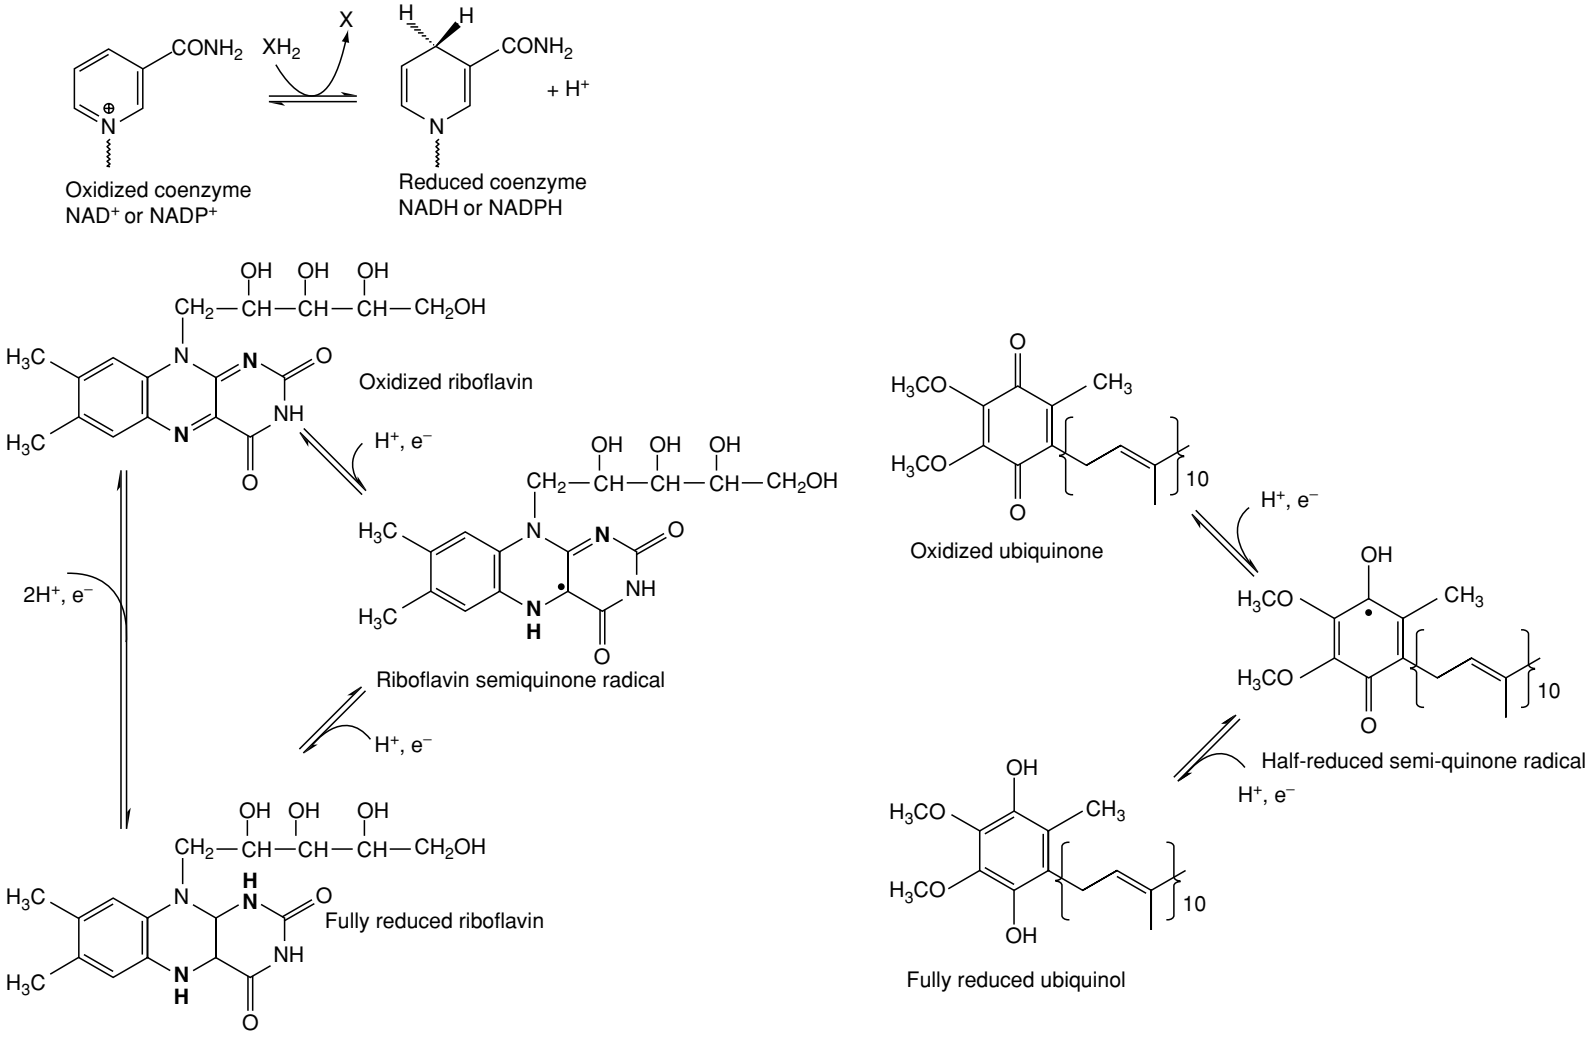

Figure 5 Oxidation and reduction of the hydrogen carriers of the electron transport chain: the nicotinamide nucleotide coenzymes (NAD and NADP), flavins and ubiquinone.

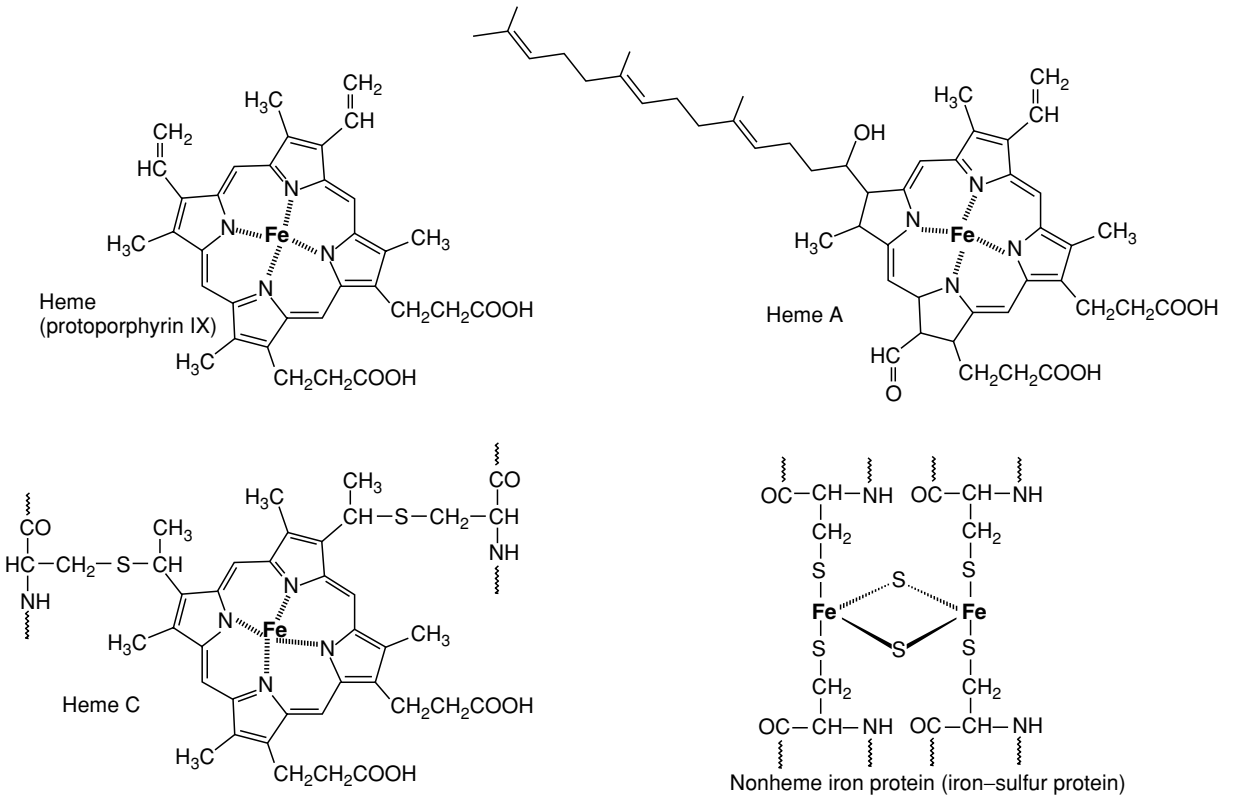

Figure 6 Types of heme in cytochromes and the binding of iron in nonheme iron proteins (iron–sulfur proteins).

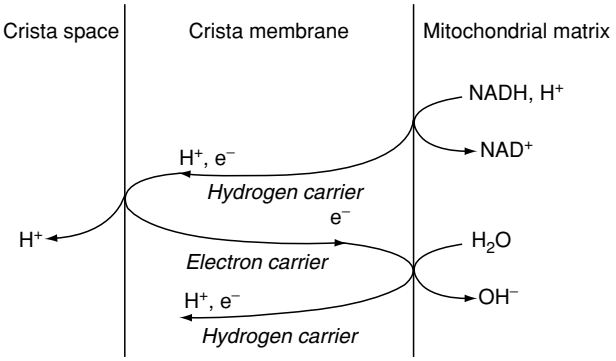

Figure 7 Proton pumping across the crista membrane in complex I.

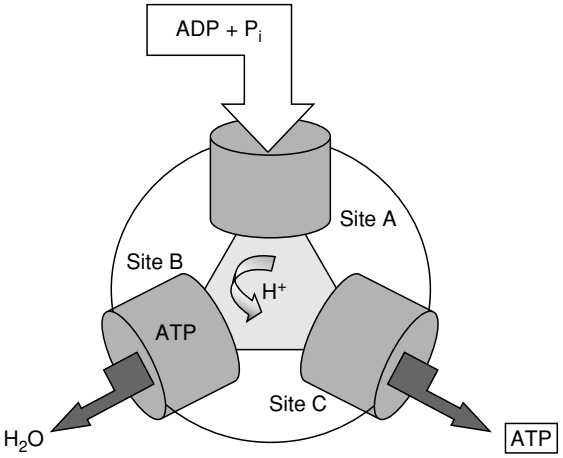

Figure 8 Three active sites of the ATP synthase complex in the mitochondrial primary particle.

ATP. If ADP is not available to bind, rotation cannot occur – and if rotation cannot occur, protons cannot flow through the stalk from the crista space into the matrix.

Coupling of Electron Transport, Oxidative Phosphorylation, and Fuel Oxidation

The processes of oxidation of reduced coenzymes and the phosphorylation of ADP → ATP are normally tightly coupled:

- ADP phosphorylation cannot occur unless there is a proton gradient across the crista membrane resulting from the oxidation of NADH or reduced flavins.
- If there is little or no ADP available, the oxidation of NADH and reduced flavins is inhibited, because the protons cannot cross the stalk of the primary

particle, and so the proton gradient becomes large enough to inhibit further transport of protons into the crista space. Indeed, experimentally, it is possible to force reverse electron transport, and reduction of NAD^+ and flavins by creating a proton gradient across the crista membrane.

Metabolic fuels can only be oxidized when NAD^+ and oxidized flavoproteins are available. Therefore, if there is little or no ADP available in the mitochondria (i.e., it has all been phosphorylated to ATP), there will be an accumulation of reduced coenzymes and hence a slowing of the rate of oxidation of metabolic fuels. This means that substrates are only oxidized when there is a need for the phosphorylation of ADP to ATP, and ADP is available. In turn, the availability of ADP is dependent on the utilization of ATP in performing physical and chemical work.

It is possible to uncouple electron transport and ADP phosphorylation, by adding a weak acid such as dinitrophenol that transports protons across the crista membrane. As shown in Figure 9, in the presence of such an uncoupler, the protons extruded during electron transport do not accumulate in the crista space, but are transported into the mitochondrial matrix, where they react with hydroxyl ions, forming water. Under these conditions, ADP is not phosphorylated to ATP, and the oxidation of NADH and reduced flavins can continue unimpeded until all the available substrate or oxygen has been consumed. Figure 10 shows the oxygen electrode trace in the presence of an uncoupler – there is more or less complete consumption of oxygen regardless of the amount of ADP present.

The result of uncoupling electron transport from the phosphorylation of ADP is that a great deal of substrate is oxidized, with little production of ATP, although heat is produced. This is one of the physiological mechanisms for heat production to maintain body temperature without performing physical work – nonshivering thermogenesis. There are a number of proteins in the mitochondria of various tissues that act as proton transporters across the crista membrane when they are activated.

The first such uncoupling protein to be identified was in brown adipose tissue, and was called thermogenin because of its role in thermogenesis. Brown adipose tissue is anatomically and functionally distinct from the white adipose tissue that is the main site of fat storage in the body. It has a red–brown color because it is especially rich in mitochondria. Brown adipose tissue is especially important in the maintenance of body temperature in infants, but it remains active in adults, although its importance compared with uncoupling proteins in muscle and other tissues is unclear.

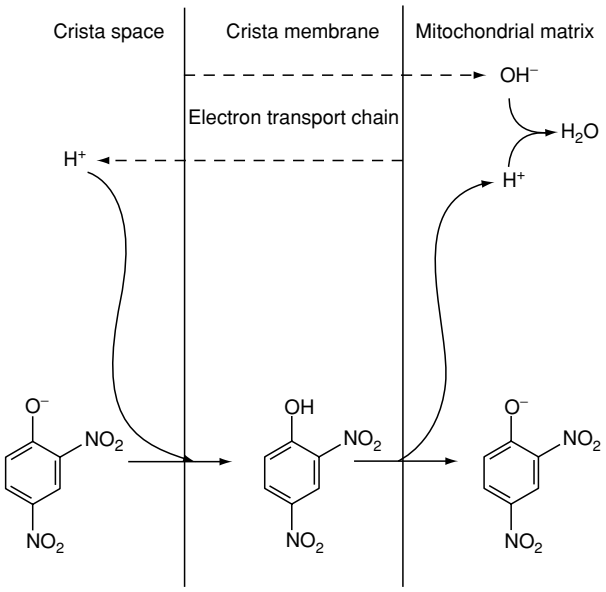

Figure 9 Uncoupling – discharge of the proton gradient by a weak acid.

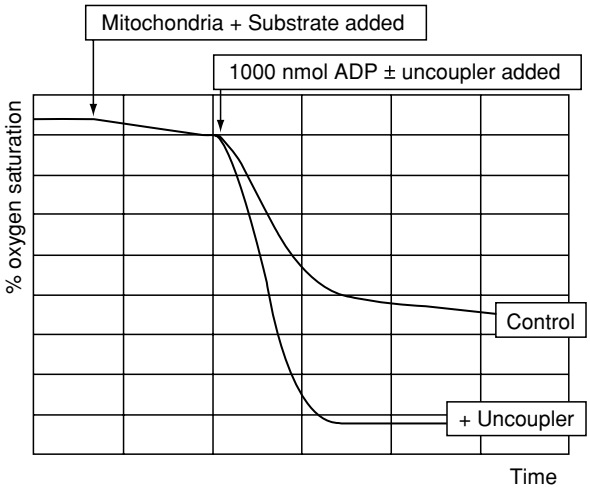

Figure 10 Oxygen electrode traces in the presence and absence of an uncoupler.

In addition to maintenance of body temperature, uncoupling proteins are important in overall energy balance and body weight control. The hormone leptin, secreted by (white) adipose tissue, increases the expression of uncoupling proteins in muscle and adipose tissue, so increasing energy expenditure and the utilization of adipose tissue fat reserves.

Respiratory Poisons and other Inhibitors

Much of our knowledge of the processes involved in electron transport and oxidative phosphorylation has come from studies using inhibitors.

1. Rotenone, the active ingredient of derris powder, an insecticide prepared from the roots of the leguminous plant *Lonchocarpus nicou*. It is an inhibitor of complex I. The same effect is seen in the presence of amytal (amobarbital), a barbiturate sedative drug, which again inhibits complex I. These two compounds inhibit oxidation of malate, which requires complex I, but not succinate, which reduces ubiquinone directly. The addition of an uncoupler has no effect on malate oxidation in the presence of these two inhibitors of electron transport, but results in uncontrolled oxidation of succinate.
2. Antimycin A, an antibiotic produced by *Streptomyces* spp. that is used as a fungicide against fungi that are parasitic on rice. It inhibits complex III, and thus inhibits the oxidation of both malate and succinate, since both require complex III, and the addition of the uncoupler has no effect.
3. Cyanide, azide, and carbon monoxide bind irreversibly to the iron of cytochrome a_3, and thus inhibit complex IV. Again, these compounds inhibit oxidation of both malate and succinate, since both rely on cytochrome oxidase, and again, the addition of the uncoupler has no effect.
4. Oligomycin, a therapeutically useless antibiotic produced by *Streptomyces* spp. Oligomycin inhibits the transport of protons across the stalk of the primary particle. This results in inhibition of oxidation of both malate and succinate, since, if the protons cannot be transported back into the matrix, they will accumulate and inhibit further electron transport. In this case, addition of the uncoupler permits reentry of protons across the crista membrane, and hence uncontrolled oxidation of substrates.
5. Atractyloside (a plant glycoside) and bongkrekic acid (a toxic antibiotic formed by *Pseudomonas cocovenans* growing on coconut – this is named after bongkrek, a mold-fermented coconut product in Indonesia, that becomes highly toxic when *Ps. cocovenans* outgrows the mold). Both compounds inhibit the transport of ADP and ATP across the mitochondrial membrane. Bongkrekic acid fixes nucleotides to the transport protein at the matrix side of the membrane, so that they cannot be released, whereas atractyloside has a higher affinity for the transport protein than does ADP, and so out-competes it for transport into the matrix.

PACKAGING

Packaging of Liquids

S D Deshpande, Central Institute of Agricultural Engineering, Nabi Bagh, Bhopal, India

Background

In modern times, packaging has been identified as an integral part of processing in the food industry. Packaging is a technique of using the most appropriate packaging media for the safe delivery of the contents from the centers of production to the site of consumption. Packaging serves as the vital link in the long line of production, storage, transportation, distribution, and marketing. The package must ensure the same high quality of the product to the consumer, as they are used to getting, in freshly manufactured products. It is important that all products should reach the consumer in a usable condition.

Modern packaging systems for liquid foods are products from a synthesis of demands from producers, distributors, and consumers. The need for hygiene is the primary reason for retail packaging of perishable liquid food products like milk. Although this was realized more than a century ago, packaging techniques for liquid milk were slow in developing. The advent of pasteurization in the 1920s made retail packaging of liquid essential, and the returnable glass bottle was soon to become universal.

The commercial development of plastic materials, starting with polyethylene (PE) in the 1940s, opened up new possibilities for improving hygiene in liquid packaging. PE ultimately became the most frequently used thermoplastic in paper and carton board coating processes, also finding uses in inplant manufacture of packages from reel stock by form–fill–seal techniques. In current efforts to make retailing still more efficient, the focus is on standardized packages and transport wrappings, the aim being to simplify routines and cut costs. One-way cartons are suitable for these requirements. These developments have gradually led to a change in retail patterns in many countries, and the replacement of returnable glass bottles by single-service paper/plastic containers has been seen in many countries.

Today, a product distinction can be made between milk and non-milk on the one hand, and fresh and long-life products on the other. The main products retailed in one-way cartons are still milk and milk products, holding approximately 80% of the carton demand in liquid packaging, but a steady increase in market share for fruit juices, mineral water, sports drinks, vegetable oils and juices, soft drinks, and wine is observed. This trend is likely to continue, ensuring a further potential for the paper bottle.

Functional Packaging

Functional packaging of products contributes to the industrial prosperity of a country through optimal utilization of resources. The packaging has to protect the contents against hazards such as the vagaries of climate and transportation. During the course of the journey, the package would be exposed to varying climatic conditions, often resulting in evaporation and condensation of water of the contents inside the package. Also, atmospheric gases like O_2 and SO_2 contribute to the deterioration of the products by the oxidation of fat-rich products or corrosion of the metal containers. While this is the case in bulk packages, the unit container, which comes directly into contact with the product, must have requisite barriers and protective properties. A scientifically

designed package should, therefore, afford protection against egress or ingress of moisture, flavor loss or odor pickup, light, oxygen, microbial and fungus attack, as well as being compatible with the food packaged. The package must preserve the quality, freshness, and functional performance of the product, afford the requisite shelf-life, and make it possible for the product to reach the consumer in prime condition.

Principles of Production

Filling and sealing machines for paper-based packages for liquids form two groups: those that work from a roll of packaging material, and those that work from premanufactured blanks, the difference reflecting the basic machine philosophy or concepts of companies like Tetra Pak and Elopak. The basic idea of Tetra Pak is that the package should be formed from a roll of packaging material, filled, and sealed in a continuous, closed process. The basic idea of Elopak is that as much of the package production as possible should be included in the converting process. Consequently, the production of blanks, being a highly specialized process, is therefore considered best performed when separated from the food-packaging plant.

Converting

In the converting process, the basic paper is coated on both sides, printed, and provided with scorelines to facilitate creasing when finally forming the package.

Filling and Sealing

When choosing a carton-based packaging system for liquids, there are three differently shaped packages presently predominating the market, namely the gable top, the tetrahedron, and the brick.

The filling and sealing procedure of a gable-top-type package starts with a blank being fed from a magazine. The lay-flat tube is then unfolded and enters a mandrel where the bottom is heated with hot air. The bottom is then folded in accordance with scorelines, and pressure is applied for finishing the bottom sealing. Now an open rectangular box, it is removed from the mandrel on to a conveyer, filled with liquid and the top sealed. The top seal is made using hot air and pressure.

The most striking feature of the tetrahedral package is the shape. The tetrahedral shape requires less packaging material than other designs, as it offers the most favorable ratio of area to volume.

The production of Tetra Brik-type packages from roll-fed machines follows basically the same principles as those for Tetra Standard, but the transverse seams are sealed parallel. The characteristic brick shape is formed after cutting off individual packages from the tube, by folding in the flaps and heat-sealing them.

Materials

The sandwich construction of the two common paper-based laminates used in liquid packaging is shown in Figure 1. If no high-gas barrier is required, the material consists of paper with a polyethylene coating on both sides. The paper layer may consist of unbleached, bleached, or semibleached sulfate pulp or laminates of these. The paper layer, being responsible for much of the machinability and mechanical properties of the package, requires a high and stable quality.

Additional barrier properties are usually provided by aluminum foil, laminated to the board, but the contact surface against the food remains polyethylene.

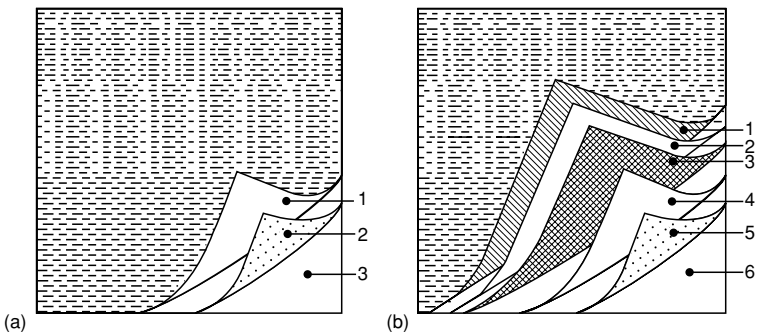

Figure 1 Sandwich construction of two common laminates for carton containers. (a) Typical laminate for short-life products like fresh milk consisting of (1) exterior PE, (2) paper, and (3) interior PE; (b) typical laminate for long-life products consisting of (1) exterior PE, (2) paper, (3) Surlyn, (4) Al-foil, (5) Surlyn, and (6) interior PE.

Packaging materials should provide the following properties:

1. high hygiene standards;
2. sufficient mechanical strength and internal bond;
3. liquid proofness;
4. interness to product;
5. light barrier;
6. low gas permeability;
7. seal ability;
8. machinability in converting and filling processes.

Canning

The process of canning is sometimes called sterilization because the heat treatment of the food eliminates all microorganisms that can spoil the food and those that are harmful to humans, including directly pathogenic bacteria and those that produce lethal toxins. Most commercial canning operations are based on the principle that bacteria destruction increases tenfold for each 10°C (18°F) increase in temperature. Food exposed to high temperatures for only minutes or seconds retains more of its natural flavor. Recent developments include the use of cans made of aluminum, very thin steel, and coated and uncoated plastic. Can openers are unnecessary for cans that have a pullable metal tab or ring attached at the top. Despite the widespread popularity of canned foods, the major limitation of canning is in the quality of the final product. Since food is not a good conductor of heat, excess heat needs to be applied to the container's surface for a period of time to guarantee sufficient heat at the center, or 'cold spot,' in order to destroy all organisms causing spoilage and disease. This method of preserving causes foods to lose juices, texture, flavor, and nutrients. The retort pouch, developed in the 1970s to alleviate this problem, is a 3-layered laminate with flexible plastic films as the outer and inner layers and aluminum foil in the middle. The pouch, which is approximately 19 mm (0.75 in) thick, is filled and sealed under vacuum. Because the pouch has a large surface-to-volume ratio, heat needs to penetrate less than 10 mm (0.38 in) from the surface to the 'cold spot,' thereby yielding greatly improved products.

Selection Criteria for Packaging Materials

Some of the important packaging considerations, which influence the choice of packaging materials, are given below.

Product Protection

The choice of packaging material has to be made depending upon the nature of the product, i.e., susceptibility of the ingredients used to undergo deterioration in contact with water, moisture, gases, light, etc. For products containing high fats, the packaging material must have high oxygen barrier properties. For such applications, material based on nylon, nitrile, or polyester may be considered. However, for products that are likely to deteriorate only by moisture gain or loss, a packaging material with sufficient moisture barrier properties may be adequate. For light-sensitive products, an opaque packaging material may be necessary. The shelf-life is another important criterion that influences packaging material specifications.

Convenience

The convenience for consumers and amenability of the packaging material to provide such features is a predominant factor in the final choice. Features such as reclosability, dispensing capability, stand-up facility, etc. are some examples of packages preferred by the end users.

Sales Appeal and Package Decoration

For some products, it may be necessary for the package to communicate effectively and visually attract the consumer while it is displayed on the shelf. Thus, the choice of packaging material is influenced by such properties as gloss, transparency, and ability to accept multicolor printing.

Product Package Compatibility

This aspect is critical, particularly for edible products. Product package compatibility testing is carried out to assess the possibility of any migration from and to the product. Any loss of product flavor or product tainting with unacceptable odor is also checked.

Packaging Machinery

For products that are mass-produced, the speed of packaging is very important, and the packaging material chosen must run smoothly on the packaging machine used. Here, the mechanical properties of the films and laminates such as tensile strength, rigidity, coefficient of friction, slip properties of the film and laminates, and their susceptibility to develop a static charge need to be considered.

Package Sealing Efficiency

However good a packaging material may be for a given product, its ability to protect the product is determined by its seal strength. Often, the product is spilled around the sealing area while filling. In such cases, sealing of the package with product contamination on the sealing surface is necessary.

Package Strength

Product distribution over longer distances invariably involves multiple handling and long storage periods. These are generally associated with both mechanical and climatic hazards. The choice of material, therefore, has to be made, based on the severity of hazards and the capacity of the material to withstand these in a given distribution situation.

Statutory Requirements

Often, there are certain regulations governing the choice of packaging material, for example, in the packaging of pesticides.

Material Availability

Any user would like to have multiple sources of procuring their packaging material. Therefore, the sources of supply and the availability of material become predominant considerations.

Cost

Sometimes, marketing success depends on how low the product is priced. The ultimate choice of packaging material is often influenced by the cost at which the functions indicated above are achieved.

The criteria discussed above are some of the more important considerations. Depending upon the type of product and the market, many additional considerations may become important. However, by and large, if the above criteria are used while selecting the packaging material, the user is likely to arrive at an optimum choice of packaging material.

Developments in Packaging of Liquid Foods

Liquid food products have been packed, preserved, and transported over the ages by a variety of methods. Wooden containers, earthen pots (glazed pottery or jars), and glass continue to be the major materials, even in the present day. All these had the benefits of being nonreactive to the food material and also efficient to contain the material resisting deformation besides being leak-proof (if properly closed). Over the years, with man's quest for newer technologies, packaging of liquid food products also gained greater importance. The need for developing alternative materials and methods for liquid food packaging has arisen for several reasons, such as to reduce the cost of packaging, improve the shelf-life, provide convenience in using the product, improve the handling during transport or in retail outlets, and also promote consumer acceptance of the product. It was further necessitated due to changed distribution systems, competition, changing consumer needs, and availability of new packaging materials and/or methods.

For transporting in bulk, liquid material can be carried in wooden drums or metal drums. Alternatively, containers can be packed in wooden crated, or fiber mold cases, e.g., glass carboys in crates, polythene, or synthetic plastic carboys can be considered. A new development in this area is the bag-in-box type of packaging for liquids. In examining the shelf-life requirements of the product, microbial spoilage in the case of fresh food products such as milk and fruit juices, due to their high susceptibility to microbial contamination and hence requirement for sterilization/pasteurization, needs to be considered. Packaging material should withstand rigorous treatments during such packaging stages.

As the industry grows, and the demand for convenience increases, the need for quality packaging undoubtedly increases. Today, packaging is cost-effective in the sense that the package is pivotal to the marketing philosophy of the urban markets offering a wide choice at a low cost. Thus, the model food package has to keep down marketing costs and offer the consumer tangible price benefit. The increased speeds on machine lines and use of flexible laminates in place of tin containers may be considered as a development.

As outlined above, the selection of the packaging material and the packaging machines depends upon the food to be packed, and the methods together can be called as a packaging system. Today, fruit juices, wines, water, oil, soup, concentrated vegetable, purées, etc. are packed in a variety of systems such as prepac, Blockpak, Zupack, Purepak, Ceka, Tetrapak, thermoforming systems, and bag-in-box systems. Facilities such as asceptic packaging, hot filling, nitrogen flushing, etc. for the product are also available.

There are the range of cartoning systems and form–fill–seal machines now available and are replacing the glass and tin containers for liquid food packaging. Among these, asceptic packaging is yet another development.

Requirements with respect to hygiene and impermeability are stringent for liquid food products. Sealing must be tight. There are basically three types of machines for the packaging of liquids, viz. vertical form–fill–seal machines horizontal form–fill–seal machines and sachet-forming machines.

All the types can be used for liquid food product packaging. They can have such secondary facilities as gas flushing, vacuum zing, etc. introduced. Standipacks and gusseted sachet packs are quite acceptable for liquid food products for consumer convenience.

Resources and Energy

Presently, one-way carton packages for milk, juices, and other noncarbonated beverages coexist with one-way and returnable alternatives like the glass or plastic bottle. At first sight, the returnable alternatives seem preferable from an energy and ecological point of view. But considering the entire process, from extraction of raw materials, through production and distribution to the handling of waste, this is not the case when compared to one-trip cartons. Investigations show that there are only minor differences, ecologically speaking, between a returnable bottle with a realistic trippage for modern retailing and a plastic-coated paper bottle.

The constituent materials of the dominant packages for the noncarbonated liquid foods, for glass bottles, cans, plastic bottles, and cartons, differ in practically every aspect: raw material consumption, energy consumption, impact on water and air, and amount and quality of waste. The overall energy requirements for the different packages are of the same magnitude (Figure 2), water and air pollutants are comparable, and a large amount of waste is generated in the use of returnable bottles if a bottle does fewer than 20 trips.

Carton-based packages using wood as the basic raw material exploit a renewable resource. Present planting of trees exceeds harvesting, so there will not be any deforestation as a result of the manufacture of paper containers.

Litter and waste may be regarded as minor problems as far as PE-coated cartons are concerned. If a plastic-coated cartonboard is left in nature, complete degradation will usually take several years, the main problem being the degradation of the polymer. Biodegradable PE has been discussed as an alternative outer coating. Although this solution would increase the rate of degradation considerably, it has never found applications. The waste problem is the more important issue when it comes to disposabilities. Nevertheless, the waste from PE-coated cartons is easily handled, does not require separate collection, and may be used as a source of energy when incinerating.

Marketing Aspects and Competition

The main alternatives in liquid food packaging are glass and plastic bottles, cans, and plastic-coated cartons. A packaging system based on cartons is facilitated by low overall costs. In fact, the one-way

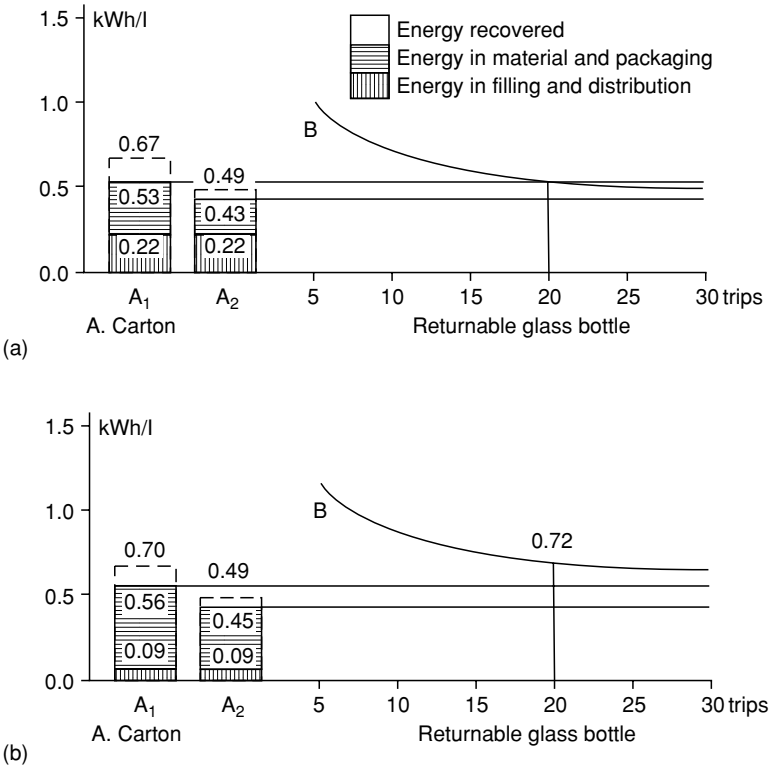

Figure 2 Comparison of energy counts for milk (a) and juice (b) packaged in cartons and returnable glass bottles. A_1 and A_2 represent the energy counts for cartons including and excluding wood energy, respectively. The figures are reproduced from data given in Sundstrom G (1982) *Milk Packages and Energy*. Malmo, Sweden: Sundstrom AB and Sundstrom G and Lundholm MF (1982) *Juice Packages and Energy*. Malmo, Sweden: Sundstrom AB.

carton container is found to be a cheaper alternative than cans and returnable glass bottles. The profitability is largely due to low distribution costs, storage efficiency, maximum use of shelf-space, and low labor costs.

For the working environment, systems based on one-way cartons are regarded as superior. Different products with very different processing qualities can be handled, including mineral water, nectars or fruit juices with a high pulp content, wine, milk, preserved dairy products, and others.

In modern retailing, the package serves the purpose of being an important source of information. Being printable and having four sides available for commercials and content declaration, the carton is its own sale promoter, offering free advertisement displayed on shelves and the consumer's table.

In Western European countries, milk represented somewhat below 80% of liquid carton demand at the beginning of the 1980s, and presently the cartons hold about 60% of the total milk market. There is currently a decline in the total milk market but an increased consumption of cartons for milk, thought to be due to the commercialization of long-life milk and the replacement of returnable bottles in the UK. Cartons have achieved a high penetration of the milk market in most Western countries, so the scope for further progress may be regarded as limited outside the UK. Furthermore, fresh milk (i.e., pasteurized milk) is believed to appeal to popular taste more than sterilized milk, and the market may well turn in favor of fresh milk where proper refrigeration conditions may be achieved.

The second largest product group is for fruit juices, holding about 15% and steadily increasing, and the third largest product group is soft drinks, holding about 5%. Other products for which the cartons are likely to increase in importance are wine, mineral water, vegetable oil, and juices.

Overview

Liquid food packaging has been vital in assuring man of a year-round supply of a variety of foods and has changed us from an agrarian to a cosmopolitan culture.

Significant changes have taken place over the last three decades, and packaging is becoming recognized as a definable and essential technology. It is considered earlier in the food product development cycle and a more organized approach to actual package development is taken.

Currently, package designs are first tested under laboratory conditions (vibration, drop tests, inclined impact) and then confirmed by actual field use, sometimes with little agreement. Improvements in agreement between field experience and laboratory testing will be improved by such developments such as:

1. Shipping hazards recorders, such as that developed by the US Army Natick Development Center (**Figure 3**), to measure and record on tape such events as number and height of drops and environmental conditions such as temperature and relative humidity.
2. In estimating shelf-lives, recognition of diurnal temperature and humidity changes, and the unsteady state nature of oxygen and water vapor permeabilities.
3. In devising more relevant tests to replace archaic techniques, such as the Muller burst test for fiberboard.

Computers can be of great help in the statistical evaluation of the massive environmental and hazards data required, defining any distribution system sufficiently to permit trade-off decisions on product loss versus packaging cost. This will also be essential in handling laboratory test data and will be useful in the graphic mode, for actual package design.

On-line, nondestructive test procedures such as the infrared seal defect technique, the sonic vacuum test technique for cans, and magnetic metal contamination detection procedures will be more plentiful. Energy costs will govern package design to a great degree and will necessitate frequent substitutions for critical materials.

There will be greater emphasis on the nonprotective functions of a packaging system. The flexible

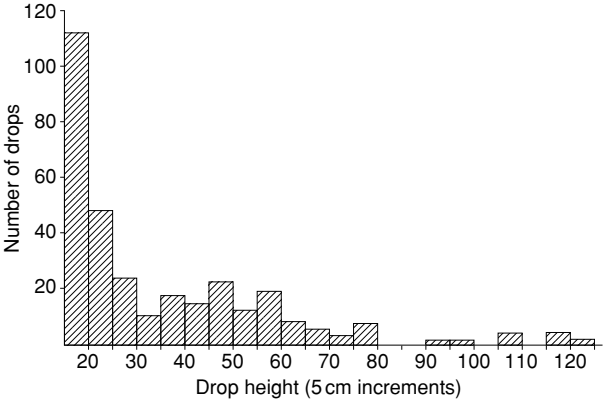

Figure 3 Frequency histogram of recorded drops. Distribution of 312 recorded drops in 5-cm increments. The system activation threshold enables drops of less than 15 cm to be recorded. This represents 1500 days and 80 000 km of shipments. From Barca FD (1975) *Acquisition of Drop Height Data during Package Handling Operations*. packaging system for thermoprocessed foods extends the boil-in-bag heating capability to nonrefrigerated foods. Untended vending systems using microwave energy for in-package product heating appear to be feasible. Liquid foods are being studied with the aim to use the flat configuration to achieve a high product quality and container designs for heating for serving and serving from the container itself.

Packaging of Solids

M Mathlouthi, Université de Reims Champagne-Ardenne, Reims Cedex, France

Background

The aim of packaging solid foods is to protect them against spoilage and to preserve their quality. Selecting a suitable packaging system for this category of products requires a good knowledge not only of the factors affecting their stability but also of the extent to which they are deformed when submitted to mechanical constraints. Both stability and resistance to being deformed are influenced by the water content and water activity (a_w). Most of the physical, biochemical, and microbiological changes of solid foods also depend on a_w. Also, lipid oxidation and other causes of decrease in quality originating from the permeation of gases, water vapor, aroma substances, and other chemicals, or the transfer of energy (light, heat) to an acceptor phase (moisture, fat, etc.) in the product must be minimized through the choice of packaging material, which should be a barrier to matter and or energy transfer. Such a barrier should not be completely tight to take into account a possible release of water vapor from the product in the inner space of the package, which might increase the relative humidity to a limit value of a_w for which the caking of powdery solid foods can occur. In addition, as solid foods are stored and distributed in their packages, one of the objectives of packaging, besides the protection of the product, is to meet the requirements for successful marketing. (*See* **Oxidation of Food Components**; **Water Activity**: Effect on Food Stability.)

Classification

This classification of solid foods is based on the degree to which they are deformed when submitted

to compression or agglomerated and compacted as a result of moisture increase. This depends on whether they are soft, rigid, or powdery products, and may influence the protectivity of the packaging material as well as its acceptance by the consumer. A special class is devoted to food powders for which flowability, density, morphology of particles, and their crystallinity play a major part. Three categories of products are distinguished:

- nondeformable solid foods like toasts, biscuits, crackers, hard cheeses, confectionery, chocolates, etc.;
- deformable products like sandwich loafs, industrial pastry, soft cheeses, meat, and meat products, etc.;
- food powders like refined granulated sugar, wheat flour, spray-dried milk, dairy-based infant formula powders, etc.

The choice of packaging solution depends on the objective sought, namely the nonperception by the consumer of any degradation of the product. As with heat treatment, absolute protection of a packaged foodstuff against alteration is not possible. Thus, protection in this context is only a commercial notion comparable to that of commercial sterilization. It was decided to classify solid foods into deformable and nondeformable products in order to discriminate between those products (deformable) for which the main origin of degradation is the barrier characteristic of the packaging material. In the case of deformation, the appearance of the product becomes the dominant criterion as regards acceptability by the consumer. For nondeformable solid foods, the product may be the origin of a change in structure of the packaging material, leading to a reduction of thickness, pinholes or tears, which modify the transfer of matter or radiation, and provoke biochemical alterations, reduction in shelf-life and, finally, rejection by the consumer. For solid foods, much more than for liquid foods, the concept of an efficient packaging system should be based on the interaction between the product, the packaging material, and the machinery involved.

To generalize for solid foods as a whole, baked goods are taken as a model for this class of food products. Indeed, it is easy to find among baked goods representation examples on nondeformable products like toasts, biscuits, or crackers, and on deformable products like bread or sponge cake. For these products, as for the majority of solid foods, a good criterion of differentiation is the a_w. For rigid baked goods, the a_w is low, about 0.05–0.30, and its value for soft products is around 0.70–0.96. Besides acting as a good reference mark for the aptitude for deforming on which we base our classification, the a_w is associated with most alterations that occur in solid foods.

As a representative product of food powders, white sugar can be taken as an example. Besides the sensitivity to moisture and temperature, the stability of packaged sugar, either granulated or cubes, depends on the stability of crystallization at the surface of the crystals, absence of amorphous or fine particles, and the minimization of the fraction of water content called 'free' water or solvent water on the water vapor sorption curve.

Causes of Alterations

Changes in packaged solid foodstuffs are perceived as being due to a mass or energy transfer across the package providing that there exists a donor (environment, packaging material, etc.) and an acceptor (mobile phase of the solid food). This approach may seem to be complicated, but it has the advantage of relying on classical equations of diffusion. The required characteristics of the packaging material are approached in a dynamic way and deduced from mathematical models of the prediction of shelf-life.

Instead of reviewing all possible matter and energy transfers and their effects on the degradation of solid foods, three major causes of alterations are described: the transfer of water vapor, the transfer of radiation (light), and the transfer of chemicals during storage.

Quality Changes originating from the Transfer of Water Vapor

Nondeformable Products

For this category of foods, an increase in a_w is generally the origin of the alteration and leads to a loss of crispness. However, an increase in moisture may be protective against lipid oxidation in low-moisture foods. In most cases, there remains in the headspace, after sealing the container, enough oxygen to initiate oxidation where an acceptor, e.g., ethylenic bonds in unsaturated fatty acids, exists. It may be noted that, in rigid baked goods with an a_w of 0.30, the risks of biochemical or microbiological alterations are absent.

Deformable Products

It may be recalled that the a_w for these foods is > 0.70, which corresponds to an increase in availability of degradation reaction sites due to an enhanced mobility of water. The risks, in this case, are due to water vapor transfer (gain or loss of weight), chemical and enzymatic reactions, and microbial spoilage. It is also observed that, in this zone of a_w values, a structural rearrangement of one of the constituents (starch) of the product may lead to an alteration known as

staling of the baked goods. (*See* **Spoilage**: Chemical and Enzymatic Spoilage; Bacterial Spoilage.)

The kinetics of alteration reactions depend on the components of food. This is the case, for example, for the oxidation of lipids. If fats are sequestered by the starchy phase, as in a dry cake (sablé), lipid oxidation does not occur, and the shelf-life of the cake is prolonged. If lipids are also on the surface of the product, as with extruded snacks, lipid oxidation becomes a limiting factor in the quality assurance of packaged solid foods. The availability of water for enzymatic reactions or microbial growth may be limited by the addition of a_w depressors, 'humectants' like sugars, polyols, glycerol, or proteins. To minimize nonenzymatic browning, it is important to reduce the duration of exposure to water vapor pressure at the optimum value ($a_w = 0.65$–0.75) for the Maillard reaction. However, at least for baked goods, the appearance of the product, which is appreciated by the consumer, is partly due to the Maillard reaction. (*See* **Browning**: Nonenzymatic.)

Food Powders

Caking is the major alteration of free-flowing food powders ingredients and results in the transformation of a pulverulent product into lumps, then into agglomerated solid, and finally into a sticky material that has lost its functionality. Such a transformation depends on the temperature and moisture content. Different stages are involved amid which are the bridging of particles, their compaction, and liquefaction. For sugar crystals, the dynamic evolution of a_w and its increase to reach 0.80 can provoke the agglomeration of particles, especially when fine crystals with an average size less than 250 μm are present. When the amount of fine particles increases (above 10%) the a_w value for caking is lowered to around 0.45.

Another origin of instability of food powders is their amorphous structure, which allows their existence below the glass transition temperature (T_g) in an out-of-equilibrium state. It is possible to reach T_g at normal temperatures if the relative humidity is increased. This might be at the origin of a situation where the viscosity is decreased at such a value that allows the product to be transformed into a rubbery material, which sticks to the package and loses its quality.

Alterations Originating from Exposure to Light

Radiation, particularly of ultraviolet light, has a catalytic effect on the quality changes in foods. Deteriorative changes like the destruction of lipid-soluble vitamins, the loss of riboflavin and other vitamins, and changes in proteins and food pigments are accelerated by light. The presence of oxygen is intimately linked to these light catalyzed reactions.

These alterations lead to rancid foods with a changed color and reduced nutritive value. The odor and color changes of the product are obviously perceived by the consumer. In order to limit the rate of light-induced deteriorative reactions, the choice of packaging material for solid nondeformable foods should insure a low oxygen partial pressure and a nontransparent package.

Alterations Originating from Food–Package Interactions

For this group of alterations, the notion of reciprocal mobility of a donor and a receptor acquires all its importance. Indeed, whatever the migration (from the product to the packaging material or from the package to the food), it is essential to have a carrier for the transfer of the migrant chemical. It is also necessary to distinguish between hydrophilic and lipophilic chemicals. For nondeformable products ($a_w \leq 0.30$), the migration of some constituents of the packaging material (low-molecular-weight polyolefins, plasticizers, lubricants, etc.) into the mobile fatty phase of the food may be observed. Likewise, the adsorption of fats by the material (polyethylene, polypropylene, etc.) in contact with solid foods may occur.

For deformable products ($a_w \geq 0.70$), the preponderant mobile phase is water, and only hydrophilic chemicals are implicated in migration, i.e., acrylic derivatives of varnish, glycol derivatives, urea, formaldehyde, etc. In this category of deformable foods, it may be that both the aqueous and fatty phases are mobile, as in some sponge cakes, and both migrations are then observed. The structure and composition of the product help to determine the preponderant mobile phase in contact with the packaging material. Although fat may be fixed to starch and water immobilized by 'humectants,' this category of solid foods is more difficult to control in terms of migration.

Stains of syrup are sometimes observed at the top of paper board package of sugar lumps. This is observed when the lumps are packed at a high temperature (above 40 °C) and not cured in a ventilated room. Such conditions (40 °C and relative humidity above 85%) lead to the diffusion of sucrose in the film of syrup surrounding the crystals. After crystallization of sugar in the film of syrup, and the release of hydration water, the syrup becomes sufficiently mobile to stick to the package. As granulated sugar may act as

an adsorption medium, odors from the environment or other volatiles from the packaging material may be temporarily adsorbed by the sugar.

Preservation

In order to protect a solid food against alteration, it is necessary to place a barrier between it and the environment. This barrier should be adapted to the capacity of adsorption of the food for the factors responsible for the deteriorative reactions. The barrier properties of the packaging material are determined by its permeability to the degradation agents, mainly gas or vapor permeating from outside.

Permeability of Packaging Material

The mass transfer of oxygen, carbon dioxide, water vapor or aroma components, or heat or radiant energy (ultraviolet, infrared, β, γ or microwave radiation) across the packaging material is generally ruled by a relation derived from Fourier or Fick's laws. In the case of unidirectional transfer, under a steady state and at equilibrium, the quantity of permeated material per unit of time (Q) is given by a Fick's first law-type equation:

$$Q = -PA\frac{\Delta p}{l}, \tag{1}$$

where P is the permeability, A is the active surface area of the packaging material, Δp is the difference in pressure (or concentration) on either side of packaging material, and l is its thickness.

The permeability coefficient, P, is a function of the number of variables, which include the structure of the packaging film, the properties of the permeate, the time, the pressure, and the thickness (the temperature is constant). Depending on the sensitivity of the product to water vapor, oxygen, or loss of aroma components, the packaging material composition and barrier characteristics are determined (see Tables 1 and 2).

Prediction of Shelf-life

The classification of solid foods determines the choice of the model transfer equation and affects the prediction of the deteriorative reaction rate. (*See* **Storage Stability**: Shelf-life Testing.)

For nondeformable foods, the most critical transfer is that of water vapor and/or oxygen. The kinetics of oxidative degradation should be adapted to each category of product, while the model equation used for water vapor transfer may be generalized.

For deformable foods with $a_w > 0.70$, water vapor transfer generally occurs from the inside to the outside of the package and is the preponderant factor of alteration. In some cases, more than one transfer has to be taken into account, for instance, water vapor and oxygen. The mathematical model of mass transfer is then obviously more complicated.

In order to calculate the shelf-life of products sensitive to moisture, eqn (2) is applied:

$$\frac{dW}{dt} = -\frac{PA(p_e - p_i)}{l}, \tag{2}$$

where dW/dt is the flow of moisture, and p_e and p_i are, respectively, the water vapor pressure in the exterior and the interior of the package. If storage takes place at a constant temperature, p_e and p_i may be replaced by $a_{w,e}$ and $a_{w,i}$, the values of outer and inner water activities, and eqn (2) can be written in integral form as:

$$t = K \int_{\text{origin}}^{\text{degradation}} f(aw)\, daw, \tag{3}$$

where t is the shelf-life of the product, and K is a constant related to the properties of the product, the permeability of the packaging material, and the conditions of storage. Eqn (3) is only valid when the degradation originates from a change in a_w due to moisture transfer. In the case of oxidative deterioration, two equations are applied, one accounting for oxygen transfer and the other for its adsorption by food. For transfer, the relation is:

$$\frac{d(O_2)}{dt} = P_{O_2} A \frac{\Delta P}{l} m_{o_2}, \tag{4}$$

where $d(O_2)/dt$ is the flow of oxygen into the package, P_{O_2} is the permeability, A is the surface of permeation, Δp is the pressure difference of oxygen between the interior and exterior of the package, m_{o_2} is the absorption capacity of food, and l, as before, is the thickness of the packaging film. It is generally supposed that oxygen is adsorbed by food, and the rate of adsorption of oxygen $d(O_2)/dt$ is given by:

$$\frac{d(O_2)}{dt} = \frac{P_{O2}}{k_1 + k_2 P_{O2}} \tag{5}$$

where P_{O_2} is the partial pressure of oxygen, and k_1 and k_2 are two constants related to the degree to which the food adsorbs oxygen. An increase in the rate of adsorption of oxygen provokes an increase of oxidation. However, many other factors affect this type of degradation (light, heavy metals, water activity, etc.), and it is difficult to find mathematical model accounting for shelf-life as regards oxidation.

Other degradations may be predicted from mathematical models, like nonenzymatic browning on model systems (reducing sugars + amino acid) in the a_w range 0.55–0.85, but a precise prediction of a real degradation in a real product is not possible.

Increase in Shelf-life

When the degradation reactions are known, it is possible to minimize their rate in order to increase the shelf-life of the product. The basis of this approach is the need to reduce the availability of the donor or acceptor of the degradation agent.

If the acceptor is water, its availability is reduced by the addition of humectants (polyols, sugars, proteins) to the formula of the baked goods. Such an addition provokes a decrease in a_w from about 0.85 to 0.75 for a sponge cake, for example, which is then screened from microbial spoilage.

Preservation against oxidation and/or microbial growth may be obtained by changing the inner atmosphere of the package, generally by using a mixture of nitrogen and carbon dioxide. A low partial pressure of oxygen, together with a carbon dioxide/nitrogen atmosphere, contributes to an increase in the shelf-life; for example, industrial pastry with a normal a_w level of about 0.90 can have its shelf-life extended to 3 months. (*See* **Chilled Storage**: Use of Modified-atmosphere Packaging; Packaging Under Vacuum; **Chill Foods**: Effect of Modified-atmosphere Packaging on Food Quality.)

The stabilization of a solid food may also be achieved by using a superficial thermal treatment using radiant energy from infrared or microwave radiation. Such a treatment applied to the packaged product can contribute to an increase in the shelf-life.

Protection of the product against degradation is also obtained by the choice of a good barrier (polymeric film or laminate), which may be transparent or opaque. The barrier properties of the packaging material change if it interacts with degradation agents like water vapor or oxygen. These interactions depend on the hydrophilic or hydrophobic character of the material. For products particularly sensitive to one or other of the degradation agents, the packaging material may include chemicals permitting the scavenging of oxygen, the adsorption of water vapor, the emission of ethanol or carbon dioxide, and so on. The packaging becomes an 'active' barrier of protection and the center of a protective chemical reaction. However, one should remember that adaptation of the packaging material to food protection must be economically feasable and that the objective is not the absolute stability of the product during storage. It is only needed for the solid food to be accepted by the consumer.

Polymeric Packaging Materials used for Solid Foods

The selection of polymeric or laminate film for solid-food packaging involves a certain number of conditions. The material must be compatible with the food in accordance with the legislation and calculated (thickness) to fit with determined barrier properties and shelf-life of the product. Depending on the level of protection and kind of product to be packed, the packaging material will be either a monolayer or a multilayer (coextruded or laminated). It may be coated or metallized, if the aim is to prevent the transfer of water vapor or light, and the structure of a foil reinforced by orientation or plasticizing.

A wide range of films used for baked goods are listed in Table 1. The transfer of gases and water vapor is expressed in commonly used units rather than in SI units. The unit for the transmission rate of gases is given in cubic centimeters of gas in 1 day for 1 square meter of film at a given thickness at constant temperature and pressure. The rate of water vapor transmission is expressed in grams per day per square meter at a specific temperature and a given difference of water vapor pressure (Δp) between the two sides of the packaging material. When the barrier characteristics required are not achievable with monolayer film, laminates of multilayer material are used. The characteristics of such laminates are listed in Table 2. As may be seen in Tables 1 and 2, the basic films are polyolefins, polyethylene, and polypropylene, copolymers like ethylene-vinyl alcohol and other polymers such as polyesters, polyamides (OPA 6 and 66) and polyvinylchlorides. The laminated plastic films are coated with regenerated cellulosics like DM, which is nitrocellulose coated on one side, MXXT, which is polyvinylidene chloride coated, or paperboard or aluminum foils. Different laminating adhesives are used.

Most foods are sensitive to water vapor, and the packaging materials generally used are good barriers to water vapor; polyesters (polyvinyldene chloride, coated or metallized film) and oriented polypropylene are the major materials found. Snacks and crisps contain fats and have a large specific area. Therefore, they require protection against light, which has a catalytic effect on lipid oxidation. The laminates used to protect these products utilize aluminum foils (see Table 2). Metallized polyester is generally coated with vaporized aluminum.

Food powders freely flowing are packaged in polyethylene sealable films, which gives a good water

vapor barrier and a transparent package allowing the product to be seen. Refined sugar is generally packed in multiwall paper packages, cardboard cartons, or polyethylene coated paper. Finished packs contain 500 g to 5 kg for domestic use. Sacks of up to 50 kg are produced for industrial utilization. An intermediate stage between the bulk transport of granulated sugar and the 50-kg sacks is the big bag called

intermediate bulk container of 1 tonne capacity. This supersack is made of woven polypropylene and it is able to stand unsupported on the pallet.

Packaging Machines

A good packaging solution for solid foods should not ignore packaging machines and the complex interactions between the machine and the packaging material. (Figure 1) shows an example of a horizontal form–fill–seal machine, a vertical pouch form–fill–seal machine, and two overwrapping machines.

The suitability of a packaging machine for a certain packaging material and product can be summarized in the following key points:

- The angle at which the wrapping material comes into contact with the folding former is important, as it may cause a mark or even a cut in the material. The tightness of the packaging film depends on the shape of the former.
- The quality of heat sealing of the packaging material depends on the temperature control, pressure, and dwell time. Optimal results are obtained when the dwell time at the melting temperature of the coating or copolymer is long enough to ensure tightness without damage to the basic material.
- The wrapping material should slip easily after sealing at high temperature. In some cases, it is even necessary to cool the plate fixed above the sealing rollers.
- The quality of cutting depends on the knife, cut angle, position of the knife in relation to the sealing jaws, etc.

Overwrapping also requires compatibility between the machine and the wrapping material, and prevention of static electricity, poor slip under hot conditions, temperature control disruption, and rolling of the film. The packaging material should be sealable on both sides, the sealing area should be sufficient, and the structure (soft or rigid) of the solid food should not affect the shape and sealing surface if a good gas tightness is desired.

Packaging machines for food powders, and especially sugar, cover a large range of sizes of packages, starting with small flat pouches containing between 4 and 10 g of sugar. These are produced using simple machines that assemble sachets by bringing together two webs of polyethylene-coated paper, heat sealing three sides, filling with sugar, and sealing the top. There are also carton packing machines, especially designed for sugar cubes. For ease of handling, 'brick-packs' are preferred. These are produced by forming a polyethylene pack and dropping it into a horizontal solid upstanding pack with similar characteristics to the paper packet.

The quality of packaged food powders should comply with the necessary regulations. Any foreign matter should be eliminated. All packages go through metal detectors to control metal contamination. Likewise, traceability of packets and even full pallets is needed for identification of the product according to EU regulations. A printed code showing the date and line of production, factory of origin, etc. is required. The spread of use of scanning at the shop point of sale imposes the printing of a bar code on each domestic package.

Aseptic Filling

L Mauer, Purdue University, West Lafayette, IN, USA

Background

Aseptic processing is a high-temperature–short-time thermal process to commercially sterilize a product and fill the cooled sterile product into a presterilized package in a sterile environment. Purposes for aseptic

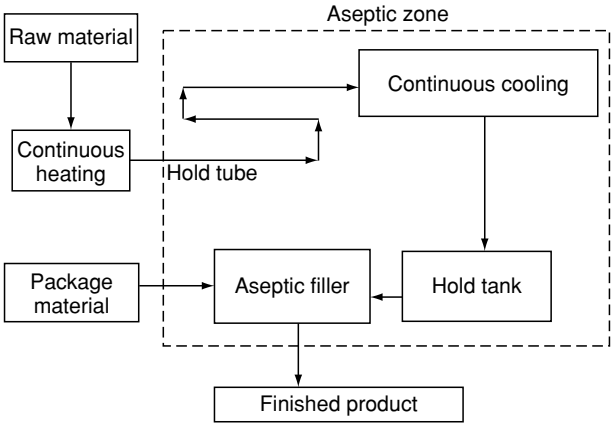

Figure 1 Aseptic process diagram.

processing include extending the storage life of food products, optimizing product quality, and reducing cost. A diagram of an aseptic processing system for consumer products is shown in Figure 1. In the aseptic process, the aseptic filler is designed to sterilize the package material, fill the sterile product into the package in a sterile environment, and then hermetically seal the package. Aseptic filling differs from other traditional methods of food packaging in that the food product and the package are continuously sterilized separately and then meet in the sterile environment provided by the aseptic filler. Important factors in the aseptic filling process are the type of product, type of package, obtaining and maintaining a sterile environment for filling, and the sealing process.

Types of Product

A variety of food products are aseptically packaged. Examples include milk and dairy products, fruit and vegetable juices, fruit juice concentrates, sport and dietetic beverages, tomato products, edible oils, puddings, soups, cheese and soy sauces, and products containing small or large particles of fruits, vegetables, or potatoes. The aseptic process must be designed so that the product is sterilized, the package is compatible with the product composition and storage needs, and the type of filler treats the product gently while maintaining sterility to achieve optimum quality. Products are usually sterilized by high-temperature heat treatments for short periods of time, cooled, and conveyed to the filler via aseptic pumps or nitrogen. Packaging and filling considerations for different product types include the following:

Low-acid Products (pH > 4.5)

The concept of aseptic heat treatments for low vs. high acid foods is similar to the canning principles for these food types. In low-acid foods, such as many milk and vegetable products, pH is not a barrier to pathogenic microbial growth. Therefore, aseptic processing conditions must be designed with stringent controls to achieve a 10-decimal reduction value for *Clostridium botulinum*, the most heat-resistant pathogen able to grow in low-acid foods, both in the food product and in the package materials. Targeting the most resistant pathogen ensures safety because all other pathogens are killed faster than it. The package must attain the same level of sterility as the product; therefore, package materials for low-acid foods may have stricter sterility controls than those for high acid foods. *Bacillus subtilis* is the most resistant organism to hydrogen peroxide sterilization of packages, and a four-decimal requirement for it exists to achieve the required reduction for *C. botulinum* in low acid foods.

Acid and High-acid Products (pH < 4.5)

In acid and high-acid foods, such as fruit juices and many tomato products, pH is a barrier to pathogenic microbial growth, most notably for *C. botulinum*. For these foods, spoilage microorganisms may cause more problems than pathogens. Processing temperatures and holding times may be lower than for low acid foods. Spoilage organisms are much more sensitive to hydrogen peroxide sterilization of packages than *B. subtilis*. *Aspergillus niger* is usually the target organism for dry and moist heat sterilization of packaging materials for use with acid and high-acid products.

Homogeneous vs. Heterogeneous Products

Knowledge of heat-transfer characteristics of a food, quality parameters, flow characteristics, mean residence time, type of heat exchanger or sterilizing system, and heat resistance and required death values for target microorganisms are important factors in designing an effective aseptic process. Homogeneous products contain no particles that disrupt heat transfer. Heterogeneous products contain particles with sufficient size to create a thermal gradient during processing. Therefore, heat treatments for homogeneous liquids may be less damaging than those required to insure commercial sterility of particulates in similar liquids. Pumps used to convey aseptically processed products must be able to maintain both product sterility and integrity; therefore, pumps used for heterogeneous products must limit shear forces so as not to damage particulate structures. Homogeneous liquids are often conveyed to a filler with either a centrifugal pump or sterile nitrogen; however, highly viscous liquids may require use of a positive displacement pump. Heterogeneous products are conveyed to the filler using a positive displacement pump that limits pressure and shear placed on

the particulates. Opening sizes in an aseptic system designed for heterogeneous products must be sufficient to allow passage of the particulates without creating pinch points. In the filler, contamination of the seal area, especially with particulates, must be avoided.

Types of Packages

The type of aseptic package used must be suitable for a product's requirements, package surfaces must withstand sterilization by heat, irradiation, and/or chemicals prior to filling, and the package must contain, protect, and preserve the food product throughout its distribution and shelf-life. Properly aseptically processed products remain microbiologically stable as long as the package remains intact. Often, shelf-life and product quality are limited more by package performance than any other factor. Needs to consider for an aseptic packaging system include:

- Compatibility of product and package – product composition, needs for maintaining quality (barrier, mechanical), and shelf-life requirements.
- Packaging material – type (plastic, metal, glass, laminate, etc.), barrier and mechanical properties, machineability, recyclability, and cost.
- Package form – size, shape, compatible machinery, sealing properties, appeal to consumer, communication of information, and cost.
- Sterilization method (heat, irradiation, chemicals, combination of methods) – efficiency, throughput, residues, compatibility with product/package/environment, worker safety, regulations, and cost.
- Filling equipment – reliability, efficiency, capacity, and cost of installation/operation/maintenance.

Aseptic Package Materials

A significant drive in the conversion from traditional to aseptic processing is the reduction in packaging costs for both materials and transportation. Traditional thermal processes require packages to withstand high temperatures, whether for in-package sterilization or for hot-filled products, as well as vacuum forces created on cooling. Packages that meet these structural requirements include metal, glass, and plastics (rigid, semirigid, some with vacuum panels incorporated into the design, and pouches). The cold aseptic filling allows for a lighter container with a greater design flexibility (squeezable, ergonomic, etc.). By weight, most plastic materials cost significantly less than glass and metals, and less plastic is needed for a cold-filled product than a hot-filled product. Plastics are the most common material used for aseptic packaging; however, plastics are more permeable to oxygen and moisture than either glass or metals. The quality of products may suffer after extended storage in permeable packages. An example of this is oxidation of dairy products in packages permeable to oxygen. To limit permeability, plastics with different barrier characteristics are often combined using lamination or coextrusion methods to optimize barrier properties. This can maximize product quality and package function while maintaining low package costs.

The variety of plastic materials used in aseptic packaging is continuously increasing, along with the use of laminates, coextrusions, and copolymers. Adhesive and thermal lamination methods are used to create multilayer packages, often with a structure based on the diagram in Figure 2. More than one barrier layer may be incorporated into a package design. Commonly used plastics include polyolefins (polyethylene, polypropylene, polystyrene), polyesters (polyethylene terephthalate), vinyl plastics (polyvinyl chloride, polyvinylidene chloride, polyvinyl alcohol), polyamides (nylon), ionomers, acrylics, fluorocarbons, and polycarbonates. Polyethylene (PE) is the most widely used polymer in packages and is available in a variety of densities: low density (LDPE), linear low density (LLDPE), medium density (MDPE), and high density (HDPE). LDPE is used in flexible bags and pouches and is a good heat-sealing material. HDPE used in blow-molded bottles is more rigid and has better barrier properties than LDPE. Polypropylene (PP) provides clarity, stiffness, and heat resistance. Polyethylene terephthalate (PET) has good barrier and clarity properties and a high tensile strength, and is resistant to high temperatures. PET is often used to meet consumer demand for round and recloseable plastic bottles. Ethylene vinyl alcohol

Figure 2 General structure of a laminate aseptic package.

(EVOH) and polyvinylidene chloride (PVDC) are generally the best plastic barriers to moisture and oxygen migration. Metal and glass are used for barrier properties either alone or within a laminate package. A paperboard layer in a laminate package is used for printing and light-barrier purposes.

Package Formation

Packages formed for the aseptic process require minimum levels of contaminating microorganisms prior to the sterilization process, and the packages must pass leak-testing procedures. Packages may be preformed or formed in the filler just prior to filling. Metals are formed into cans, and metal films may be incorporated into laminate structures. Glass is blow-molded into bottles and jars. Plastics and laminated materials are blow-molded or thermoformed into various package shapes. The blow-molding process involves the melting of a glass or plastic, forming a parison (tube), and then blowing the parison into the package shape (designated by the mold) using sterile air or nitrogen. Extrusion, injection, and stretch blow-molding methods are used for different package applications. A sheet of plastic is heat-softened then molded to shape via vacuum, pressure, or matched mold forming in the thermoforming process. Cups and trays are thermoformed packages.

Aseptic Package Systems

Package forms and filler types are interwoven to the extent that discussion of one is not complete without discussion of the other, as the aseptic process hinges on the placing of a sterile product into a sterile package in the sterile filler environment. Common aseptic package forms are discussed in this section, leaving classification of filler types for a later section.

Cartons The brick-style, paperboard packaging used for cartons is recognized as the traditional aseptic package used for juice boxes. The laminate material used for carton formation generally consists of multiple polyethylene, paper, and aluminum foil layers. Outer and inner polyethylene layers provide protection and sealing properties, the paperboard is printed with product information and provides stiffness, and the aluminum foil contributes gas- and light-barrier functions. Cartons are prefabricated, or rolls of the laminate material are sterilized and formed in the filler just prior to filling and sealing. Cartons are sterilized using hydrogen peroxide and hot air.

Bottles The convenience of plastic bottles that are clear, round, resealable, recyclable, and able to be formed in a variety of shapes and sizes is a driving force in the beverage industry. Aseptic milk, creamer, sports, and nutritional beverages in PET, PE, and PP bottles are currently available to consumers. Bottles for use with high-acid products are generally sterilized using steam, a combination of heated air and steam, or heat of formation (extrusion and blow molding). Bottles for low-acid products are sterilized with hydrogen peroxide.

Cups The thermoformed cup is a common aseptic package for puddings, particulates, fruits, purees, and baby food. Package materials for cups include PS, PP, and laminates of PS, PVDC/EVOH, and LDPE materials. Cup lids are often aluminum foil coated with LDPE or other heat-sealant plastic. Cups are generally sterilized using hydrogen peroxide or saturated steam under pressure.

Pouches Pouches for institutional and fast food chain use are easier to open, take up less space for transportation, storage, and waste, and decrease product loss when compared with traditional metal cans. Form-fill-seal systems are used for converting a sheet film of plastic (LDPE, laminate) into a pouch. Plastics formed as lay-flat tubes require fewer seals to form pouches than the sheet films. Aseptic products available in pouches include tomato-based sauces, ice cream mixes, cheese sauces, and puddings. Pouches are often sterilized using hydrogen peroxide.

Bag-in-box The bag-in-box aseptic packaging system is used for bulk packaging (1–10 000 or more liters). The product is filled into a presterilized plastic bag. The bag is placed into a protective container, such as a corrugated box or metal drum, either before or after filling. A laminate of barrier (PVDC, EVOH) and heat sealant (LDPE) plastics is commonly used for bag formation. Tomato, fruit juice, and dairy products are packaged using the bag-in-box system. Preformed bags are sterilized by ionizing gamma irradiation. The exterior of bags for low-acid products is also sterilized with steam or hydrogen peroxide vapor.

Metal cans The metal can traditionally used in thermal processes also has advantages for use with aseptic products despite the added weight over plastic materials. The durability, consumer acceptance, barrier properties, and recyclability of metal cans combined with the ability to sterilize the cans with superheated steam instead of chemicals make the metal can attractive for some applications. Aseptic dietetic beverages, pudding, and cheese sauces are available in metal cans. Superheated steam is used to sterilize metal cans prior to filling.

The Sterile Environment

Obtaining a Sterile Environment

Establishing, maintaining, and validating sterility in an aseptic system are essential. Processes used for obtaining a sterile environment for products, equipment, and packages include thermal, chemical, irradiation, and mechanical treatments along with combinations of these. Thermal processes include saturated steam, superheated steam, hot air, mixtures of hot air and steam, and extrusion/heat of formation (although extrusion may not be acceptable for sterilization purposes). Heat is the most common method for product sterilization and is often used for equipment sterilization as well. The most common chemical used for sterilization is hydrogen peroxide (20–35% concentration), and a combination of hydrogen peroxide treatment followed by hot air is often used to reduce the level of hydrogen peroxide to less than 0.5 p.p.m. on packages and equipment. Peracetic acid and ethylene oxide also have applications; however, regulations for acceptable chemicals, uses, and residue limits must be checked. Chemicals are applied by dipping, spraying, or rinsing, or in vapor form. Irradiation treatments may include ultraviolet radiation, infrared radiation, and ionizing gamma radiation. Mechanical processes are generally designed to reduce initial microbial load to a level the aseptic system is designed to handle. If an initial microbial load is too high, sterility might not be achieved during aseptic processing. Therefore, water rinsing or flushing, air blasting, brushing, and ultrasound methods are used to reduce the initial load on equipment and packaging prior to other sterilization processes.

Equipment and packages must attain the same level of sterility as the products they will come into contact with. Therefore, equipment is sterilized with hydrogen peroxide or a time/temperature steam sterilization at least equivalent to what the product will receive. Thermal processes for equipment used with low-acid foods will be higher, both time and temperature, than for high-acid products. Packages, other than metal cans, may not withstand high temperature treatments; therefore, chemical and irradiation sterilization procedures are commonly used.

Maintaining a Sterile Environment

Once equipment, packages, and products are sterilized, the challenge is to maintain sterility during the filling and sealing operation. This is accomplished using either an overpressure of sterile air or continuous flow of superheated steam, the latter generally being used for the metal can aseptic process. Air is sterilized by filtration, usually using a series of high-efficiency particulate air (HEPA) filters. Since all equipment must attain commercial sterility, the HEPA air filters also must be sterilized. The positive pressure maintained by a continuous sterile air flow prevents contamination during the filling process when the product may be exposed to air. If the integrity of an aseptic zone is compromised because of line stoppages or other occurrence, it is necessary to repeat the initial sterilization process.

Validating Sterility

Validating sterility is a combination of implementing an appropriate hazard analysis critical control point program, documenting product and filler sterilization procedures, filing the process with the appropriate agency, maintaining accurate temperature, time, pressure recording devices, and testing all aseptically processed foods for sterility using appropriate microbiological sampling techniques. Challenge testing with inoculated foods is part of validating a thermal process.

The Sealing Process

At the end of the filling process, packages are often sealed using heated sealing bars, jaws, and plates. The temperature, pressure, and time of sealing must be strictly controlled for each sealing compound to maximize package integrity. Common heat sealant polymers include polyethylene, polypropylene, ethylene vinyl acetate, and polyvinyl chloride. These compounds have demonstrated a desirable mechanical strength of the seal (impact strength, tensile strength, tear strength, seal strength, puncture resistance) and product holding properties (chemical resistance, product compatibility, oxygen and moisture barrier properties). Problems occur when particulates, fibers, or other food contaminants are caught in the seal area and prevent a completely fused seal. To avoid seal contamination, especially with particulate foods, the filler must be designed to avoid or remove product from the seal area prior to fusion.

Types of Fillers

The filling method depends on both the type of product (high or low acid, homogeneous liquid, viscous product, size of particulates, etc.) and type of package (retail, institutional, cup, pouch, bottle, etc.) desired for the end product. Common filler classifications are named for the processes that occur in the filler and are outlined below.

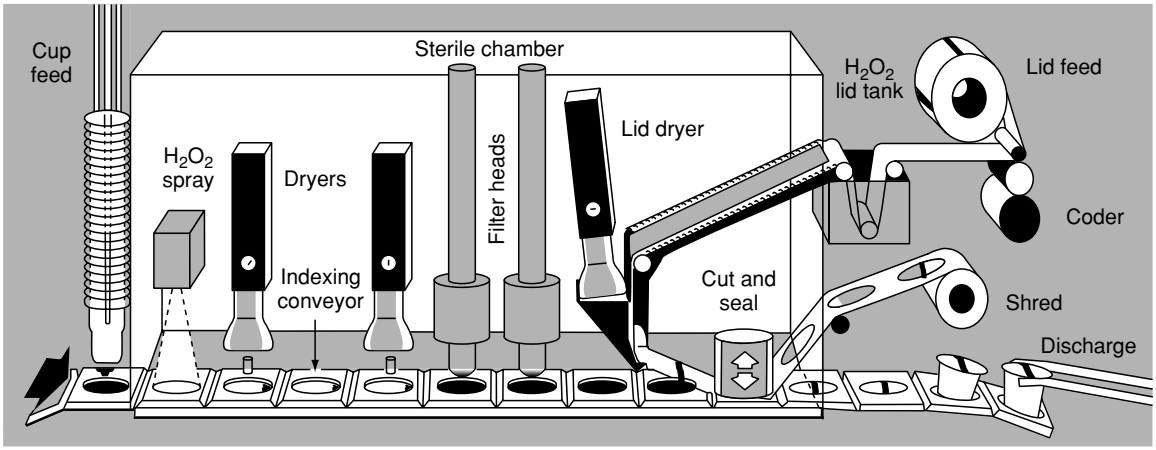

Figure 3 Aseptic filler design.

Fill and Seal

In the fill and seal process, a preformed sterile container (bottles, cups, irradiated pouches, bag-in-box) is aseptically filled and sealed. The fill and seal process for cups is shown in Figure 3. In bulk packaging systems (500-liter bins, large totes, million gallon storage tanks), product is filled directly into a sterilized large storage container. This system is often used for seasonal food products to extend the supply throughout the year.

Form, Fill, and Seal

Brick pack juice boxes and pouches (LDPE, laminate) enter the filler as a roll of packaging material and are sterilized, aseptically formed into the box or pouch shape, filled, and thermally sealed in the form, fill, and seal process.

Thermoform, Fill, and Seal

In the thermoform, fill, and seal process, the packaging material (PS, PP, laminates) enters the filler as roll stock and is sterilized, heated, thermoformed (usually into cups), filled, and thermally sealed with presterilized lid material (aluminum foil coated with LDPE).

Blow Mold, Fill, and Seal

Plastic bottles are formed, filled, and sealed in the blow mold, fill, and seal filling process. An extrudable material (PET, PP, PE) is blow-molded into a container that is filled and sealed in place before the mold opens. For low-acid products, a chemical sterilization after the bottles are formed is used to insure sterility prior to filling.

Advantages and Disadvantages of Aseptic Filling

Advantages of aseptic filling include a high product quality, decreased storage space for packaging materials, decreased weight of packaging materials, decreased package costs, decreased shipping costs for packaging materials, reduced energy consumption, increased flexibility for package options, increased convenience for easy open containers, feasibility of long-term bulk storage, and increased shelf-life and storage time for products. Disadvantages include the high cost of aseptic fillers, potential for product contamination in the aseptic filler owing to the complexity of the system, decreased recyclability of pouch and laminate package materials compared with metal and glass packages, and slower line speeds than traditional process methods. For many, the advantages far outweigh the disadvantages.

PALM KERNEL OIL

K G Berger, Chiswick, London, UK

Introduction

Palm kernel oil is obtained from the oil-rich seed of the oil palm (*Elaeis guineensis Jackqu*). A description of the oil palm and its development into a major crop is given in the entry on **Palm Oil**. The production process of the kernels in the oil mill is also described there.

The quantity of palm kernel oil produced is on average 12% that of palm oil. World production in 1998 was 2.9 million tons.

Production of the Oil

The palm kernels leave the oil mill at about 50% oil content and up to 8% moisture. Further processing typically consists of:

1. Comminution in hammer mills to approximately 2-mm pieces.
2. Cooking to 110–120 °C in a continuous cooker. This breaks the oil cells and reduces moisture to 2.5%.
3. Pressing in a screw press at high pressure to yield crude palm kernel oil and a meal containing 7–9% oil. The meal is used for animal feed.

An alternative process is to submit the broken nuts after step (1) to a cold pressing at low pressure, leaving a meal containing 10–12% oil. This may be further treated by solvent extraction, depending on the market prices of oil and meal.

Refining

Palm kernel oil may be refined either by an alkali or by the physical process, as described in the entry on **Palm Oil**. However, because most of the fatty acids present are of 12 carbon atoms or less, the deodorization temperatures used are lower – typically 220 °C in the alkali process and 230–235 °C in the physical process.

Further Processing

Palm kernel oil is treated by fractionation or hydrogenation and/or interesterification to obtain products with closely defined functionality. These processes are described in the entry on **Palm Oil**.)

Chemical Composition and Physical Properties

The fatty acid composition of palm kernel products is given in **Table 1**, while **Table 2** gives the glyceride composition by carbon number. Typical values for the minor components of palm kernel oil are given in **Table 3**.

Palm kernel oil has a high content of lauric and shorter-chain fatty acids and a low content of unsaturated acids. Coconut oil has a somewhat similar

composition. They contrast strongly with the other common vegetable oils, which contain no shorter-chain fatty acids. In consequence the physical properties are unusual, as will be seen from Tables 4 and 5. Palm kernel oil has a relatively high solid fat content and a rather hard structure at 20 °C, but melts sharply at 28 °C – well below mouth temperature. These properties are accentuated in palm kernel stearin. As is clear from the last two columns of Table 5, hydrogenation raises the solids content further, but the products are still substantially molten at mouth temperature. Hydrogenated palm kernel olein, on the other hand, having a higher content of long-chain saturated acids, has a higher melting point. The products shown in Table 5 are examples of the properties that can be obtained by further processing. A wide range of proprietary products based on palm kernel oil is available, giving variations in physical properties required for specific food applications.

The data shown in Tables 1–4 are average figures taken from an extensive survey of Malaysian palm oil. The figures are not significantly different from those recently obtained for oils from other sources in other producing regions.

Food Uses of Palm Kernel Products

The most important applications of palm kernel oil products are in the confectionery industry, where its high solid fat content and sharp melting characteristics are important. However, palm kernel oil itself melts at too low a temperature for some applications. It is therefore hydrogenated to give a variety of products, one of which is indicated in Table 5. Hydrogenated palm kernel oil is suitable for chocolate-type couvertures for biscuits and sugar confectionery, and for biscuit cream fillings. Hydrogenated palm kernel oil is also used to replace butterfat in filled milk, coffee creamers, and imitation cream. The higher-melting-point grades tend to leave a waxy residue on the palate. They can be improved by fractionating to remove the highest melting point components. A superior and more expensive product is obtained by the direct fractionation of palm kernel oil. The stearin has good contraction when it solidifies and is therefore suitable for molded chocolate. (*See* **Cocoa**: Production, Products, and Use.)

The palm kernel olein produced is the lower-value fraction. It may be hydrogenated (Table 5) to give a range of confectionery fats of somewhat lower quality. Alternatively, palm kernel olein is used in margarine blends. It is a useful component of

interesterified mixtures for various applications (Table 6).

Palm kernel oil without modification is used for chocolate coatings for icecream bars, usually in a blend with liquid oil or palm oil to give the right consistency without excessive brittleness.

Palm Kernel Products in Margarine

1. Palm kernel oil forms a eutectic with palm oil in a mixture containing about 30% palm kernel oil. This feature is used to improve the mouth feel (rapid melting) in the following formula:
   Palm oil 63%
   Palm stearin 7%
   Palm kernel oil 30%
2. Palm kernel olein (30 parts) interesterified with palm stearin (70 parts) forms a margarine stock. To make margarine, 60 parts are blended with 40 parts liquid oil.
3. Equal quantities of fully hydrogenated palm kernel oil and fully hydrogenated palm oil are interesterified. A margarine high in polyunsaturated fatty acids is made by blending 12% of this hard stock with 88% of a liquid oil such as sunflower oil.

PALM OIL

K G Berger, Chiswick, London, UK

Introduction

Palm oil is obtained from the fruit flesh of the oil palm (*Elaeis guineensis* Jacqu.), a native of the equatorial region of West Africa. Unrefined oil obtained from wild palms has been a traditional food source for the indigenous population for thousands of years. However, its use for edible purposes elsewhere had to await the development of suitable refining processes to produce a bland pale-colored oil. Today, palm oil is the second most abundant edible oil after soya bean oil and is in universal use.

The Oil Palm

The oil palm flourishes best in lowland regions of high rainfall and close to the equator. Optimum conditions are a rainfall of 1700 mm or more per annum, evenly distributed through the year and a position within 10° N and S of the equator, but it also grows in isolated locations outside these limits, i.e., between 15° N and 20° S. The plant can be grown in a variety of tropical soils, regular and sufficient water being apparently more important than soil, provided that the plant nutrient requirements are supplied. Unfavorable soil factors are poor drainage and high laterite or sand content. Special techniques have been developed to enable peat soils to be used.

The oil palm is a single-stemmed plant bearing a number of fronds in a simple head. A mature palm may have up to 50 fully opened fronds. One inflorescence arises from the axil of each leaf; male and female inflorescences occur on the same palm. Both consist of a central stem carrying about 200 flower bearing spikelets. Each spikelet on the male inflorescences carries about 1000 flowers, and on the female inflorescence 15–30 flowers. Pollination is by insects, the most effective being the weevil, *Elaeidobius kamerunicus*, native to West Africa. Ripe fruit develops in about 155 days after fertilization, but the bulk of the oil is synthesized in the final 2–4 weeks. The fruit bunch, containing 1500–2000 individual fruits weighs 20–30 kg.

Considerable variation occurs in the wild palms, and three types have been classified according to fruit type. The most common wild type is the dura, characterized by a relatively thin layer of flesh covering the seed, which consists of a hard thick shell within which lies the kernel. A small proportion of plants, called pisifera, bear fruit with a thick layer of flesh and a small kernel with a very thin or no shell. Another small proportion of plants in the wild, the tenera, has relatively thick flesh with a shell and kernel of intermediate size.

The tenera type was found to be a natural cross (D×P) of dura and pisifera palms. When plantations were first being developed in West Africa (in Belgian Congo, now Zaire), the superior economic performance of the tenera was recognized, and the heritability of shell thickness was discovered. Subsequent development of improved planting material therefore centered on selecting the best dura and pisifera plants for crossing. The continuing efforts of plant breeders have resulted in progressive increases in yield, as shown in Table 1.

A slow development of oil palm plantations occurred in Indonesia after World War I, soon to be followed by Malaya. By 1938, Indonesia had 90 000 ha and Malaya 30 000 ha under oil palm. After 1960, the area under oil palm increased rapidly in Malaysia, reaching 3.2 million ha by 2001. Developments in Indonesia were slower, with 2.4 million ha in 2001. These two countries are by far the largest producers of palm oil and the main suppliers to the world market. Plantation developments in Central and South America have reached about 500 000 ha in all, with Colombia, Ecuador, and Brazil having the largest areas.

A unique feature of the oil palm is that the fruit yields two distinct types of oil. Palm oil from the flesh is the major product, whereas palm kernel oil is

obtained from the seed. Its chemical and physical characteristics are quite distinct from palm oil, and it has different applications. (*See* **Palm Kernel Oil**.)

Commercial Importance

The importance of palm oil in the world's oils and fats economy is shown in Table 2, giving the total production of 17 major oils and fats, and individual figures for soya, palm, palm kernel, and rapeseed oils. The figures given are 5-year averages and include production forecasts to the year 2002. Figures in brackets are the percentage of total. Production figures for sunflower oil (not shown in Table 2) are similar to those of rapeseed oil, and that the other oils among the 17 included in the total show little or no growth trend.

Table 2 shows that palm and palm kernel oils together have increased their share of edible oil supplies regularly for more than 20 years, and are forecast to continue to do so. World production of palm oil in 2001 was 23.6 million tonnes of which 17.6 million tonnes were exported to world-wide destinations. Eighty-eight percent of the exports were of Malaysian and Indonesian origin.

In those African countries where the oil palm grows, it continues to hold its position as the major traditional food oil with an annual production of about 1.5 million tonnes in the region. While much of it is still eaten in the crude form, the consumer is also increasingly demanding processed products.

In a number of Latin American countries, palm oil is seen as an efficient means of reaching self-sufficiency, and current production of about 1.4 million tonnes is mainly for local consumption. In contrast, domestic consumption in Malaysia is less than 10% of production. The crop is mainly grown for export, as a successful diversification from rubber. Indonesia, the second largest producer, requires a higher proportion of its production for internal consumption, but is increasing production and exports rapidly.

The importance of palm oil in the world market is based on several factors.

1. It is comparatively cheap, often with an appreciable discount to soya bean oil, the market leader.
2. It has technical attributes, useful in food manufacture, especially its good stability to oxidation, and its natural solid fat content.
3. It is a perennial crop, planted for an economic life of 25–30 years. It mainly grows in equable climates in regions little affected by earthquakes or hurricanes, so that production fluctuates less from year to year than does that of annual crops.

Harvesting and Processing of the Fruit

Various traditional primitive methods of oil recovery are still widely used in West Africa. Typically, the fruit bunch is cut off, and allowed to ferment a few days, so that the fruit detaches easily. The fruit flesh is softened by boiling or by further fermentation, then mashed in a pestle and mortar or under foot. Hot water is added, the oil skimmed, and the water is then boiled off in a separate container. The oil is used without any refining.

In contrast, the modern plantation is usually associated with a mechanical oil mill with a processing capacity of 5–60 tonnes of fresh fruit bunches (FFB) per hour. The harvesting of FFB is still done manually, using an ax, or a sickle-type blade fixed to a pole, depending on the height of the palm. Ripeness is judged by the number of detached fruit that have fallen below the bunch. The frond and then the bunch are cut off. The bunch and any loose fruit are picked up and carried manually, by barrow, in a light animal-drawn vehicle, or with a light mechanical vehicle to the nearest estate road. It is important not to compact the soil close to the palms. Transport is then by lorry to the oil mill. Bunches are emptied into a chute, and filled into sterilizer 'cages' mounted on

wheels, which are then moved into a horizontal cylindrical pressure vessel on rails. Typically, up to 7 × 2.5 tonnes of fruit are cooked in one load. Steam at 304 kPa (3 atm) is applied for about 1 h. The contents of the cage are then fed to a 'bunch stripper' consisting of a horizontal rotating drum with baffles. Bunches are repeatedly lifted and dropped, so that the fruit is shaken out. It is then transported to a 'digester', a vertical steam-jacketed cylinder fitted with rotating beater arms. The fruit is thoroughly mashed and passes directly to a single or a twin-screw press. The press extrudes a liquid at one end, consisting of about 53% oil, 7% finely divided solids, and 40% water, and a press cake containing the fruit fiber and the nuts at the other end. The liquid phase passes through a vibrating screen to a settling tank. After about 2 h, the upper layer is clarified in a sealed centrifuge; the oil is then dried under vacuum and pumped to storage. The lower layer is treated in a sludge centrifuge, or in a three-phase decanter, the oil phase being returned to the settling tank.

The cake formed by the press fiber and nuts is processed in a separate stream. The cake is broken up by rotating arms on a conveyor, and the fiber is removed in a 'polishing' drum. The nuts are partially dried by a warm air stream in a silo, before being cracked in a centrifugal cracker. Nuts drop on to a rotor, which throws them against a peripheral ring of hardened metal. Kernels are separated from shells in a pneumatic column and/or a hydrocyclone, washed, and dried with hot air to below 8% moisture.

The production of palm kernel is usually carried out in a separate factory.

Treatment of Wastes

Three aqueous waste streams arise in the oil mill:

1. condensate from the sterilizing process;
2. aqueous effluent from the centrifuges;
3. waste water from nut processing.

Typically, for every 1 tonne of oil produced, the combined aqueous waste is 2.5 tonnes containing 0.6% oil and 3.9% dissolved and suspended solids. After removal of any supernatant oil, this effluent is treated until the water is of a quality suitable for discharge or reuse in the process. A number of processes have been adopted. Typically, treatment involves:

1. 1–2 days in an open acidification pond;
2. up to 20 days in a tank for anaerobic digestion;
3. about 20 days in a lagoon with vigorous aeration for anaerobic digestion.

The press fiber, after separation of the nuts, is used as fuel in the mill boilers. Consequently, the mill is usually self-sufficient in fuel for steam and electric power. Some shell may be used in the boiler. Alternate uses are as hard-core on estate roads or as raw material for charcoal.

Recently, an alternative treatment process has been developed. The waste stream is partly dewatered in a decanter centrifuge, and then treated in a rotary drier, using heat from the boiler flue, or produced by burning empty fruit bunches. The resulting solid is used as a fertilizer in the plantation.

Refining of Palm Oil

Crude palm oil may be refined by the traditional alkali refining process. In view of its natural strong red color, a highly active bleaching earth may be required. Table 3 gives a flow sheet for a typical process.

Crude palm oil usually contains 3–5% of free fatty acids, and so the process losses in alkali refining tend to be rather high. This has led to the development of physical or steam refining, where the use of a somewhat higher temperature in a modified deodorizer enables the free fatty acids to be removed by distillation instead of neutralization. The process has proved to be more economical and is now being adopted for other oils. A flow sheet for physical refining is given in Table 4.

Further Processing of Palm Oil

Palm oil is subjected to further processes in the refinery in order to make it more widely useful in food applications.

The following processes are carried out on a large scale in order to modify the physical properties:

- fractionation;
- hydrogenation;
- interesterification.

Brief descriptions of the processes will be given here, and the properties of the products will be described in a later section.

The major glyceride components of palm oil range from triolein (melting point 5 °C) to tripalmitin (melting point 66 °C) with a number of mixed glycerides of intermediate melting point.

Crystallization from the melt of this mixture at a controlled temperature, followed by separation of the liquid and solid phases, results in palm olein and palm stearin. The characteristics of these products depend on the temperature chosen for crystallization and the efficiency of the separation process. This may be by centrifugation, filtration on a rotating band filter, or in a plate and frame filter. A

modification of the latter has each frame fitted with an inflatable diaphragm, which enables pressure to be applied to the solids, and results in very efficient separation of the olein. Fractionation from solution in acetone or hexane is more costly and is only used when a sophisticated midfraction is required (see later sections).

Hydrogenation

Hydrogenation is a standard process in the edible oil industry. It involves treating the oil with an activated nickel catalyst with hydrogen under pressure and at an elevated temperature. Vigorous stirring is required, since the liquid and gas phases have to contact at the surface of the catalyst. The oil is neutralized, washed, and bleached before hydrogenation, to avoid deactivation of the catalyst. (*See* **Vegetable Oils**: Oil Production and Processing.)

Interesterification

When a glyceride oil is stirred with sodium methoxide (or other alkali catalyst) at a temperature of about 90 °C, the fatty acid radicals are detached from their original positions, and new glycerides are formed with a random distribution of fatty acids. Examples of interesterified products will be given in later sections. (*See* **Vegetable Oils**: Oil Production and Processing.)

Chemical Composition of Palm Oil and Fractions

Average fatty acid composition data from refined palm oil and standard palm olein and stearin, as traded, are shown in Table 5. Tailor-made fractions are also available for specific requirements. The last column shows the composition of a midfraction obtained from palm oil under special conditions, which is suitable for use in confectionery fats. Triacylglycerol compositions for the same products are given in Table 6.

Physical Properties of Palm Oil

Many food products require a consistent or semisolid fat as an ingredient in order to achieve the required structure. An important feature of palm oil is its natural content of solids. The average solid fat content of palm oil products is given in Table 7. Palm stearins of a wide choice of composition and solid fat contents are available, for example, with solid fat contents at 20 °C ranging from 35 to 72%.

Minor Components of Palm Oil

Data for the minor components of palm oil, collected from published sources, are given in Table 8. The main sterols present are β-sitosterol (58%), campesterol (22%) and stigmasterol (11%). The main carotenoids are β-carotene (56%) and α-carotene (35%). The carotenoids are removed in the normal refining process. The tocol content is unusual in having a high proportion of unsaturated tocotrienols. Details for crude and refined products are given in Table 9. The tocols are important as vitamin E and as potent natural antioxidants. (*See* **Antioxidants**: Natural Antioxidants; **Carotenoids**: Occurrence, Properties, and Determination.)

Food Uses of Palm Oil

Frying

Palm oil has a good stability at the high temperatures used in frying (usually 175–185 °C), because of its content of natural antioxidants, the absence of highly unsaturated fatty acids, and the moderate content of linoleic acid. Consequently, palm oil or palm olein is widely used domestically and in industry, especially for deep fat frying whether in a batch process, as in restaurants and fast food outlets such as British 'fish and chip' shops, or in continuous fryers. Palm oil is used for doughnut frying, because the solids content assists the adhesion of the sugar coating. Palm oil is also used for the frozen 'French fry' industry and for instant noodle frying in Japan and China. For potato crisps (American 'chips'), palm olein is preferred, or a blend of palm olein with a more unsaturated oil such as sunflower or soya bean oil.

Bakery Fats

Texturized palm oil is used as such in some types of biscuits. For other biscuits and for cakes, a formulated shortening is required to obtain good aerating properties. Some formulae with a satisfactory performance are given in Table 10.

Vanaspati

Vanaspati may be defined as a cheaper alternative to butterfat, having a melting point of about 37 °C and a granular crystalline structure with little or no free oil. It is generally based on vegetable oils suitably hydrogenated or on a blend of oils. Vanaspati is the customary domestic cooking fat in the Indian subcontinent and the Middle East. When formulated from liquid vegetable oils, the desired structure requires a hydrogenation giving a high content of *trans* fatty acid isomers (30–60%). This is regarded as undesirable according to current nutritional advice. A number of formulae based on palm oil and having low or zero *trans* fatty acids are given in Table 11.

Margarines

Margarines can be classified as being for table use in blocks or in tubs, general bakery margarines, and puff-pastry margarines.

The textual properties are the textual properties appropriate for each application, and these can be obtained by blending a variety of ingredients. Table 12 shows some formulae based on palm oil.

Confectionery Fat

Palm oil midfraction (see Tables 5–7) is used as a major component of blends designed to have physical properties like cocoa butter, and compatible with it in mixtures. Palm olein, partly hydrogenated under conditions giving a high content of *trans* fatty acids, is

useful as a confectionary fat with limited compatability with cocoa butter, or for use in toffee, bakery coatings, and confectionery centers.

Miscellaneous Uses

Palm oil is used instead of butterfat in icecream and in filled milk or coffee whiteners. Partly hydrogenated palm oil is used in dried soups, where its stability against oxidation is important.

Special Products

Using a modified refining process, red palm oil and palm olein, retaining about 80% of the carotenoid content of the crude oil, have become commercially available. Red olein has found uses in the manufacture of attractively golden-colored potato crisps, whereas red palm oil is being used in nutritional intervention studies in South Africa and India. This is potentially a very important use, in view of the high incidence of xerophthalmia in developing countries.

A commercial process is also in operation to obtain a 99% pure concentrate of the tocopherols and tocotrienols from the palm fatty acid distillate, the byproduct of physical refining. The concentrate is used in health supplements.

Properties and Determination
Physiology

Properties and Determination

G F M Ball, Wembley, London, UK

Background

In 1933, a research team led by R. J. Williams isolated from a variety of biological materials an acidic substance that acted as a growth factor for yeast. Williams' team elucidated the chemical structure of the purified substance and named it pantothenic acid because of its apparently widespread occurrence (Greek *pantos*, meaning everywhere). Pantothenic acid was established as a vitamin in 1939, when it was shown to be identical to a 'filtrate factor' required by rats for normal growth, and to a chick antidermatitis factor. Sometimes referred to as vitamin B_5, pantothenic acid is a member of the water-soluble B-group vitamins.

Structure and Physicochemical Properties

The biological activity of pantothenic acid is attributable to its incorporation into the molecular structures of coenzyme A and acyl carrier protein. The molecular structures of pantothenic acid and related compounds are shown in Figure 1. Pantothenic acid ($C_9H_{17}O_5N$; molecular weight = 219.23) is composed of pantoic acid linked by an amide bond to β-alanine. The pantothenic acid molecule, having a chiral carbon atom, exhibits optical isomerism as well as being optically active. Only the D(+) isomer occurs in nature. Synthetic pantothenic acid is a racemic (DL) mixture, and, since only the D isomer is biologically active, this fact must be considered if the DL mixture is to be used therapeutically. Pantothenic acid is a pale yellow oil that is extremely hygroscopic and so is unsuitable for commercial application. For human food supplements, calcium D-pantothenate [$(C_9H_{16}O_5N)_2Ca$; molecular weight = 476.53] is used.

The corresponding alcohol of pantothenic acid, pantothenol (referred to commercially as panthenol), is widely used as a source of pantothenate activity for pharmaceutical vitamin products, because it is more stable than the pantothenate salts, especially in liquid multivitamin products that must be slightly acid to preserve the thiamin content. Pantothenol does not occur naturally and itself has no pantothenate activity, but it is converted quantitatively to pantothenic acid in the body.

The stability of pantothenic acid and its calcium salt in aqueous solution is highly dependent on the pH. In contrast to other B-group vitamins, pantothenic acid becomes more stable as the pH of the solution increases. Solutions of calcium pantothenate are most stable between pH 5 and 7 but, even so, are not stable to autoclaving, and therefore, sterilization by ultrafiltration is necessary for pharmaceutical preparations. Below and above these pH values, solutions of calcium pantothenate are thermolabile. Alkaline hydrolysis yields pantoic acid and β-alanine, whereas acid hydrolysis yields the γ-lactone of pantoic acid. Pantothenic acid is unaffected by atmospheric oxygen and light.

Dietary Sources

Pantothenic acid is widely distributed in foods of both animal and plant origin. In concentration units of mg per 100 g, the vitamin is particularly abundant in liver (8), kidney (3), heart (2.5), egg yolk (4.6) broad beans (4.9), and peanuts (2.7). Lesser amounts are found in beef (0.6), chicken (1.2), potatoes (0.4), broccoli (1.2), oatmeal (1.0), and milk (0.35), but these will be important food sources if consumed in sufficient quantity. Outstandingly high amounts are found in the ovaries of tuna and cod (232) and in royal jelly from the queen bee (50). In contrast, highly refined foods such as sugar, fats and oils, and cornstarch are totally devoid of the vitamin.

Coenzyme A is the major pantothenic acid-containing compound present in foods of both animal and plant origin, accompanied by small amounts of other bound forms (phosphopantothenic acid, pantetheine, and phosphopantetheine). Notable exceptions are human and bovine milk in which free (unbound) pantothenic acid constitutes around 90% of the total pantothenate content.

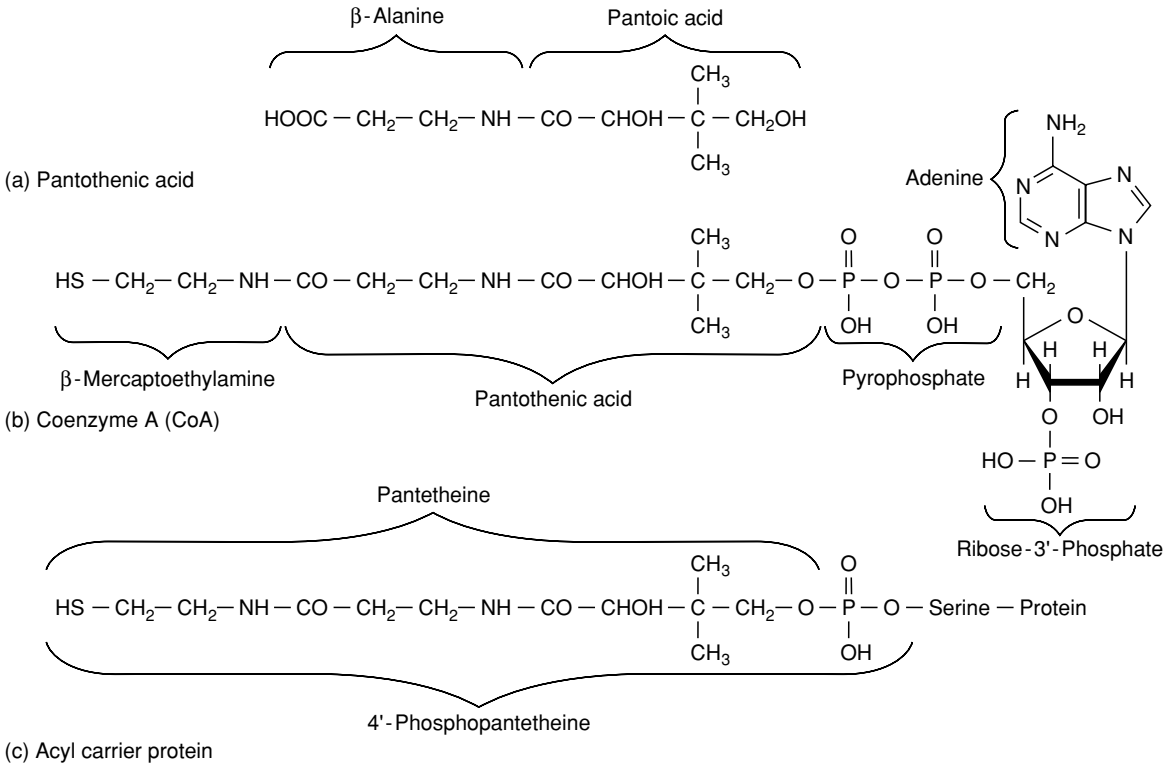

Figure 1 Structures of (a) pantothenic acid, (b) coenzyme A, and (c) acyl carrier protein.

Pantothenic acid has a good stability in most foods during home cooking but is susceptible to leaching. The roasting of meat causes degradation of less than 10%, but the meat drippings contain 20–25% of the initial vitamin content.

Estimates of dietary intakes of pantothenic acid should be based not on the raw food values, but on the cooked food values, otherwise falsely high estimates of intake will be obtained. Table 1 presents data taken from a study in which the pantothenic acid content of 75 processed and/or cooked foods was determined by radioimmunoassay. The foods selected for analysis were those commonly consumed in the USA. Samples were brought to a ready-to-eat stage, following any package directions, and using only the edible portion. Results indicated that the canning of foods incurs large losses of pantothenic acid, as does the conversion of grains to various cereal products, and the processing of meats to produce fat- and cereal-extended products such as frankfurters and sausages.

Little information is at hand regarding the nutritional availability to humans of pantothenic acid in food commodities. In one study, based on the urinary excretion of pantothenic acid, the availability for male human subjects ingesting 'the average American diet' ranged from 40 to 61%, with a mean of 50%.

Analysis

Pantothenic acid in its various bound forms (mainly coenzyme A) is routinely determined by microbiological assay. Other published methods include radioimmunoassay, enzyme-linked immunosorbent assay, gas chromatography, and high-performance liquid chromatography. For all of these techniques, it is necessary to liberate pantothenic acid from its bound forms by enzymatic hydrolysis, because only the free vitamin can be measured. Hydrolysis is not required, however, for calcium pantothenate-supplemented foods or for milk in which the free vitamin predominates.

Extraction from Food

Neither acid nor alkaline hydrolysis is applicable for the liberation of bound pantothenic acid, since the vitamin is degraded by such treatments. The only practicable alternative is enzymatic hydrolysis, and this was successfully accomplished through the simultaneous action of intestinal phosphatase and an avian liver enzyme. This double enzyme combination liberates practically all of the pantothenic acid from coenzyme A, but it does not release the vitamin from acyl carrier protein. The phosphatase splits the coenzyme A molecule between the phosphate-containing

Table 1 Pantothenic acid content of processed and/or cooked foods purchased in Utah, USA

moiety and pantetheine, while the liver enzyme breaks the link in pantetheine between the pantothenic acid and β-mercaptoethylamine moieties. Both enzymes are available commercially as powdered extracts. Liver enzyme preparations contain a relatively high amount of coenzyme A, which is converted to pantothenate during the incubation period, thus creating an unacceptably high blank value. Such preparations can be purified quite simply by treatment with Dowex 1-X4 anion exchange resin. Intestinal phosphatase preparations contain negligible amounts of coenzyme A and do not require purification.

Microbiological Assays

Microbiological methods, as applied to the determination of the B-group vitamins, are based on the absolute requirement of a particular microorganism (the assay organism) for the vitamin in question (in this case, pantothenic acid); that is, the organism can multiply only when the vitamin is present in the surrounding medium. In a typical turbidimetric microbiological assay, aliquots of a standard solution of pantothenic acid, or aliquots of the sample extract containing pantothenic acid, are added to an initially translucent basal nutrient medium, complete in all respects except for pantothenic acid. Following inoculation with the assay organism, the organism multiplies in proportion to the pantothenic acid content of the standard or sample, and the extent of the growth is ascertained by measuring the turbidity produced. Over a defined concentration range, the measured response will be directly proportional to the amount of pantothenic acid present, and, within this range, the sample solution and standard pantothenic acid solution can be compared accurately. The usual assay organism is *Lactobacillus plantarum* (ATTC (American Type Culture Collection) No. 8014), which can also be used for assaying nicotinic acid and biotin. The basal nutrient medium can also be used for assaying nicotinic acid and biotin, with the exclusion of the relevant vitamin from the formulation. Fatty acids are stimulatory in the presence of suboptimal amounts of pantothenic acid, so a preliminary ether extraction step may be necessary.

In the standard turbidimetric procedure, the basal nutrient medium is prepared at twice its final concentration. Multiple aliquots of a standard solution of pantothenic acid and of enzyme-treated extracts of the test food are added to a series of uniform assay tubes in amounts suitable to produce gradations in growth between no growth and maximum growth. The contents of all tubes are diluted with water to the same volume, and an equal volume of the basal medium is added. The tubes are sterilized, cooled to a uniform temperature, and then inoculated with an actively growing culture of *L. plantarum*. The tubes are incubated for 6–24 h at any selected temperature between 30 and 40 °C held constant to ±0.5 °C until growth has reached the maximum permitted by the limiting vitamin present, pantothenic acid. The growth response to standard and test extract is then determined by measuring the turbidity produced. The data obtained from the standards are used to construct a standard curve from which the pantothenic acid concentrations of the various sample aliquots are derived. The use of multiple aliquots allows a validity check to be carried out: the pantothenic acid concentration found should be directly proportional to the volume of aliquot taken. The amount of pantothenic acid present in the original sample is then calculated at the different test levels, and the results are averaged to obtain the final result.

An alternative method, the radiometric microbiological assay, is based upon the measurement of radioactive $^{14}CO_2$ generated from the metabolism of a ^{14}C-labeled nutrient by the test organism. The radioactivity is measured automatically by means of a commercially available gas flow system incorporating an ionization chamber. Sample preparation for this technique is simplified due to the fact that

colored, turbid, or precipitated debris does not interfere with the $^{14}CO_2$ output or detection; furthermore, the scrupulous cleaning of glassware required for turbidimetric assays is unnecessary. An assay for pantothenic acid in human milk and blood is based on the measurement of $^{14}CO_2$ produced from the metabolism of L-[1-^{14}C]methionine or L-[1-^{14}C]-valine by the yeast *Kloeckera brevis* (ATCC 9774). Metabolic CO_2 can also be measured nonradiometrically with the aid of an infrared CO_2 analyzer, which measures automatically the infrared radiation absorbed by the CO_2 band at 4.2 μm.

Radioimmunoassay

The radioimmunoassay is based on the competition for a fixed, but limited, number of antibody binding sites by antigen (a substance capable of binding to a specific antibody) and a trace amount of radiolabeled antigen added to the sample extract. In this case, the antigen is the analyte, pantothenic acid. The presence of larger amounts of unlabeled analyte results in less radioactivity being bound to the antibody.

Wyse and colleagues raised antibodies to pantothenic acid by coupling a bromoacetyl derivative of pantothenic acid with reduced and denatured bovine serum albumin and injecting this immunogen into rabbits. For the assay, each tube contained diluted antiserum, pantothenic acid standard solution or sample extract, and radiolabeled sodium *d*-pantothenate. After incubation, neutral saturated ammonium sulfate was added to facilitate suspension of the antibody-bound pantothenic acid, which was then centrifuged. The washed precipitate, containing antibody-bound pantothenic acid, was dissolved in tissue solubilizer, and the radioactivity was counted in a scintillation counter. The amount of pantothenic acid in each unknown was determined by reference to a standard curve constructed by plotting on logit-semilog paper log concentration of nonradioactive pantothenic acid in the standard vials (ng per 0.50 ml) versus the percentage of the counts bound. Results from the radioimmunoassay and AOAC microbiological assay for pantothenic acid in 75 processed and cooked foods were highly correlated ($r = 0.94$). However, there was a statistically significant difference ($p < 0.05$) between the two assay results for all foods and for the subgroups meats, breads and cereals, and fruits and vegetables. At $p < 0.01$, only meats were significantly different. For breads and cereals, the microbiological assay results averaged 6.6% higher than those of the radioimmunoassay. For fruits and vegetables, the microbiological assay results were 11.6% higher; for meats, the results were 23.2% higher. It was postulated that bacterial enzymes in the assay organism promote further breakdown of bound pantothenic acid, or nonenzymatic breakdown occurs during the long microbiological incubation period.

Enzyme-linked Immunosorbent Assay (ELISA)

An ELISA is an enzyme-linked immunoassay in which one of the reactants is immobilized by physical adsorption on to the surface of a solid phase. In its simplest form, as used in food analysis applications, the solid phase is provided by the plastic surface of a 96-well microtitration plate. The generally preferred format for vitamin assays in food analysis is a two-site noncompetitive assay used in the indirect mode. This format employs two antibodies: a primary antivitamin antibody raised against an immunogen (in this case, a pantothenic acid–protein conjugate), and an enzyme-labeled, species-specific second antibody, which binds specifically to the primary antibody. To perform such an assay, a protein conjugate of pantothenic acid is immobilized to the well surface of the microtitration plate, the attached protein being different to that used for the immunogen. The protein adsorbs passively and strongly to the plastic, and, once coated, plates can usually be stored for several months. To perform the assay, the standard solution or sample extract is added to the well, followed by a limited amount of primary antibody. After incubation, the antibody becomes distributed between immobilized vitamin and free vitamin according to the amount of vitamin initially present. After phase separation, achieved by well emptying and washing, the second antibody is added in excess, and the plate is incubated for a second time. Excess unbound material is removed, and the amount of bound enzyme is determined by addition of substrate and spectrophotometric measurement of the colored product. Unknown samples are quantified by reference to the behavior of vitamin standards.

Finglas and colleagues developed a noncompetitive ELISA, which is highly specific for pantothenic acid and does not recognize coenzyme A, panthenol or pantheneine. The primary antivitamin antibody was raised in rabbits according to the method of Wyse and colleagues (*see* section Radioimmunoassay), and the enzyme-labeled, species-specific second antibody (alkaline phosphatase-labeled antirabbit IgG) was obtained commercially. Microtitration plates were coated with pantothenic acid–keyhole limpet hemocyanin as the immobilized phase of the assay. A high correlation coefficient ($r = 0.999$) was reported when ELISA values obtained for six foods were compared with corresponding values obtained by a microbiological method using *L. plantarum*. Gonthier and

colleagues improved the sensitivity of the ELISA by using an immunogen composed of pantothenic acid coupled to thyroglobulin by a 6-carbon atom linker (adipoyl dichloride). By contrast, the bromoacetyl linker used in Finglas' pantothenic acid–bovine serum albumin immunogen contains two carbon atoms.

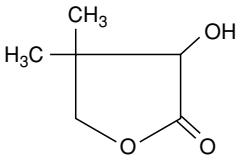

Figure 2 Pantoyl lactone.

Gas Chromatography

Salts of pantothenic acid present in pharmaceutical preparations have been analyzed by gas chromatography after conversion to volatile acetate, trifluoroacetate, or trimethylsilyl derivatives. An alternative approach to derivatization is to chromatograph the pantoyl lactone formed from pantothenic acid by acid hydrolysis (Figure 2). This approach is applicable to foodstuffs, because the hydrolysis reaction liberates the lactone from the free and bound pantothenic acid in the food matrix with a recovery of at least 95%. Davídek and colleagues applied this technique to the determination of pantothenic acid in fresh beef liver, spray-dried egg yolk, soybean flour, whole-grain wheat flour, and dried bakers' yeast. Samples were hydrolyzed by treatment with dilute hydrochloric acid, and the neutralized hydrolysate, after filtration, was extracted with dichloromethane. The combined extracts, to which ethyl laurate was added as an internal standard, were concentrated by rotary evaporation, and then analyzed by gas chromatography using a polar stationary phase of 10% Carbowax 20M and a flame ionization detector. Gas chromatographic results correlated with results obtained by the currently accepted microbiological method ($r = 0.975$), and no significant difference was found between the two sets of results ($p > 0.05$). Davídek and colleagues used a packed column of dimensions 2.4 m × 2 mm i.d. in which the stationary phase was coated on to a porous support material of diatomaceous earth treated with dimethyldichlorosilane. Woollard and colleagues upgraded the column to a more efficient 30 m × 0.25 mm open-tubular capillary column coated with stationary phase (BPX70).

High-performance Liquid Chromatography (HPLC) and Capillary Electrophoresis

The pantothenic acid molecule does not contain a characteristic chromophore, and hence it exhibits only very weak absorbance at 204 nm, owing to the presence of carbonyl groups. Detection at wavelengths below 220 nm is subject to interference from the many organic compounds present in a typical food sample extract prepared for HPLC. The problem of weak and nonspecific absorbance, coupled with the low concentrations of pantothenic acid in foods, has thwarted attempts to apply HPLC to the determination of pantothenic acid in foodstuffs, although the technique has been successfully applied to pharmaceutical products. Chemical treatment of the pantothenic acid molecule to form a derivative that fluoresces or absorbs at a higher wavelength is a possibility, but, so far, reproducible results have not been obtained using such an approach. Refractometry as a means of detection lacks the required sensitivity and specificity.

Recognizing these problems, Woollard and Indyk in New Zealand developed an HPLC method for determining free endogenous D-pantothenic acid in milk and supplemental calcium pantothenate in infant formulas. Sample preparation simply entailed addition of acetic acid to the milk or reconstituted infant formula, followed by centrifugation and membrane filtration. This treatment resulted in a protein- and fat-free extract that could be directly injected (10-µl aliquot). The problems of poor detection specificity in the low-ultraviolet region of the spectrum were overcome by the use of a photodiode array detector that provided multiwavelength detection (selected wavelengths were 200, 205 and 240 nm) and on-line spectral analysis. The HPLC system incorporated an on-line mobile phase degasser – an important feature, as dissolved oxygen constitutes a source of interference at low ultraviolet wavelengths. Among several reversed-phase columns investigated, the column selected for routine use was of dimensions 250 × 4.6 mm i.d. and packed with Luna (Phenomenex) 5 µm C_8 (octyl) of 100 Å pore size, 400 $m^2 g^{-1}$ surface area, and 13.5% carbon load. The Luna material is based on low-acidity silica, exhaustive end-capping, and shielded bonded phase ligand. The mobile phase was phosphate buffer (0.1 M, pH 2.25): acetonitrile (97:3, v/v) delivered initially at 1.4 ml min^{-1} and increased to 1.8 ml min^{-1} at 18 min. Following completion of the sample schedule, the column was purged sequentially with acetonitrile:water (50:50), water (100%), acetonitrile:water (50:50), and finally acetonitrile (100%) for column storage between runs. The retention time of the pantothenic acid was around 15 min, but the next sample was not injected until a major unknown peak with a retention time of about 35 min was removed (Figure 3).

Reversed-phase columns do not retain acidic solutes in the ionic state, but if the mobile phase is buffered to pH 3 or lower, the acidic solute will be nonionized and act as a neutral solute. This technique is known as ion suppression. Under these conditions, residual silanol groups on the silica support will also be nonionized. The net result is retention of undissociated acidic solutes with no peak tailing, owing to the elimination of electrostatic interactions between acidic solutes and silanol groups. A potential problem with certain reversed-phase column packings is that the siloxane (≡Si—O—Si≡) bond linking the alkyl ligand to the silica support is subject to hydrolysis at low pH, resulting in loss of bonded phase. Although longer-chain ligands such as C_{18} are relatively stable at a low pH, short-chain bonded phases, including small endcapping groups, are especially susceptible. The problem of hydrolysis and loss of bonded phase can be minimized by the use of 'shielded' stationary phases, which are sterically protected from attack by hydrolyzing protons. Results obtained by HPLC correlated with those obtained by microbiological assay utilizing *L. plantarum* ($r = 0.971$), and there was no significant difference ($p > 0.05$) between the two sets of results.

Reversed-phase HPLC with ion suppression is unable to separate the D and L enantiomers in synthetic calcium pantothenate. However, separation

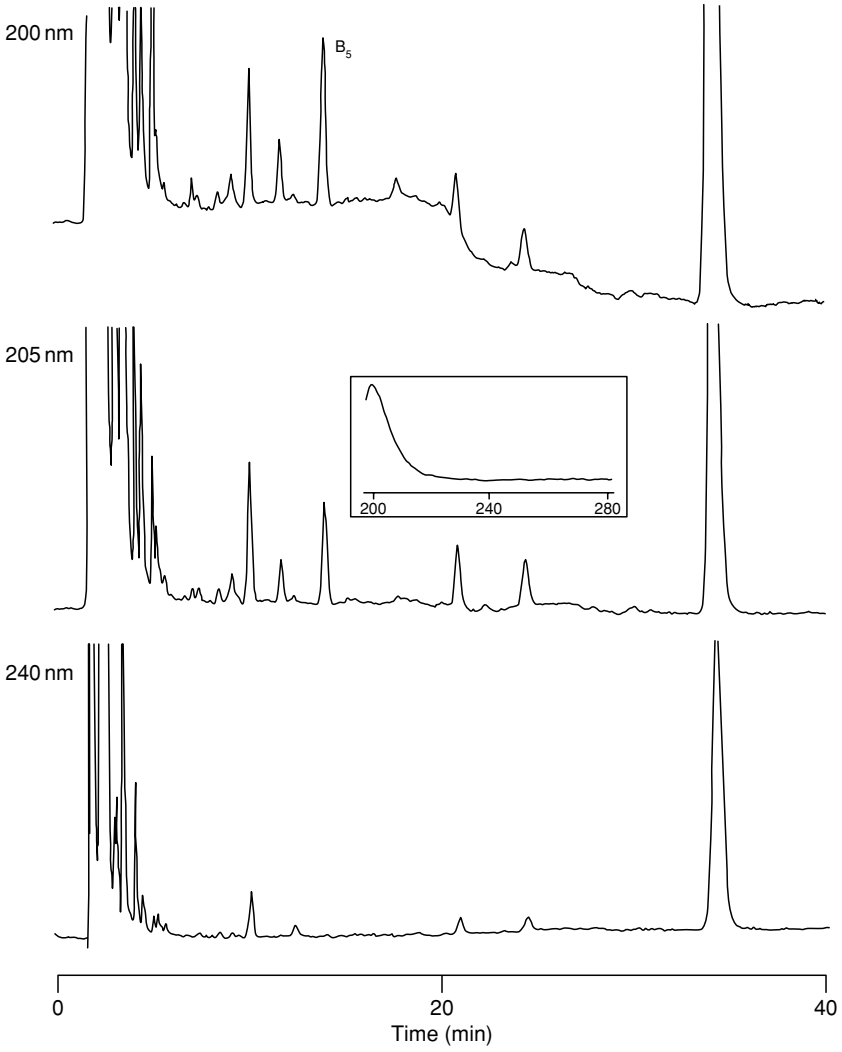

Figure 3 Multiwavelength UV chromatogram (200, 205, 240 nm) of a typical infant formula extract obtained with a Luna C_8 (octyl) column. The insert illustrates a UV spectral scan of pantothenic acid. Chromatographic parameters are given in the text. Reprinted from Woollard DC, Indyk HE and Christiansen SK (2000) The analysis of pantothenic acid in milk and infant formulas by HPLC. *Food Chemistry* 69: 201–208, with permission from Elsevier Science.

of enantiomers in DL pantothenic acid has been reported using a chiral selector in capillary electrophoresis. Optimum separation was obtained using a pH 7.0 phosphate buffer containing the chiral selector (60 mM 2-hydroxypropyl-β-cyclodextrin) and 10% (v/v) methanol. The enantiomers were unresolved when a buffer of pH 3.0 was tried, implying that dissociation of pantothenic acid was necessary for its chiral resolution under the conditions employed.

Overall Appraisal of Analytical Techniques

The 'free' (no enzyme treatment) or 'total' (after enzyme treatment) pantothenic acid content of a food has been traditionally determined by the turbidimetric microbiological assay using *L. plantarum*. This assay has been adopted as an official method by the AOAC on the basis of collaborative study. Once the facilities are in place, the microbiological assay can be used routinely to determine other B-group vitamins with minor changes in protocol. Inherent problems include stimulation or inhibition of bacterial growth by other compounds, and nonlinear response (drift) for various volumes of food extract analyzed. The radioimmunoassay produces results that, although correlated with microbiological assay results, are significantly lower. The use of radioisotopes would not be permitted in the vicinity of commercial food production. The ELISA is a better substitute for the microbiological assay, as results from the two techniques are in good agreement. The high technology of the ELISA is built into the reagents, so the assays are simpler to perform than microbiological assays. Routine use of the ELISA for determining pantothenic acid will depend on the commercial availability of standardized assay kits. Little interest seems to have been taken in gas chromatography, but the technique of chromatographing the lactone hydrolysis product merits further investigation using modern capillary columns. High-performance liquid chromatography is becoming increasingly popular for determining vitamins in foods, although the poor detectability of pantothenic acid limits the sensitivity of this technique. Capillary electrophoresis also suffers from poor sensitivity but, when used with a chiral selector, has the advantage of separating active d and inactive l enantiomers of racemic calcium pantothenate added to foods.

Physiology

G F M Ball, Wembley, London, UK

Background

The biological activity of pantothenic acid is attributable to its incorporation into the molecular structures of coenzyme A (CoA) and acyl carrier protein. CoA performs multiple roles in cellular metabolism, whereas acyl carrier protein is involved in fatty acid biosynthesis. A wide variety of functional proteins are modified by the addition of acetyl, acyl, and isoprenyl groups through reactions that directly or indirectly involve CoA. These modifications allow the regulation of such important processes as gene transcription, signal transduction, and vision.

Metabolism

Intestinal Absorption

Ingested CoA, the major dietary form of pantothenic acid, is hydrolyzed in the intestinal lumen to pantetheine by the nonspecific action of pyrophosphatases and phosphatase. Pantetheine is then split into pantothenic acid and β-mercaptoethylamine by the action of pantetheinase secreted from the intestinal mucosa into the lumen. Within the alkaline medium of the luminal contents, pantothenic acid exists primarily as the pantothenate anion. Absorption of the liberated pantothenate takes place mainly in the jejunum.

At physiological intakes, pantothenate must move across the brush-border membrane of the intestinal epithelium from a region of lower concentration in the lumen to one of higher concentration in the cytoplasm of the absorptive cell (enterocyte). Such 'uphill' movement requires active transport – a mechanism that depends ultimately upon the expenditure of metabolic energy, i.e., the energy released from the hydrolysis of adenosine triphosphate produced during cellular metabolism. The precise mechanism of pantothenate absorption is secondary active transport in which a transmembrane protein (inappropriately called a carrier) mediates the sodium-coupled transfer of pantothenate across the brush-border membrane. The carrier spans the membrane in a weaving fashion and effects solute transfer through a conformational change in its molecular structure. The immediate energy source for the transport mechanism is the concentration gradient of sodium across the brush-border membrane. The gradient is maintained by the constant extrusion of sodium from the enterocyte by the action of the sodium pump at the basolateral membrane. The sodium pump is driven by metabolic energy and is the primary driving force for pantothenate absorption. As the transport process does not respond to an electrical gradient, it nust be electroneutral, indicating a 1:1 cotransport of Na^+ and pantothenate$^-$ by the same carrier. The mechanism by which pantothenic acid exits the absorptive cell at the basolateral membrane has not been established.

Intestinal microflora have been reported to synthesize pantothenic acid in mice, but the contribution of bacterial synthesis to body pantothenic acid levels or fecal loss in humans has not been quantified.

Unlike other water-soluble vitamins (ascorbic acid, biotin and thiamin) that are absorbed by specific carrier-mediated systems, the absorption of pantothenic acid is not regulated by its level of dietary intake. The absence of clear-cut deficiency symptoms in humans and the lack of toxicity at high doses could explain why a regulated absorption mechanism has not evolved for pantothenic acid.

Tissue Uptake and Metabolism

After absorption, free pantothenic acid is conveyed to the body tissues in the plasma from which it is taken up by most cells. A so-called sodium-dependent multivitamin transporter that mediates placental and intestinal uptake of pantothenate, biotin and the essential metabolite lipoate has been cloned from rat placenta and rabbit intestine. Messenger RNA transcripts of this transporter have been found in many tissues (intestine, liver, kidney, heart, lung, skeletal muscle, brain and placenta) suggesting that this carrier protein may be involved in the uptake of pantothenate, biotin and lipoate by all cell types.

In mammalian tissues (but not in red blood cells), CoA is synthesized from pantothenic acid in five enzymatic steps. Three substrates are needed to synthesize CoA: pantothenic acid, ATP, and cysteine. The rate-controlling step in the synthesis is the conversion of pantothenic acid to 4′-phosphopantothenic acid by pantothenate kinase. Tissue levels of CoA are kept in check by feedback inhibition of pantothenate kinase by CoA, acetyl-CoA, or a related metabolite.

In the event of a drastically reduced intake of pantothenic acid, such as would occur during food deprivation, the liver, and possibly other tissues, is able to maintain nearly constant CoA levels for some considerable time. In fasting rats, pantothenic acid uptake by the liver is stimulated by the natural rise in glucagon, and incorporation of pantothenic acid into CoA is stimulated by glucagon and cortisol.

In contrast to the liver, uptake of pantothenic acid by heart and skeletal muscle of fasting rats is reduced, and yet the rate of pantothenic acid conversion to CoA is increased. Evidently, myocardial and muscle CoA synthesis is not governed by the availability of pantothenic acid to these tissues, but rather is controlled intracellularly by regulation of enzymes involved in the CoA synthetic and/or degradative pathways.

Pantothenic acid derived from the degradation of CoA is excreted intact in urine. The amount excreted varies proportionally with dietary intake over a wide range of intake values. Both fasting and diabetes result in decreased excretion, thus conserving whole-body pantothenic acid under these conditions.

Biochemical Functions of Coenzyme A and Acyl Carrier Protein in Cellular Metabolism

A molecule of pantothenic acid is incorporated into the structures of CoA and acyl carrier protein. Though the functional sulfhydryl group of these coenzymes is not part of the pantothenate moiety, the steric configuration of pantothenic acid is important for enzymatic recognition.

Acetyl-CoA and succinyl-CoA are energy-rich thioesters that play important roles in the tricarboxylic acid cycle. Acetyl-CoA is also required for the acetylation of choline to form the neurotransmitter, acetylcholine. The amino sugars D-glucosamine and D-galactosamine react with acetyl-CoA to form acetylated products, which are structural components of various mucopolysaccharides. The biosynthesis of cholesterol begins with the condensation of two molecules of acetyl-CoA to form acetoacetyl-CoA. The latter reacts with acetyl-CoA to form 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA), which in turn is reduced to the key intermediate, mevalonic acid. CoA is required at two steps in each cycle of the β-oxidation of fatty acids. Acyl carrier protein, as an integral part of fatty acid synthase, is involved in the biosynthesis of fatty acids.

Physiological Roles of Coenzyme A in the Modification of Proteins

Many diverse cellular proteins are modified by acetylation and/or by the covalent attachment of lipids. The modifications fall into three main categories: acetylation, acylation, and isoprenylation. The alterations in protein structure may be relevant to the association of proteins with the plasma membrane or with subcellular membranes, protein–protein binding, or the targeting of proteins to specific intracellular locations. In some cases, the modifications are cotranslational, i.e., they take place on the growing polypeptide chain associated with the ribosome during protein synthesis; in other cases, they are posttranslational.

Most soluble proteins are modified at their amino termini with an acetate group that is donated by CoA. Acetylation alters the protein's binding affinity for receptors or other proteins.

A wide variety of proteins are modified with long-chain fatty acids donated by CoA. The two fatty acids most commonly attached to proteins are myristic acid (14:0) and palmitic acid (16:0). The enzyme linking myristate to amino-terminal glycine residues by an amide bond is *N*-myristoyl transferase. For myristoylation to take place, the protein substrate must have a glycine residue at position 2, immediately following methionine, and preferably a hydroxyamino acid (typically serine) at position 6. Myristoylated proteins include G protein α subunits (signal transduction), ADP-ribosylation factors (vesicular transport), myristoylated alanine-rich C kinase substrate protein (cytoskeletal rearrangements), recoverin (vision), proteins of the immune system, and several enzymes. Palmitoyl transferases link palmitate to the side chains of cysteine residues by a thioester bond. The cysteine residues can reside at any point in the primary structure of the protein; there is little evidence for any specific sequence requirements. Unlike the highly stable amide linkages to myristate, modifications of proteins by palmitate occur in thioester or oxyester linkages that are subject to hydrolysis by esterases. Cycles of palmitoylation and depalmitoylation allow the modified protein to have a regulating function. Palmitoylated proteins include G protein α subunits, many plasma membrane-anchored receptors, cytoskeletal proteins, gap junction proteins, neuronal proteins, and the enzymes acetylcholinesterase and glutamic acid decarboxylase. Palmitate modification is also a prerequisite for the budding of transport vesicles from Golgi cisternae.

Two important isoprenoids, the 15-carbon farnesyl pyrophosphate and the 20-carbon geranylgeranyl pyrophosphate (**Figure 1**), are metabolic products of mevalonic acid. Attachment of either isoprenoid chain is the first step in the modification of proteins bearing a C-A1-A2-X motif, where C is a carboxy-terminal cysteine residue, A1 and A2 are aliphatic amino acids, and X is an undefined amino acid. The attachment is a thioester bond with the terminal cysteine. Isoprenylated proteins include Ras proteins (signal transduction), Rab proteins (vesicular transport), nuclear lamins A and B (assembly and stabilization of the nuclear membrane), G protein γ subunits, and the enzymes phosphorylase kinase and rhodopsin kinase.

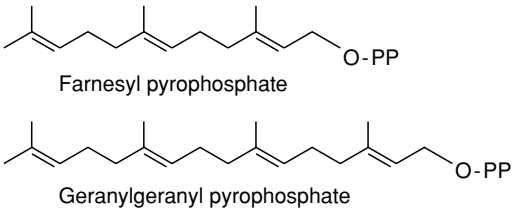

Figure 1 Structures of farnesyl pyrophosphate (C15) and geranylgeranyl pyrophosphate (C20).

The physiological implications of selected acetylation and acylation modifications of proteins are discussed below.

Acetylation of β-Endorphin

Amino-terminal acetylation plays an important role in regulating the biological activity of the brain neurotransmitter β-endorphin. This peptide has morphine-like analgesic activity and also affects sexual behavior and learning. Acetylation deactivates *β*-endorphin by rendering it unable to bind to specific receptors. The modification is posttranslational and occurs before or during the packaging of the peptide into the secretory granules of multineurotransmitter neurons in the pituitary gland.

Histone Acetylation

The DNA in cell nuclei does not exist in the 'naked' state – rather, it is compacted into chromatin by winding around specific DNA-binding proteins called histones. The fundamental repeating unit of chromatin is the nucleosome, which appears in electron micrographs as beads on a string. Each nucleosome consists of core histones (H2A, H2B, H3, and H4), linker histones (H1 or variants thereof) and variable lengths of linker DNA. Two molecules each of the core histones form a barrel-shaped nucleosome core particle, around which 146 base pairs of DNA are wrapped in nearly two complete turns. A model of the octamer of core histones is shown in Figure 2. The linker histone acts as a clamp, preventing the unwinding of DNA from the octameric complex. Each of the four types of core histone comprises a globular, hydrophobic carboxy terminus and an extended hydrophilic amino-terminal tail containing a number of positively charged amino acid residues. The tails lie on the outside of the nucleosome, where they can interact ionically with the negatively charged phosphate groups of the DNA backbone. During the periods between cell division, the 'beads on a string' chromatin filaments form higher-order structures by winding into a solenoid containg six nucleosomes per turn. In these structures, the tails of the core histones still extend outside the nucleosome.

The organization of chromatin into nucleosomes is an essential feature in the regulation of gene transcription – the step in protein synthesis in which messenger RNA is synthesized from DNA. During transcription, the enzyme RNA polymerase II combines with a host of protein transcription factors to form a multiprotein complex at a precise site on the DNA called the promoter. The polymerase moves along the DNA, temporarily unwinding and separating the two strands. As it moves along, RNA is formed by the linking of ribonucleotides under the influence of the enzyme and using one of the DNA strands as a template.

It is necessary to control gene transcription so that only those proteins needed by a particular cell for a specific purpose are synthesized. When a protein is not needed, nucleosomes prevent transcription by impeding the access of factors required to initiate and regulate this process. When protein synthesis is required, changes in cell physiology cause a partial and localized alteration of chromatin structure (chromatin remodeling) in a manner that permits the binding of initiating and regulatory factors.

One important chromatin remodeling system involves the post-translational modification of core histones by acetylation. Nuclear histone acetyltransferases (HATs) catalyze the transfer of an acetyl group from acetyl-CoA on to the ε-amino group of specific lysine residues present exclusively in the amino-terminal tails of each of the core histones. Neutralization of the positively charged lysines reduces the net positive charge of the histone tails and weakens their association with DNA. The displacement of the flexible tails permits subtle changes in nucleosomal structure and a partial unwinding or loosening of the core DNA. The result is an increase in accessibility of transcription factors to their DNA-binding sites. Acetylation does not occur randomly; multiple HATs have specificities for different lysines in the histone tails. Histone deacetylases (HDACs) counter the effects of HATs by restoring the nucleosomes to their transcriptionally repressive configurations.

In the overall scheme (Figure 3), the chromatin structure is transiently and reversibly altered to allow or prevent access of the transcription factors by targeting HATs or HDACs to the core promoter, thereby activating or repressing transcription, respectively. It is now clear that transcriptional activators function by recruiting coactivators, and it is the coactivators that possess HAT activity. Repressors inhibit transcription indirectly by recruiting HDACs via a bridging corepressor.

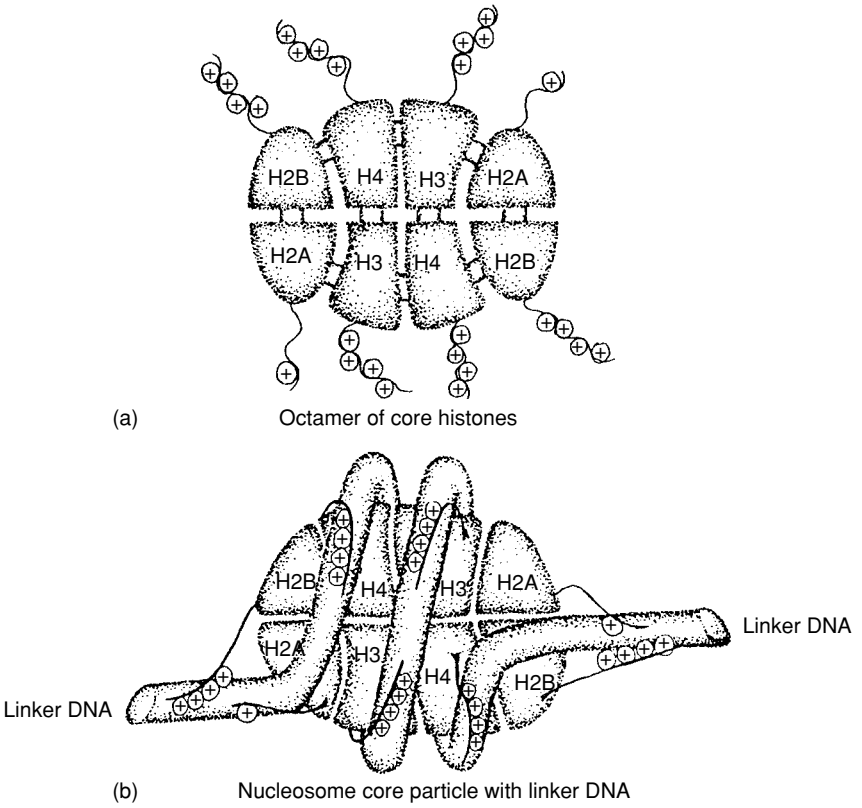

Figure 2 Models for (a) the octamer of core histones, and (b) the nucleosome core particle with linker DNA. From Csordas A (1990) *Biochemical Journal* 265: 23–38 with permission.

α-Tubulin Acetylation

Microtubules are long, stiff, hollow cylinders composed of polymerized α- and β-tubulin dimers. As constituents of the cytoskeleton, microtubules provide structural support for the cell. They also act as lines of transport for the organized movement of mitochondria and other organelles to desired locations within the cell, facilitate delivery of transport vesicles from the Golgi complex to the apical membrane in epithelial cells, and become associated with the centrioles and chromosomes to form the spindle during mitosis and meiosis (cell division). A subset of the α-tubulin is modified, like the histones, by post-translational acetylation of the ε-amino group of specific lysine residues. In contrast to histone acetylation, the acetylation of α-tubulin stabilizes the polymeric structure of the microtubule; deacetylation is coupled to depolymerization.

Acylation of G Proteins

Peptide hormones, being hydrophilic, cannot cross the lipid bilayer of the cell plasma membrane. To overcome this problem, the hormones bind to specific cell surface receptors, and a member of the family of guanine nucleotide-binding regulatory proteins (G proteins) acts as a signal transducer in coupling these receptors to intracellular effector proteins – enzymes that generate the second messenger (e.g., cyclic 3′,5′-adenosine monophosphate, cAMP). The second messenger mediates the biological action of the hormone through the activation of protein kinases.

The posttranslational attachment of palmitate to the G protein α subunit provides the means for reversible translocation of the subunit between the plasma membrane and the cytoplasm. The model shown in (Figure 4) applies to the α_s subunit responsible for stimulation of cAMP synthesis. In the unactivated state, the palmitoylated α subunit–GDP complex, α_{pal}–GDP, is associated with the β/γ subunits and the plasma membrane. Receptor activation stimulates release of GDP and binding of GTP to form active α_{pal}–GTP; the α and β/γ subunits dissociate from each other but remain at the plasma membrane by virtue of their respective palmitate and isoprenyl attachments. Palmitate is rapidly cleaved from α_{pal}–GTP by a palmitoyl esterase, and the depalmitoylated α subunit is released from the membrane into the cytoplasm. Intrinsic GTP hydrolysis converts the active GTP-bound subunits in both membrane and cytoplasm

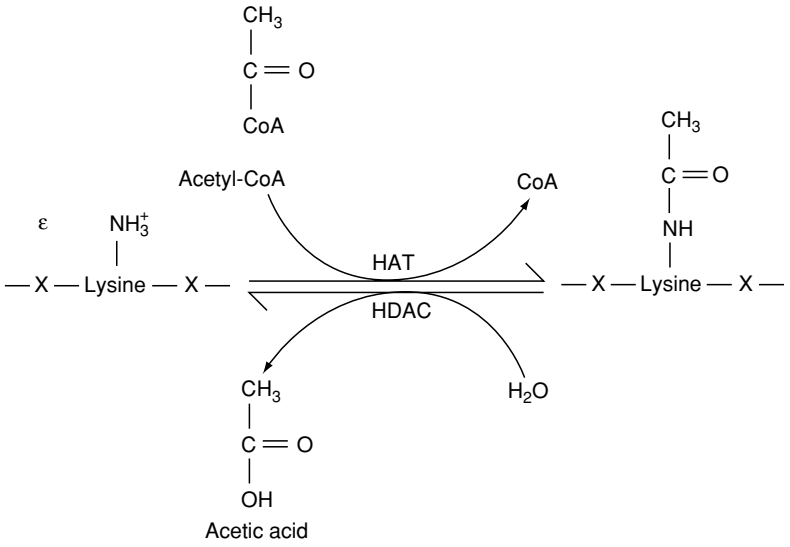

Figure 3 Opposing activities of histone acetyltransferases (HAT) and histone deacetylases (HDAC) in the control of transcription through chromatin remodeling.

into the inactive GDP-bound forms. Reattachment of palmitate to the cytoplasmic subunit by a palmitoyl transferase facilitates the return of the α_{pal}–GDP to the plasma membrane.

The G protein α subunit is further modified by the cotranslational attachment of myristic acid. This increases the affinity of the α subunit with the β/γ subunits, with the plasma membrane, and with the effector protein.

Palmitoylation of Asialoglycoprotein Receptors

The hepatic asialoglycoprotein receptor mediates the endocytosis of desialylated glycoproteins containing terminal galactose or *N*-acetylgalactosamine. (Endocytosis refers to the cellular uptake of macromolecules by entrapment within inward foldings of the plasma membrane, which then pinch off to form intracellular vesicles.) There is evidence that a cycle of palmitoylation and depalmitoylation regulates the ligand-binding activity of the asialoglycoprotein receptor. Inactivation of the receptor by depalmitoylation prevents the rebinding of dissociated ligand molecules and ensures that ligand is shuttled to lysosomes for degradation rather than nonproductively recycled back to the cell surface.

Deficiency in Animals and Humans

Pantothenic acid deficiency has been induced experimentally in many species of animals and birds by feeding diets containing low levels of the vitamin. The wide range of deficiency signs, histopathological abnormalities, and metabolic changes indicate disorders of the nervous system, reproductive system, gastrointestinal tract, and immune system. Rodents are particularly prone to necrosis and hemorrhage of the adrenal glands with consequent impairment of adrenal endocrine function. In young animals, the earliest sign of deficiency is a decline in the rate of growth. Distinctive visible signs are depigmentation of fur in rats and mice, and rough plumage and exudative lesions around the beak and eyelids of chickens. 'Goose-stepping' of the hind legs in pigs and ataxia (falling down to one side) in chicks are associated with demyelination of the motor neurons.

Human pantothenic acid deficiency has been carefully studied in healthy male volunteers given an emulsified artificial diet by stomach tube. In one study, two subjects received the basic diet devoid of pantothenic acid, a second pair received the same diet with added antagonist (ω-methyl pantothenic acid), and a third pair (the controls) received the diet supplemented with pantothenic acid. After about 4 weeks, subjects receiving the antagonist and those in the deficient group began to show similar symptoms of illness. Clinical observations were irritability, restlessness, drowsiness, insomnia, impaired motor coordination, and neurological manifestations such as numbness and 'burning feet' syndrome. The most persistent and troublesome symptoms were fatigue, headache, and the sensation of weakness. Among the laboratory tests, the loss of eosinopenic response to adrenocorticotropic hormone indicated adrenocortical insufficiency.

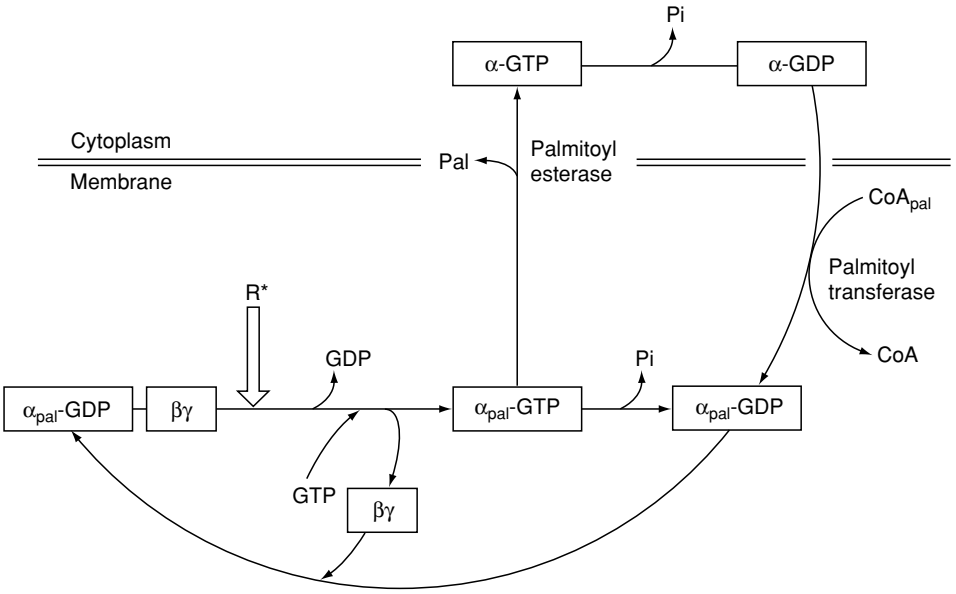

Figure 4 Model of $G\alpha_s$ palmitoylation and depalmitoylation as a means for reversible translocation of the subunit between the plasma membrane and the cytoplasm. R* indicates receptor activation. Modified from Wedegaertner PB and Bourne HR (1994) Activation and depalmitoylation of $G_{s\alpha}$. *Cell* 77: 1063–1070, with permission.

Dietary Intake

A recommended dietary allowance (RDA) for a nutrient is derived from an estimated average requirement (EAR), which is an estimate of the intake at which the risk of inadequacy to an individual is 50%. In the case of pantothenic acid, no data have been found on which to base an EAR, and an adequate intake (AI) is used instead of an RDA by the Food and Nutrition Board of the US Institute of Medicine. The AI for infants up to 12 months old (1.7–1.8 mg day^{-1}) reflects the observed mean intake of breastfed infants. The AI for children aged 1–3 years (2 mg day^{-1}) is extrapolated from adult values. The AIs for children aged 4–13 years (3–4 mg day^{-1}), and adolescents and adults of both sexes (5 mg day^{-1}) are based on pantothenic acid intake sufficient to replace urinary excretion. AIs for women during pregnancy and lactation are 6 and 7 mg day^{-1}, respectively.

There are no known toxic effects of oral pantothenic acid in humans or animals.

PAPAYAS

J H Moy, University of Hawaii at Manoa, Honolulu, USA

Introduction

Papaya, a mildly sweet, melon-like tropical fruit belonging to the family Caricacae, is a native of tropical America (Central America and the Caribbean, including Mexico, Costa Rica, and the Bahamas). After the Spaniards took the fruit to Luzon Island in the Philippines in the mid sixteenth century, it reached Malacca shortly afterward, and then India. It has been widely grown throughout tropical and subtropical regions such as Australia; Hawaii, Florida, Texas, California, and Puerto Rico in the USA; Peru; Venezuela; various parts of Central and South Africa; and Bangladesh, Pakistan, and India. The Australians call it 'pawpaw' while the Venezuelans call it 'lechosa.'

Fruit size may vary from less than 0.5 kg to 3 kg. A climacteric fruit, it is mainly consumed fresh when ripened after harvest. Ripening is judged by the approximate percentage of yellowness on its skin, and more accurately by measuring its total soluble solids (TSS) contents with a refractometer. Export-grade papayas grown in Hawaii should have a minimum of 11.5% TSS. Firmness, as gaged by touch or by a texture-measuring device, is another way of judging ripening. The firmness is related to the biochemical changes in three fractions of pectins in papayas, and is not a very accurate index of ripeness. Green papayas can also be consumed as a salad or in soups, both of which are quite popular in South-east Asia.

Hawaii, part of the USA, is the world's largest exporter of papayas, with about 16 000 t in 1999, valued at US$14.15 million. Most of the outshipments are to the US mainland, with about 25% going to Japan. Brazil is the second largest exporter, with most papayas going to European countries such as Germany, France, and the UK. Kenya, the Ivory Coast, and Malaysia also ship papayas to European markets. For recent shipment statistics, (*See* **Fruits of Tropical Climates**: Commercial and Dietary Importance.)

Species and Cultivars

Papaya belongs to the family Caricaceae – a small, somewhat anomalous family with four genera and 31 species, of which three are in tropical and subtropical America and one in Africa. The genera and the number of included species are: *Carica*, 22; *Facaratia*, 6; *Farilla*, 1; and *Cylicomorpha*, 2. The edible fruits are found only in *Carica*, of which *C. papaya*, the common papaya, is extensively grown. Other species include: *C. chilensis, C. goudotiana, C. monoica*, and *C. pubesceus*. *C. candamarcensis*, known as mountain papaya, grows to a height of about 2.5 m, tolerates low temperature, and thrives well at an elevation between 1500 and 2000 m. *C. monoica* grows in the Amazon basin.

A large number of papaya cultivars are grown in different parts of the tropical and subtropical regions. However, none are true cultivars because they do not reliably transmit the parental characters to all their progeny. Some of the better known cultivars are listed below, with their average weight in kg in parentheses:

1. Washington (0.9–1.0)
2. Honey dew (1.1–1.5)
3. Coimbatore 1 (1.2–1.5) – a selection from the progenies of cv. *Ranchi*
4. Coimbatore 2 (1.0–1.5) – a high papain-yielding cultivar
5. Coimbatore 3 (0.9–1.0) – a hybrid between Co. 2 and Sunrise Solo
6. Coimbatore 4 (1.3–1.5) – a cross between Co. 1 and Washington (The coimbatore cultivars were released from the Tamil Nadu Agricultural University, Coimbatore.)
7. Pusa Delicious (1.0)
8. Pusa Majesty (0.95)
9. Pusa Giant (1.9)
10. Pusa Dwarf (1.0) (The pusa cultivars were bred at the India Agricultural Research Institute Regional Station, Pusa, Bihar.)
11. Sunrise Solo (0.4–1.0) – red-fleshed
12. Sunset Solo (0.4–1.0) – red-fleshed
13. SunUp (0.4–1.0) – a genetically transformed sunset, red-fleshed
14. Kapoho Solo (0.5–1.4) – yellow-fleshed

15. Waimanalo Solo (0.5–1.4) – yellow-fleshed
16. Rainbow (0.5–1.4) – a transgenic cross between Kapoho and SunUp, yellow-fleshed (The two transgenic cultivars have been grown on the island of Hawaii since 1998)
17. Pink-Fleshed Sweet (0.85)
18. Thailand (1.9–2.2)

Other important cultivars are: Guinea Gold, Sunnybank, and Hybrid 5 (Australia); Hortus Gold and Honey Gold (South Africa); Tai Ning No. 2, Panama red and Solo No. 1 (Taiwan); Red Rock and Cariflora (Florida, USA); Red Fleshed, (Philippines); Madhubindu, Barwani, Ranchi, and Peradeniya (India).

Figure 2 (see color plate 120) Thailand cultivar growing in Thailand, weighing 2.50 kg.

Botany and Horticulture

Papaya is a herbaceous, unbranched plant. Its stem is supported by phloem fibers encircling a hollow stem, which can grow up to 8–10 m high. Its leaves are large, deeply lobe-shaped with long hollow petioles, and spirally crown the stem. Flowers, male and female, can be on the same plant (monoecious) or on separate plants (dioecious), or as male and female parts on the same flower (hermaphrodite).

Papaya fruits are mostly round in the female tree and cylindrical and pear-shaped in the hermaphrodite tree. Underneath the smooth, thin skin (green when immature, orange-yellow when ripe) is a thick layer of deep yellow to orange-red pericarp with an elliptical, central cavity containing many small, round black seeds coated with jelly-like tissues (Figures 1 and 2).

Planting

The three major environmental factors to consider in selecting a site to grow papayas are temperature, moisture (rainfall and soil drainage), and wind. The hermaphrodite papaya plant preferred for commercial orchards is more sensitive to its growing environment than the female papaya plant. Selection of a suitable site is therefore critical. Another condition to consider is the amount of sunlight the site receives to support plant growth and fruit production. Insufficient sunlight results in fruits with inadequate sugar and low yields, and encourages plant diseases that affect papaya production.

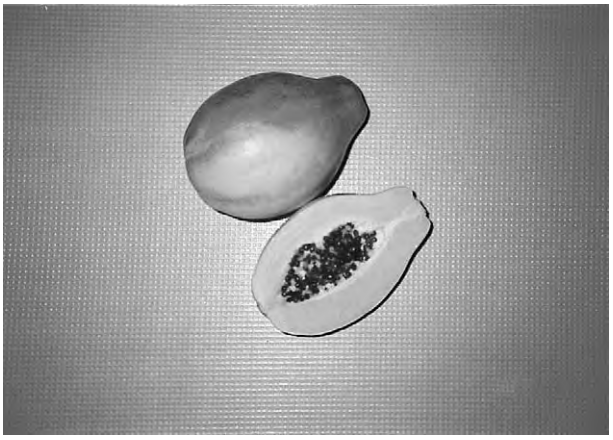

Figure 1 (see color plate 119) Rainbow cultivar growing in Hawaii, weighing 0.66 kg.

The temperature of the site is the most important factor. Optimal production is generally limited to elevation under 160 m within a temperature range of 16–31 °C. Temperature below 16 °C could cause carpeloidy, resulting in 'cat-face' deformity when floral stamens develop abnormally into fleshy, carpel-like structures. High temperature (32–35 °C) may induce female sterility, in which normally hermaphroditic papaya plants produce male flowers, resulting in poor fruit set and production.

A minimum monthly rainfall of 10 cm and an average relative humidity of 66% are considered ideal for papaya growth and production. Drip irrigation can supplement low rainfall. Good soil drainage is also essential. When soil drainage is restricted, papaya is susceptible to fungal root diseases. The plants are severely affected by waterlogging and can be killed when subjected to puddled conditions for even a few hours. The Puna area on the island of Hawaii is well-suited to commercial papaya production because of the very porous lava soils.

Papaya plants must be protected from wind. Plants exposed to constant wind develop deformed, crinkled leaves. When wind stress damage is excessive, the plant growth, fruit set, fruit quality, and productivity will be reduced. Wind-blown dust can cause sap bleeding that harms fruit appearance. In coastal

areas, salt spray carried by wind can desiccate leaves and kill papaya plants. Winds of 64 km h^{-1} can uproot papaya trees growing in mineral soils, especially when accompanied by heavy rain. Windbreaks should be established well in advance of planting a papaya crop. On the other hand, adequate air movement is important in reducing incidence of fungal diseases such as *phytophthora* and *anthracnose*. These diseases can become severe when there is excessive free moisture and high humidity around the plant.

Papaya can either be seeded directly or transplanted into a new field. Direct seeding can be practiced in porous soil. Six-week-old seedlings can be transplanted into less porous fields. Planting in 'virgin' lands or fields in which papaya has not been grown before is preferred because of low disease and insect pressure. However, it is becoming increasingly difficult to find such fields. Other important horticultural aspects of planting papaya are plant sex selection, thinning, fertilizer applications, leaf trimming, weed control, pest management, and disease control.

Transgenic Cultivars

For more than four decades, papaya production in the Hawaiian island chain was severely affected by the papaya ringspot virus (PRV). In the 1960s, papaya planting was forced to move from the island of Oahu to the Puna area of the island of Hawaii. Since 1992, the introduction and subsequent spread of PRV in commercial orchards in Puna has resulted in a significant decrease in papaya production in the state of Hawaii.

The only solution seemed to be to produce a transgenic cultivar that would be resistant to the virus. Faced with this extremely challenging task, molecular biologists from Cornell University, the University of Hawaii, and the Upjoin Company collaborated from 1987 to 1991 to obtain the first transformed plant that appeared to have PRV resistance. It took several more years for plant breeders at the University of Hawaii to inbreed the resistant plant to produce a tree-breeding, redfleshed cultivar that was named UH sunup (also referred to as *SunUp*). Because the papaya industry wanted a yellow-fleshed fruit, plant breeder Richard Manshardt crossed *SunUp* with *Kapoho* to produce a yellow-fleshed F_1 hybrid that was named *UH Rainbow* (also called *Rainbow*).

SunUp is totally resistant to the virus, but *Rainbow*, in greenhouse studies, has shown susceptibility to PRV until about 7 weeks of age. This is referred to as young plant susceptibility. The plants become fully resistant to PRV after 3 months of age. The hybrid *Rainbow* has some differences from the *Kapoho*: (1) a lower sex-segregation ratio; (2) plants grown from seeds of F_1 hybrids do not breed true; (3) a higher sensitivity to calcium deficiency; (4) more sensitive to *phythophthora* and will require timely application of fungicides; and (5) ripens faster than *Kapoho* but slower than *Sunrise* fruits.

These two lines of transgenic cultivars have been rigorously reviewed and approved by three US agencies: the US Department of Agriculture (USDA), the Environmental Protection Agency (EPA), and the Food and Drug Administration (FDA). The USDA determined that these new plants would not contaminate other existing germ plasma, and they would not foster a new strain of virus. The USDA concluded, therefore, that they posed no hazards to agriculture in the USA. The EPA sets tolerance limits for regulated chemicals. The coat protein used in the genetic engineering process was considered a pesticide, to be regulated because its function is to eliminate diseases. The EPA subsequently agreed with University of Hawaii scientists that there was no tolerance required for coat protein. The FDA's job is to protect the public from unsafe products. The FDA was satisfied that the nutrients of the original material (fruit) were retained, and therefore did not require a toxicity test. All three agencies declared the two transgenic cultivars safe for human consumption.

Those wishing to purchase seeds of transgenic papaya cultivars must adhere to a licensing process as well as sign a sublicense agreement with the Papaya Administrative Committee in the state of Hawaii.

Nutrient Composition and Fruit Chemistry

Nutrient Composition

The papaya fruit is a good source of ascorbic acid (vitamin C) and carotenoids (provitamin A), two important nutrients for people in the subtropical and tropical regions. Table 1 shows the nutrient composition of papaya from data published in 1965, 1990, and 1999.

Chemistry and Biochemistry

Sugars are the principal carbohydrates in papayas, with very little starch. Refractometric measurements of total soluble solids (%TSS) show some differences in various cultivars. Those grown in Florida have been reported to range from 5.6 to 7.2%; those in India vary from 6.5 to 13%, while the Hawaiian cultivars measure 11.5–13.5%. The sugars in ripe papayas in which the invertase has been inactivated were reported to be 48% sucrose, 30% glucose, and 22% fructose.

Papaya is a low-acid fruit, with the total titratable acidity of about 0.1% calculated as citric acid. The

Sources of data: Wenkam NS and Miller: CD (1965) *Composition of Hawaii Fruits*. Bulletin 135. Honolulus, Hawaii: Hawaii Agricultural Experiment Station, University of Hawaii at Manoa; Muthukrishnan CR and Irulappan I (1990) In: Bose TK and Mitra SK (eds) *Fruits*: Tropical and Subtropical, pp. 303–335. Calcutta: Naya Prokash. Moy JH, Paull RE, Bian X, Chung R and Wong L (1999) Quality of tropical fruits irradiated as a quarantine treatment. In: Moy JH and Wong L (eds). *Proceedings of the workshop on the use of Irradiation as a Quarantine Treatment of Food and Agricultural Commodities* pp. 45–53. Honolulu, Hawaii: College of Tropical Agriculture and Human Resources, University of Hawaii and Dept of Hawaii, State of Hawaii.

pH of the pulp ranges from 5.5 to 5.9, far higher than the pHs of other tropical fruits at 3.2–4.5, which explains the low tartness of the papaya fruit. The organic acids in papayas are mainly equal amounts of malic and citric acid, with smaller amounts of ascorbic and α-ketoglutaric acid.

The volatile flavors of papayas were reported to consist of 124 compounds. Linalool is the major component with characteristic fresh papaya aroma and flavor. Benzyl isothiocyanate, another major component, has a pungent off-aroma. Other off-aroma, off-flavor compounds in papaya pulp have been identified as butyric, hexanoic, and octanoic acids and their corresponding methyl esters. These components were analyzed with gas chromatography and mass spectrometry. (*See* **Chromatography**: Gas Chromatography; **Flavor (Flavour) Compounds**: Structures and Characteristics; **Mass Spectrometry**: Principles and Instrumentation.)

Carotenoids are the pigments of the ripe papaya flesh, which is deep yellow. Red-fleshed papaya cultivars additionally contain lycopene, which gives the pulp an orange-red color. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

In addition to papain being an economically important enzyme in green papaya, several other enzymes play a role in the stability and quality of processed papaya products. Pectinesterase (3.1.1.11), the enzyme responsible for gel formation in unheated papaya purée, contributes to some increase in acidity in purée as a result of demethoxylation of the carboxyl groups in the pectins. Thioglucosidase (myrosinase) (3.2.3.1) is responsible for generating benzyl isothiocyanate, a sulfurous, pungent, odiferous compound which contributes to the off-aroma of papaya products. When fruit tissues are macerated, acid phosphatase (3.1.3.2) catalyzes the hydrolysis of the P–O bond of orthophosphoric monoesters, producing ROH and phosphoric acid, which increases the acidity of the purée. Another enzyme, β-fructofuranosidase (invertase) (3.2.1.26), is responsible for the hydrolysis of sucrose to fructose and glucose.

Harvesting, Handling, and Storage

Summer fruits become mature in 22 weeks, while 26 weeks are needed during the winter. Fruits are typically harvested weekly or twice weekly at color-break (a tinge of yellowness on a green fruit) by hand, or with the aid of a cut-off 'plumber's helper' (a rubber suction cup) attached to a pole for hard-to-reach fruits. Fruits can also be harvested with a ladder, or from a large fruit bin mounted on a tractor high-lift. Careful handling with minimal bruising and abrasion helps with postharvest sorting, packing, shipping, and marketing.

To control fungal decay of postharvested fruit, a dip in hot water at 49 °C for 20 min was found to be very effective. Hot-water spray with fungicide or a wax dip containing fungicide is also effective.

Storing papayas at temperatures below 7 °C after harvest can result in chill injury. The recommended storage temperature is 10 °C.

Quarantine Treatment

Fruit flies and other insect pests are prevalent in the tropics and the subtropics. Most soft tropical fruits are prone to infestation by fruit flies. A quarantine treatment approved by the plant quarantine authority of each country must be applied to fruits before they can be exported to noninfested areas. Up until 1984, chemical fumigants such as ethylene dibromide (EDB) were widely used, until tests showed them to be carcinogenic to laboratory animals. Since then, quarantine treatment options are thermal or cold treatment, or irradiation.

Papayas grown in Hawaii are infested with four species of fruit flies: the Oriental fruit fly (*Dacus dorsalis*), the Mediterranean fruit fly (*Ceratitis capitata*), the melon fly (*Dacus cucurbitae*), and the Malaysian fruit fly (*Bactrocera latifrons*). After EDB was banned, a double-dip hot-water treatment (42 °C for

30 min, 49 °C for 20 min) was used but was abandoned after 3 years because a high percentage of treated fruits became injured by the heat. Subsequently, two other thermal treatments were used. One is a modified vapor heat treatment, and the other is called a high-temperature forced-air (HTFA) procedure. Both are very similar. The difference is the relative humidity of the heated air admitted to the treatment chambers. The air in the vapor heat treatment has moisture added to the air throughout, with the relative humidity kept at 90% or above. In the HTFA method, ambient air is heated and admitted into the chamber, and only in the last hour of a 4-h treatment is the relative humidity required to be kept at 90–100%. Both methods require about 4 h to reach the endpoint, which is when the center of the fruit reaches 47.2 °C. Fruits are then cooled with a water spray for about 30 min. Several fruit packers in Hawaii are using these methods, which work quite well. However, both are time-consuming and commodity-specific. Total uniformity in heating is also difficult to achieve because of variation in fruit size, fruit ripeness (affecting thermal conductivity and heat transfer rates), and physical locations within a chamber. After heat treatment, it is common to find lumpy texture and lack of flavor in a few percent of the heat-treated fruits in each batch, caused by enzymes responsible for ripening being inactivated by heat.

Cold treatment requires that fruits be kept at 1 or 2 °C for 12–14 days to immobilize and inactivate fruit fly eggs and larvae before the fruits can be taken to the supermarkets. Not many tropical fruits can tolerate this time–temperature regime, papaya being one of them.

Though somewhat controversial, several decades of research in Hawaii and in other parts of the world have proven that irradiation is the most efficacious quarantine treatment procedure. The treatment is efficient (15–20 min in a commercial irradiator) and effective (all fruits are thoroughly irradiated to cause the fruit fly eggs and larvae to be sexually sterilized, regardless of fruit size and ripeness). Irradiated papayas ripen normally or slightly delayed, and their chemical, physical, nutrient, and sensory qualities are well retained. Radiation sources can be gamma-rays (from cobalt-60), an electron beam (with limited penetration), or X-rays (converted from e-beam). Fruits irradiated will not become radioactive because there is a limit on the energy level used. In April 1995, Hawaii became the first place in the world to use irradiation as a quarantine treatment of its papayas and other tropical fruits. The generic quarantine dose approved by the USDA is 0.25 kGy. Starting in 2001, more countries will be using this technology to treat their fruits for export markets.

Processed Products

Chunks (Refrigerated or Frozen)

After being washed, deseeded, and peeled, papayas can be cut into chunks, then refrigerated or frozen as a convenient food. It is available in some supermarkets in the salad section. Another niche market for this type of product is the airlines. A number of airlines prefer the convenience of serving these prepared fruits to their passengers. The frozen chunks are more suitable for serving with ice cream or for further manufacturing into dessert products.

Canned (Mixed with Other Fruits)

Papaya can be made into a canned product, or as a cocktail of several fruits. Chunks or dices of papayas or mixed fruits can be filled into a can and covered with hot (75 °C), acidified syrup (*c.* 40° Brix with pH adjusted to 3.6–3.8 with citric acid: 40° Brix = 40 g of sugar mixed with 60 g of water at 20 °C). After the air in the head space in the cans (*c.* 6.3–8.0 mm) has been exhausted by steam, the cans are sealed and pasteurized with steam, or in a boiling-water bath. (*See* **Canning**: Principles.)

Purée

Papaya purée is prepared in the form of a free-flowing paste, without seeds, skin, or unwanted fiber. The purée can be an intermediate product used for manufacturing several end products such as juices, nectars, jams, jellies, syrups, and dried fruit rolls or leathers. Papaya purée and other fruit purées in the USA can be manufactured with a high degree of mechanization. Several aspects of purée manufacturing are important to produce a quality product.

1. Ripe papaya fruits should be steamed for 2 min to coagulate the latex in the peel, preventing the latex from entering into the purée. Also, steaming increases purée yield by softening the outer layers of the fruit, and inactivates enzymes in the peel. The fruits are spray-cooled to remove the residual heat.
2. Fruits are sliced, crushed, and dropped into a centrifugal separator. All the skin and most of the seeds are separated. The remaining seeds are separated in a paddle pulper fitted with rubber paddles and a small screen (*c.* 0.80–0.85 mm).
3. The purée is acidified with citric acid (a 50% solution) to a pH of about 3.4–3.6 to inhibit gelatin of the purée. Acidification also helps control microbial activity and enhances the effect of subsequent heat pasteurization.

4. A smooth purée can be obtained by passing the liquid through a paddle finisher with a 0.50 mm screen to remove seed specks and undesirable fiber.
5. The purée is pasteurized in a heat exchanger at 94 °C for 2 min, then cooled to a few degrees above ambient temperature.
6. The purée can be aseptically packed in suitable flexible containers, or frozen in bulk at − 20 °C or below.

Beverages

Juice, drinks, nectars, and cordials can be prepared from papaya purée through formulation by adding appropriate amounts of water, sweeteners, and acidulants to the purée. Commonly used acidulants include citric acid, malic acid, lemon and lime juice. These beverages can be pasteurized in bottles or cans after being acidified to a pH below 4.4.

Dried Products

Several forms of dried products can be prepared from papaya slices. Since papaya is a soft fruit when fully ripe, three-quarter ripe fruits are more suitable for preparing dried slices. Drying can be carried out in a hot-air drier, a vacuum drier or a freeze drier, with increasing product quality but correspondingly higher cost. Solar drying of papaya slices is also a very practical means of preserving papaya with good quality. The final moisture content of dried papaya should be around 5–8% (wet weight basis). Good packaging is important to retain quality and to prevent insects from entering the package. University of Hawaii researchers have designed and built a continuous solar drier on the island of Kauai in Hawaii, capable of drying 450 kg of papaya slices within a 24-h period. This drier uses only renewable energy – solar and biogas.

University of Hawaii researchers have also developed a vacuum-puff freeze drying process to make high-quality juice powder, including papaya. The process involves mixing a papaya purée with a small amount of sucrose, freezing the mixture, and then placing it into a freeze drier. Initially, the purée–sucrose or juice–sucrose mixture puffs into a foam when raised to its freezing point. It then refreezes under a good vacuum. The endpoint is reached when 1% of moisture is left. The freeze-dried product is a crystalline powder, and can be rehydrated into a nectar, similar to freeze-dried coffee. Freeze-dried powders also retain the color and flavor of the original purée or juice with the right degree of sweetness.

Papain

Source

A milky latex in immature papaya fruit contains an enzyme called papain. Papain from the dried latex is in great demand on the international markets, especially in the UK and the USA.

Properties

Papain is a proteolytic enzyme, capable of hydrolyzing or breaking down protein materials.

Applications

In the food, pharmaceutical, textile, and tanning industries, papain is used as a meat tenderizer; for clearing beer; in the manufacture of cosmetics such as face creams and dental creams; in degumming silk and rayon; in the preshrinking of wool; and in tanning leather.

In the medical field, papain can be used to treat necrotic tissues, dyspepsia and other digestive ailments, ringworm and roundworm infections, skin lesions and ulcers, eczema, and other skin diseases and kidney disorders. Papain is used in detecting stomach and intestinal cancers and also in correcting diphtheria.

Production

The latex of a green papaya drips into a container after the skin is slit. Papain is the dried latex in powder form. The collection of latex is very labor-intensive. Papain production is influenced by several factors:

1. Fruit size and shape: oblong fruits 36 cm in length and 28 cm in diameter were found to give the highest papain yield. In general, papain yield increases with increasing fruit size.
2. Fruit maturity: unripe but fully grown fruits yield maximum papain, especially when fruits have been grown to 75–90 days after fruit set.
3. Season: the flow of latex is low if the temperature is below 10 °C.
4. Cultivars: in India and Sri Lanka, cultivars found to have high papain yield were Washington, Philippine, Botanist's Selection, Peradeniya and Coimbatore 1.

Yield

Papain yield varies from 1.23 to 7.45 g per fruit among nine cultivars, with the cultivar Washington recording the highest mean yield of 7.45 g per fruit. In a papaya tree, the total papain yield can vary from 150 g to 227 g.

Role of Papaya in Human Health

The flesh of papaya contains high levels of three carotenoids: β-cryptoxanthin, β-carotene, and lycopene. Different papaya cultivars vary in concentrations and ratios of these carotenoids. It has been reported that many individual carotenoids, including β-carotene and lycopene, have the ability to prevent transformation of cells to cancer phenotypes in a model system *in vitro*. No study has considered carotenoid combinations as they occur in fruits, such as papaya, and the possibility of synergistic effects via multiple inhibitory mechanisms. Research has been proposed to study the effectiveness of various combinations of carotenoids as inhibitors of cancer development in mammalian systems, and the cellular and molecular mechanisms if it proves to be effective. The implication is that fruits rich in carotenoids and lycopene such as papaya and tomato could be beneficial to human health.

Occurrence and Detection

J Melo-Cristino, Faculdade de Medicina de Lisboa, Lisbon, Portugal
J Botas, formerly of Hospital de Santa Maria, Lisbon, Portugal

Importance of Parasites in Human Infection

Parasites are a heterogeneous group of invertebrate animals, including unicellular microrganisms (protozoa) and multicellular organisms with organ systems (helminths), which can infect a diversity of other animals, including humans.

Human infections are frequently acquired by ingestion of contaminated water or food. They are important all over the world and their prevalence can be very high, especially in tropical and subtropical regions. Many parasites have a worldwide distribution, but others occur in limited endemic areas. However, frequent and rapid travel of people from nonendemic areas (tourists, scholars, business people, military personnel, immigrants, etc.) returning from visits to endemic areas contributes to infection by such parasites.

The spectrum of human disease is extremely wide. Many parasites are not noticed, and the infection is asymptomatic, while others are major human pathogens and are responsible for high morbidity and mortality. Infections may have an acute onset with intense symptoms or may require months or years before becoming clinically evident. Recently, some parasites

have become more important as they have been recognized as major pathogens in immunocompromised hosts, particularly in patients with acquired immune deficiency syndrome (AIDS). (*See* **HIV Disease and Nutrition.**)

Protozoa Involved in Foodborne and Waterborne Human Infection

The most significant foodborne and waterborne protozoa are shown in Table 1. They are classified into phylum Sarcomastigophora (amoebae and flagellates), phylum Ciliophora (ciliates), phylum Apicomplexa (coccidia), and phylum Microspora (microsporidia). Characteristics for differentiation include motility and stages in life cycles and replication.

Motility is accomplished by different mechanisms, namely pseudopodia in amoebae, flagella in flagellates, and movement of rows of cilia in ciliates. Coccidia and microsporidia are essentially nonmotile obligate intracellular parasites.

The life cycles of amoebae, flagellates, and ciliates include two stages, the trophozoite and the cyst. The trophozoite is the vegetative, motile, feeding stage usually found in the intestine. The cyst is the resting, resistant, thick-walled infective stage excreted in feces. Replication is accomplished by binary fission of trophozoites or by development of several trophozoites inside mature cysts.

Coccidial life cycles include stages of asexual development (trophozoite, schizont or meront and merozoite) and stages of sexual differentiation (microgamont and macrogamont) that lead to the production of oocysts, which are shed in feces. The oocyst, containing sporozoites, which may require a period of maturation outside the host, is the resistant and infective stage. Microsporidia multiply by binary fission or multiple fission, producing spores which are excreted in urine or in feces. The spore possessing the infective agent or sporoplasm is the resistant stage.

Helminths Involved in Foodborne and Waterborne Human Infection

The most significant foodborne and waterborne helminths are shown in Table 2. Helminths comprise the phylum Nematoda (nematodes) and the phylum Platyhelminthes (trematodes and cestodes).

Nematodes or roundworms have cylindrical bodies, separate sexes and a complete digestive system. Life cycles can be simple and direct or complex with one or more intermediate hosts. Hosts are defined as intermediate hosts when they harbor an asexual stage of the parasite and definitive hosts when they harbor the sexual stage.

Trematodes or flukes have flattened leaf-shaped bodies, and most are hermaphroditic with an incomplete digestive system. They have complex life cycles, with snails serving as first intermediate hosts and other aquatic animals as second intermediate hosts. Some trematodes may also encyst on aquatic plants.

Cestodes or tapeworms have segmented ribbon-like bodies, are hermaphroditic, and lack a digestive system. Some have direct life cycles, while others need one or more intermediate hosts. Infective stages of helminths include eggs laid by adult worms and asexual stages encysted in animal tissues or on plants.

Occurrence of Parasites in Foods and Water and Mechanisms of Entry into the Food Chain

Parasites have access to food and water by two routes. One is by contamination with the feces of infected humans or animals passing infective resistant stages such as cysts and oocysts of protozoa and eggs of helminths. Another route exists when an infective

Trichuris trichiura		

viable stage of the life cycle of a parasite is present in animal tissues or on plants.

Environmental contamination with human or animal faeces is correlated with socioeconomic conditions and occurs more frequently in areas with poor sanitation and poor personal hygiene. However, even in developed countries, the use of animal or human feces as a fertilizer may be responsible for the contamination of natural water courses, wells or water supplies. As a consequence, fruits and vegetables may be contaminated during irrigation. Flies and other arthropods may also have an important role in passive transmission.

Prepared food may also be contaminated either by use of polluted water during preparation or by food handlers who are carriers. Asymptomatic carriage is common, and carriers may be reservoirs of the parasites and may excrete infective stages, continuously or intermittently, for long periods of time. Many excreted stages (cysts, oocysts, and eggs) are very resistant and may survive in the environment for weeks or months.

Parasites which may cause human infection transmitted by water or foods contaminated with feces include all protozoa shown in Table 1 and the helminths *Ascaris lumbricoides, Enterobius vermicularis, Trichuris trichiura, Capillaria hepatica, Hymenolepis nana, H. diminuta, Echinococcus granulosus, E. multilocularis*, and *Multiceps multiceps*.

Cryptosporidium parvum and *Cyclospora cayetanensis*, in particular, have been responsible for several large outbreaks resulting from either contaminated drinking water or contamination on food (fruits or vegetables).

Many of them are human intestinal parasites with no known animal reservoirs, including the amoebae, *Dientamoeba fragilis, Isospora belli, A. lumbricoides, En. vermicularis*, and *T. trichiura*. Therefore, their presence implies contamination with human feces. Furthermore, the presence of human commensal or nonpathogenic amoebae also implies contamination with human feces and reflects the possibility of transmission of pathogenic species.

The most significant helminths causing human infection by ingestion of foods containing viable asexual infective stages are shown in Table 3. *Toxoplasma gondii* and *Sarcocystis* spp. are protozoa which may be transmitted to humans by ingestion of infected meat.

Ingestion of raw or improperly cooked meat, as well as sausages, dried, cured, and smoked meat from animals serving as intermediate hosts, is a frequent cause of infection. Examples of parasites transmitted by beef include *To. gondii, Sarcocystis* spp., and *Taenia saginata*. Pork is implicated in the transmission of *To. gondii, Sarcocystis* spp., *Taenia solium*, and *Trichinella spiralis*. Other livestock raw meat may transmit *To. gondii*. Crustaceans involved in transmission of parasites include crabs (*Paragonimus westermani, Angiostrongylus* spp.), prawns and shrimps (*Anisakis* spp., *Angiostrongylus* spp.). (*See* **Shellfish**: Contamination and Spoilage of Molluscs and Crustaceans.)

Uncooked aquatic vegetables, where infective metacercariae encyst, such as water chestnuts and watercress may be responsible for human infection with the trematodes *Fasciolopsis buski* and *Fasciola hepatica*, respectively.

Fate on Processing/Storage

Protozoal cysts or oocysts and helminth eggs are moderately or highly resistant to chlorination at concentrations used to disinfect water, e.g., *Cryptosporidium* spp., *Giardia intestinalis, A. lumbricoides*, and *T. trichiuria*. They are, however, generally susceptible to heat and to freezing at −20 °C.

Helminth-encysted metacercariae or infective larvae in meat, fish, or crustaceans are generally killed by heating and by prolonged freezing at −20 °C. However, they often resist smoking, curing, or pickling, e.g., *Tr. spiralis*.

Detection in Foods and Water

Incrimination of foods and water in the transmission of parasites is almost always indirect and based on epidemiological association. Direct isolation of these parasites from foods or water is very difficult. Water-filtration techniques for detection of cysts, oocysts, or eggs may be used, but too often with poor results. Enrichment culture media are not currently available in microbiology laboratories. Thus, it is not possible to recover small numbers of parasites from foods or water by *in-vitro* culture methods. Furthermore, the viability and infectivity of a parasitic stage cannot be assessed.

Direct incrimination of food in human infection is obvious when ingestion of an infected food is the only possible way for the infection to occur. All parasites in Table 3 belong to this group. Encysted larvae of *Tr. spiralis*, *Ta. solium*, and *Ta. saginata* may be detected in raw meat after specific procedures, such as enzymatic digestion. A similar approach to raw fish may have little practical value. Other helminths, e.g., *E. granulosus* and *F. hepatica*, may be detected by the examination of viscera from livestock animals.

Detection in Humans

The diagnosis of a parasitic infection can be made directly by the finding and identification of the parasite, or indirectly by immunological methods detecting specific antibodies. DNA probes, other molecular techniques, and immunological methods using monoclonal antibodies for the detection of specific parasitic antigens in serum and in body tissues have recently been described and are promising powerful diagnostic tools for the future.

Intestinal parasites are currently diagnosed by morphological identification of trophozoites, cysts, oocysts, eggs, or adult worms in feces, whereas tissue parasites are generally diagnosed by immunological methods.

Microscopic examination of fecal specimens by direct wet mount, wet mount after concentration and/or permanent stains, is the most important method for the diagnosis of intestinal or biliary parasites. As excretion is variable, at least three specimens should be examined, the specimens being collected at 2- or 3-day intervals.

Tissue parasites may occasionally be diagnosed by direct detection and identification in biopsy material from lesions. History of traveling into endemic areas combined with appropriate clinical symptoms and radiological, ultrasound, or computed tomography examinations may be very important diagnostic clues. However, detection of rising titers of specific antibodies is the most useful way to establish the diagnosis. Current immunological methods include complement fixation indirect immunofluorescence, indirect hemmaglutination, enzyme-linked immunosorbent assay, immunoelectrophoresis, and double-diffusion tests. In immunocompromised patients, these tests are less satisfactory for the diagnosis of infection. Recently, several easy-to-use antigen detection tests have become available and are of particular value in the diagnosis of *Giardia intestinalis*, *Cryptosporidium parvum*, and *Entamoeba histolytica*. (*See* **Immunoassays**: Principles; Radioimmunoassay and Enzyme Immunoassay.)

Specific Examples

Cryptosporidium spp.

Cryptosporidium spp. have a worldwide distribution and are responsible for enteric infection in humans and many animals, especially cattle and sheep. Infection is acquired by ingestion of water or food containing oocysts, which are excreted in an infective form that does not need maturation outside the gut. Transmission can occur from animals to humans (zoonotic) as well as from humans to humans (nonzoonotic).

Oocysts are highly resistant to chlorination but are sensitive to heat and prolonged freezing. Diagnosis is by microscopic detection of oocysts in fecal specimens stained by the acid-fast technique or immunofluorescence, as well as by antigen detection assays.

Giardia intestinalis

G. intestinalis has a worldwide distribution and is responsible for the most frequently reported human protozoal infection. Giardias is an intestinal infection associated with poor socioeconomic conditions. Infection is acquired by ingestion of food or water contaminated with feces. Cysts are the infective stage excreted in feces of humans and other animals. Asymptomatic carriage and excretion are frequent. Cysts can be found in water, sewage, vegetables, fruits, and other food. They resist chlorination but are killed by heat and by prolonged freezing. Diagnosis is by microscopic identification of cysts in fecal specimens. Trophozoites may sometimes be detected in feces from patients with diarrhea.

Toxoplasma gondii

Toxoplasmosis is a worldwide zoonosis. Prevalence of human infection increases with age and is generally 30–70%. Infection is acquired by ingestion of infective oocysts from cat fecal contamination or by ingestion of improperly cooked meat from animals serving as intermediate hosts, e.g., pork, mutton, and beef. Oocysts need a period of maturation outside the cat bowel. Cysts in meat are killed by heating, by smoking or curing, and by prolonged freezing at −20 °C. Diagnosis is by demonstration of specific immunoglobulin (IgM) antibodies or increasing IgG antibody titers in blood by immunological tests. These tests are not satisfactory in immunocompromised patients with latent or reactivated infections.

Ascaris lumbricoides

A. lumbricoides has a worldwide distribution but is more prevalent in areas of poor sanitation, with 25% of the world's population estimated to be infected. It is the most common helminthic parasite causing human infection. No animal reservoir is known. Infection is acquired by ingestion of water or food contaminated with embryonated eggs from human feces. *A. lumbricoides* eggs need a maturation period outside the gut and can remain infectious for months. Diagnosis is by microscopic detection of eggs in fecal specimens. Occasionally, adult worms are eliminated in feces.

Taenia solium

Ta. solium is prevalent in Africa, South-east Asia, Central and South America, eastern Europe, Spain, and Portugal. The human is the definitive host and the pig the intermediate host. Human intestinal infection is acquired by ingestion of undercooked pork containing a larval stage called the cysticercus.

Humans can also harbor the larval stage of *Ta. solium* in tissues. This potentially severe disease, called cysticercosis, occurs after ingestion of water or foods contaminated with *Ta. solium* eggs (from human feces) or by autoinfection when eggs from adult worms hatch in the intestine, producing a larval form that penetrates the intestinal wall and enters the circulation to reach structures such as muscle, brain, lungs, and eyes. Diagnosis is by macroscopic detection of segments of the adult worm (proglottids) or by microscopic detection of eggs in fecal specimens. Cysticercosis may be diagnosed by radiological or scanning examinations and by detection of rising titers of specific antibodies. Sometimes, identification of cysts after surgery may be the only means of definitive diagnosis.

Trichinella spiralis

Trichinosis, the infection due to *Tr. spiralis*, is a disease of carnivorous animals which accidentally occurs in humans. It has a worldwide distribution but is more prevalent in temperate regions. Human infection is acquired by ingestion of raw or poorly cooked pork or pork products containing encysted larvae. Laboratory diagnosis is confirmed by the detection of spiral larvae in biopsy muscle tissue from the patient, sometimes after trypsin digestion of muscle fibers. Demonstration of rising titers of specific antibodies is also available for diagnosis.

Illness and Treatment

J Botas (formerly of) **and J Melo-Cristino**, Hospital de Santo Maria, Lisboa, Portugal

Protozoal Infections

Illness

Protozoa are a major cause of morbidity and mortality worldwide, either in developing or in western countries. Some of those able to infect humans by the oral route have long been known to cause disease, but others are only now being increasingly recognized as pathogenic in immunocompromised hosts, especially in patients with acquired immune deficiency syndrome (AIDS). They are very diverse in epidemiology, symptomatology, treatment, and preventive measures.

In immunocompetent hosts most infections are asymptomatic, but overt local or systemic symptoms may be present, which may be severe in some cases. However, protozoal infections are particularly troublesome, sometimes life-threatening, in immunocompromised patients.

Acute, self-limited diarrhea is the most common symptom caused by protozoa listed in Table 1, but sometimes more intense manifestations do occur, including abdominal cramps, flatulence, anorexia, vomiting, malabsorption, weight loss, and fever. In AIDS patients, insuperable chronic watery diarrhea with malabsorption and, eventually, wasting syndrome may be due to some of these parasites.

Blood, pus, and mucus in stools are the result of invasion of the intestinal wall and common only in intestinal infection by *Entamoeba histolytica*, which is also able to cause systemic infection, especially liver abscesses, manifested by fever, weight loss, abdominal pain, and hepatomegaly.

Humans may be either intermediate or definitive hosts for *Sarcocystis* spp. and, while intestinal infection is thought to be asymptomatic, parasites in muscle may cause swelling and pain. Microsporidia have only recently been recognized as human pathogens in AIDS and very few cases have been reported in non-AIDS patients. *Pleistophora* spp. has been found in muscle biopsy, *Encephalitozoon* spp. in liver and the central nervous system and *Nosema* spp. in disseminated infection. (*See* **HIV Disease and Nutrition**.)

Treatment

Susceptibility of protozoa to chemotherapy correlates roughly with metabolism and, accordingly, with species. Several drugs are active against different protozoa. For some of them, e.g., diloxanide furoate, the exact mechanism of action is still uncertain. Others, e.g., metronidazole, are broad-spectrum antibiotics, interfering with the DNA of susceptible infectious agents.

Some antibiotics are active directly against protozoa, but others exert their effect on enteric bacteria necessary for proliferation of protozoa, e.g., *Entamoeba histolytica*. Most of these drugs are contraindicated in pregnancy and treatment of pregnant women often must be delayed until after delivery.

Metronidazole is effective against most flagellates and amoebae and is an alternative choice in the treatment of *Balantidium coli*. Other nitroimidazoles (tinidazole and ornidazole) have similar activity and less untoward side-effects, including headache, metallic taste, nausea, vomiting, and diarrhea.

Emetine and dehydroemetine have considerable side-effects, gastrointestinal and systemic, and are

[a]Nonpathogenic for immunocompetent humans.
[b]Infection often serious in immunocompromised patients. Infection usually with *C. parvum*: avian species of doubtful significance.
[c]Importance as human pathogens, particularly in patients with acquired immune deficiency syndrome (AIDS), has only recently been recognized.

reserved only for extraintestinal amoebiasis. They are not active against *E. histolytica* in the bowel and diloxanide furoate, tetracycline, paramomycin, or iodoquinol must be added in order to treat simultaneous intestinal infection.

Iodoquinol is also effective against *Dientamoeba fragilis* (sensitive also to paramomycin and tetracycline) and is used as an alternative drug against *Balantidium coli*. Infections due to *Giardia intestinalis* may be treated with quinacrine, metronidazole, or furazolidine. Tetracycline is the drug of choice against *B. coli* and *D. fragilis*. Iodoquinol must be used with great caution, as it may cause myelitis and optic atrophy. This is the reason why it is no longer available in most developed countries.

Treatment of protozoal diseases in AIDS patients is far from satisfactory. There is no effective specific therapy for microsporidia or *Cryptosporidium* spp., perhaps the most common agent of infection of the bowel in AIDS. *Isospora belli* and *Sarcocystis* spp. respond poorly, if at all, to antifolates, which include co-trimoxazole, sulfadiazine, and pyrimethamine.

Prevention

Despite high prevalence and easy fecal–oral transmission of protozoa, foodborne and waterborne infections, although surely underestimated, seem rare. Good sanitary conditions and personal hygiene are keystones in preventing these infections. Protozoal cysts and oocysts differ in sensitivity to adverse conditions (heat, desiccation, freezing, chlorination) and some are amazingly resistant.

In countries with poor sanitary conditions, water should be boiled and uncooked vegetables and unpeeled fruits avoided, as they may have been washed with contaminated water. Flies and other arthropods may also be vehicles for fecal contamination of food. But even when a visitor takes every possible precaution to avoid these infections, a local food handler, even in the best hotel, may be a cyst passer not aware of the elementary rules of personal hygiene.

For some species there are several possible animal reservoirs, which lessens the effectiveness of preventive measures. Even for these species with humans as the only hosts, patients in some institutions, especially those who are mentally handicapped, are a difficult group to control. The occurrence of sexual transmission of some protozoa by oral–anal and oral–genital sex is also considered important and is difficult to control.

Helminthic Infections

Illness

Helminths are probably the most common infectious agents of humans. Two of those transmitted orally, *Ascaris lumbricoides* and *Trichuris trichiura*, are each thought to cause 1000 million infections worldwide. Humans may be, for different helminths, definitive or intermediate hosts and clinical manifestations, when present, depend on localization and worm burden. Unlike protozoa, helminths are not generally considered opportunistic pathogens in immunocompromised hosts.

Most intestinal infections caused by helminths listed in Table 2 are asymptomatic. Gastrointestinal symptoms are related to the number of worms in the bowel. Diarrhea and abdominal pain are the most common complaints, but malabsorption and weight loss may occur and, if untreated, infection may even be fatal, e.g., *Capillaria philippinensis*. *Enterobius vermicularis* is frequently responsible for anal pruritus, especially nocturnal, and restless sleep in children.

Some parasites compete for absorption of specific nutrients, with symptoms resulting from their deficiency, e.g., *Diphyllobothrium latum* causes

Table 2 Foodborne and waterborne helminths causing human infection

	Toxocara spp.		*Taenia solium*
	Trichinella spiralis		*Spirometra* spp.

deficiency of vitamin B_{12} and consequently megaloblastic anemia and neurological symptoms. (*See* **Cobalamins**: Physiology.)

Systemic infections, although sometimes asymptomatic, are more commonly associated with symptoms which depend on localization of the parasite. Liver and biliary tract are targets for some helminths, e.g., *Capillaria hepatica, Clonorchis sinensis, Fasciola hepatica*, and *Opistorchis* spp., and symptoms of hepatitis and cholangitis may occur. Furthermore, increased incidence of cholangiocarcinoma seems to be associated with these infections.

Spirometra spp. and *Dracunculus medinensis* are present in subcutaneous tissue, causing pain and swelling or chronic ulcers with protrusion of worms. Lung is infected by *Paragonimus westermani*, with resulting bronchopulmonary symptomatology, including cough, hemoptysis, bronchitis, or lung abscesses.

Infections by *Angiostrongylus* spp., *Bayliascaris procyonis*, or *Multiceps multiceps*, when symptomatic, cause central nervous system disease, especially seizures. Visceral larva migrans syndrome (fever, hepatomegaly, and eosinophilia) is caused principally by *Toxocara* spp., but may also be due to *Angiostrongylus* spp., *Anisakis* spp., and *Capillaria* spp.

Larvae of *Trichinella spiralis* may be responsible for fever, edema, myositis and, rarely, encephalitis, pneumonia, or myocarditis. Larvae may encyst in different tissues, resulting in space-occupying lesions when they are big enough. Cysts of *Echinococcus granulosus* are found more frequently in liver and lung and are often multiple, but cysts of *E. multilocularis* have an unlimited germinal membrane and spread either locally or to distant sites like neoplastic metastases.

Treatment

Susceptibility of helminths to chemotherapeutic agents correlates with species even more closely than is the case with protozoa. Some drugs are preferred because they act in the bowel, expelling adult worms, while others must be absorbed and act systemically, in order to kill parasites in tissues. For most of them, the exact biochemical mechanism of action is still unknown. Some cause spastic paralysis of adult worms, e.g., pyrantel pamoate, while others cause flaccid paralysis, e.g., piperazine, with resulting expulsion of worms by peristalsis.

Mebendazole is the drug of choice for intestinal nematodes and replaced thiabendazole, which is much more toxic. In higher doses it is also used in the treatment of infections by *T. spiralis*, *E. granulosus* and *E. multilocularis*. Liver and bone marrow toxicity are not uncommon with high doses.

Other benzimidazole drugs (albendazole and flubendazole) are new alternatives which are perhaps less toxic. Pyrantel pamoate, pyrvinium pamoate and piperazine offer no pharmacological advantages over mebendazole. Mebendazole is also the drug of choice in systemic infections by nematodes, but is much less effective. Removal of worms is the best treatment for *Anisakis* spp. and *D. medinensis*.

Praziquantel is effective against most trematodes and cestodes. It is the drug of choice for either intestinal or systemic infections due to these parasites and failures have only been reported in *F. hepatica* (bithionol is the preferred drug for fascioliasis). Untoward side-effects, including nausea, abdominal pain, and headache, although not uncommon, are mild and transient.

Niclosamide is equally effective against intestinal cestodes, is less expensive, and has fewer untoward side-effects than praziquantel. Although imidazoles might be tried, surgery is still the best treatment for *M. multiceps* and *Spirometra* spp. and should be considered in echinococcosis, in which it is the only treatment when the cyst is calcified.

Although drugs now available to treat helminthic infections are less toxic than before, some authors still prefer, particularly in intestinal infections, treating only heavy infections, or using low doses of drugs to reduce the number of parasites in order to avoid undesirable side-effects. In contrast, reinfection with *Enterobius vermicularis* is so easy that some authors prefer to treat all household contacts. As with protozoal therapy, treatment of pregnant women is better delayed until delivery.

Prevention

Foodborne and waterborne infections are common with both helminths and protozoa, although direct person-to-person, fecal–oral contamination is also responsible for transmitting some infections. Good personal hygiene and sanitary conditions are thus mandatory for prevention and control of these infections. Flies and other arthropods may transmit eggs from feces to food and water. Vegetables may be contaminated either by encysted larvae (aquatic vegetables) or after contact with contaminated water.

Veterinary inspection of meat is very important in parasites which are infectious by macroscopic cysts or larvae. Raw meat or fish may transmit several helminths and should be avoided. Larvae and eggs may be extremely resistant to adverse conditions and remain viable for prolonged periods of time in salted, smoked, or undercooked meat and fish, as well as in chlorinated water. Snails, crayfish, crabs, and prawns may harbor larvae and so should be properly cooked. (*See* **Fish**: Spoilage of Seafood; **Shellfish**:

Contamination and Spoilage of Molluscs and Crustaceans.)

Specific Examples

Cryptosporidium spp.

Cryptosporidium spp. were recently recognized as an important cause of diarrhea in humans. Infection is frequently symptomatic and in immunocompetent hosts symptoms include mild acute self-limited watery diarrhea, sometimes with abdominal cramps, flatulence, nausea, anorexia, and weight loss. In immunocompromised patients, especially AIDS, chronic diarrhea and profound weight loss may occur and are an important cause of morbidity and mortality.

Spiramicin has been used for treatment with doubtful efficacy; no effective therapy is available. Nonspecific symptomatic therapy is important to avoid fluid and electrolyte imbalance, as in acute diarrhea of other etiology. Prevention may be difficult, as oocysts are extremely resistant and fully infectious when passed in stools. Good sanitary conditions and personal hygiene are of utmost importance. Precautions with stools in hospitals and other institutions should be taken in order to avoid outbreaks.

Giardia intestinalis

Giardiasis is now the most commonly reported protozoal infection worldwide. About 20–50% of infected people present symptoms, usually self-limited acute diarrhea, but chronic diarrhea with malabsorption may follow. Treatment with quinacrine has a high degree of efficacy, but the drug is poorly tolerated (vomiting, abdominal pain). Metronidazole and other nitroimidazoles are equally effective and better tolerated. Furazolidine has no advantages over quinacrine, either in efficacy or in untoward gastrointestinal side-effects. Good water control is the most important way of prevention. When necessary, water should be filtered or boiled. Chemical treatment is of doubtful efficacy.

Toxoplasma gondii

Toxoplasmosis in immunocompetent people is generally asymptomatic or may resemble an infectious mononucleosis. Tissue cysts, however, remain viable for life. In immunocompromised patients, such as AIDS patients, transplant recipients and patients submitted to immunosuppressive therapy, either acute or reactivation of latent infection, may be responsible for severe or fatal toxoplasmosis, mostly of the central nervous system. Congenital toxoplasmosis may present several clinical manifestations, some severe (encephalitis, retinitis), depending on the time of pregnancy when infection was acquired.

The combination of pyrimethamine plus sulfadiazine is the most effective therapy for toxoplasmosis and has been the choice in immunocompromised patients. To avoid relapses, it must be maintained for life in AIDS patients and as long as immunodeficiency persists in other cases. Bone marrow toxicity and skin rash are frequent with this combination and may cause replacement of sulfadiazine by clindamycin. Acute toxoplasmic infection in immunocompetent hosts is only to be treated when symptoms are severe or persistent.

Infection in pregnant women, either with or without symptoms, must be treated. Spiramycin can be used throughout pregnancy and after the first trimester, pyrimethamine plus sulfadiazine can be used. None of the available drugs is active on cysts, but only on vegetative forms. Oocysts are present in cat feces in large numbers and so contacts must be avoided by seronegative pregnant women and immunodeficient patients. In meat, cysts do not resist prolonged freezing (−20 °C), heating (66 °C), smoking, or curing.

Ascaris lumbricoides

Clinical manifestations of *A. lumbricoides* infection are diverse, being related to worm burden. Bronchopulmonary complaints may be present, due to migration of larvae through the lungs. If infection is slight, adult worms cause no symptoms, but heavy infections may be responsible for malabsorption or even intestinal obstruction. Other rare manifestations may be due to abnormal worm migration. Mebendazole is the treatment of choice. Pyrantel pamoate or piperazine are effective alternatives. Good sanitary conditions are keystones in prevention. Infection is also avoided by hand washing after contact with soil.

Taenia solium

Human intestinal infection by *Taenia solium* is generally asymptomatic. Symptoms due to cysticercosis depend on organ involvement, the central nervous system being the system most commonly affected (by seizures), followed by orbit, muscle, liver, and lungs. Niclosamide is widely used in the treatment of intestinal taeniasis. It is effective and has few untoward side-effects, but is not active against larvae. Praziquantel is highly active against adults and larvae, and should be preferred. Calcified cysts will not respond to drugs and may justify surgery. Symptomatic treatment of seizures may also be necessary. The most effective prevention is by good sanitary conditions, avoiding contamination of animal and human food and water by human feces. Veterinary

inspection of meat decreases the risk of ingestion of cysticercus, as does thorough cooking of pork.

Trichinella spiralis

Most intestinal and tissue infections by *Trichinella spiralis* are subclinical, symptoms depending mostly on the number of viable larvae and their localization. Diarrhea is the most common symptom due to adult worms in the gut, but abdominal discomfort and vomiting may also occur. Systemic invasion by larvae is more often symptomatic, with fever, myalgia, periorbital edema, and headache. Occasionally, myocarditis, pneumonitis, or encephalitis may occur. Mebendazole and thiabendazole are the drugs of choice for treatment, along with salicylates and bed rest. The most effective method of prevention is thorough cooking of pork.

PARENTERAL NUTRITION

C C Ashley and L Howard, Albany Medical College, Albany, NY, USA

Definition and History

The development of central venous catheters in the 1960s provided for the safe infusion of hypertonic nutritive solutions. As placement of these catheters became more widespread, so did the use of parenteral nutrition (PN). In the early 1970s, this also became an available therapy for patients with chronic intestinal insufficiency living at home. Today, a variety of vascular access options are available to patients, and portable pumps can be used to infuse outside of the home/hospital setting. PN is sometimes called total parenteral nutrition (TPN), but this is an overstatement because several hard-to-solubilize but important nutrients are left out. Another term, 'hyperalimentation,' has also gone out of vogue, as we learn the downside of overproviding substrate, especially in a stressed patient.

Indications for Therapy

Wide availability does not necessarily imply broad applicability. Only recently has the evidence for and against the use of parenteral nutrition in a variety of clinical settings become better defined. Enteral routes of nutritional support are generally cheaper, safer, and equally efficacious. PN is indicated in those patients where delivery of nourishment via the gut is either unsafe or not possible. Candidates for PN should be carefully selected because the therapy is costly, cumbersome, and risky. A systematic approach to choosing candidates for PN is detailed in **Figure 1**.

The first step in the process requires the clinician to form a clinical judgement about whether the severity and nature of the patient's illness will lead to nutritional impairment. Initial considerations are whether a lengthy course of chemotherapy will provoke nausea and reduce oral intake to negligible levels; whether severe intestinal ileus will make it impossible to use the gut; and whether a planned surgery is likely to significantly reduce the patient's absorptive surface. The second step is to assess whether the patient is at increased risk for malnutrition because of limited nutritional reserves. The physician must determine whether the patient is an alcoholic. Are they already on catabolic drugs such as steroids? Are they vulnerable by virtue of age or chronic illness such as diabetes? The third step is to determine whether the patient is already malnourished. Loss of more than 20% of lean body mass, serum albumin depression signs of vitamin or mineral deficiency independently indicate a high-risk nutritional status. The fourth step is the most critical. The physician must decide whether the quality of life and prognosis can be positively effected by the provision of specialized nutritional support and therefore whether this therapy should be recommended to the patient. The

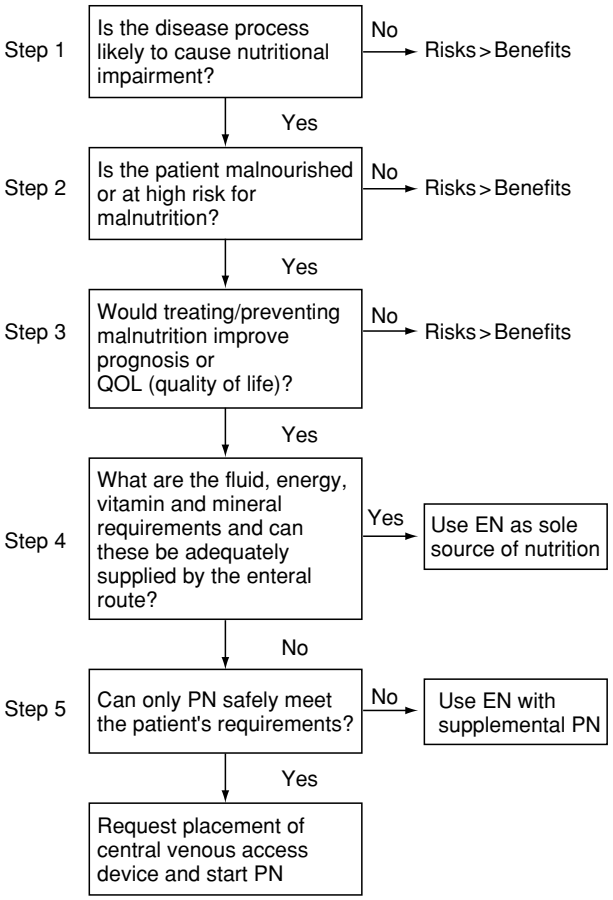

Figure 1 Systematic approach to assessing candidacy for total parenteral nutrition. Adapted from Howard L (1998) Parenteral and enteral nutrition. In: Fauci AS, Braunwald E, Isselbacher KJ and Wilson JD (eds) *Harrison's Principles of Internal Medicine*, 14th edn., chapter 78, figure 78-1, p. 473. New York: McGraw-Hill, with permission.

remaining steps are concerned with choosing the route of delivery for the indicated specialized nutritional support. A summary of common clinical scenarios, where provision of PN is considered, is shown in Table 1.

Evidence Base for PN

Insufficient evidence exists to assess the utility of PN in many specific clinical settings, but there are several broad areas where prospective randomized controlled studies support the use of PN.

Perioperative

Strong evidence exists to support the use of PN in the perioperative setting when the patient has severe protein–calorie malnutrition. The benefit is a modest (several studies found 10%) reduction in postoperative complications.

Table 1 Various indications for parenteral nutrition

Obstruction
Anatomical (congenital malformation, strictures, adhesions)
Functional (prolonged postoperative ileus, intestinal dysmotility)
Hypermetabolic state/wasting syndromes
Critical illness
Multisystem organ failure and bowel ischemia
Severe pancreatitis
Burns
Cancer
Bone-marrow transplantation
HIV
Malabsorption/mucosal disease
Insufficient surface area from short bowel syndrome
Proximal enteric fistula
Severe inflammatory bowel disease
Severe chemotherapy related mucositis
Radiation enteritis

Critical Illness

In critical illness, there is support for the use of PN in patients with severe protein–calorie malnutrition using modest calories. Complication rates are lower when lipids are not infused as a part of this specialized nutritional support. Excessive exogenous carbohydrate enhances hypermetabolism and lipogenesis, leading to increased carbon dioxide production; this makes ventilatory weaning more difficult.

Wasting Syndromes

Cancer Like noncancer patients, cancer patients suffering from severe protein–calorie malnutrition benefit from perioperative PN when undergoing cancer surgery. There are some data to suggest that bone-marrow-transplant patients benefit from PN supplemented with glutamine and that PN during the cytoreductive phase enhances long-term survival.

HIV HIV patients appear to benefit from specialized nutrition support if their wasting reflects poor intake or malabsorption; they do not benefit if their weight loss is principally cytokine-related wasting. The route of nutrition support is more controversial. In one well-controlled study, PN was not superior to enteral nutrition in repleting lean body mass, but it did add more weight as water and fat. One small study showed a longer survival in PN HIV patients compared to those who received diet counseling alone.

Chronic Renal Failure

PN improves survival in acute renal failure. A solution using just essential amino acids is not superior to the usual essential–nonessential combination. In

chronic renal failure requiring dialysis, 15% of patients become significantly malnourished. PN may be indicated if there is severe bowel dysmotility associated with autonomic neuropathy, as may occur with diabetes. Routine use of intradialytic PN has not been shown by randomized studies to clearly alter survival.

Pancreatitis

In pancreatitis, PN can decrease mortality rate and reduce rates of infectious complications when it is used early in the management of the most severe cases.

Short Bowel Syndrome

The prognosis of acute short bowel syndrome has been dramatically improved by PN, so much so that a randomized study of PN vs. enternal nutrition (EN) would be unethical. In the adaptive phase, an open study purported to show that supplementation with growth hormone and glutamine improved bowel adaption, but this was not confirmed in a more rigorous controlled trial.

Inflammatory Bowel Disease

In inflammatory bowel disease, Crohn's disease, or ulcerative colitis, specialized nutritional support (SNS) is often necessary for severe disease associated with protein calorie malnutrition, but there are no clear data that show any advantages of PN over EN. SNS alone is not superior to steroids in reducing remission or preventing relapse; however, it may be the preferred approach in a growing child.

Technical Details

Route

Peripheral PN PN can be delivered via peripheral intravenous access, but this route is appropriate only for formulations of modest osmolarity (e.g., less than 900 mOsm or 10 g of dextrose per 100 ml), since small veins quickly sclerose and become useless for further infusion. Peripheral PN is best used in a supportive role for patients with inadequate oral intake. Patients who are unable to meet their fluid and electrolyte needs can be supported in this way without exposure to the complications of central venous access. However, peripheral PN is not a long-term solution.

Central PN Central access is a prerequisite when infusing formulations of PN that are more complex and more hyperosmolar. The catheter used to deliver PN should be a dedicated line used for nothing else in order to minimize the risk of infection. If additional intravenous therapy is needed, additional access sites should be arranged. Sometimes, multilumen catheters are used, but studies have shown higher infection rates in multilumen catheters versus single lumen catheters.

Conventional central venous line In the setting of an acute requirement for parenteral therapy or as a bridge to the placement of a longer-lasting device, an externalized central venous line (CVL) inserted by the conventional Seldinger technique in the subclavian or internal jugular vein is acceptable for the delivery of PN. This catheter may be placed at the bedside as long as full aseptic precautions are taken. This can be a considerable advantage over other devices that may take several days to arrange.

Peripherally inserted central venous catheter The peripherally inserted central venous catheter (PICC) can be placed at the bedside in the antecubital fossa by specially trained personnel. PICCs placed at the antecubital fossa are subject to mechanical stress from flexion and extension of the elbow. They are a short-term option. For long-term use, especially in patients going home on PN, PICC lines are best placed to the upper arm (brachial vein) under ultrasound and fluoroscopic guidance. Such lines are not subject to the same level of mechanical stress. One disadvantage common to all PICCs is that they are more difficult for home patients to care for without nursing support, because the patient has only one free hand.

Tunneled catheter The chief advantage of tunneled catheters is that an exit site low on the chest wall permits a patient at home to see their catheter site and manipulate the catheter with both hands. This considerably simplifies the act of catheter access and improves patient independence. Tunneled catheters have a dacron cuff just under the skin which aids catheter fixation and prevents bacteria from accessing the blood stream through the tunnel. Patients with an externalized catheter are usually advised to cover their access devices with an adhesive/occlusive dressing before showering or bathing in order to keep it dry. Swimming is not recommended.

Subcutaneous port Subcutaneous ports are often preferred by long-term patients, who have active lifestyles and want to swim. Subcutaneous ports are less obtrusive and therefore cause less disturbance to body image. The disadvantage of these catheters is that they require a needle stick for accessing, but this uncomfortable procedure is made easier by the use of topical anesthetics. Also, it is rarely possible to

clear an infected part and hence removal is necessary. For this reason they are not wise in patients with a history of frequent line sepsis.

Infusion Method

Continuous Once a route is decided upon and available, a method of delivery must be selected. Most patients begin PN as a continuous infusion. Continuous infusion is the least complicated method of delivering PN, since a metabolic steady state is quickly achieved and maintained. This is the method of choice in patients who are critically ill, hemodynamically compromised, have marginal renal function, or are brittle diabetics. However, continuous infusions are not optimal from the perspective of most patients. Long-term patients frequently seek some freedom from their parenteral infusion. If a long-term continuous infusion is necessary, portable pumps are available that allow patients to perform most activities of daily living without needing to disconnect.

Cycled TPN infusions can usually be compressed to a period between 10 and 12 h, depending upon the volume and calories needing to be infused. Most home patients opt to infuse during night time hours. This leaves the patient free for a period of between 12 and 14 h a day to be more active. When the infusion is cycled on and off daily, the risk for dehydration rises especially toward the end of the infusion-free period and in patients with significant gastrointestinal (GI) losses. The risk of both hyper- and hypoglycemia is increased at the start and conclusion of the daily infusion. Swings in serum glucose levels demonstrate the impact of carbohydrate delivered directly to the systemic rather than the portal circulation.

Intermittent In patients requiring less PN support, it may be possible to provide PN every second or third day. The complication of such a regimen is making sure that mineral and vitamin requirements are met.

Establishing a Nutrient Formula

Once the need for parenteral support is established and the route and method of delivery are decided on, the formulation can be determined. The first step is to estimate the total nutritional requirement of the individual patient. The requirement of an individual patient may vary from day to day, depending upon abnormal Gl losses. Over time, bowel adaption occurs, so fluid and nutrient requirements may significantly decrease.

Fluid requirements

Basal The normal daily fluid requirement is 25–35 ml kg^{-1} (for adults) and 120 ml kg^{-1} (for infants). In a 70-kg man, normal losses are 1600 ml of urine daily, 800 ml of insensible losses, 100 ml of stool losses and 350 ml per degree Celsius per day of fever.

Extraordinary fluid losses Fluid losses can vary considerably in patients who require TPN, often because of excessive loss from the GI tract. In the example shown in Table 2, the patient requires twice the usual volume of fluid because of extraordinary losses through his jejunostomy. All fluid losses must be meticulously reviewed in order to ensure adequate replacement. Commonly excessive losses from the GI tract will precipitate a greater oral intake.

Calorie requirement The total amount of calories required is determined by weight and the patient's level of stress. Between 20 and 40 kcal kg^{-1} day^{-1} is usually provided to adults and 80–110 kcal kg^{-1} day^{-1} to infants. In patients who are simply starved but not stressed, 35–40 kcal kg^{-1} day^{-1} (100–110 kcal kg^{-1} day^{-1} for infants) can be effectively utilized. In patients who are moderately stressed and malnourished, slightly lower amounts are provided, e.g., 30–35 kcal kg^{-1} (80–100 kcal kg^{-1} day^{-1} in infants). In patients who are severely stressed, calories are kept modest (< 25 kcal kg^{-1}), since the stress induces a catabolic state that prevents efficient utilization of high levels of calories. Excessive calories precipitate hepatic steatosis and retention of carbon dioxide.

Carbohydrate content Glucose provides 3.4 kcal g^{-1} because it is glucose monohydrate. The carbohydrate content of the formulation varies from 4 to 7 g kg^{-1} day^{-1} and usually accounts for 50–60% of total calories.

Table 2 Daily fluid requirements

Normal man (70 kg)			
35 ml day^{-1} × 70 kg = 2.5 l			
In:	1.2 l of fluid	Out:	1.6 l of urine
	1.0 l of water in food		0.8 l insensible losses
	0.3 l of water from metabolism of food		0.1 l stool
Same patient status post high jejunostomy			
In:	2.2 l of fluid	Out:	1.6 l of urine
	1.0 l of water in food		0.8 l of insensible losses
	0.3 l of water from metabolism of food		4.1 l of jejunostomy losses
	3.0 l TPN		

The patient needs to have enough parenteral fluid to maintain an adequate urine output. Short-bowel patients have an increased risk of kidney stones. Adapted from Howard L (1998) Parenteral and enteral nutrition. In: Fauci AS, Braunwald E, Isselbacher KJ and Wilson JD (eds) *Harrison's Principles of Internal Medicine*, 14th edn., chapter 78, figure 78-4, p. 476. New York: McCraw-Hill.

Fat content Fat solutions provide 10 kcal g^{-1} rather than the expected 9 kcal g^{-1} because the lipid is made iso-osmolar with glycerol. The fat content of the formulation varies from 0.5 to 1.0 g kg^{-1} day^{-1} and usually accounts for 30% of total calories.

Protein content Amino acids provide 4 kcal g^{-1}. The protein content of the formulation varies from 0.8 g kg^{-1} for a nonstressed patient to 1.5 g kg^{-1} for a severely catabolic patient. Amino acids generally account for 10–15% of total calories. A patient whose protein requirements are adequately met will be in nitrogen balance based upon the following formula:

$$\text{Nitrogen balance} = \text{nitrogen intake} - \text{nitrogen loss}$$

(nitrogen intake is 14% of all protein or amino acid intake in g per 24 h; nitrogen loss is urine urea nitrogen in g per 24 h + 4 (a constant for other losses)).

In the long term, protein balance can be assessed by wound healing, resumption of growth, and/or restoration of body composition.

Electrolytes and minerals PN solutions are based on a standard physiologic preparation of electrolytes. The content of specific electrolytes can be varied to replace patient losses or avoid excessive levels in patients with impaired renal or hepatic excretion. Extraordinary losses of alkali and chloride salts are more the rule than the exception in patients with large volumes of GI fluid loss. Serum chemistries must be intensively monitored until a state of equilibrium is established, after which, periodic assessment remains necessary. The necessary electrolyte replacement can be based on the composition of the abnormal fluid losses (see Table 3).

Vitamins and trace elements Parenteral provision of vitamins and trace elements is complicated by systemic infusion and altered enterohepatic cycles. In addition, some micronutrients may adhere to formula bags and delivery tubing or be destroyed by exposure to light (vitamin A). Some nutrients (divalent cations and fat-soluble vitamins) are especially at risk for deficiency in patients with bowel disease and steatorrhea. Others, cleared by the liver, may accumulate in toxic amounts in patients with liver dysfunction and in that setting should be supplied only in reduced amounts (Cu, Mn). Still others are at risk for toxic levels of accumulation in the setting of chronic renal failure (Se, Mb, I). The daily parenteral requirements for essential fatty acids, minerals and vitamins are summarized in Table 4.

Medications and other additives Daily central venous infusions create an opportunity for delivery of a variety of medications by the intravenous route. Any admixing must take into account compatibility with the PN formulation and any cycling of PN delivery that may create an unsafe or inefficacious situation for an added medication (see Table 5).

Complications

Catheter Failure

Infection Catheter-related infection heads the list of serious complications, since it is both common and potentially devastating. More serious than any individual infection is a pattern of infections that increases the risk of endovascular colonization. The incidence of infection is higher in children. Mortality from these infections is low, but the dangers are real,

Table 3 Enteric fluid volumes and their sodium, potassium, chloride and bicarbonate contents[a]

	l day^{-1}[b]	*Na (meq l*$^{-1}$*)*	*K*[c] *(meq l*$^{-1}$*)*	*Cl (meq l*$^{-1}$*)*	*HCO*$_3$[d] *(meq l*$^{-1}$*)*
Oral intake	2–3				
Enteric secretions					
Saliva	1–2	10	30	10	30
Gastric	2	60	9	90	0
Bile	2–3	150	10	90	70
Small bowel	1	100	5	100	20
Colon	Variable	40	100	15	60

[a]Enteric secretions are also rich in divalent cations (Ca, Mg, Zn, Cu), and their loss is increased by steatorrhea, a high bowel fistula, or prolonged gastric suction.

[b]Of the total oral and enteric fluid presented to the upper small bowel, normally 50% is absorbed in the jejunum, 40% in the ileum, and 10% in the colon. In short-bowel patients, the colon may absorb greater amounts, up to 3 l day^{-1}.

[c]Potassium losses are small except in secretions distal to the ileocecal valve. The colon ion exchange is partly controlled by aldosterone, and therefore, Na depletion increases K loss in the stools.

[d]Bicarbonate losses must be replaced in parenteral solutions as acetate or lactate because of potential precipitation of bicarbonate with ingredients such as calcium.

From Howard L (1998) Parenteral and enteral nutrition. In: Fauci AS, Braunwald E, Isselbacher KJ and Wilson JD (eds) *Harrison's Principles of Internal Medicine*, 14th edn., chapter 78, figure 78-5, p. 477. New York: McGraw-Hill.

Table 4 Daily parenteral requirements of essential fatty acids, minerals, and vitamins

Nutrient	*Daily parenteral requirement for an adult*
Essential fatty acids, % kcal	2–4
Calcium, g (meq)	0.2–0.4 (10–20)
Phosphorus, g	0.4–0.8
Potassium, g (meq)	3–4 (75–100)
Sodium, g (meq)	1–3 (45–130)
Chloride, g (meq)	3–4 (85–120)[a]
Magnesium, g (meq)	0.2–0.3 (15–25)
Iron, mg	1–2
Zinc, mg	3–12
Copper, mg	0.3–0.5
Iodine, mg	0.15
Manganese, mg	2–5
Chromium, μg	15–30
Molybdenum, μg	20–120
Selenium, μg	50–100
Ascorbic acid, mg	100
Thiamin, mg	3
Riboflavin, mg	3.6
Niacin, mg	40
Biotin, μg	60
Pantothenic acid, mg	15
Pyridoxine, mg	4

From ME Shils and RO Brown (1999) Parenteral nutrition. In: Shils ME, Olson JA, Shike M and Ross AC (eds) *Modern Nutrition in Health and Disease*, 9th edn, chapter 101, table 101.13, p. 1688. Philadelphia, PA: Lippincott, Williams & Wilkins.

since patients can, through multiple infections, use up their sites for central vascular access. Infection can be limited to the device, spread to the bloodstream, and/or involve local tissue either at the exit site or along the tunnel. Definitive treatment of catheter-related infection usually involves removal of the device. A variety of methods have been tried to reduce the risk of infection in patients dependent upon PN. All patients are instructed to use scrupulous sterile techniques when accessing their device. The device should be accessed only to deliver specialized nutritional support and should not be used for the infusion of other products or blood draws. Some access devices are impregnated with antibiotics or bacteriostatic agents. An antibiotic solution lock after the use of a catheter can reduce catheter sepsis and is used in patients with frequent infection. To remove the biofilm on the internal surface of the catheter which allows invading bacteria to grow and limits antibiotic sterilization – intermittant thrombolytics can be used likewise endoluminal brushes. Endoluminal brushes have been used both to identify infected lines and to clear catheters.

Bleeding Bleeding occurs either locally because of bleeding from a leaking catheter or from a systemic

coagulopathy. Most catheter leaks can be addressed by clamping or crimping the catheter proximal to the leak and then having the catheter repaired. Subcutaneous bleeding around a port usually responds to pressure.

Air embolism Air embolism is a feared complication of central venous access. Patients need to be reassured that dangerous volumes of air are large and rarely happen through an access device. If concern for this complication is real, and the amount of air delivered is unknown, patients crimp off their catheter and lie flat on their left side so that air is trapped in the right auricle or ventricle and does not pass on into the pulmonary artery and the lungs where the 'bubble' will disrupt gas exchange. Over 20 min, even large trapped bubbles will dissolve.

Phlebitis Phlebitis is a relatively common complication with peripherally inserted access devices. Inflammation of the small vessel, which is initially entered, can result in local pain, swelling, erythema, and heat. There may or may not be associated cellulitis. The internal surface of the catheter usually remains sterile. If conservative local therapies are insufficient to provide relief, the line should be removed, since phlebitis can progress to thrombosis and more serious complications.

Migration After initial placement, catheters can migrate in the wrong directions. For example, a line placed via the subclavian vein can end up in the internal jugular. The peripherally inserted central catheters can propagate into the heart from the superior vena cava or right atrium. The resulting endocardial irritation can result in palpitations, skipped beats, and, rarely, more serious arrhythmia. When fluoroscopy is available at the time of the placement, these complications are easily correctable. It is useful to note at the time of insertion just how much of a CVL or PICC remains externalized.

Crimping and breakage If infusion becomes difficult, and the pump signals blockage, the first consideration should be the site of central access. Crimping of the catheter is common with peripherally inserted access introduced through the veins of the antecubital fossa. Repeated flexion and extension at the elbow can introduce a kink in the catheter itself and result in breakage. The diagnosis of catheter breakage is straightforward, since it usually occurs as separation of the catheter from the external hub or as a simple breach in the external catheter wall. Rarely is a catheter sheared off internally. None the less, a central catheter should never be withdrawn with any amount of force, as there have been incidences of catheter embolization requiring extraction under fluoroscopy.

Blockage Catheters can become blocked by thrombus, built-up fibrin and platelet deposits, crystals of infused minerals or drugs, or by lipid precipitate from intravenous fat solutions. Vigorous and frequent flushing with heparinized saline and the use of heparin-impregnated catheters has been useful in reducing the frequency of thrombotic luminal obstruction. Accumulation of fibrinous material on the outer surface of the catheter tip is relatively common and can produce a ball valve effect, allowing infusion but preventing blood withdrawal. Fluoroscopic confirmation of catheter position and clots is useful. Current treatment for thrombus or fibrin is 0.5–1 mg of tissue plasminogen activator. Crystalline material may be dissolved by 0.1 N HCL and lipid by small amounts of alcohol. Checking for blood return from access devices is discouraged because the process of drawing blood into the catheter promotes the process of fibrin and platelet precipitation and contributes to higher rates of intraluminal catheter obstruction and infection, shortening the usable life of the devices. Catheter thrombosis is frequently associated with catheter infection.

Underfeeding

Ideally, the amount of specialized nutritional support delivered to the patient is sufficient to meet the needs of the patient. Because the process of determining those needs is imperfect, it is likely that either too much or too little support will be delivered. Because the complications associated with overfeeding can be dramatic, it is now preferred to err on the side of underfeeding, especially in the patient who is under stress. In order to optimize the patient's response to specialized nutritional support, prospectively determined goals should be used to gauge the success of therapy. The clinician should assess the patient's wound healing, strength to wean from a respirator, cough effectively, and mobility. If such an evaluation is neglected, the patient may inadvertently be denied the full benefit of parenteral support.

Overfeeding

Overfeeding is the provision of one or more of the nutrient components of parenteral nutrition in an amount or at a rate that exceeds the physiologic utilization and excretion of the nutrient.

Hyperglycemia Excessive provision of carbohydrate can occur in both diabetic and nondiabetic patients and is more likely to occur in those who are

critically ill. Hyperglycemia should be treated by reducing the carbohydrate calories. The use of insulin is only appropriate in patients known to be insulinopenic.

Fluid overload Fluid overload is possible in patients who have reduced cardiac reserves and in persons with healthy hearts whose PN volume is added to an already generous regimen of crystalloid or colloid. It is essential to consider the total volume of other fluids delivered when determining a volume for PN.

Fatty liver Delivery of carbohydrate or fat calories in excess of that which can be used by the patient creates hepatic steatosis. In the case of a patient with impaired liver function, this can occur more rapidly. Chronic hepatic steatosis leads to cholestasis and, occasionally, irreversible fibrosis and cirrhosis. This appears to occur more readily in children than adults.

Refeeding syndrome This classic complication of starvation can occur after prolonged starvation from any cause; it happens when the nutrient supply is restored too rapidly. The underfed patient has depleted stores of adenosine triphosphate (ATP) with normal or low circulating levels of potassium, phosphorus, and magnesium. Once metabolism is restored, phosphate is drawn into cells to be coupled to adenosine monophosphate (AMP) and adenosine diphosphate (ADP). Magnesium is also drawn into cells to act as a cofactor for a number of cellular processes, for example, the conjugation of phosphate to ADP and the Na–K ATPase. Finally, potassium is drawn into cells to participate in the vigorous metabolism of newly supplied energetic compounds. This leads to depleted serum magnesium, potassium, and phosphate. This transcellular shift can have dire consequences, as a result of altered membrane conduction, resulting in arrhythmia, edema, and heart failure.

Allergic Reactions

Reactions to any component used in the delivery of PN are possible. Allergic reactions to latex are well known. Autoimmune reactions to heparin are also recognized, and even the small amount present in the lumen of an impregnated catheter is sufficient to trigger the heparin-induced thrombotic thrombocytopenia syndrome. Reactions to the actual components of the nutrient formulation are unusual.

Withdrawal of Support

Once PN is begun in a patient, when does one stop? There are three situations in which withdrawal of therapy is appropriate: first, when the patient can wean from PN to more physiologic EN; second, when desired by the patient; and third, when further treatment is futile, and the risks clearly outweigh the benefits. Assessing PN nutrition repletion and transposing to use of the GI tract is an important clinical step that often has to happen gradually. Every patient must agree to both initiation and stopping PN therapy. Occasionally, after experiencing nutritional rescue by PN, the patient or family desire continuation of therapy and are fearful of the consequences of weaning off. When continued nutritional support is felt to contribute nothing to the patient's quality of life or prognosis, it should be withdrawn like any other futile therapy. This process is ethically straightforward but emotionally charged and medicolegally complicated. The best way to avoid these difficult situations is to avoid PN in every case where its use is not clearly indicated, and the course of therapy is not prospectively defined.

PASSION FRUITS

D B Rodriguez-Amaya, Universidade Estadual de Campinas, Campinas, SP, Brazil

Introduction

Because of the intense, fragrant, and distinctive aroma and flavor, passion fruit has been the object of investigations and is in increasing demand worldwide. Native to Brazil, this fruit owes its name to the delicate and beautiful flowers, some features of which the early Christian missionaries to South America found symbolic of the Passion of Christ.

Species and Cultivars

Passion fruit belongs to the *Passifloraceae* family, which consists of 12 genera and over 500 species, widely distributed in tropical America, Asia, and Africa. *Passiflora*, the principal genus, has approximately 400 known species, about 50–60 of which bear edible fruits, but only a few are of any commercial importance. Many are known only in native markets in South and Central America and the West Indies. Commercial production of passion fruit is based on the purple species *Passiflora edulis* Sims and the yellow form *Passiflora edulis* f. *flavicarpa* Degener. It is still in question whether the yellow passion fruit is a mutant of the purple *P. edulis* or its hybrid with other species. These two forms are commonly called granadilla, parcha, or parchita in Spanish, maracuja in Portuguese, and lilikoi in Hawaiian.

Aside from the skin color, the purple and yellow passion fruits differ in horticultural performance and fruit properties. The purple species is more resistant to cold injury, is less acid, and is considered superior in aroma and flavor. The yellow form is faster growing, has a greater resistance to soil fungi, has more vigorous vines, bears crops over longer periods, and has a greater yield of fruit and pulp, larger fruits, and more acid juice.

P. quadrangularis L. or 'giant granadilla,' widely distributed in the tropics, is the most cultivated species after *P. edulis* in tropical America. It bears the largest fruits, which are more elongated, up to 25 cm long, and fleshy instead of hollow. The seeds are much larger, brownish, and flattened. The rind is not so hard as in the purple and yellow passion fruits. The juice content is much lower and is somewhat inferior in flavor and color. The pulp can be eaten like a melon, with or without the addition of sugar, or cooked with milk. When green, this fruit can be used as a vegetable as green papaya.

P. ligularis Juss, 'sweet granadilla' or 'water lemon,' is cultivated in the mountains of Mexico and Central America. The fruit is mostly eaten out of hand or used in drinks or icecream. Its translucent white pulp is almost a liquid, acid with sweet aroma. The peel is resistant so the fruit can be transported well, without being damaged. Colombia, where this species is cultivated in the Western Cordillera, exports this fruit to Europe.

P. mollissima, 'banana passion fruit' or 'curuba,' grows widely in the Andes and is distributed from Venezuela and Colombia to Peru and Bolivia. The flavor is more astringent and less acid than *P. edulis*. The sieved pulp is mixed with milk and sugar and served as a drink. It is also used in marmalades and desserts and for flavoring icecream

P. maliformis L. is known as 'sweet cup' in the West Indies, 'chulupa' in Colombia, and 'granadilla de hueso' in Ecuador. It is a little-known species but

may have a good future because of its excellent aroma and flavor.

Botany and Horticulture

The purple passion fruit crops best at higher altitudes in the tropics. It is produced commercially in Australia, South Africa, Kenya, Papua-New Guinea, New Zealand, Sri Lanka, and India. The yellow form thrives in humid tropical lowlands. It is the passion fruit most cultivated in Brazil, Peru, Venezuela, Hawaii, and Fiji. Both wild and cultivated passion fruits are also found in Bolivia, Malaysia, Indonesian, Taiwan, and the Philippines. Production of passion fruit is also possible in frost-free areas in the temperate zone, although fruiting is more limited than in the tropical regions.

The plant is a woody, perennial vine that bears a large number of purple or yellow, oval or round fruits 4–7.5 cm in diameter. It climbs with the aid of tendrils that spring from the same axils as the flowers. The alternate evergreen leaves, deeply three-lobed when mature, are finely toothed, 7.5–20 cm long, deep green and glossy above, paler and dull beneath, and, like the young stems and the tendrils, tinged with red or purple, especially in the yellow form. A single, fragrant flower, 5–7.5 cm in diameter, is borne at each node on the new growth. Clasped by three green leaf-like bracts, it consists of five greenish white sepals; five white petals; a fringed corona of straight white-tipped rays, vivid purple at the base; five stamens with large anthers; the ovary; a prominent, centrally located, triple-branched style and three stigmas. The stigmas are at the apex of the androginophore, the anthers situated below them, making self-pollination difficult.

The *P. edulis* Sims bears fruits, weighing about 35 g, with a deep purple leathery skin that wrinkles when the fruits are fully ripe. The *P. edulis* f. *flavicarpa* Degener has a yellow skin softer than that of the purple fruit and is usually larger, weighing about 80 g. It does not shrivel as badly. The rind is about 3 mm thick and has a whitish layer internally, similar to the albedo of citrus fruit. Inside the fruit is a cavity filled with a juicy mass of intensely fragrant, translucent yellow–orange pulp, with a distinctive sour-sweet flavor, in which are embedded numerous small, flattened, oval, edible, black (in purple passion fruit) or dark brown (in yellow passion fruit) seeds.

Although a hermaphrodite, the passion fruit flower is self-sterile. Cross-pollination depends on pollinators such as large bees, the carpenter bee (*Xylocopa varipuncta*) and the honey bee (*Apis melifera*) being the most important. To overcome the lack of natural pollination, hand pollination is practiced in many countries. Artificial pollination has been found to be more efficient, and fruits from hand-pollinated flowers are larger and juicier than fruits from insect-pollinated flowers.

Passion fruit species have different periods for flower opening, which are usually short, rarely passing 8 h. The flowers of *P. edulis* open at dawn and close at midday; those of the *P. edulis* f. *flavicarpa* open at noon and close in the evening. Thus, the time for possible pollination is limited.

The purple and yellow passion fruits rarely hybridize in the field but can be crossed manually. A number of successful hybrids have been produced in Queensland, Florida, and Hawaii. Commercial production in Australia, in fact, now depends almost exclusively on commercial hybrids. Hybrids are intermediate in skin color and character between the two parents and have been selected in terms of agronomic characteristics, including resistance to viral and fungal diseases, high yield, extended cropping season, and flavor quality similar to the purple form.

In countries where the fruit is grown commercially, the usual method of propagation is by seeds. However, vegetative propagation, mainly from rooted cuttings and grafting, is becoming important to obtain disease-resistant plants and high yields.

The plant can grow in different types of soil, preferably sandy-clay soil, provided it is deep, relatively fertile, with good amount of organic matter, has good drainage and a pH between 5.0 and 6.5. A temperature between 21 and 32 °C favors development of this plant, the optimum being 26–27 °C. Long exposure to sunlight (between 10 and 12 h of daylight) is required for flowering. Annual rainfall should be between 800 and 1750 mm and well distributed throughout the year. Heavy rainfall during the peak of flowering will impede pollination. Irrigation is recommended during the dry periods, and pruning is necessary for good production. Frost and strong winds are limiting factors to passion fruit cultivation. The vines are usually supported by trellises in commercial plantations or by wires strung between wooden or concrete posts in small domestic farms.

The plant starts to produce fruit a year after planting, but has a short productive life, varying from 3 to 5 years, although longer periods have been reported. The highest yield is obtained on the second or third year, decreasing thereafter.

On average, 60–70 days are required from pollination to maturation of the fruit. Thus, two or more harvesting seasons per year are possible, depending on the climatic conditions, geographic location, cultural practices, and other factors. In the tropics, production is almost uninterrupted, but in subtropical regions, vegetation ceases in winter, production

being stopped during this period and in the spring months. Thus, in these regions, the productive period is reduced to 6 or 7 months per year.

Upon ripening, the passion fruits fall from the vine and are picked from the ground at least once a week, preferably more often in wet weather. The fruits are transported in lug boxes and, if not processed immediately, placed into cold storage. A temperature of 6.5 °C with a relative humidity of 85–90% is recommended. Under these conditions, the fruits can be stored for 4–5 weeks. Storage temperatures below 6.5 °C cause chill injury; at higher storage temperatures, the fruits suffer more losses due to moldiness.

Diseases and Pests

Production of passion fruit may be adversely affected by various diseases and insect pests. Common diseases are woodiness (thickening and hardening of the pericarp) or the mosaic disease, due to a virus transmissible by aphids, and several diseases of bacterial and fungal origin. Bacterial diseases include grease spot caused by *Pseudomonas passiflorae*, blast due to *Pseudomonas syringae* and bacterial spot caused by *Xanthomonas passiflorae* or *Xanthomonas campestris* pv. *passiflorae*. Diseases brought about by fungi are: brown spot by *Alternaria passiflorae*; leaf spot or septoria blotch by *Septoria passiflorae*; *Fusarium* wilt by *Fusarium* spp., such as *Fusarium oxysporum* f. *passiflorae*, or crown canker by *Fusarium lateritium* and *Fusarium sambucium*, which enter the plant at lesions and cracks; root rot caused by *Thielaviopsis basicola*; antrachnosis by *Colletotrichum gloeosporioides*; cladiosporioses by *Cladosporium herbarium*; and collar rot by *Phytophthora cinnamomi*.

Among the insect pests that can damage passion fruits, the most important are: (1) fruitflies, notably *Dacus dorsalis*, *D. cucurbitae*, or *D. vertebrates*, or larvae of the fruitflies *Anastrepha* spp., *Ceratitis capitata* and *Dacus tryoni*; (2) caterpillars of the butterflies *Dione juno juno* and *Agraulis vanillae*; (3) fruit mites *Tenvipalpus californicus*, *Brevipalpus papayensis*, *B. phoenicis*, *Polyphagotarsonemus latus*, *Tetranychus mexicanus*, *T. desertorum*; (4) pasion fruit or fruit bug *Diactus bilineatus* and *Holymenia clavigera*; and (5) leafhopper *Scolypopa australis*. Purple passion fruit vines can also be damaged by nematodes, such as *Meloidogyne javanica*, *M. arenaria*, *M. incognita*, *Scuttellona truncatum*, *Helicotylenchus* sp., and *Pratelenchus* sp. The yellow passion fruit is nematode-resistant. (*See* **Insect Pests**: Insects and Related Pests; Problems Caused by Insects and Mites.)

Chemical Composition

The chemical composition of the fruit and the juice is known to vary appreciably, being affected by factors such as variety, degree of ripeness, plant status, date of picking, season, climate, locality or region, soil composition, and cultural practices.

Although other tables on the composition of passion fruit are available in the literature, a list based on USDA data is presented in Table 1 because this is constantly updated.

The purple passion fruit juice is a good source of ascorbic acid and carotene, a fair to good source of riboflavin and niacin, and a fair source of mineral matter. On an overall basis, the yellow passion fruit has less ascorbic acid, °Brix, °Brix/acid ratio, and reducing and total sugars, but a higher acid and carotene content.

Carbohydrates constitute the second largest constituents of passion fruit (Table 1), and three sugars, glucose, fructose, and sucrose, make up 86% of the total carbohydrates, the rest being starch. The sugar composition of yellow passion fruit consists of 29%

Table 1 Composition of passion fruit and juice[a]

Constituents	*Fruit, purple*	*Juice, purple*	*Juice, yellow*
Proximate

[a]Values per 100 g of edible portion.
From USDA Department of Agriculture, Agricultural Research Service (2002) *USDA Nutrient Database for Standard References, Release 15*.

fructose, 38% glucose, and 32% sucrose. The purple passion fruit has 34% fructose, 37% glucose, and 29% sucrose.

The nitrogen content of the juice is reported to vary from 0.10 to 0.19%, and the crude protein content ($N \times 6.25$) from 0.6 to 1.2%. The free amino acids found in purple passion fruit juice are leucine, proline, threonine, valine, tyrosine glycine, aspartic acid, arginine, and lysine.

The total acid content (expressed as citric acid) ranges from 2.4 to 4.8% w/w with an average of 3.4% for the purple passion fruit juice. The yellow passion fruit juice from Hawaii has an acidity ranging from 3.0 to 5.0%, with an average of 4.0%. The predominant acid is citric acid (about 83% of the acids), followed by malic acid (16%) and lesser amounts of lactic (0.87%), malonic (0.20%), and succinic (trace) acids. The same organic acids are found in the purple fruit juice, but the relative amounts are different. Citric acid is also the most abundant (41%), followed by lactic (23%), malonic (15%), malic (12%), and succinic (7.6%) acids.

An early study identified in purple passion fruit the carotenoids phytofluene, α-carotene, β-carotene, and ζ-carotene, of which β-carotene dominated. Later, β-apo-12′-carotenal, β-apo-8′-carotenal, cryptoxanthin, auroxanthin, and mutatoxanthin were also detected. Recently, 13 carotenoids were conclusively identified in yellow passion fruit: phytoene, phytofluene, ζ-carotene, neurosporene, β-carotene, lycopene, prolycopene, monoepoxy-β-carotene, β-cryptoxanthin, β-citraurin, antheraxanthin, violaxanthin, and neoxanthin, with the yellow ζ-carotene predominating. A recent study showed cyanidin 3-glucoside to be responsible for the purple color of the rind of *P. edulis*, accounting for 97% of the total anthocyanin content. Small amounts of cyanidin 3-(6″-malonylglucoside) (2%) and pelargonidin 3-glucoside (1%) were also found.

As in other fruits, the volatile composition of passion fruit is extremely complex, consisting of numerous compounds, and the unique flavor and aroma cannot be attributed to any single constituent. A compendium in 1990 listed 84 esters, 33 aldehydes and ketones, 71 alcohols and acids, and 25 miscellaneous volatiles identified in passion fruit. The volatile constituents present in the highest concentrations are the C-2 to C-8 esters of the C-2 to C-8 fatty acids that occur in many fruits. Some volatiles are probably degradation products of carotenoids, such as linalool, β-ionone, dihydro-β-ionone and the lactone of 2-hydroxy-2,6,6-trimethylcyclohexylideneacetic acid (dihydroactinidiolide), an oxidation product of β-ionone, these compounds being detected in both purple and yellow passion fruit. Dihydro-β-ionone and 1,1,6-trimethyl-1,2-dihydronaphthalene (3,4-dehydroionene), a possible degradation product of β-ionone, have been found only in purple passion fruit. Other compounds, such as edulans, megastigmatrienes, and sulfur-containing compounds, not included in the listing cited above, have also been reported as volatile constituents of passion fruit.

Out of some 300 volatile flavoring constituents of passion fruit drinks, only 22 were found likely to contribute to the passion fruit flavor. Of these, 6-(but-2′-enylidene-1,5,5-trimethylcyclohe-1-ene and (*Z*)-hex-3-enyl butanoate contributed 30 and 11%, respectively, of the passion fruit flavor profile. Several esters present in the juice at relatively high concentrations had negligible flavor impact values.

The flavor and aroma of the purple passion fruit are often described as more pleasing than those of the yellow fruit; this difference is reflected in the volatile composition. The purple passion fruit has higher levels of the major esters ethyl, butyl, and hexyl butanoates, and butyl and hexyl hexanoates, and of the terpene ketones, β-ionone and dihydro-β-ionone. Some important flavor constituents of the purple passion fruit are absent in the yellow fruit: 2-heptyl acetate, butanoate, and hexanoate, the edulans, dihidroionone, 1,1,6-trimethyldihydronaphthalene, and the megastigmatrienes. There are also differences in the terpene hydrocarbons, the yellow fruit having relatively high concentrations of (E)-β-ocimene, myrcene, limonene, and 1,4-*p*-methadiene, whereas only (E)-β-ocimene is present in a significant concentration in the purple variety. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

The immature fruits have lower juice, sugar, ascorbic acid, and carotene contents. These fruits are more acidic and inferior in flavor compared with the partially and fully ripe fruits. Changes in the volatile composition during maturation have also been reported, the compounds of greatest flavor significance reaching maximum concentrations in the fruit that have just fallen from the vine. This observation indicates that the common practice of harvesting passion fruit after it falls is likely to provide fruit of the best flavor, provided that gathering from the ground is not delayed. Another study, however, found the fallen fruit to be lower in soluble solids, sugar, acidity, and ascorbic acid, suggesting that the customary harvesting practice should be avoided. Anthocyanins and carotenoids also increase during ripening.

Production, Utilization, and Processing

Reliable and updated production statistics on passion fruits are not available. Although it is one of the better known so-called exotic fruits, it has not reached the

point of being one of the fruits for which production is monitored by FAO. The major producing countries, listed in decreasing order of area of production in 1987, are: Brazil, Peru, Sri Lanka, Ecuador, Australia, Kenya, South Africa, Venezuela, Papua-New Guinea, Fiji, New Zealand and the USA (Hawaii). These countries account for 80–90% of the world's production of passion fruit. Taiwan and Colombia have been markedly increasing production, a good part of which is destined for export. Commercialization of the fresh fruit is limited, with Kenya being the principal exporter to Europe, especially to the UK. It is estimated that 50% of the world's production of passion fruit juice is exported. Brazil, Peru, and Colombia are the principal exporters of the juice, the major importers being the UK, Germany, France, Switzerland, the USA, and Japan.

After cutting the fruit in half, the pulp and seeds can be scooped with a spoon and eaten as is, or the pulp can be sieved to make a refreshing drink. Because of its intense flavor and high acidity, the passion fruit juice is considered a natural concentrate and is often diluted, sweetened, or blended with other fruit juices. The whole or sieved pulp is also used as a flavoring for yogurt, icecream, sherbet, meringue, or cake topping.

In Australia, there is appreciable consumption of the fresh fruit, although the bulk of passion fruit production is processed into juice, consumed locally as carbonated beverages. The juice is also used as a flavoring for icecream, confectioneries, and tropical fruit salads. Australian consumers are used to eating and drinking passion fruit products with the seeds still present, the seeds being regarded as evidence of passion fruit content. Elsewhere, the seeds must be removed.

Production of passion fruit in Fiji and Papua-New Guinea is largely for export to Australia and New Zealand as frozen, unsweetened pulp or juice. A significant part of production in Fiji is also consumed in homes and restaurants as mixed drinks. Passion fruit products in Sri Lanka include jams and sweetened and unsweetened juices. In India, this fruit is processed into passion fruit squash.

Most of the passion fruit produced in Hawaii is consumed as drinks blended with other fruit juices, such as orange and/or guava, the remainder being used as frozen juice bases. Passion fruit juice is considered too acidic for icecream, but this characteristic is advantageous in the preparation of sherbet. Minor uses are as a flavoring for syrups and as a pie filling.

The principal passion fruit products in Brazilian market are the juice and the frozen pulp, these two products serving as the base for other products such as drinks, yogurt, icecream, confectioneries (cakes, meringues, and chocolate fillings), gelatin, marmalades, and fruit cocktails. Fresh fruits are also marketed. In Venezuela, popular products include passion fruit juice, passion fruit icecream, and a bottled passion fruit and rum cocktail.

Passion fruits are preserved by freezing or thermal processing. Two characteristics of this fruit favor freezing. Firstly, the flavor is extremely sensitive to heat, so it is difficult to heat-process the juice without markedly altering the flavor. Secondly, the high starch content causes the accumulation of gelatinous deposits on the heating surfaces of the heat exchanger, lowering its efficiency, as well as causing deterioration of juice flavor. Enzymatic degradation of starch and centrifugal procedures for removing starch have been recommended.

Production of passion fruit juice can be done manually, as in many small cottage industries, consisting simply of hand-slicing the fruit, scooping out the pulp, and separating out the seeds either through sieving or expression through a cloth.

In Hawaii, the processing of passion fruit is highly mechanized, a centrifugal separator being the favored method for extraction of the pulp. A typical extractor has a capacity of 1725 $kg\,h^{-1}$ of passion fruit with an extraction efficiency of 94%. Its main disadvantages are: (1) some seeds are cut in the slicing operation, which necessitates the use of a fine screen in the finishing operation; and (2) there may be some extraction of skin flavors.

In Australia, the converging cone extractor is the most commonly employed extractor. In another method, a modified apricot-pitting machine and plunger are used. Since Australians are accustomed to consuming passion fruit products with the seeds, further processing to remove the seeds from the pulp is not necessary. Elsewhere, consumers' preference for seedless passion fruit products necessitates further processing.

The extraction unit most commonly utilized in Brazil is a three-stage system, consisting of a cutter, a perforated cylinder with a series of beaters that separates the rind from the pulp and seeds, and a pulper that separates the juice from the seeds and does the finishing of the juice.

Much of the earlier canned passion fruit juice was considerably overcooked. More recent processes make use of slightly higher temperature and shorter heating times. The most successful method for thermal processing of the juice employs a spin cooker. This cooker is an inexpensive, easily constructed unit, utilizing rapid can rotation to transfer heat quickly. Pasteurization to an 88 °C center temperature is achieved in about $1\frac{3}{4}$ min, after which the cans are rapidly cooled with a cold water spray while still

rotating. The color and flavor retention in this method is much better than in any alternative method of heat preservation.

To concentrate passion fruit juice, centrifugal evaporators have been successfully used in Brazil and Australia. The main advantage is the short residence time (0.2–1.0 s), which minimizes heat damage. Passion fruit concentrate can be stored at −18 °C for 6 months, 4 °C for 3 months, and 20 °C for 1 month with good color and flavor retention and no microbial spoilage.

Passion fruit juice may be quick-frozen directly from the finisher. Preferably, a slush-type or scraped-surface freezer should be used to hasten the freezing process, aside from increasing the freezing capacity of the processing plant. The juice may also be frozen directly in containers in an air-blast freezer. This product is sold to manufacturers of juice blends and of foods with passion fruit as an ingredient or as a major flavor component.

According to folk medicine, passion fruit has sedative and muscle-relaxant properties. Medicinal utilization of the leaves has also been cited.

In the extraction of juice from the passion fruit, about two-thirds of the bulk is refuse, of which 90% is rind and about 10% is seeds. Passion fruit rind has been found to be satisfactory as a supplementing feedstuff for dairy cows, and so it is commercially utilized as feed for dairy animals in Hawaii. In Brazil, the passion fruit rind is used as a component of rations for cattle and hogs. Other possible uses of subproducts, such as pectin from the rind and oil from the seeds, have not reached the industrial scale.

PASTA AND MACARONI

Contents

Methods of Manufacture

R Cubadda, University of Molise, Campobasso, Italy
M Carcea, National Institute for Food and Nutrition Research, Rome, Italy

Background

The current range of products referred to as pasta is relatively vast, and products vary widely in terms of shape, color, composition, storage requirements, and use. However, all share a basic technology that involves the preparation of a dough made by mixing a flour with a liquid (mainly water), which is then processed (namely by extrusion) to obtain the required shape and dimension of the product itself.

It is a popular belief that pasta originated in China, where it was manufactured with soft wheat flour. From there, it is supposed to have been introduced into Europe (Italy) by Marco Polo in AD 1292 after his travels to the Far East. However, the production of dried pasta, as it is manufactured today, is comparatively recent. The first attempt to produce extruded pasta instead of cut noodles from a sheeted dough was made in Italy in the 1800s using a hand-operated mechanical wooden press. For many years, pasta production was home-based, and only at the turn of this century did it become an industry, owing to the invention of the steam engine and hydraulic presses, and to the development of artificial instead of natural drying. The first continuous press, which replaced the traditional batch method, was introduced in 1933. The final step towards a fully automated system was achieved in the early 1950s, with the introduction of the automatic weighting and packaging equipment in pasta factories.

Today, the whole process, from reception of raw materials to mixing, kneading, extrusion, drying, packaging, and dispatching, can be performed automatically by several pieces of machinery controlled by computers. Moreover, the diffusion of pasta throughout the world and the popularity of the traditional dry product have stimulated the development of production technologies leading to new convenient commodities such as fresh, precooked, and frozen pasta.

Raw Materials and Their Properties

The raw material of choice for pasta production is semolina from durum wheat, although, for various reasons, the industry uses flours from soft and hard wheats, corn, and other cereals. Durum wheat semolina is the only raw material permitted for pasta production by national laws in Italy, France, and Greece. Special pasta is also produced by adding a great variety of other ingredients (i.e., fresh, frozen, or powdered eggs, powdered spinach, tomatoes, carrots and other vegetables, soy protein, wheat gluten, milk protein, vitamins, and minerals) to the two basic components, semolina (or flour) and water. This section deals with the production of pasta using the traditional raw material durum wheat semolina. However, the manufacture of pasta with flour or blends of flour and semolina is also mentioned. (*See* **Wheat**: The Crop; Grain Structure of Wheat and Wheat-based Products.)

Semolina quality requirements vary from country to country. In Germany, Austria, and Switzerland, for example, semolina color is very important, whereas in Italy, the factors affecting cooking quality are synonymous with semolina quality. In today's pasta industry, uniform semolina granulation is also a desirable factor for uniform flow in semolina feeders and for proper dough development in continuous presses. A high ash content is usually indicative of longer-extraction semolina and imparts a dull color. If the wheat is not properly cleaned, or the kernels are smudged and/or damaged by severe mildew, brown and black specks can appear in the semolina. Commercial semolina with fewer than 200 specks per dm^2 is desirable, and gives pasta with a good esthetic appearance. A low level of lipoxidase, which, during pasta processing, may destroy the yellow color given to semolina by natural carotenoid pigments (carotenes and xanthophyls), is also desirable. Nevertheless, the major quality requirement in most traditional pasta consuming areas is the ability of semolina to be processed into pasta with a good cooking quality.

According to the existing literature, gluten quality and quantity are the most important factors affecting cooking quality, but starch and minor constituents such as soluble and insoluble pentosans, lipids,

lipoproteins, various enzymes, and products of enzyme reactions could also be involved. At present, little information is available on the physicochemical changes and on the behavior of starch and minor constituents during processing, cooling, and storage of pasta. It is well known that semolina quality varies widely among durum wheat varieties. Semolinas from certain durum wheat varieties grown in some locations produce pasta with a good cooking quality and/or yellow color, whereas other durum wheat varieties give semolina that produces pasta with insufficient cooking characteristics or pigment. Consequently, attention is paid to check the quality of durum varieties in order to produce the desired semolina.

Common soft wheat flour is less pigmented, translucent, and flinty than durum wheat semolina, and gives a gluten with an elastic strength suitable for making bread, but not for manufacturing a superior pasta product. However, flours milled from common hard wheats with strong gluten, a high protein content, and superior rheological characteristics are acceptable for producing pasta. The color and cooking quality of pasta from common wheat flour can be improved by adding proportional amounts of egg. As far as the water used for pasta making is concerned, it should be pure drinking water with no off-flavors.

Method of Manufacture

In a modern pasta factory, pasta products are formed by extrusion on large automatic machines that perform several processing operations. Production lines for processing short and long pasta are shown in Figure 1. The essential equipment includes:

- A series of metal silos that receive the various types of semolina or flour (coming either directly from a mill adjoining the pasta factory or from outside mills);
- An automatic continuous press;
- A spreader predrier for long pasta or shaker predrier for short pasta;
- A drier; and
- A storage and packing unit.

(*See* **Extrusion Cooking**: Principles and Practice.)

Mixing

The automatic press is one of the most important machines in a pasta factory. It performs three essential processing operations: mixing, kneading, and extruding.

In the mixing stage, water is added to the semolina so that the moisture content of the dough is approximately 30%. The flow of ingredients is regulated by volumetric or gravimetric dosers with constant and proportioned outputs. It is very important that the water is absorbed evenly by the semolina or flour particles to obtain a thoroughly homogeneous dough that will prevent the dried pasta from having faults (white spots, for instance). For this reason, the

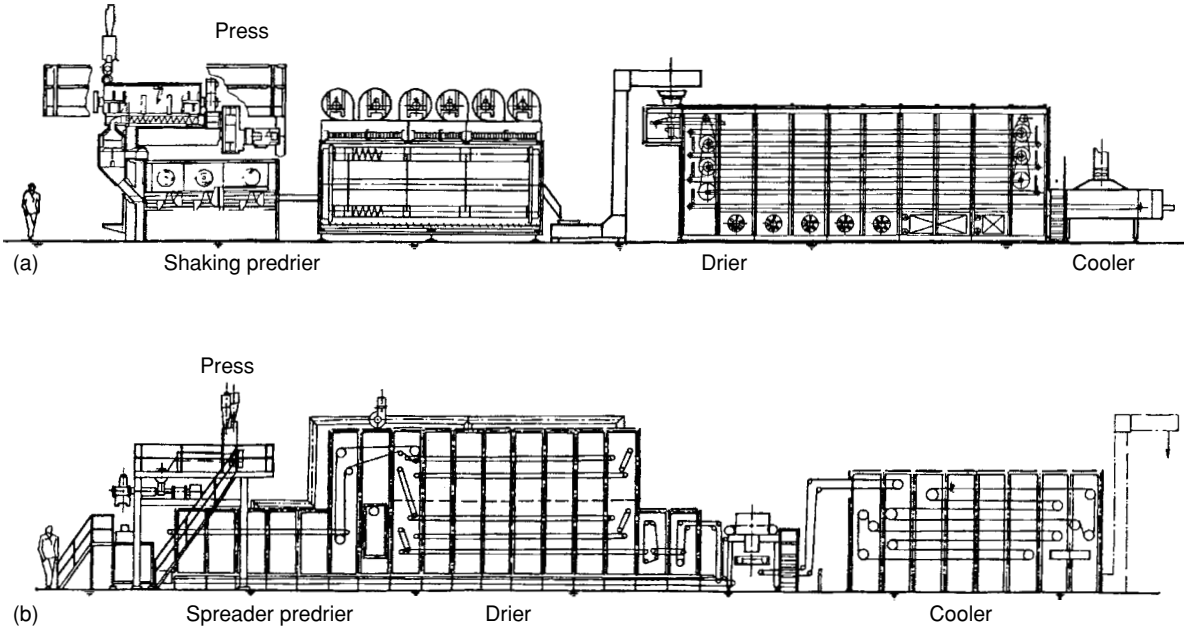

Figure 1 Modern production lines for processing (a) short and (b) long pasta. Reproduced from Pasta and Macaroni, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

semolina particles must have the same size (for a typical semolina, a maximum of 25% of particles should pass through a 0.180-mm mesh sieve), and the time needed for the liquid to be absorbed by the particles has to be evaluated while taking into account their average size and the temperature of both flour and liquid. Steps should be taken to insure that the lower the flour temperature, the higher the temperature of the liquid in the dough.

Depending on the pasta shape and type, warm water at 40–65 °C is generally used. A uniform dough is obtained by mixing the ingredients in a special twin-shaft mixing chamber for 15–17 min for short pasta, and 16–20 and 16–18 min for long pasta and long egg pasta, respectively. The shafts of the mixer turn in opposite directions to limit the amount of dough balling that can occur.

The latest development in press technology is represented by new systems that are able to carry out the dough-making in a very short time (about 2–3 min) instead of the 15–20 min necessary for normal dough preparation. A very short dough-making time increases considerably the line production speed, since it can better match the speed of the following steps (predrying, drying, etc.). For this reason, at present, fine granulometry semolina is preferred, which best suits short dough-making times. Moreover, short dough-making times allow for a reduction in the press size (output capacity being equal) and consequently a better plant compactness and smaller dimensions.

Modern continuous presses are equipped with vacuum-producing equipment to remove any air bubbles from the pasta dough during mixing and just before extrusion. The aim of this operation is to avoid the formation of small bubbles, which can give the end product a white, chalky appearance. In addition, air bubbles can facilitate the oxidation of pigments, resulting in a pale and unattractive pasta, and can weaken the dried product.

Extruding

The extrusion screw is the core of the pasta press, and special attention is paid to its design and construction, just as to the compression cylinder. In fact, it is vital to prevent the dough from being overworked, an occurrence that would adversely affect the quality of the finished product. The dough is forced by the screw into the extrusion head. Even under the best operative conditions, a considerable amount of heat is generated during this process; therefore, the barrel and the extrusion head are equipped with a water-cooling jacket to reduce the heat and to maintain a constant extrusion temperature of no more than 40 °C. Higher temperatures could cause the deterioration of the cooking quality of the finished product.

The process in the press is completed by the extrusion of the dough through a die to make a variety of product shapes that are cut to the required length with a rotary cutter. Until recently, pasta dies were made of bronze. Now, new dies with Teflon on the extruding surface are used. Teflon extends the life of the die and improves the appearance of the product. Bronze dies are still used for small special productions characterized by the rough surface of pasta. Special equipment is required to form particular shapes such as nests, skeins and Bologna-type pasta. The cut pasta is then hung over drying rods or spread evenly, all automatically, ready for the drying stage.

Drying

Drying is the most difficult and critical step in the pasta-making process. The objective of this process is to decrease the moisture level of the extruded pasta from about 30% to less than 12.5% without causing any damage to the finished product. To achieve this, the air temperature and relative humidity must be properly controlled. If the drying is too slow, the pasta products tend to spoil or become moldy. However, if they are dried too rapidly, moisture gradients occur that may cause checking or cracking. Usually, uniform temperature and ventilation are insured in all parts of the dryer. This is achieved through a suitable hot-air circulation system using low-pressure spiral ventilators located in various parts of the dryer. Moreover, automatically controlled periods of hot-air circulation alternate with periods of rest to allow for moisture equilibration between the inner part of the pasta and its surface.

In modern plants, the drying cycle can be subdivided into three distinct stages: (1) predrying, (2) drying, and (3) cooling. Although identical basic components are used, the manufacture of different types of pasta requires machines that are technically different. The most widely used dryer for long pasta is basically made of a single complex consisting of:

- an extruded-pasta supporting structure on one or more levels;
- a separate drive unit for the section on one or more levels;
- a heat ventilation unit;
- an unloading unit; and
- a regulation and control unit.

The initial predrying takes place in the first part of the dryer, where special aluminum or steel rods loaded with pasta are normally at only one level. During this stage, the product moisture is reduced to 17–18%,

as a consequence of quick evaporation of the inside water excess of pasta. Surface drying has to be avoided to prevent closing of the interstices through which the remaining water can reach the surface by capillarity and evaporates. This predrying stage lasts a short time and is followed immediately by a longer drying stage.

For the final drying, driers with more than one level are used. The product hanging on the rods is moved by means of special conveyor chains in the one-level section and with a system of racks, which alternate vertical and horizontal movements, in the section with more than one level. From a technological point of view, the drying differs from the predrying phase for a more gradual moisture reduction and particularly for the alternation of water evaporation and its even distribution inside the product.

The predrying stage of short pasta is generally carried out with vibrating trays, called shaker predryers, whereas there is a great diversification in the machines used for the next drying steps. Two different kinds of equipment are used: the belt dryer and the rotary dryer. The belt dryer is more suitable for large shapes, which must be treated delicately. These dryers receive the product from the shaker predriers by means of conveyor belts. An oscillating band evenly distributes the product on the whole upper belt width. The product, after having reached the far end of the belt, falls on the following ones, repeating this route as many times as the existing number of belt dryer tiers. Drying is achieved by means of aerothermal units in which hot water is kept in forced circulation by a pump. The rotary dryers can be used for both the preliminary and final drying of small- and medium-sized and Bologna-style pasta products. The rotary driers are essentially composed of a rotating drum, supported on rollers and driven by a multiple-speed gearbox. The product advances forward one cell for each revolution of the drum. Drying is achieved by means of a battery of air-circulating fans and heat radiators that are located above the drum.

At present, the drying technology varies greatly from factory to factory and from country to country, the main difference being in the degree of temperature used during the process. However, two systems can be recognized: (1) traditional or conventional drying, which uses 'low' temperatures not higher than 60 °C, and (2) 'high'-temperature drying, which uses temperatures between 70 and 85 °C, even though there is a trend to seek higher temperatures. Of course, the total drying time varies, depending on the system employed. High-temperature drying has been without doubt the most important innovation in pasta technology in recent times. This new technique has the advantage of appreciably reducing the drying time, compared with traditional methods, and of reducing microbial contamination. The former characteristic allows the construction of drying lines that maintain the same production capacity as the traditional lines, but they are smaller, more compact and constructed to facilitate maintenance operations.

With the increasing popularity of high-temperature drying among pasta manufacturers, considerable attention has been given to the effect of this treatment on the cooking quality, color, and chemical composition of the final product. The effect of high-temperature drying on the cooking quality is still controversial. The main reason is that the available information comes from investigations where the method of application of the high temperature during the drying cycle and the intrinsic characteristics of the raw materials are different. However, experimental evidence is accumulating to prove that semolina protein quality and quantity can influence cooking quality jointly or independently as a consequence of the drying technology adopted (i.e., low- or high-temperature drying). Different temperatures modify components and influence cooking quality in different ways. At low temperatures (40–50 °C), protein quantity and quality are equally important in determining the final pasta results, whereas at high temperatures (≥ 80 °C), protein quantity is more important and is strongly correlated with the resultant pasta quality. Some researchers have reported that pasta proteins are in fact polymerized by high drying temperatures, whereas starch granules appear embedded in the protein matrix. As a consequence, there may be an improvement in the cooking quality of pasta. Pasta cooking quality is determined by a physical competition between protein coagulation into a continuous network and starch swelling with spherules scattering during cooking. If the former prevails, starch particles are trapped in the network alveoli, promoting firmness in cooked pasta, whereas if the latter prevails, the protein coagulates in discrete masses lacking a continuous framework, and pasta will show softness and usually stickiness on cooking. High-temperature drying partially overcomes this competition by producing a coagulated protein framework in dry pasta without starch swelling.

Drying conditions also have a significant effect on the retention of lysine in spaghetti. As lysine is the limiting amino acid in wheat, any reduction in its availability has an important bearing on the nutritional quality of pasta. A decrease in the amount of total lysine has been reported as being directly proportional to the increase in temperature. The loss of lysine depends mainly on the blockage of the amino

group as a consequence of the Maillard reaction. (*See* **Browning**: Nonenzymatic.)

Cooling and Packaging

The final drying is followed by a cooling treatment that must be carried out with certain precautions to avoid damage to the pasta through humidity imbalance within the shape. After this stage, the end product is unloaded, sent to storage silos, and then sent to the packaging section.

Pasta products are packaged in various ways, depending on their particular shapes and sizes. The most widely used packages are cellophane bags and packets, cartons, and special trays. All these are automatically weighed, packed, and collected by machines on continuous cycles. Sometimes, semi-automatic machines may be required.

Considerations of Quality

A good cooking quality is the most important requirement for pasta products. Aroma, taste, and, sometimes, uniformity of shape and color and breaking strength of uncooked pasta are also important to the consumer. Although it can be interpreted according to the individual taste and habits of the consumer, the cooking quality of pasta is generally regarded as the capacity of the product to maintain its shape when cooked in boiling water and to retain a good texture after cooking without becoming a thick, sticky mass. The parameters involved in the evaluation of pasta cooking quality can be defined as follows:

- stickiness is the state of surface disintegration of cooked pasta;
- firmness is the resistance of cooked pasta when sheared between the teeth;
- bulkiness is the degree of adhesion of pasta shapes after cooking.

As already mentioned, cooking quality depends essentially on the type of raw materials used and on their intrinsic characteristics, although it can be affected by the manufacturing conditions.

As far as the nutritional quality of pasta is concerned, the nutritive value appears to be completely independent of the use of durum wheat semolina or bread wheat flour. However, the addition of other ingredients such as eggs, vegetables, soy or vegetable protein concentrates and isolates, individual nutrients, etc. produces remarkable changes in the nutritional value of common pasta.

The protein quality of pasta can be influenced by a reduced bioavailability of lysine caused by severe drying conditions. This has to be considered when adding high-quality protein integrators to the raw materials.

Dietary Importance

L J Malcolmson, Canadian International Grains Institute, Winnipeg, Manitoba, Canada

Background

The term 'pasta' is used to describe products made from a flour–water dough that fit the 'Italian' style of extruded foods. The primary ingredient used in the manufacture of pasta is a coarsely ground flour from durum wheat, called semolina. In the commercial manufacture of pasta, semolina and water are mixed into a dough, which is then extruded through a die to produce the desired size and shape of pasta. The product is then dried or sold fresh. Common pasta products

include spaghetti, vermicelli, linguine, rotini, rigatoni, and macaroni.

In contrast, the term 'noodle' is used to describe an 'Oriental' style of sheeted and cut products made from grains other than durum wheat. Grains used to produce noodles include common or bread wheat, rice, barley, and buckwheat, as well as legumes such as mung bean.

The earliest written record of pasta in the Italian diet was reported to be 1279, although noodle products were most certainly part of earlier cultures of China and the later cultures of many other countries. Today, pasta products have become an important part of the diet in many countries. This has been influenced in part by changes in consumers' perception of pasta. Once thought of as starchy and fattening, pasta is now considered to be nutritious and convenient. Table 1 lists the average per capita consumption of uncooked pasta in selected countries. The low consumption of pasta products in Asian countries such as China and Japan compared with other countries is a reflection of the much higher consumption of noodle products in these countries compared with 'Italian'-style pasta products.

The widespread consumption of pasta throughout the world is likely due to its simple formulation, relative ease of processing, extended shelf-life in the dry form, low cost, and versatility. Pasta's versatility stems from the fact that it is available in numerous shapes and sizes, and can be prepared and served with other foods as an appetizer, main dish, side dish, salad, soup, or dessert, thus allowing menu flexibility for the consumer. Because pasta is relatively bland in flavor, it lends itself to be complemented by sauces and other food ingredients.

Table 1 Average yearly per capita consumption in selected countries

Country	*Per capita consumption (kg)*
Italy	28.0
Venezuela	12.7

Nutritional Value of Pasta

Although the nutritional content of pasta can vary widely, depending on the ingredients used in its preparation and added sauces, pasta provides significant quantities of complex carbohydrates, protein, B vitamins, and iron, and is low in fat. A typical 140-g serving of cooked macaroni or spaghetti provides approximately 6 g of protein, 40 g of carbohydrates, and 2 g of dietary fiber, whereas whole wheat pasta provides approximately 8 g of protein, 38 g of carbohydrates, and 3 g of total dietary fiber. The fat content of a 140-g serving of pasta is less than 1 g.

Fortification of pasta products with thiamin, riboflavin, niacin, iron, and, more recently, folic acid is permitted in many countries. The vitamin and mineral content of enriched and whole wheat pasta is provided in Table 2.

In recent years, studies have been undertaken to examine the beneficial role of pasta in the diet. Evidence exists indicating that a diet rich in pasta may lower the incidence of cardiovascular disease, be helpful in managing diabetes, and be useful to individuals with a specific gluten intolerance or individuals suffering from celiac disease.

According to a review published by Costantini, subjects who consumed diets rich in pasta had lower levels of serum low-density lipoproteins and total lipoproteins than those who did not consume pasta-rich diets. This finding suggests that diets rich in pasta may be responsible for lower incidents of cardiovascular disease, provided the pasta is prepared and served using other low-fat ingredients.

The exact role of pasta in the dietary management of diabetes is not fully understood. However, it has been speculated that diets rich in pasta result in reduced rates of both starch uptake and gastric emptying, thereby resulting in a lowered postprandial blood glucose and insulin response.

Table 2 Vitamin and mineral content of cooked pasta (140-g serving)

Product	*Thiamin (mg)*	*Riboflavin (mg)*	*Niacin (mg)*	*Folate (μg)*	*Iron (mg)*	*Calcium (mg)*	*K (mg)*	*P (mg)*	*Mg (mg)*	*Zinc (mg)*
Enriched	0.20	0.20	2.4	10.0	2.0	10.0	44	76	26	0.8
Whole wheat	0.20	0.00	1.0	8.0	1.4	22.0	62	124	42	1.2

K, potassium; P, phosphorus; Mg, magnesium. Source: NutriQuest™ (1999).

Peptides derived from the gliadins of durum wheat have been shown to be less aggressive to celiac disease. Thus, pasta derived from durum wheat may be useful in the diets of individuals suffering from gluten intolerance, depending on the severity of the reaction.

The nutritional value of pasta can be increased by the addition of other food ingredients to increase the protein or fiber content. Research has been undertaken to investigate the effects of various protein sources on pasta quality. Studies have been published showing the successful addition of whey derivatives, nonfat dry milk, soy, corn, legumes (bean, lentil, cowpea), lupin, amaranth, buckwheat, and maize. By blending durum wheat semolina with other plant protein sources, the limiting amino acids lysine and threonine are compensated for by the other protein sources. Protein-enriched pasta products are currently available in some countries. Egg-enriched pasta is also popular in many countries. Whole grain cereals such as barley and legumes as well as the use of whole wheat have also been used to increase the mineral, vitamin, and dietary fiber content of pasta.

The addition of natural colorants such as black squid ink, puréed spinach and carrot, tomato paste, and beet juice has also received considerable attention, and many of these products are currently being sold in the marketplace. The use of herbs and chocolate has also gained popularity in the production of more flavorful product lines. These ingredient additions are made to enhance the flavor and color of the final product, since the nutritional properties are not changed substantially.

Effects of Processing and Cooking on the Nutrient Content of Pasta

The effect of drying and cooking on the nutritional content of pasta has also been studied. Drying conditions have been found to significantly affect the bioavailability of lysine retention in spaghetti. Losses as high as 47% have been found for spaghetti dried at 80 °C and as low as 22% for pasta dried at 45 °C. Other researchers have reported that the extent of lysine losses is a function of both drying temperature and length of exposure to high drying temperatures. With continued improvements in drying technologies, the deleterious effects of high-temperature drying on available lysine will likely be minimized. Furthermore, whether these losses are significant, given that pasta is combined with other foods in the diet, is also questionable. Studies that have examined the loss of vitamins during drying reported higher losses of thiamin and riboflavin with increasing drying temperatures. These losses were smaller for thiamin under industrial drying conditions. The effect of cooking on the retention of B vitamins has suggested that a good portion, namely 50–75% of the vitamins, is retained following cooking. With fortification of B vitamins during processing, these losses are not as significant as they may be in products that are not fortified.

As a wheat-derived staple food, pasta is second only to bread in world consumption. Its worldwide acceptance can be attributed to its low cost, ease of preparation, versatility, long shelf-life, and nutritional and sensory properties. With the greater emphasis towards the consumption of cereal based foods as a result of changes in dietary nutritional recommendations, the importance of pasta in the diet of many countries will continue to remain high.

PASTEURIZATION

Contents

Principles

R A Wilbey, The University of Reading, Reading, UK

Introduction

Pasteurization has become widely accepted as an effective means of destroying vegetative pathogens in food products, with the least possible damage to the sensory qualities of the product. The heat treatment also reduces the general microbial population, so that an increased shelf-life is normally obtained. Bacterial spores and some heat-resistant enzymes will survive pasteurization processes and limit the shelf-life of the product.

Historical Origins

Cooking is an age-old method of preparing many traditional foodstuffs, and for centuries it was generally appreciated that cooked products would normally take longer to putrefy than if they were raw.

In the latter part of the 18th century there was great interest in understanding the mechanism of putrefaction. Lazzaro Spallanzani demonstrated that putrefaction may not occur in a heated sealed flask of an infusion, but that aerial contamination could result in putrefaction. The presence of microorganisms was demonstrated, and it was recognized that there was a possible division into organisms that could be killed by boiling and those that would survive this heat treatment. Subsequent experiments by Franz Schutz in the early 19th century demonstrated that it was not the air itself that caused spontaneous putrefaction, but a contaminant carried in the air. Similar experiments were carried out by Theodore Schwann at the same time.

Methods for the preservation of foodstuffs were developed in parallel with this pioneering work on the basic understanding of why foods spoil. Carl Wilhelm Scheele used heat for the conservation of vinegar, and Nicholas Appert developed the preservation of foods by heating in cans. In 1824 William Dewees recommended that milk for infants be heated to near to boiling (but not boiled) then cooled as preparation for infant feeding.

The credit for the development of a mild method of processing foods, now particularly associated with milk, has been given to Louis Pasteur, after whom the pasteurization process was named. Pasteur had, amongst his many interests, an interest in fermentations. The poor hygiene conditions associated with the production of food and beverages at that time often led to unwanted fermentations, causing putrefaction and loss of product. His experiments confirmed that fermentations were not spontaneous but the result of microbial metabolism. While some of his earlier work was with lactic fermentations, most of his work in this field was based on alcoholic fermentations, brought about by yeasts. The conversion of ethanol to acetic acid was demonstrated to be brought about by bacteria, subsequently classified as *Acetobacter*. Both yeasts and *Acetobacter* could be destroyed by relatively mild heat treatments, at about 55 °C in an acid medium such as wine, in closed vessels.

While Pasteur's work on beer, wine, and vinegar laid the foundations for hygienic processing, his complementary work on the relation between specific organisms and disease also aided the recognition of the public health implications of hygiene and of heat treatments.

By the late 19th century the economic benefits from improving the shelf-life of milk and other products were appreciated, though the microbiological and public health implications of pasteurization were not fully understood. Pasteurization of wine was adopted in both France and the USA and is still used for some wines, though filtration, higher alcohol levels, and better production hygiene have largely displaced heat treatment.

Introduction to the Dairy Industry

The heat treatment of milk on a commercial scale did not develop until the end of the 19th century, with the production of commercial pasteurizers in Germany and Denmark. The earlier treatment systems were aimed at improving the storage life of milk, often using simple continuous-flow techniques to reduce costs. The realization that milk was a potential carrier for diseases such as tuberculosis led to the development of a low-temperature long-time (LTLT) batch process, the first commercial plant being installed by Charles North in New York in 1907. It was not till 1922 that pasteurization was legally recognized in the UK when the term was defined in the Milk and Dairies (Amendment) Act, using a LTLT process at 62.8–65.5 °C for a minimum of 30 min.

LTLT pasteurization was the first safe method adopted, but the processing of milk was revolutionized by the invention in the UK of the plate heat exchanger, capable of regeneration. The development of a modular heat exchanger that could be relatively easily cleaned, together with a microbiologically effective holding tube system and a flow diversion valve, enabled milk to be heat-treated with safety on a far larger scale than had been possible with the batch-based LTLT system. With better appreciation of the thermal death characteristics of pathogens, this continuous process was able to take advantage of higher process temperatures with a corresponding shorter hold, and became known as the high-temperature short-time (HTST) process. In the UK, as in the European Community, the minimum heat treatment permitted is 71.7 °C for 15 s. It has been suggested that 15 s was originally chosen as the minimum time to allow an adequate margin for the response rate of the temperature-sensing and control system at that time.

Subsequent developments in the design of process equipment have led to the construction of pasteurization plants that may be cleaned in place (CIP), with much greater thermal efficiency and with much more sensitive and responsive instrumentation and control systems. It is now technically possible to pasteurize at higher temperatures with little or no hold – the so-called 'flash' processes.

Development of safe HTST processes for milk insured that in-bottle LTLT pasteurization of milk, pioneered by Charles North in 1911, although capable of producing a high-quality product virtually free of postpasteurization contamination, was too expensive and thus unable to compete in the marketplace. The only in-bottle milk processing that continued was for sterilized milk and this product is also diminishing with the development of continuous UHT processes. (*See* **Heat Treatment**: Ultra-high Temperature (UHT) Treatments.)

The LTLT process has found an application in cream processing. With most UK dairies now producing over half of their milk as semiskimmed plus some skimmed milk, large but variable volumes of cream are produced from the separation and inline standardization processes. Carrying out separation and cream holding at 63 °C avoids problems of varying throughputs with HTST processes.

The drive to minimize energy costs has led to the widespread use of regeneration in plate heat exchangers, where the cold raw material is preheated by the hot pasteurized product. This process can enable heat recoveries in excess of 90%, giving energy savings for both heating and refrigeration. There is a risk associated with this process, however, as in simple systems with one pump, the pressure of the raw liquid will be higher than that of the pasteurized product, so if there were a leak within the heat exchanger there could be contamination of the pasteurized product. Apart from regular checks on the integrity of the heat exchanger, for many products the problem can be avoided by introducing a second pump after the preheater plus some means of maintaining a higher pressure in the downstream section of the heat exchanger, either by flow restriction within the heat exchanger or by a backpressure valve at the exit. Where such pressure drops are undesirable, double heat exchanger plates may be used. These pairs of thinner heat exchanger plates are constructed without gaskets between the pairs so that, in the event of one of the pair failing, the leaking liquid would leak out through the gap between the plates to give a failure indication without the risk of contamination of the other flow path. Maintenance of heat exchanger plates has been eased by the introduction of clip-in gaskets that do not require adhesive.

Basic Aims of Process

The basic aim of pasteurization is summarized by the definition adopted by the International Dairy Federation (IDF): 'pasteurization is a process applied to a product with the aim of avoiding public health hazards arising from pathogenic microorganisms associated with milk by heat treatment which is consistent with minimal chemical, physical and organoleptic changes in the product'.

This definition would be equally applicable to other commodities if one were to substitute the name of that product for 'milk' in the definition.

To achieve the public health objective of pasteurization in a particular product, it is essential to be aware of the pathogens associated, or potentially associated, with that product. The thermal death characteristics of the organism(s) in that product must also be known.

In most of the early work the death characteristics were expressed in terms of a temperature–time combination that would destroy the target pathogen. In the case of milk, tuberculosis was recognized as a major disease associated with milk consumption and *Mycobacterium tuberculosis* was found to be the most heat-resistant pathogen normally associated with milk. Temperature–time combinations needed to destroy *M. tuberculosis* were published by North in 1911, North and Park in 1927, Hammer in 1928 and Dahlberg in 1932; these data are included in Figure 1.

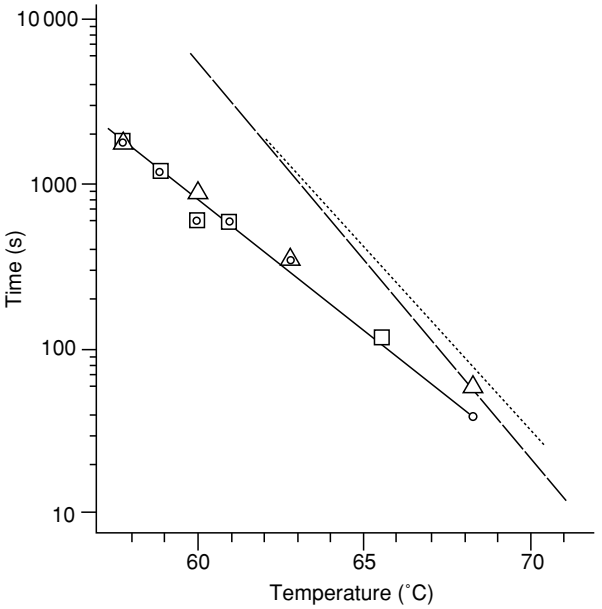

Figure 1 Time–temperature conditions for destruction of *Mycobacterium tuberculosis* in milk. Continuous line, based on data from North and Park (squares), Hammer (triangles), and Dahlberg (circles). Dashed line, virtual loss of alkaline phosphatase. Dotted line, reduction in cream line. Adapted from North and Park (1927) The American Journal of Hygiene 147: VII March, cited by Davis JG (1955) *A Dictionary of Dairying* p. 787. London: Leonard Hill.

This knowledge enabled safer process conditions to be set up for LTLT and subsequently for HTST processes. However, with better understanding of the kinetics of thermal death rates, more quantitative data may now be obtained.

When organisms are subjected to a moist heat above their normal temperature range there is a drop in the number of survivors with time: the logarithm of the number of survivors being inversely proportional to the exposure time. Thus for a given temperature, the time taken for a 10-fold reduction in survivors, the D value, may be obtained. D values are expressed in minutes or seconds and must be accompanied by the temperature, e.g., D_{72} for 72 °C. While D values are a good approximation for the behavior of bacterial populations, there can be a 'tail' of more heat-resistant strains leading to an overestimate of the lethality of the process. The term D may also be used without a subscript to describe the number of orders that the population may be reduced by in the course of a thermal or other process, e.g. a 10^{12} reduction may be described as a 12D process.

The D value will decrease with increasing temperature. The rate of change is usually given as a z value, the z value being the change in temperature required to give a 10-fold change in the D value. Typical z values for mesophiles are 4–6 °C in high water activity (a_w) systems, though some authorities use a value of 8 °C. The data in Figure 1 for *M. tuberculosis* implies a z value of 6.3 °C. Some care is needed in using z values as they can vary with temperature and, as with the D values, will vary with the product being heated. Capillary tubes have been used for the estimation of thermal death data. While this method may be appropriate for low-viscosity foods, increases in viscosity during the heat treatment may give different results to those from pilot and full-scale treatments.

By using the D and z values it is possible to estimate the risks associated with a temperature–time combination, i.e., the probable level of survivors for a given level of contamination in the raw material. This is easy for a batch process such as with LTLT pasteurization, since the hold is easily measured and the contribution of the heating and cooling stages to the overall lethality of the process is small. With HTST processes, however, the temperatures are higher and the heating and cooling stages may have a significant contribution to the overall lethality of the process. Thus it is essential that the process be characterized in terms of temperature and minimum time.

Minimum time is critical as the microbiological risk (particularly the public health risk) is associated with the minimum heat treatment given to the product. Since most HTST processes are continuous, the flow characteristics of the system must be taken into account. From a microbiological viewpoint, turbulent flow in the pasteurizer will give the best results as there will be a narrower spread of flow rates and hence residence times in the equipment. However, in practice, slower flow rates may be needed to conserve desirable product characteristics or to avoid excessive pressures.

Once the plant has been characterized it is possible to analyze the process quantitatively in relation to a given risk. For instance, safe conditions for milk have been established as a minimum hold of 15 s at 72 °C. If the lethality of this process is given an arbitrary value of one unit, for instance P^*, which uses a z value of 8 °C, then we can calculate the contribution of each stage of the process to the overall lethality. An alternative unit, the pasteurization unit (PU) has also been used; in this case, taking 1 min at 60 °C ($z = 10$ °C) as the standard unit so that a safe process for milk at that temperature would need to be ≈60 PU if 63 °C/30 min is taken as the standard for a safe process. A comparison between PU and P^* values is made in Figure 2. A temperature of 10 °C is appropriate for spores but is higher than normal for vegetative pathogens – appropriate z values should be chosen to meet the substrate pathogen conditions applying to that foodstuff. Changes in the pH or a_w of the foodstuff will alter the D and z values.

It will be seen from Figure 2 that the contribution of temperatures below 65 °C to overall lethality in an HTST process is so small that it may be ignored. However, at higher temperatures the effect of heating and cooling becomes more important. This may be illustrated by comparing two model heat treatments in heat exchangers where the rate of change of temperature is 1 °C s^{-1} (Figure 3).

With the HTST process A, the hold at 72 °C provides the main contribution to the lethality of the process; the heating and cooling stages contribute less than 30% to the total lethality of the process. Raising the final temperature to 80 °C as in B extends both the heating and cooling times and introduces exposure to higher temperatures; the result is that, despite there being no hold, the total heat treatment is well in excess of the minimum safe treatment.

While the primary concern in pasteurization is to obtain a safe food, this is irrelevant if the sensory quality of the food is reduced excessively, either by overcooking or due to the persistence of other less temperature-labile factors (microbiological or biochemical). Cooked flavors may be acceptable in some foods, e.g., clotted cream, but not in others such as wine.

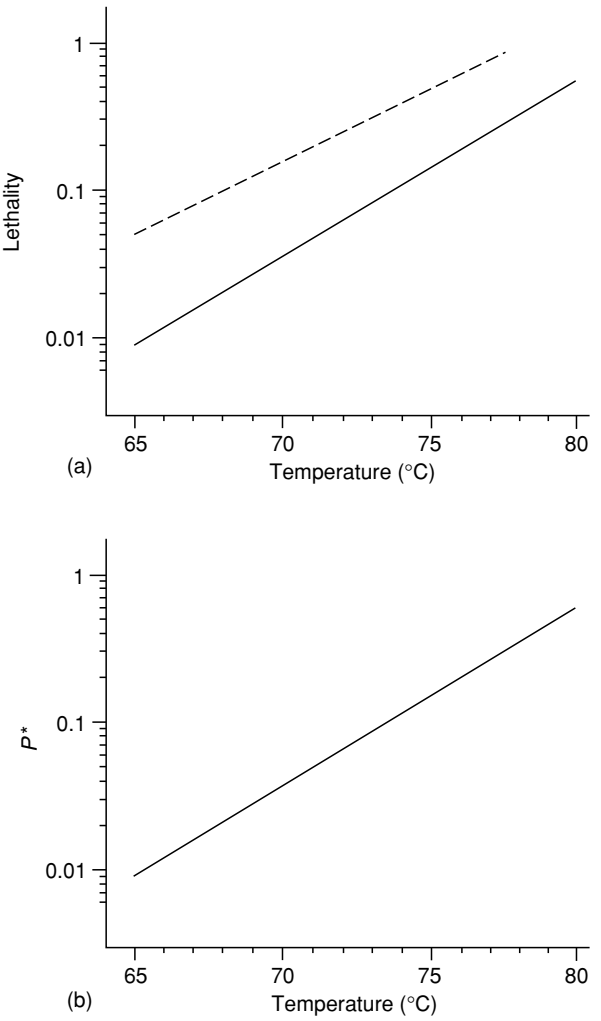

Figure 2 Lethal effect of a 1-s exposure at typical pasteurization temperatures: (a) lethality; (b) P^*. Straight line, P^* ($z = 8$ °C); dashed line, PU ($z = 10$ °C).

Heat treatments may also bring about undesirable changes in the stability or functional properties of food products, often related to protein denaturation. In milk the denaturation of agglutinin (an immunoglobulin fraction) reduces the rate at which cream forms in milk on standing: the denaturation is more pronounced when more severe heat treatments are used so that less cream separates from the milk. This has been an important consideration in processing milk for bottling (Figure 1), where the consumer has associated cream separation with milk quality, but it is not relevant to the production of homogenized milks where cream separation would indicate a processing failure. Similarly, the protein denaturation associated with pasteurization of liquid egg white

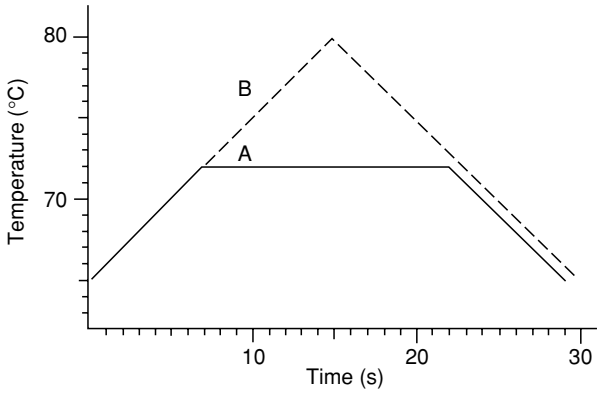

Figure 3 Example of two heat treatment profiles (A and B) with P^* values using the same heating and cooling rates. ($P^* = 1$ for a 15-s exposure at 72 °C with $z = 8$ °C.)

	A	*B*

Hold	1	0
Cooling	0.16	1.8
Total P^*	1.4	4.2

reduces the foaming properties of the product slightly, giving less volume and/or a longer whipping time than with the raw egg white.

Protein denaturation may also be used beneficially to indicate that a satisfactory heat treatment has been given, using an assay of a suitable enzyme occurring naturally in the product. The indicator enzyme should be denatured under conditions slightly more severe than those needed for microbial stability. Ideally the activity of the indicator enzyme should not be subject to wide variation with season or source.

Alkaline phosphatase is denatured under slightly more severe conditions than are required for destruction of *M. tuberculosis*, so the absence of alkaline phosphatase activity is generally used as an indicator for satisfactory pasteurization of milk. The presence of alkaline phosphatase activity may indicate either an insufficient heat treatment or contamination by raw milk. The pasteurization of liquid egg in the UK (minimum 64.4 °C for 2.5 min) is not sufficiently severe to inactivate alkaline phosphatase but will denature α-amylase, whereas the milder treatment required in the USA (minimum 60 °C for 1.75 min) aimed at achieving a 9D reduction in *Salmonella enteritidis*, will leave residual α-amylase activity.

Bacteria are more resistant to heat treatment when the a_w of the medium is lowered. Thus more severe heat treatments are normally used for pasteurization of sweetened products such as icecream and dessert products. Examples of heat treatments are given in Figure 4.

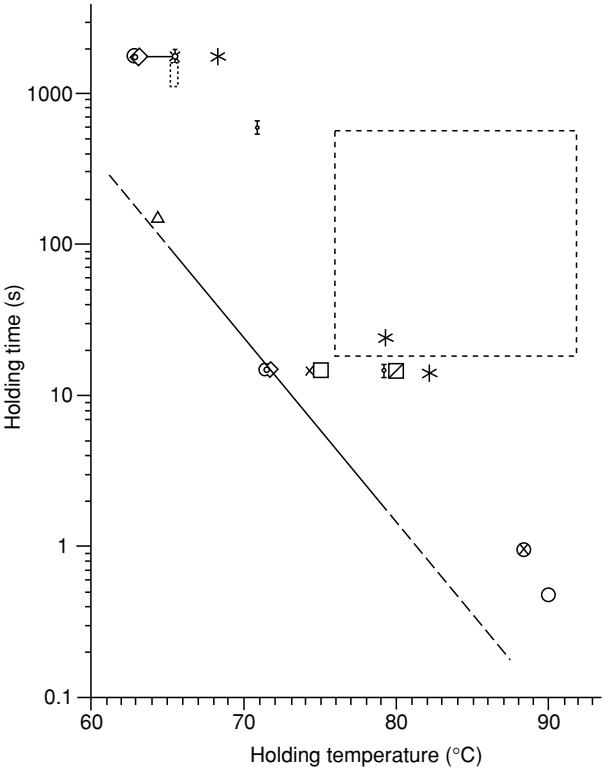

Figure 4 Examples of heat treatments used in pasteurization processes. o Milk (UK); O milk (USA); Δ liquid egg (UK); ◇ cream (UK); □ cream (International Dairy Federation: IDF); ▨ cream (≥35%, IDF); X milk products >10% fat or added sugar (USA); ✳ eggnog and frozen mixes (USA); ⌶ icecream (UK); --- fruit juices; $P^* = 1$ for milk. The dotted boxes indicate the range of values normally associated with low-temperature long-time (LTLT) and high-temperature short-time (HTST) pasteurization processes.

In fruit juices the pH is usually below 4.5 so that growth of pathogenic bacteria will not be supported, though pathogens may survive for some time. Yeasts and some lactobacilli may grow and cause spoilage of the juice, plus molds may grow at the surface. Heat treatments to eliminate yeasts and lactobacilli are more severe than for elimination of vegetative pathogens, e.g., 70 °C/60 s or 85 °C/30 s for citrus juices.

Survival of enzymes can cause problems on storage of fruit juices. In apple juice extraction, polyphenol oxidase will cause rapid browning of cold extracted juices if the juice is not immediately treated with antioxidants such as ascorbic acid or sulfur dioxide. HTST treatment at 89 °C/90 s will denature polyphenol oxidase as well as potential spoilage organisms.

In citrus juices the presence of pectinase will lead to breakdown of the cloud associated with the fresh juices. HTST treatment at 90 °C/10 s or 85 °C/4 min will denature the pectinase. For many fruit juices, including apple and orange, the juice is extracted in the country of origin, heat-treated, and concentrated.

The concentrate is then stored and transported in bulk before reconstitution and final heat treatment.

With any perishable product, the shelf-life is controlled not only by the survivors of the heat treatment but also by the posttreatment contaminants. With mild heat treatments such as the pasteurization of milk the total count may be reduced by two orders so the shelf-life will be a function of the original count, the postpasteurization contamination, and the storage temperature. Fruit juices, though subjected to more severe treatment, will also have their shelf-lives restricted by posttreatment spoilage so that the same juice may be packed as a short shelf-life chilled product or, by aseptic handling and packaging, as a long-life product stable at ambient temperatures. The advantages resulting from avoiding postprocess contamination have led to the retention of in-container pasteurization for many fruit juices and fruit drinks.

The principle of pasteurization has also been applied to the surface treatment of beef and other carcasses following slaughter. Both steam and hot water at 80 °C have been used for reduction of the surface microflora, including *Escherichia coli*. This treatment reduces both the spoilage rate and the potential public health risks associated with raw meat.

Pasteurization of Liquid Products

R A Wilbey, The University of Reading, Reading, UK

Background

Liquid products are relatively easy to pasteurize, since their flow properties permit fast heat transfer by a mixture of convection and conduction. Three basic types of process have evolved to meet the requirements of the food industry: these are batch, in-container, and continuous processes.

Batch Pasteurization

Batch processing represents the simplest approach, where the bulk of the liquid is heated, and possibly cooled, within a vessel with either a jacket or a heating coil. This method was originally used for pasteurization of milk and is still used for small-scale production of icecream and yogurt mixes.

Batch processing suffers from a number of disadvantages. The product flow rate within the tank is relatively slow, and so the heat transfer rates are low, whereas increasing the severity of mixing will increase the power consumption of the plant and may damage the product. The overall heat transfer is also slow because of the relatively low surface:volume ratio, a problem that worsens exponentially with increasing vessel size. Slow heating and cooling rates contribute to a relatively high level of chemical changes in relation to the biocidal effects of the heat treatment, which can limit both the temperature and applicability of the process. Thermal efficiency of batch processing is usually low, as heat is not easily or economically recovered during the cooling process.

Against these disadvantages, batch pasteurization has the advantage of relative simplicity and lower capital cost. Thus, it has been used widely for small-scale processing, particularly where daily outputs are likely to be less than 1000 l per day.

The basic batch pasteurizing setup will usually consist of a jacketed tank with a mixer, temperature sensor and recorder, plus a source of heat and control

system. The mixer should be mounted off-center to avoid excessive cavitation and swirling. A control system is essential to maintain the product at the desired holding temperature for what is usually an extended period, e.g., 30 min at 63 °C for milk or 66 °C for icecream mix. With many small batch pasteurizers, the cooling is carried out within the vessel, and the control system will actuate the changeover from heating to cooling medium.

Apart from the risk of contamination of the product towards the end of the holding period, there are two potential design/operational faults that can occur with batch pasteurizers. Inadequate heating of the head space within the pasteurizer may lead to condensation dripping back into the product with a consequent risk of contamination. The potentially more serious risk is that of cross-contamination from raw materials. The raw material feed must be kept separate from the pasteurized product exit pipe, normally by using a top feed, bottom drain setup, as illustrated in Figure 1. Furthermore, the drain valve must be located close to, or preferably integral with, the vessel, so that all liquid in the drain pipe between the vessel and valve will also receive an adequate heat treatment. The control system and/or the plant operating instructions must insure that the drain valve is closed before any raw materials are filled into the batch pasteurizing vessel.

The different mixing requirements and shear sensitivities have led to a wide range of types of mixers being used in batch pasteurizers. For icecream mix manufacture, an emulsification stage is required, which, on a small scale, can be carried out by using a high-shear mixer. (*See* **Emulsifiers**: Organic Emulsifiers; Uses in Processed Foods), and thus high- and low-shear mixers may be placed into the same vessel.

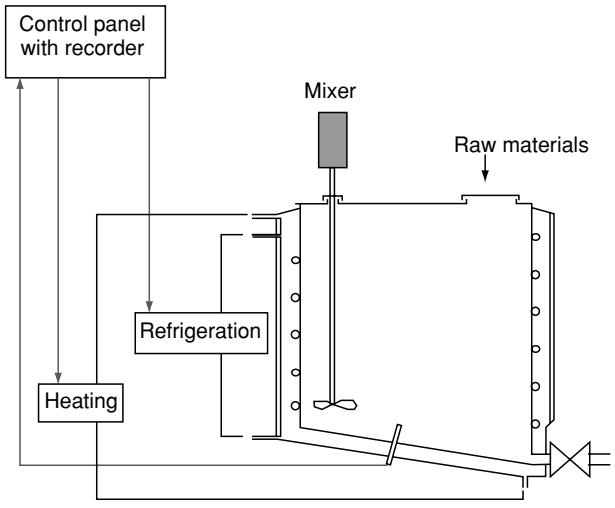

Figure 1 Outline of a simple batch pasteurizer.

Pasteurizer vessels for shear-sensitive products such as cream have used large, slow-moving paddles and rocking coils, though there have been contamination problems resulting from leaks when passing coolant through the paddles.

Where outputs of about 1000 l h^{-1} are required, some processes use two batch pasteurizers in a semicontinuous or flip-flop mode. The vessels are equipped for mixing and heating, together with a temperature sensor, recorder, and control system. In the case of icecream, the emulsification is left to the end of the heat treatment (66 °C for 30 min or 72 °C for 10 min), the heat-treated mix being pumped to a high-pressure homogenizer then cooled by passage through a plate heat exchanger. This plant configuration is outlined in Figure 2. A flip-flop mode of operation is sometimes used for heat treatment of yogurt mix, where holds of 85 °C for 30 min may be applied to the mix (though it is advisable to homogenize the mix before the hold).

Although the semicontinuous mode of operation overcomes some of the objections to batch heat treatment, there remain two serious disadvantages in terms of economics and product quality. It is difficult to recover heat during the cooling phase, thus raising the cost of processing. Product quality can be compromised by the need to empty the tank, after holding, at a rate equivalent to the time taken to prepare, heat, and hold the succeeding batch. This means that the actual hold used will vary from the nominal hold to greater than twice that time when the last part of the batch is removed. Though this excess holding time can be reduced by using three tanks rather than two, there remains a significant average over-processing that can lead to cooked flavors and textural defects in the product. (*See* **Browning**: Nonenzymatic; Enzymatic – Biochemical Aspects; **Protein**: Interactions and Reactions Involved in Food Processing; **Vitamins**: Overview.)

In-container Pasteurization

Batch pasteurization of bulk liquids has a further disadvantage: the pasteurized product must then be dispensed into containers for storage, distribution, and sale. This introduces the likelihood of recontamination of the product and, without the use of aseptic handling systems, limits the shelf-life and requires refrigerated storage to minimize the growth of contaminants. Such postpasteurization contamination (PPC) may be avoided by moving the heat treatment downstream so that pasteurization is carried out in the final container.

The principle of in-container pasteurization is identical to that of batch pasteurization, but in this case, the heat-exchange surface is the container wall,

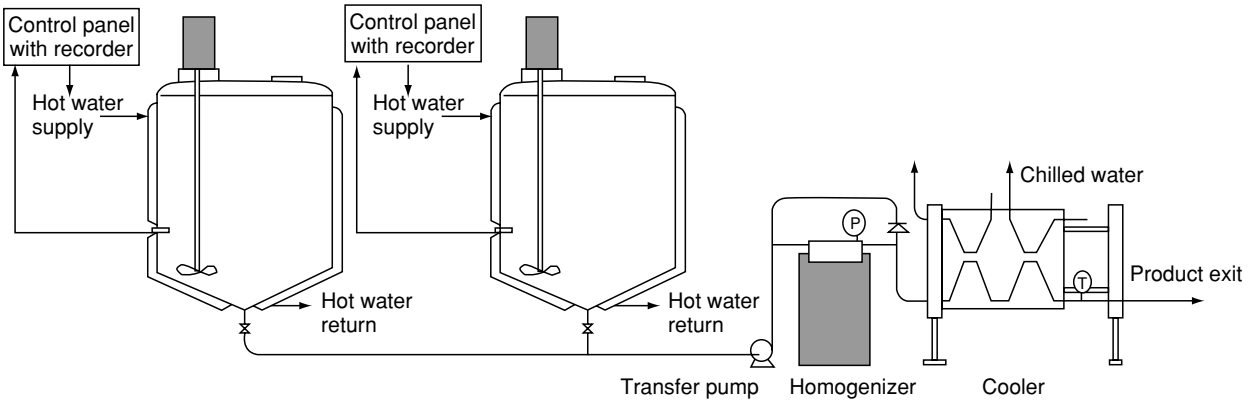

Figure 2 Outline of a semicontinuous pasteurizer.

whether plastic, glass, aluminum, or coated steel. The simplest operations may use a tank of hot water or a steam chamber for heating, followed by immersion in cold water for cooling. Adequate disinfection of the cooling water is essential to avoid contamination, either directly via pinhole leaks or indirectly via contaminated films on the surface of the pack. Unlike bulk batch pasteurization, the product temperature cannot be readily measured during the heat treatment, so test containers with the product must first be set up with temperature sensors and run through the process to establish safe processing conditions. The development of radio telemetry and solid-state logging systems now facilitates continuing checks on product temperatures, but the main control is via the temperature of the heating medium.

The majority of in-container pasteurization operations have moved to continuous processes, based on the conveyance of the containers through a tunnel where the heating and cooling operations may be carried out by spraying water over the containers. The total process time is approximately 1 h, requiring a long tunnel to give the desired holding time and capacity. The width of such tunnels increases with the capacity, as a number of containers will be treated in parallel, so that machines can be up to 25 m long and 7 m wide. Modular construction is essential.

Typical products handled in tunnel pasteurizers are soft and carbonated drinks, fruit juices, beers, sauces, and, occasionally, semisolid products such as jams and puddings. Pasteurization of acid products in this manner can yield products of a very high microbiological quality, where refrigeration is not essential for a long shelf-life.

Tunnel Pasteurizer

The product must first be filled into clean containers and sealed. A scanner or check-weigher is used to guard against under-filling. The stream of containers must then be split into groups corresponding to the number of lanes through the pasteurizer. The conveyer system must be open to permit the heat exchange liquid to drain through and must be made of corrosion resistant material, e.g., stainless steel. A combination of fixed and moving grid may be used to convey the containers on an intermittent rather than continuous basis. The conveyer speed is variable to allow for changes in throughput and holding time.

Heating is carried out by a series of zones in which increasingly hotter water, e.g., 25, 36, and 47 °C, is sprayed over the containers, as illustrated in Figure 3. This incremental heating has two advantages: glass bottles are unlikely to suffer thermal shock, and the incremental system can allow surplus hot water (usually generated by steam injection) to cascade over into the next hottest reservoir, thus reducing the energy loss. The relatively poor heat-transfer characteristics of the containers require an extended heating time, since product flow within the container will be relatively poor, being primarily due to convection currents.

Some energy may be saved by using warm water from the cooling section to preheat the incoming containers, the cooled water then being returned to the cooling part of the tunnel. Process integrity demands that not only water temperature at the various stages be monitored but the flow checked, for instance by monitoring the feed pressure to the spray bars.

Control of In-container Pasteurization

Many tunnel pasteurizers are built for processing a specified product and packaging system and are optimized for that combination. Nevertheless, the performance of the machine must be checked in order for the safety of the process to be proved. This is done by monitoring the center temperature of test containers passing through the pasteurizer under operational conditions. An example of a temperature–time plot

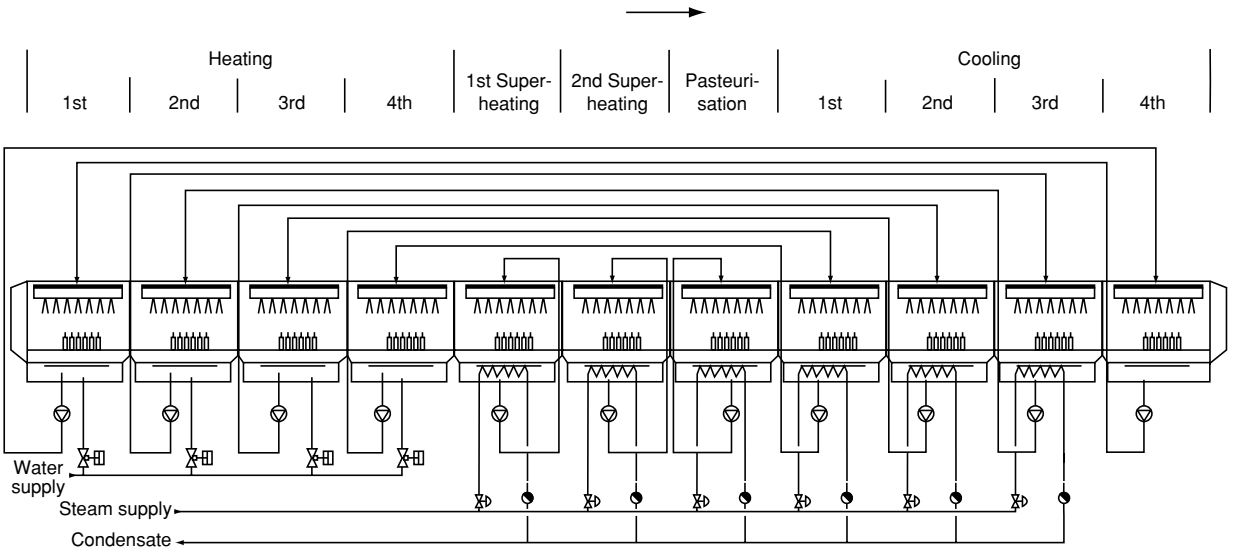

Figure 3 Schematic layout of the water circulation system in the Etna P85 tunnel pasteurizer. (Courtesy of Simonazzi srl.)

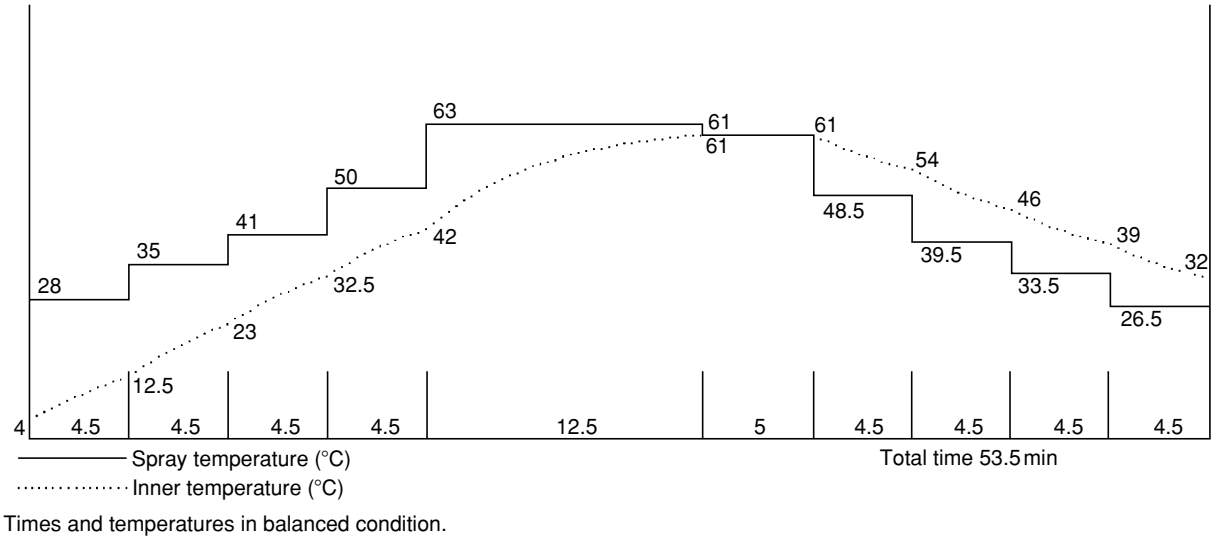

Figure 4 Time–temperature plot for an eight-stage tunnel pasteurizer. Dotted lines indicate water temperatures. (Courtesy of Simonazzi srl.)

for a soft drink is given in Figure 4. The temperature–time data must then be converted into a relevant measure of the lethality of the process, such as the use of pasteurization units (PU). For beers, the PU used is a 1-min exposure at 60 °C, assuming a z value of 7 °C, 20 PU being accepted as a safe process with little effect on flavor, providing the dissolved oxygen has been kept low, preferably below 0.1 p.p.m. (*See* **Pasteurization:** Principles.)

Major problems can occur when the tunnel pasteurizer stops, whether through a fault in the pasteurizer itself or in the production system downstream of it. The risk then is that the containers within the system will be over-processed if no remedial action is taken. Most systems are arranged to shut off the hot water sprays in the event of a stoppage, thus avoiding further heating. Some systems may have extra cooling sprays, the best systems using a computer model of the process to model the actual process during the stoppage, predict when the held product has had sufficient heat treatment, and modify the heat treatment given to the material on start-up, including variation of the conveyer speed.

Continuous Pasteurization Processes

Continuous pasteurization processes take advantage of the shorter exposure times needed at higher

temperatures, and these are often referred to as high-temperature, short-time (HTST) processes. The development of HTST processes has been dependent on the development of hygienic heat exchangers, most notably the plate heat exchanger.

The concept of the plate heat exchanger is brilliantly simple. A pair of plates are separated by a thin elastomer seal, so that the liquid flows as a thin layer, 1.5–5 mm thick, depending upon the seal design, minimizing the distance through which heat must travel. This gives an exceptionally high surface:volume ratio, typically in excess of 500:1 (compared with 5:1 for a 1000-l batch pasteurizer). The plates are rippled, e.g., as shown in Figure 5, so that the flow is broken up, and turbulent flow can be maintained at relatively low velocities over a larger surface area than suggested by the overall dimensions of the plate.

All the plates in the heat exchanger can be pressed with one tool, different heat exchanger configurations being achieved by the presence or absence of the ports cut at the corners of the plate and by the design of the elastomer seal. Plates are now designed so that the seals are held in place without the need for adhesive, speeding up maintenance. The range of flow rates over a plate is limited by the efficiency of heat transfer at lower flow rates, while the pressure drop and possible product damage provides the upper limit. This capacity limitation may be overcome by arranging plates in parallel so that there is an optimal flow across each plate. Similarly, the time permitted

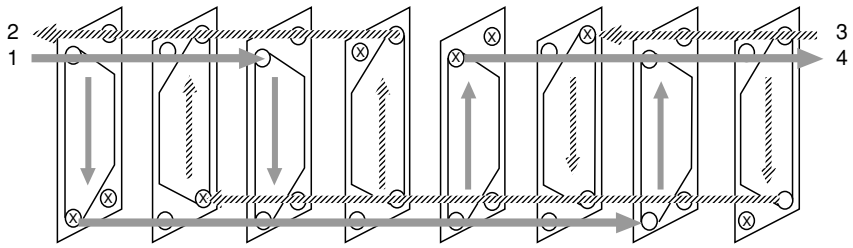

Figure 6 Arrangement of heat exchanger plates in parallel and series. 1, Cold product in; 2, Cool water out; 3, Hot water in; 4, Hot water out; x, blanked-off ports.

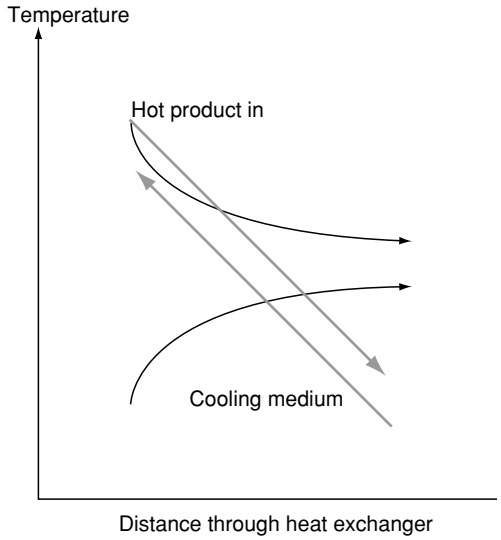

Figure 7 Illustration of co-current (——) and counter-current (——) flow through a heat exchanger using equal flow rates.

for heat exchange can be lengthened incrementally by arranging plates in series, as illustrated in Figure 6.

The heat-exchange medium is normally arranged to flow countercurrent to the product. This reduces the temperature differential between the two media, increasing the overall efficiency of heat transfer, as illustrated in Figure 7. In most cases, the heat-transfer medium will be flowing at a higher rate than the product, but with extremely heat-sensitive products such as fermented milks, similar flow rates must be used to minimize the temperature differential.

With heat-sensitive foods the build-up of a fouling layer will limit the running time of the HTST pasteurizer, owing to both pressure build-up and loss of heat exchange. The nature of the fouling layer will vary with the medium but is most commonly protein, with or without mineral deposition. Fat and carbohydrate components may become associated with fouling layers as they build up. Mineral deposits are common where hard water is used for cleaning and disinfection; additional sequestrant in the cleaning solution or periodic acid cleaning may be required. The running time may be extended by using a wider gap between the plates, though this would require a correspondingly larger heat exchanger to compensate for lower heat-transfer rates. Larger gaps have also been used when liquids have small quantities of suspended solids, e.g., orange juice containing cells that can become lodged within the plate pack and even with back flushing are very difficult to remove. Tubular heat exchangers may be used as an alternative to plates where fouling is a serious problem but thermal efficiency would suffer.

The use of a plate heat exchanger has made it much easier to recover heat by using the hot heat-treated product to heat the incoming untreated liquid. Heat recoveries of up to 95% may be achieved by this 1:1 flow, the recovery being limited by the increasing capital cost of providing further heat exchange capacity as temperature differentials decrease and the hygiene issue of the relatively low flow rates permitting the build-up of a biofilm at temperatures that will permit microbial growth and may eventually cause significant spoilage of the product.

This heat recovery, often referred to as 'regeneration,' may also pose a hygiene risk. This risk arises because, in a simple flow-through system, the pressure of the raw liquid will be greater than that of the heat-treated liquid downstream of it. Thus, any leakage could be from the raw into the pasteurized product and could have serious public health implications. The design of heat exchanger plates seeks to avoid this problem by insuring that the two liquids are separated by either the heat exchanger plate or by two seals, one for each product with a vent to the atmosphere between. Partial failure of one seal is not a major problem as the product would leak on to the floor, but the development of a crack or pinhole crevice could lead to cross-contamination. Most heat exchanger plates are made from a corrosion and stress crack-resistant stainless alloy (e.g., AISI 316), but failure can eventually occur, and checks are needed. The risk can be avoided by using a second pump to drive the downstream part of the process at a higher pressure, raising the pressure in the downstream

regeneration section either through the design of the final cooling section or by incorporating a back pressure valve into the heat exchanger discharge, when this will not damage the product. An alternative system now available is to use double plates; these plate pairs have no internal gaskets other than around the ports, so that any leakage, whether from a port or through a crack in the plate, would leak out of the heat exchanger stack and become obvious. The introduction of the air gap between the pairs reduces the heat transfer rate and would need more plates to achieve the same regeneration efficiency. It must be remembered that the savings from the use of regeneration are twofold; the first saving is from a reduction of heat input, and the second, often greater, saving comes from reduction in the refrigeration requirement.

Figure 8 illustrates a typical arrangement for the pasteurization of liquid milk. Raw milk should be taken from well-mixed bulk storage, *e.g.*, a 100 000–200 000 l silo tank, and fed to a float balance tank, which provides a constant head to the pasteurizer feed pump. Centrifugal pumps are frequently used to feed pasteurizers because of their relatively low cost, but their output is dependent on the pressure that they operate against. In the case of beer, the pump arrangement must allow an over-pressure to maintain the carbon dioxide in solution throughout the process, giving a total working pressure in excess of 8 bar. Shear-sensitive products such as cream require the use of a gentler pump such as a lobe pump, which also has the advantage of a constant output against moderate variations in pressure. Where a centrifugal pump is used, it must be accompanied either by a flow controller or by a second constant-output pump to guarantee a fixed flow rate. This requirement for a constant flow rate is set by the need to guarantee a constant residence time in the holding tube at the completion of heating. The heating is normally divided into two sections, the first preheating section using regeneration and the second heated by hot water or steam.

Sometimes, the preheating section is partially bypassed by a length of pipe with a fine control valve. This may be used to reduce the thermal efficiency during cleaning, but the main use is to control the final temperature of products such as milk for cheesemaking, where the milk will be cooled to incubation temperature (e.g., 30 °C) without the need for final cooling and without upsetting the pasteurization temperature (typically 72–73 °C). A small flow of cold raw milk past the preheater can lower the regeneration efficiency and hence raise the final milk temperature. This implies that the limit for thermal

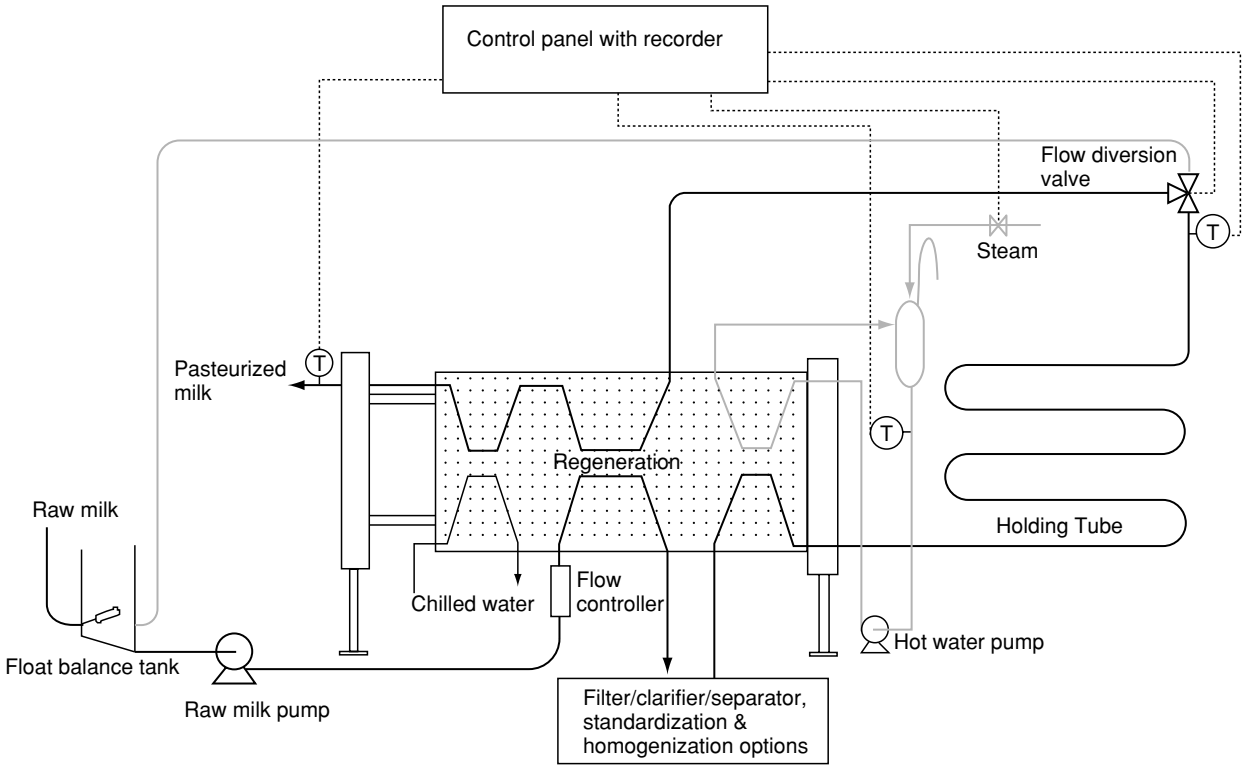

Figure 8 Schematic diagram of a milk pasteurizer.

efficiency is ≈63% when pasteurizing milk for cheesemaking.

In the simpler plants, preheated milk may be filtered before being subjected to final heating, etc. Many modern plants, however, have replaced filtration by centrifugation, sometimes simply for clarification but more often to separate the cream. The cream may be fed back into the skimmed milk to produce standardized milks for subsequent processing. Standardization may be carried out as a continuous process, the milk then passing to a high-pressure homogenizer that will provide a constant output irrespective of back-pressure (thus requiring a pressure-relief valve). The temperature provided by preheating is usually sufficient for homogenization of milk or cream, and incorporation of homogenization at this point avoids contamination from the homogenizer. Higher temperatures (≈65–80 °C) are desirable for icecream emulsification, so the homogenizer may then be placed at the beginning of the holding tube.

Hot water is the most common heating medium, energy being provided by steam injection and the condensate being returned to the boilers. Water temperature is controlled by sensing the water temperature, the controller generating a signal to open the pneumatically operated steam control valve when the temperature drops below the preset level. Some small pasteurizers, e.g., $\leq 200\,l\,h^{-1}$, may use electrical heating only. A few larger pasteurizers may use low-pressure steam as the heating medium, though this is less easy to control and is best avoided for temperature-sensitive products.

Most pasteurizer designs require the product to be held for a fixed period of time in order to achieve the desired lethality. The most reliable method of achieving this is to use a holding tube, the design of which is critical. Any bacteria present in the liquid to be pasteurized can be treated as solid particles in suspension, and the rate at which they progress along the holding tube will depend upon the flow pattern that is induced within it. The flow pattern may be deduced by estimating the Reynolds Number (Re) for that liquid under those process conditions, i.e.,

$$Re = v\,\rho\,d/\mu,$$

where v is the velocity, ρ is the specific gravity at the holding temperature, d is the pipe diameter, and μ is the dynamic viscosity at the holding temperature. When $Re \leq 2000$ for flow in tubes, the flow is said to exhibit streamline or laminar flow, where there is a large variation in velocity across the tube, with the velocity in the center being twice the average velocity, i.e., the minimum time taken for a particle to pass along the tube would be half that of the average, as illustrated in Figure 9. Values of 2000–4000 are said to characterize critical or intermediate flow patterns, where the geometry of the tube, e.g., the incidence of bends, will affect the flow pattern. At $Re \geq 4000$, the flow in a tube will exhibit turbulent flow, where the distribution of velocities is much narrower, and the minimum residence time may be as high as 0.83 that of the mean. Turbulent flow is designed into most holding tubes, but the holding efficiency is assumed to be 0.75. The advantages of turbulent flow in holding tubes are tighter control of the lethality of the process and less chemical damage to the product for that lethality.

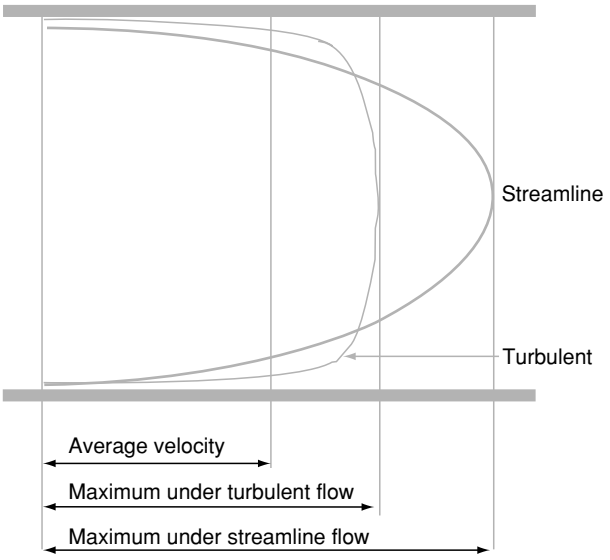

Figure 9 Illustration of the relationships between flow velocities in a tube under turbulent and laminar flow regimes.

The second issue for holding tubes is heat loss. Heat is readily lost even from polished stainless surfaces, particularly with smaller plants where the surface:volume ratio is higher. Holding tubes must never be situated in draughty locations such as close to doors, since sudden draughts can lead to a drop in holding temperature that will cause the process to fail. Where cold and variable ambient conditions are expected, the holding tubes must be insulated, and if a long hold is being used, e.g., holding whole liquid egg at 65 °C for 150 s in the UK or 60 °C for 210 s in the USA, auxiliary heating of a box around the holding tube should be considered.

The temperature of the hot product is normally sensed by a fast responding probe close to the end of the holding tube. The signal generated is used to both provide a permanent record of the heat treatment and to generate a signal to the flow diversion valve. Should the temperature in the holding tube fall outside a preset range (e.g., 72–78 °C for milk) or a failure in any of the services (steam, air, power), the

valve must move into the divert position and the heated product be sent back to the balance tank. Only when the temperature is in the desired range should the valve permit product to flow forward into the downstream, cooling sections of the plant. This action protects the downstream part plant from contamination by under-processed material and hence avoids risk to the consumer. The recorder fitted to the pasteurizer must record the pasteurization temperature, final product temperature, and status of the flow diversion valve throughout the operation.

In most large-throughput plate heat exchangers, the bulk of the cooling will be achieved by regeneration, with final cooling by chilled water. Chilled water may be produced directly by refrigeration or indirectly via an ice bank. Where cooling by glycol or brine solutions is employed, more stringent controls are needed to avoid freezing. In all cases, the coolant must be of good microbiological quality and product contamination avoided. With rheologically simple liquids such as beer and milk, the cooling would use countercurrent flow to achieve the optimal exit temperature. However, with more complex liquids such as cream, where the viscosity is dependent on many factors, including the time–temperature–shear profile during cooling, a mixture of co- and counter-current cooling may be employed. For the thickest creams, there is only partial cooling in the heat exchanger, with the remaining cooling being achieved after filling, in the retail container. This approach demands the highest hygiene standards during filling and effective cooling of the containers.

Tubular Heat Exchangers

Although plate heat exchangers are excellent machines for pasteurization of low-viscosity liquids, there can be problems with those liquids either displaying higher viscosities, a tendency to foul at modest temperatures or containing suspended particles. The introduction of tubular heat exchangers enables a greater path width, e.g., 5–10 mm, so that fouling becomes less critical and particles less likely to become trapped.

In the case of fruit juices containing pulp, simple tubular heat exchangers provide an effective means of pasteurization though with higher capital and running costs. This may be attributed to lower surface:volume ratios than are possible with plate heat exchangers and to problems in heat recovery. The surface:volume ratio can be increased by adopting an annular design, and heat exchange may be improved by adopting a rippled wall profile to promote turbulence. Detail improvements in the design of tubular heat exchangers have reduced the cleaning problems, particularly in permitting product–product heat exchange, and so direct heat regeneration has become possible. Control systems are similar to those for plate heat exchangers.

Although most fruit juices have pH values below 4.5 and are not considered high risk, pear juice, banana purée, and tomato juice may be low acid. Regardless of the public health risk, heat treatment is needed if rapid spoilage is to be avoided. Pasteurization at over 70 °C for 15 s should inactivate vegetative spoilage organisms such as yeasts, mold mycelia, and *Lactobacillus fermentum* in a high acid juice. More severe conditions such as 87 °C for 15 s would be needed for inactivation of spoilage enzymes, and for inactivation of *Byssochlamis* spp. ascospores, temperatures in excess of 100 °C would be needed. Tomato juice has been processed at 115 °C for 15 s.

Concluding Comments

Low-acid products must be kept refrigerated after pasteurization and have a relatively short shelf-life. Postpasteurization contamination poses a major threat to product quality and can only be avoided by using either in-container treatments or aseptic filling techniques. The advantages and disadvantages of the pasteurization processes are summarized in Table 1.

Table 1 Summary of the main advantages and disadvantages of pasteurization systems

Advantages	*Disadvantages*
Batch tank	*Batch tank*
Low capital cost	High energy cost
Low maintenance cost	Poor cooling characteristics
Very flexible	PPC risk depends on downstream hygiene
Suitable for small quantities	
In-container tunnel	*In-container tunnel*
Avoids PPC	High capital cost
High capacity possible	High space requirement
Consistent lethality	Product containers must be heat-resistant
More efficient than batch	Less efficient than HTST
Low cleaning requirement	Higher maintenance than others
Plate heat exchanger	*Plate heat exchanger*
Moderate capital cost	Viscosity limit
Low maintenance cost	Particulates limit
Low space requirement	Shear can damage product
High energy efficiency	PPC risk depends on downstream hygiene
Consistent lethality	Fouling problems with temperature-sensitive products

Pasteurization of Viscous and Particulate Products

G Tucker, Campden & Chorleywood Food Research Association, Chipping Campden, UK

Background

For food products of high viscosity, the choice to pasteurize in a continuous system has distinct advantages over one where the process takes place in the container (see **Figure 1**). This is because the heat transfer from a heating or cooling medium to a viscous food is far from ideal, but careful design and selection of the heat exchange system can overcome this limitation. Of principal concern are the economics of food production, which become attractive in continuous systems for high volumes and long production runs. Further economic benefits can be realized by minimizing the product's exposure to the adverse effects of high temperatures, long processing times and high shear preparation methods, resulting in improved product quality, reduced processing costs, increased safety, and increased plant throughput. This chapter considers both continuous and in-container processing systems.

Continuous Processing Considerations

A challenge in the design of heat-transfer equipment are the so-called prepared food products, such as tomato products, soups and sauces, and dessert products. These products are normally of high viscosity as well as of complex composition. Also, in most cases, the particle content is significant. With respect to the rheological or flow behavior, the products are typically non-Newtonian, showing, in many cases, quite extraordinary behavior.

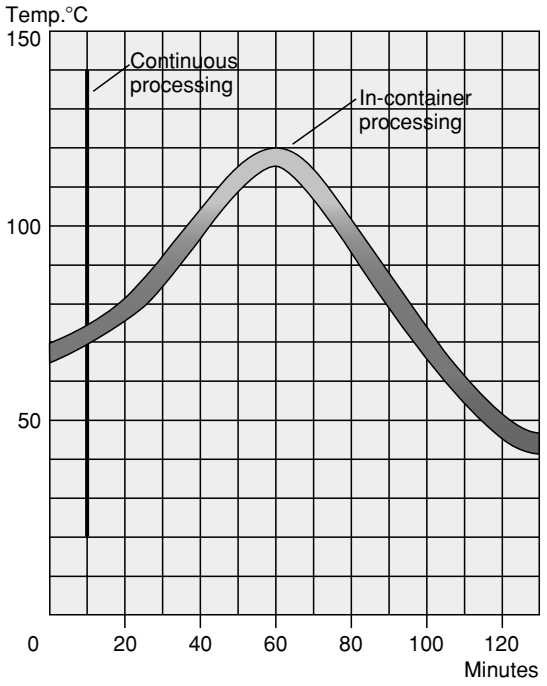

Figure 1 Time/temperature graph for comparison of in-container and continuous processes.

The microbiological demands of a pasteurization process are still to achieve commercial sterility, i.e., the end product must be free from pathogenic and spoilage organisms capable of growth under normal storage and distribution conditions as well as being free from toxins. Depending on the rheological properties of the product and the possible presence of particles, the design and choice of equipment can vary significantly from case to case.

Flow Behavior

In the design and choice of heat exchangers, the flow behavior of the product has to be taken into consideration. The flow behavior will affect, for instance, the residence time distribution and hence the design of heat exchangers and holding cells to obtain the sufficient thermal treatment. The basic difference between laminar (streamline) and turbulent flow is well known (see **Figure 2**), as is the effect on the velocity profile from heating or cooling of the product. For example, the maximum velocity in laminar flow is theoretically twice the mean velocity, and in turbulent

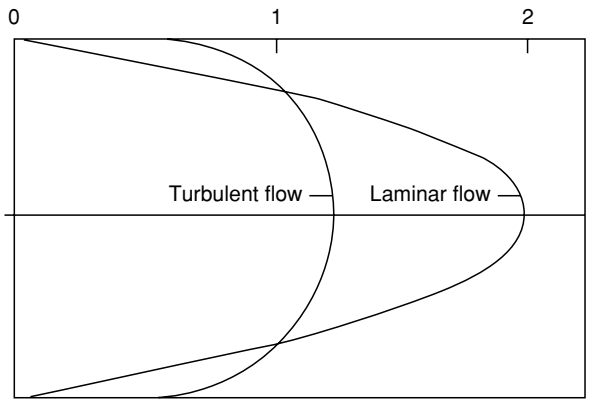

Figure 2 Velocity profiles for turbulent and laminar (streamline) flow showing the ratio of maximum velocity to average velocity.

flow around 10% higher. For viscous products, however, the flow conditions are nearly always laminar.

For liquid foods that have a complex flow behavior the velocity profiles in pipe-flow depend on the flow behaviour index. This index can range from 1.0 in simple materials such as water, milk, or fruit juice, to 0.7 in starch-based sauces, to 0.3 in tomato paste, and in theory can go to 0.0. With decreasing flow behavior index, the velocity profile increases in flatness, which means in practice that the maximum velocity decreases from twice the mean velocity. Maintaining the factor of two for the calculation of the necessary holding cell length thus creates overcooking of the product, but it is a safe assumption and one that most of the industry adopts.

A further complication to the viscous flow behavior arises with additives that give elastic properties, e.g., xanthan or gellan gum. These are sometimes used to enhance the particle-carrying properties for a carrying fluid in continuous processing. The so-called *yield value*, which normally is a measure of the product's willingness to flow by itself, e.g., from a storage tank, is also a measure of the particle carrying abilities. A significant yield value, typical of paste-like products, also adds to the flatness of the velocity profile.

Choice of Heat Exchanger

The choice of optimal heat exchanger depends to a great deal on the flow conditions. Fluids with low viscosities and no particles are preferably treated in a plate heat exchanger (see Figure 3). This is the most economic option. The food product and heating (or cooling) media flow in alternate channels to provide good heat-transfer characteristics. The plates are 0.5–1.25 mm thick, separated by 3–6 mm, and sealed with gaskets.

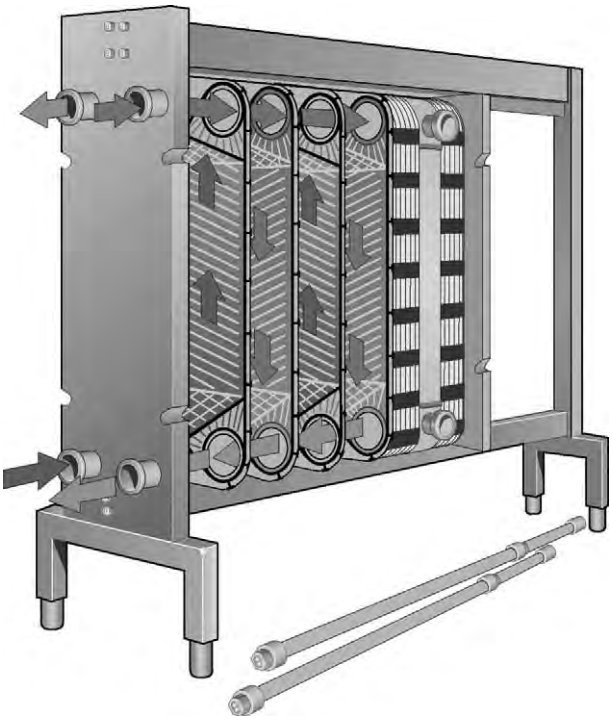

Figure 3 Plate heat exchanger.

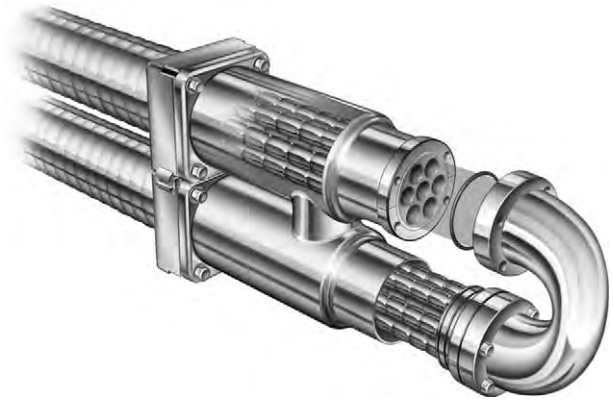

Figure 4 Multitube tubular heat exchanger.

For fruit juices with pulp and fibers up to 5 mm in length, special types of plates are available with wide gaps. Even with foods of higher viscosities, the plate heat exchanger can be utilized as long as the pressures developed are not too high, which can cause failure of the gaskets. Attempts to pasteurize foods with particles can result in blocked flow channels and increased pressure until the gaskets fail.

For fruit juices with fibers up to 15 mm in length, a multitube tubular heat exchanger (see Figure 4) is preferable to the plate heat exchanger. Also, foods of moderate to high viscosity with only small particles (< 5 mm) will flow through a multitube exchanger

without problems. The typical inside diameter of each tube is 14 mm, and these can be grouped in bundles of four, seven, 12, 19, 27, or 37 tubes. Other combinations of tube diameters and tube bundle numbers are available, depending on the equipment supplier. Most commercial tubular heat exchangers are 6 m long.

However, if the fluid is significantly viscoelastic, i.e., exhibits a large yield value, often in combination with a high viscosity, there is a risk of maldistribution across the tubes of a multitube exchanger. In the worst case, the product flow will stop in some of the tubes, causing overcooking of parts of the product and subsequent cleaning problems. Examples of such products are hot break tomato paste or a stiff dessert pudding. In these cases, the concentric tube is the best choice, which has only one product channel and eliminates this risk. At the same time, the narrow gap and the two service medium channels surrounding the product channel provide efficient heat transfer (see Figure 5).

Finally, if large particles are present, the monotube is the optimal choice of tubular heat exchanger (see Figure 6). The drawback with a monotube compared to multi- or concentric tubes is a reduced thermal efficiency due to the thicker product layer. This is illustrated in Figure 7, which shows the cross-sectional flow areas of each tube type. However, to a great extent, the particles present in the product will work as 'internal mixers' and hence will promote heat transfer.

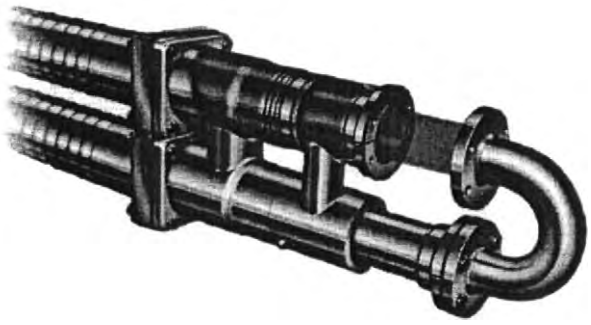

Figure 5 Concentric tubular heat exchanger.

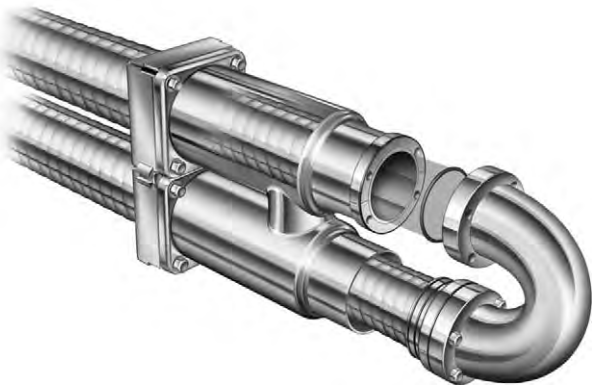

Figure 6 Monotube tubular heat exchanger.

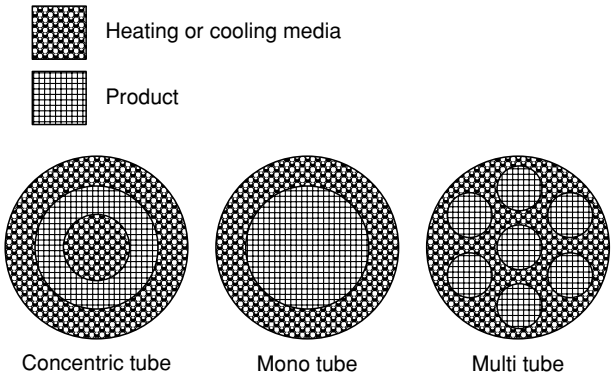

Figure 7 Cross-sectional tube designs for tubular heat exchangers.

If the food viscosity is high, and there is the chance of product fouling the heated or cooled surfaces of a tubular heat exchanger, the scraped surface heat exchanger must be employed (see Figure 8). In principle, a scraped surface heat exchanger is a monotube equipped with a rotating internal scraper. The scraper keeps the heating surface free from any deposits and also promotes turbulence. Hence, this type of heat exchanger is ideal for products of a very high viscosity, possibly also containing large particles.

Heat-transfer Correlations

Design models for heat exchangers are normally based on empirical correlations of the dimensionless Nusselt, Prandtl, and Reynolds numbers. The derived equation is basically of the form $Nu = f(Re, Pr)$. By using dimensionless numbers, only a limited number of experiments have to be performed in which the product and heating/cooling medium flow rates and the product physical properties are varied in order to cover a large range of Reynolds as well as Prandtl numbers. The physical properties are changed preferably by changing the temperatures of the fluids involved. Decreased and increased temperatures can normally vary the viscosity of the product significantly.

The definition of the Nusselt (Nu), Prandtl (Pr) and Reynolds (Re) numbers is as follows:

$$Nu = \frac{\alpha d_h}{\lambda}$$

$$Pr = \frac{c_p \mu}{\lambda}$$

$$Re = \frac{d_h \rho}{\mu}$$

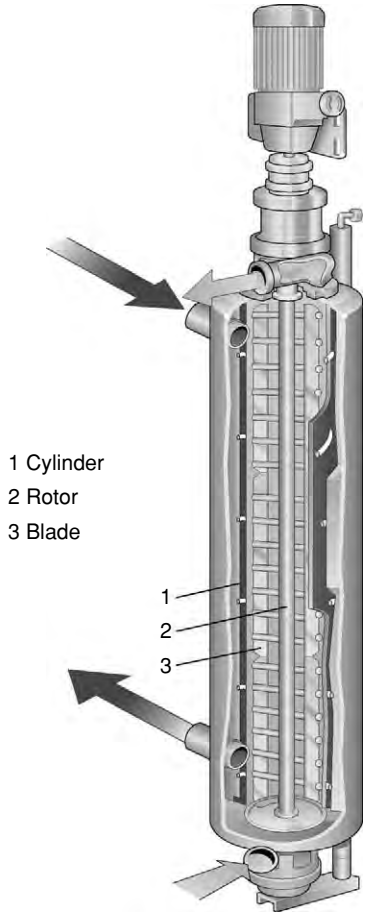

Figure 8 Scraped surface heat exchanger.

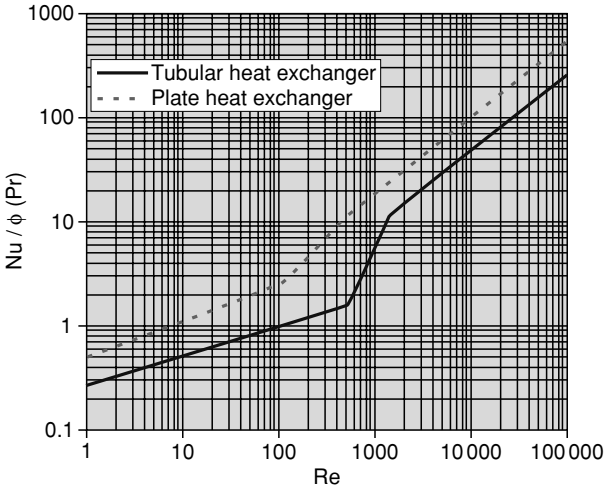

Figure 9 Comparison of *Nu–Pr–Re* correlations for plate and tubular heat exchangers.

where α is the individual heat transfer coefficient (W/m^2K^{-1}); d_h is the hydraulic diameter (m); λ is the thermal conductivity of liquid ($W/m^{-1}.K^{-1}$); c_p is the specific heat of liquid ($J/kg^{-1}.K^{-1}$); μ is the dynamic viscosity of liquid (Pa.s); v is the velocity ($m.s^{-1}$) and ρ is the density ($kg.m^{-3}$). A comparison of tubular heat exchangers with plate heat exchangers shows that the thermal performance, as read off in a typical *Nu–Pr–Re* graph, is better for the plate heat exchanger, mainly due to the complex corrugated pattern including a large number of contact points in the product channel (see Figure 9).

From systematic laboratory tests and from experience of commercial plants, it has been found, however, that to completely model the heat transfer of liquid food products, several more parameters have to be included. Such parameters include, for instance, particle content, particle shape, and size as well as the type of particles. In addition, the softness or hardness of the particles can effect the heat transfer by their influence on the laminar boundary layers at the exchanger surfaces.

Particulate Processes

Flow rates of particulates and carrier liquids should be balanced to give even thermal processing of the product. This relies on controlling the density of both phases to prevent sedimentation or flotation of the particulates. The limiting step will be the heat transfer to the center of the fastest and largest of the particulates, which should be determined by experimentation in the measurement of residence time in the holding tube and of thermal conductivity. Once determined, an estimation of the pasteurization level can be obtained using a mathematical procedure to solve conduction-based heat transfer equations. Before production of the food product commences, a full microbiological validation of the process safety should be conducted.

Batch Processing Considerations

Batch systems fall into two main categories, the most common being where the viscous food is pasteurized in its container, and the alternative is to carry out the processing within a large container (e.g. a closed vessel) and fill into individual containers. The advantage of the former method is that both food and container are pasteurized during the process, which allows the integral package to be commercially sterile and the potential shelf life extended. The disadvantage is that the containers need to be strong enough to withstand high temperatures (80–100°C) and the swings in pressure differential.

Irrespective of the method used, heat transfer from the media to the product thermal center is poor, because of the viscous boundary layers that develop on

the inside surface of the containers. The effect is to form an insulating layer that impairs heat transfer if there is no mixing inside the containers. This results in lengthy processing times to achieve pasteurization and so few companies will process viscous foods without agitation.

In-container Systems

The traditional package is the metal can processed in a steam atmosphere, although glass jars, pouches and flexible plastic or aluminum trays can now be successfully processed in steam or hot water. These containers require an air overpressure to counteract the natural expansion of the gases present in the headspace and those released from the food as it rises in temperature. The desired effect is to push the lid or sides back to their original position and therefore minimize the stress on the seals. Examples of viscous foods pasteurized in their containers are fruit pie fillings, tomato salsas and cook-in-sauces.

The first equipment (introduced by FMC Corporation in the 1930s) to increase heat transfer to this type of food was the reel & spiral cooker-cooler. This imposes rotation of cans around their central axis and allows heating times to be reduced substantially (e.g. from 90 minutes to 15 minutes). Cans travel on a helical reel through the steam heating and water cooling sections, and in doing so rotate at high speeds. The continuous operation of the cooker-cooler allows a high throughput to be achieved and favors high volume production.

More recently, end-over-end container rotation has become popular, where the containers are constrained in baskets that rotate. Being a batch system, this offers greater production flexibility and is not restricted to cylindrical metal cans. However, heat transfer enhancement is not as great as with the cooker-cooler and so the throughput is lower and operating costs higher. Sauce products in plastic pouches are processed in steam and air mixtures, using low rotation speeds (2 to 10 rpm) to induce mixing without damaging the delicate pouch.

In-vessel Systems

The vessel acts in a similar way to a heat exchanger in that it raises the food temperature to that required for pasteurization. A typical vessel size is around 800 to 1 000 kg, and comprises a hemispherical steam-jacketed base with cylindrical sides above. A hinged lid is usually present to reduce heat loss and prevent foreign objects falling into the food. With viscous foods it is essential that the food is well-mixed, otherwise laminar boundary layers develop and the food burns on to the heated surface. Horizontal agitators with scraped surface blades offer the most effective mixing, although recirculating pumps and vertical mixing blades are alternatives. Examples of viscous foods pasteurized this way are fruit preparations, confectionery, cook-in-sauces and tomato products.

Once pasteurized, the food can be filled either hot or cold into the containers. A hot-fill process will only require a short hold time at high temperature to ensure the inside container surfaces are pasteurized. This is usually achieved in a raining water tunnel pasteurizer, although it is possible to omit this step if the food's acidity is high (pH < 3.8), the filling temperature above 95°C and the containers pre-warmed or of low heat capacity. The shelf life of a viscous food of low pH will be many months if hot-filled, and determined by its chemistry. A cold-fill process will not guarantee commercial sterility of the container, and as such requires far greater attention to hygiene in order to minimize the introduction of microbial contamination during filling. Most cold-filled products are sold chilled and have shelf lives up to 14 days.

Heat transfer issues are similar to those for continuous processing in terms of transferring heat from steam or hot water to the core of a viscous food. Boundary layer generation on the inside walls of a food container limit the heating effect, which becomes more detrimental as the food viscosity increases. Agitation of the food container can overcome this resistance to some extent but it is important to match the rotational conditions to the product viscosity, otherwise the benefits will not be realised. Food containers can be rotated either axially in a continuous canning system or end-over-end in a batch retorting system. The continuous system offers greater efficiency for long production runs whereas the batch system offers greater flexibility.

Thermal Process Validation

Although pasteurization of the food is the desired condition, the food is referred to as commercially sterile. A pasteurization process usually operates to 6 log reductions of the target organism (further details on pasteurization treatments can be found in the CCFRA guidelines), and this differs from fully sterilized foods where the intention is to achieve at least 12 log reductions in *Clostridium botulinum* spores. The lower target log reductions for pasteurization are because of the reduced risks associated with the target microbial species when compared with the lethal botulinum toxin. The following equation is used to calculate the process or F-value from heat resistance data on the target pathogenic or spoilage organisms. When the F-value is divided by

the decimal reduction time (D_T) this gives the number of log reductions of surviving spores.

$$F = D_T \ (\log N_0/N)$$

where N_{final} is the final number of organisms after a specific time-temperature history; $N_{initial}$ is the initial number of organisms; D_T is the decimal reduction time at a fixed temperature (T) to reduce the number of organisms by a factor of ten (minutes).

To prove that the pasteurization process has achieved the F-value it will be necessary to conduct validation studies using an approved method. Various methods can be selected, and their choice depends on the costs and on the nature of the food and the process type. Temperature measurements provide the cheapest method but are not appropriate for all foods, and so microbiological methods are required as alternatives.

In a validation using temperature measurements, the heat resistance data for the target organism is used to convert the measurements to log reductions. For a viscous food, the position within a container that heats slowest is usually the geometric center and so the probes are placed at the centers of several containers. To validate a process for a food containing particulates, a large food chunk or piece is usually attached to the end of a temperature probe. While this will work for incontainer processes, this method cannot be used for continuous processes.

Microbiological Methods for Process Validation

These are often referred to as direct methods, but they in fact rely on measuring the achieved log reductions for a process using a non-pathogenic organism and converting this to an F-value using the same equation. If there are no surviving organisms then it is only possible to conclude that the process achieved greater than e.g. 6 log reductions for a 10^6 initial loading. In this situation, there will be uncertainty as to whether the organisms died as a result of the process, during transportation to or from the factory, or if the spores germinated during the come-up time making them more susceptible to destruction at milder temperatures than for the heat resistant spores. Hence, controlling how these tests are performed is critical and the expertise to conduct a test using encapsulated spores or organisms tends to be restricted to a limited number of microbiology laboratories. A microbiological method can be conducted using organisms distributed evenly throughout a food product or concentrated in small beads.

The inoculated pack method is also known as the count reduction method and involves inoculating the entire food with organisms of known heat resistance. For ease of handling, the organisms are usually in the spore form. It is essential that some organisms survive the heat process in order that the containers can be incubated and the surviving organisms counted. The average thermal process received by a container can be calculated using the equation for F-value. If the product is liquid it is relatively easy to introduce the organisms but for solid products it is necessary to first mix the organisms in one of the ingredients to ensure that they are dispersed evenly throughout the container. Typical levels of the inoculum are between 10^3 and 10^5 organisms per container. An alternative is to use a gas-producing organism and estimate the severity of the process by the number of blown cans.

Encapsulating spores or organisms in an alginate bead allows the organisms to be placed at precise locations within a container or within the food particulates. The alginate bead can be made up with a high percentage of the food material so that the heating rate of the bead is similar to that of the food. This method has been used for continuous processes where the food contains particulates that require evaluation at their centers, and conventional temperature sensing methods cannot be used. Large numbers of alginate beads are used to determine the distribution of F-values that can occur in continuous processes as a result of the distribution of particle residence times. Estimating the exact number to use in a test is not straightforward because it depends on the F-value distribution, which is not known until after the test is conducted and the results analyzed. The number of organisms used will be greater than for an inoculated container test and can be of the order of 10^6 per bead. It is also important that not all are destroyed by the heat process otherwise it is not possible to estimate an F-value.

General Conclusions

When pasteurizing a viscous food, the limits to heat transfer are to overcome the development of boundary layers that impair heat transfer rates at the heated surfaces. Some degree of agitation is advantageous irrespective of whether it is a continuous heat exchange process or one processed in a container. If particulates are introduced then this imposes a further limitation to heat transfer rates. The concepts of high temperature short time (HTST) treatments do not apply easily to viscous foods either with or without particulates. Hence, most thermal processes will be considerably longer than those for foods of lower viscosity. Minimizing the thermal impact is a challenge to food processing companies operating in a market where the consumer demands products of

increased viscosity or consistency, but high quality is also essential.

Other Pasteurization Processes

G J Swart, Dairy Belle, Olifantsfontein, South Africa
C M Blignaut and P J Jooste, University of the Orange Free State, Bloemfontein, South Africa

Background

Conventional pasteurization processes usually employ continuous heat-transfer mechanisms. The primary aims of these processes are to destroy pathogenic organisms in liquid foods such as milk and to extend the shelf-life of the product for a limited period of time. (*See* **Heat Transfer Methods**.)

In addition to the conventional processes, other methods exist that employ alternative heating methods, no heating at all, or methods that are not generally regarded as true pasteurization processes. These processes may, under certain circumstances, have the same effect on foods as the conventional pasteurization techniques. It is with this in mind that the following processes have been included in this article, namely pasteurization by irradiation, microwave pasteurization, ohmic heating, 'pasteurization' by blanching, as well as lesser-known versions of the pasteurization process, namely 'cold' pasteurization, extrusion pasteurization, thermization, and chemical preservation using hydrogen peroxide.

Pasteurization by Irradiation

Foods are irradiated for different reasons. When the aim of food irradiation is the inactivation of certain spoilage microorganisms that may be present in foods without necessarily leading to sterilization, the process is called 'radurization.' The 'radicidation' of foods, however, is aimed at the inactivation of pathogenic nonspore-forming bacteria and, in some cases, will also inactivate toxigenic fungi, viruses, and parasites. Both radurization and radicidation have an effect comparable to that of heat pasteurization. To understand the process better, the following aspects are dealt with in this discussion, namely the basic theoretical principles, factors influencing the process, uses, product suitability, nutritional implications, and, finally, the acceptability and current status of the process.

Basic Theoretical Principles

The underlying principle of food irradiation (and therefore also irradiation pasteurization) is based on chemical changes caused in foods by a form of energy called 'ionizing radiation.' Different kinds of radiation are included in this concept. Only a few of these are suitable for use in the treatment of foods, namely X-rays, γ-rays (from ^{60}Co or ^{137}Cs), and electron beams (cathode rays and β-rays). Nonionizing radiation, such as ultraviolet radiation, is essentially absorbed at the food surface and does not have effective penetration properties. Although limited work has been done with ultraviolet radiation, research in this regard concentrates more on extending the shelf-life of fruit and vegetables by controlling fungal spoilage, such as fusarium rot (caused by *Fusarium solani*) charcoal rot (caused by *Marcrophomina phaseolina*) and soft rot (caused by *Rhizopus stolonifer*). Ultraviolet lamps are also used to inhibit the formation of bacterial slimes on surfaces. Of the two radiation treatments, processes using ionizing radiation are more important in the context of the present assignment. (*See* **Irradiation of Foods**: Basic Principles.)

In the case of either radurization or radicidation, an irradiation dose of less than 10 kGy will have the desired effect. For radurization the doses required vary within the 1–5 kGy range. Sometimes, even less will suffice, e.g., beer radurization at 500 Gy. An acceptable end product, however, is not necessarily guaranteed. For the radicidation of foods, the radiation doses vary according to the targeted organism. To control *Salmonella* contamination, for example, doses of between 2 and 6.5 kGy have been recommended to reduce the contamination level three- to sevenfold. An estimated sevenfold reduction of other pathogenic nonspore-forming foodborne

bacteria, such as *Shigella*, *Mycobacterium*, *Escherichia*, *Staphylococcus*, *Streptococcus*, and other species, may also be obtained using doses ranging from 5 to 8 kGy. It should always be remembered that the suggested doses may be influenced by the nature of the food to be irradiated. It is, therefore, essential to take note of the factors that generally influence irradiation processes. (*See* ***Escherichia coli***: Occurrence; ***Mycobacteria***; ***Shigella***; ***Staphylococcus***: Properties and Occurrence.)

Factors Influencing the Process

The success of any form of irradiation depends on the influence and interaction of certain factors. These should also be taken into account when deciding on pasteurization by way of irradiation, since it could influence the postirradiation properties of the food. These factors include:

1. the resistance of some organisms to radiation;
2. the rate at which radiation is applied;
3. the water content of the food to be irradiated;
4. the influence of temperature on subsequent effects in the irradiated food;
5. the presence of oxygen and additives during irradiation;
6. the possibility of combining irradiation with other treatments to obtain the desired effect;
7. the penetration ability of the selected type of ionizing radiation within stated radiation limits;
8. the elemental composition of the food (as a whole) to be irradiated;
9. the magnitude and composition of the initial microbial population present in the food to be irradiated;
10. the susceptibility of the product (such as fruit and vegetables) to radiation damage;
11. cost factors with regard to the process.

Since the above-mentioned factors influence the end result, attention should be given to the applications of the process, product suitability, and nutritional implications that may result from irradiation.

Uses, Product Suitability, and Nutritional Implications

In order to understand the use of radurization and radicidation, it is essential to take into account the fact that these treatments should supplement normal food-processing practices. Radurization especially is used solely to prolong the shelf-life of products. As such, it has shown promise with fresh products such as fish, meat, poultry, vegetables, fruit, baked goods, etc. (*See* **Irradiation of Foods**: Applications.)

Radicidation is usually applied to products in which radurization is not normally able to completely eliminate pathogenic nonspore-forming bacteria. Such foods include fruits and fishery products (e.g., shellfish and fishmeal), although it is necessary to mention that radicidation of shellfish has little effect on the presence of viruses. Irradiation of meat products, such as poultry and pork at radiation levels up to 7 kGy, have, however, been successful in controlling pathogens, such as *Salmonella*, *Campylobacter*, and *Listeria* species. These pathogens cannot be controlled by good manufacturing practice alone. (*See* ***Campylobacter***: Properties and Occurrence; ***Listeria***: Properties and Occurrence.)

With regard to nutritive value, it has been shown that normal nutritional values are retained in proteins, lipids, and carbohydrates after irradiation. The nutritional availability of minerals can, however, be altered by the treatment, and a small amount of vitamins may be destroyed. These losses, however, compare favorably with those incurred during conventional processes. These aspects should have a positive influence on the acceptability and current status of radurization and radicidation. (*See* **Irradiation of Foods**: Processing Technology.)

Acceptability and Current Status of the Process

Irradiation of foods is the one process for which safety aspects have been considered very thoroughly. These include aspects such as microbiological implications, effects on nutritional value, and the possible production of toxic substances, carcinogens, and radioactivity in treated foods. It may be concluded that treated foods can be considered safe on all counts (especially at the dose levels required by radurization and radicidation), provided that:

1. approved doses are applied;
2. the foodstuffs to be irradiated do not possess abnormal levels of elements that could be rendered radioactive; and
3. acceptable packaging materials are used.

A limiting factor with regard to both radurization and radicidation processes is the possible development of objectionable changes in the properties of some foods, such as flavor, odor, color, texture, perceived freshness, etc. Negative effects of irradiation can, however, be counteracted by using the treatment in association with other processes. Lower doses of radiation (radurization) accompanied by a refrigeration process are proving to be technically and economically feasible.

It should be mentioned that irradiation can also have a product-enhancing effect, e.g., the enhanced flavor of brandy. Research with regard to this aspect of the process is continuing. Table 1 demonstrates the current interest in low-dosage irradiation and fields

of application. It clearly shows the wide interest (both positive and negative) generated by the process.

In conclusion, it should be stated that the current status of the process depends on individual countries and their health standards. Before commercial exploitation of the process by a manufacturer, the government of the country involved should approve or have approved it. Although many countries permit food irradiation, doubts still exist in some quarters with regard to the safety of the process. (*See* **Irradiation of Foods**: Legal and Consumer Aspects.)

Microwave Pasteurization

Microwave processing of foods has been the focus of much research since the 1940s. As a food-processing method, however, it became of practical interest in the 1960s with the development of multikilowatt conveyorized ovens. The microwave principle only came into general use in the 1980s, when microwave heating applications started to increase. One of these applications was pasteurization using microwave energy. To understand the process better, this article concentrates on the basic theoretical principles of the process as well as its applications and acceptability.

Basic Theoretical Principles

Microwaves are electromagnetic radiant energy waves with wavelengths of between 0.025 and 0.75 m and frequencies of approximately 2450 and 915 MHz in the case of food applications. Most countries have standardized on 915 or 896 MHz for industrial use. The energy level for a specific foodstuff is chosen according to the amount of energy lost in the process due to packaging, for example, since this adversely affects the penetration capability of the microwaves. If a high penetration level is required, a microwave frequency with a lower loss factor should, therefore, be selected.

Another important aspect is the fact that microwave energy has an effect on dipolar molecules such as water molecules. Application of microwave energy causes these molecules to oscillate, causing intermolecular friction and, ultimately, producing heat. Heating is, therefore, achieved inside the foodstuff being irradiated, depending on the type of applicator and the foodstuff being treated. All in all, the treatment facilitates control and the prevention of overprocessing in the case of pasteurization.

Applications and Acceptability

Microwave pasteurization as a process has been applied especially to milk and milk products. The Bach process (using a dual-frequency application) claims great success with regard to cultured milk products. In the case of fluid milk, patents exist for a microwave heat exchanger used in the pasteurization of milk. In spite of the fact that different processes, such as

the high-temperature/short-time, multitherm, and in-pack continuous process, have been developed, the feasibility of microwave pasteurization of milk on an industrial scale has not really been established.

Microwave pasteurization has the following advantages and disadvantages:

1. Amino acids may be altered during the process, and this aspect should be looked into in more detail.
2. Microwaves are successful in pasteurization because of their heat-generating action. The effect it has on microorganisms as such, however, needs to be resolved more fully.
3. Microwave-pasteurized products retain the properties of the fresh product.
4. The process shows promise as a high-efficiency, low-energy process. This limits bacterial build-up in usually restricted flow areas of the system.
5. The design of the system is of paramount importance for successful processing.
6. The effectiveness of heating is related to applicator design and can be either more or less even than conventional methods.
7. The operating costs are high.
8. Magnetrons have a relatively short lifespan and are essential in the conversion of electrical energy to microwave energy.
9. Depending on the design, less factory space may be required.
10. Safety is of great importance, since damage can be caused to the eyes and other tissues that absorb microwaves.
11. Both small static microwave ovens (home pasteurization) and complex, moving-belt microwave tunnels (industrial application) may be used. A schematic diagram of a microwave system for processing foods under pressure is given in Figure 1.

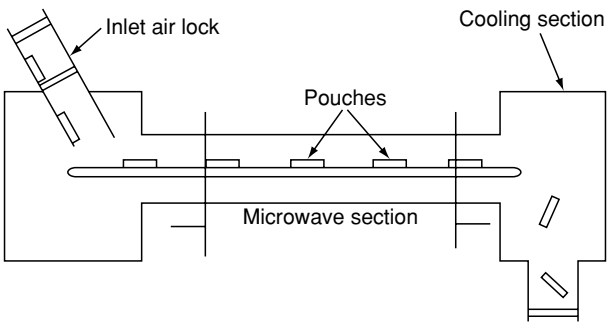

Figure 1 Schematic diagram of a microwave system for processing foods under pressure. From Decareau RV (1985) *Microwaves in the Food Processing Industry*. London: Academic Press, with permission.

12. Microwaves are not necessarily effective in killing bacteria, especially in higher-density products. Manual mixing has been suggested to facilitate more uniform heat distribution. Research in this field is continuing.
13. Heat-sensitive products can be treated to great advantage using microwave technology.

In conclusion, many questions relating to microwave pasteurization and microwave technology in general still remain to be answered. Continuing research should, however, make more general applications a reality.

Blanching

Although blanching is not traditionally seen as a pasteurization process, some authors deem it to be a 'kind' or 'type' of pasteurization. While pasteurization, however, has as its main function the destruction of pathogenic microorganisms, it also destroys certain natural food enzymes in the process. Blanching, however, is applied primarily to inactivate natural enzymes in fruits and vegetables to be processed. Its secondary effect is that it reduces the microbial load. Both pasteurization and blanching are similar in that they employ temperatures below 100 °C.

A process involving acid blanching and the addition of ethylenediaminetetraacetic acid to a canning brine has been a recent topic of research. The results have shown potential with regard to the control of spoilage and botulinal toxigenesis in canned products. This draws a further parallel between blanching (a preparatory method) and pasteurization (a processing method). (*See* **Canning**: Principles.)

With this in mind, the reader is referred to the article on canning for further information.

Ohmic Heating

Ohmic heating is a new food-processing operation which offers a major advantage in the continuous processing and particulate food products.

Basic Theoretical Principle

Ohmic heating occurs when heat is internally generated by the passage of an electrical current through a food product and is in this way similar to microwave heating. In the case of ohmic heating, the penetration depth, however, is virtually unlimited, and heat penetration is more effective. The process depends on the electrical conductivity of the product. Fats, sugars, and syrups are, therefore, not suitable for this type of processing, while foods that contain dissolved ionic salts conduct electricity sufficiently and are,

therefore, suitable for ohmic heating. If both the liquid and solid phases of a product contain sufficient dissolved ionic salts, heat penetration is more rapid than with conventional heating. (*See* **Heat Treatment**: Electrical Process Heating.)

Design of Ohmic Heaters

The ohmic heater is based on a well-known principle, and the apparatus provides an alternative to tubular or scraped-surface heat exchangers for the processing of viscous and particulate food materials. The design of an ohmic heater relies on the principle that an electrical potential is generated across a moving column of product. For safety reasons, the heater column inlet and outlet electrodes are earthed.

Figure 2 illustrates the electrical configuration and construction of the electrical resistance heater.

The heater column is arranged in such a manner that an upward flow occurs in the column while the product is progressively heated to the required temperature. Back pressure is maintained at a constant 1 bar when heating products up to 90 °C, but a pressure of 4 bar is required up to the maximum temperature of 140 °C. The back pressure is controlled by regulation of the pressure on the surface of the product in a presterilized tank using sterile compressed air.

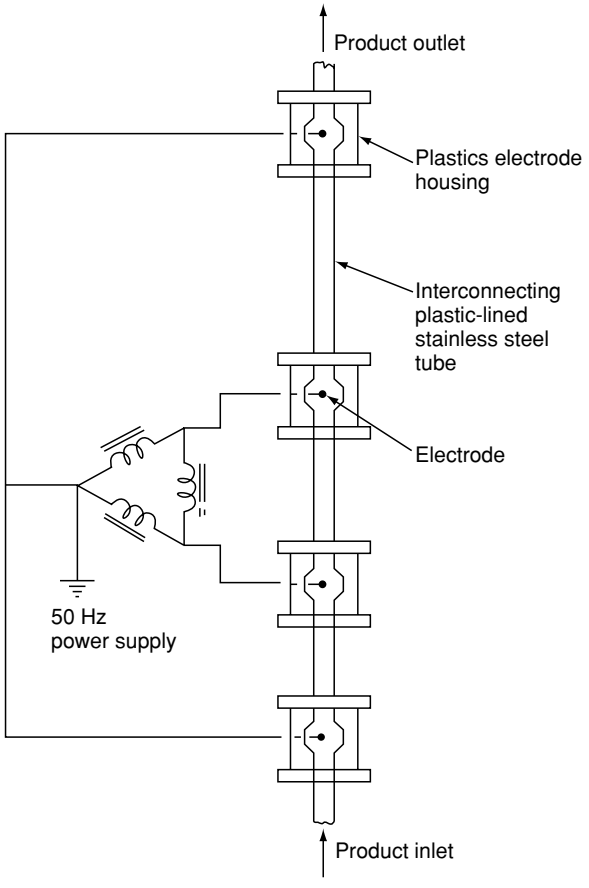

Figure 2 Electrical configuration and construction of the electrical resistance heater. From Skudder PJ, Biss CH and Coombes SA (1988) Ohmic heating: a breakthrough in profitable food manufacture. *Food Review* 15(5): 24, 27.

Acceptability and Applications

The ohmic process offers several advantages over more conventional particulate processing methods. These are:

1. the ability to handle food materials containing particles as large as 25 mm^3;
2. the absence of moving parts (feed pump excluded), which can damage shear-sensitive food products;
3. the ability to heat food products in a continuous flow without the need for any heat-transfer surfaces;
4. a considerably reduced risk of fouling;
5. the generating of heat in the product solids without reliance on thermal conductivity through liquids;
6. the absence of noise during the operation;
7. low maintenance costs;
8. the ease of control and instantaneous start up or shut down;

Examples of food products which have been processed successfully in this manner with minimal structural damage include meat chunks, prawns, diced or sliced carrots, baked beans, and sliced mushrooms. Fruits, such as diced apple and whole strawberries, have also been successfully heat-treated using the ohmic heating principle, and product quality reportedly varies from good to excellent. Ohmic heating has been developed by the APV company as a feasible practical process, and the reader is referred to the article on ohmic heating for further information.

Other Processes

To conclude this article, attention will be given to less well-known, product-specific processes, namely cold pasteurization, pasteurization by extrusion, thermization and chemical preservation by hydrogen peroxide.

Cold Pasteurization

As the name implies, the cold pasteurization technique does not make use of heat to reduce the microbial load. Instead, microporous membrane filters are used to retain the majority of bacteria and yeasts. In this respect, the technique is similar to any other pasteurization process. This process is mainly used in the case of heat-sensitive products, such as draught

beer, wine with less than 17% alcohol (especially sparkling wine) and pulp-free fruit juices. (*See* **Filtration of Liquids**.)

Pasteurization by Extrusion

Although extrusion may not, in general, be comparable with conventional pasteurization, research has shown that the microbial load of thermosensitive food powders, such as egg white powder or whey powder, could be reduced by an extrusion process without any loss of functional properties of proteins and carbohydrates, for example. This advantage, however, depends on the barrel temperatures and contact times, since high temperatures combined with longer contact times lead to a loss of functional properties as a result of mechanisms such as starch gelatinization and protein denaturation. The feasibility of this process as a form of pasteurization is not very clear, and therefore requires further investigation. (*See* **Extrusion Cooking: Principles and Practice**.)

Thermization

The thermization process is a subpasteurization heat treatment of milk at 62–65 °C for 10–20 s, followed by refrigeration. It is used as a prepasteurization treatment of raw milk to safeguard milk quality during prolonged storage in insulated silos. The process is also used as a postpasteurization treatment of dairy products. Research has shown that this process effectively reduces both the total and psychrotrophic bacterial counts, enabling thermized milk to be stored for up to 3 days longer at 8 °C. In this way, detectable sensory changes and the concomitant decrease in shelf-life are limited.

Thermization is only successful if applied to raw milk and products of good quality.

Chemical Preservation by Hydrogen Peroxide

Hydrogen peroxide is undoubtedly a most effective germicidal agent. It has been proven as an effective bacteriostatic and bactericidal agent and has been used in a treatment (30 min; 49–55 °C, 0.08% by weight) that has been suggested as a substitute for pasteurization. The peroxide concentration, temperature used, exposure time, and bacterial species and number all influence the effectiveness of the process. (*See* **Preservation of Food**.)

Treatment by this method destroys coliforms, anaerobic spore-formers and also a number of pathogens. The most resistant pathogen has been found to be *Mycobacterium tuberculosis*. Treatment at levels of 0.115% (v/w) hydrogen peroxide, however, completely inactivates this pathogen. Gram-positive organisms are not inactivated to the same extent as Gram-negative organisms.

Application of hydrogen peroxide as a milk preservative has been attempted in the dairy industry. Certain countries with underdeveloped milk collection industries and high environmental temperatures have expressed interest in this preservation method. The addition of catalase after exposure or the catalase from microorganisms and leucocytes, together with heat treatment, completely destroys or decomposes the hydrogen peroxide. The breakdown products (water and oxygen) are virtually undetectable in milk.

Hydrogen peroxide treatment of milk may be applied to reduce the total bacterial count and to extend the keeping quality. This treatment should, however, be supplemented by approved processing methods to ensure complete destruction of all pathogens. The question of whether hydrogen peroxide treatment of milk may be allowed depends on the specific country and its health regulations.

PASTRY PRODUCTS

Contents

Types and Production

J B Harte, Michigan State University, East Lansing, MI, USA

Background

There are many types of pastry dough. Shortcrust or standard plain pastry contains four ingredients – flour, fat, water, and salt – that are mixed, rolled, and cut into shapes. Alterations in the proportions of these ingredients, the addition of other ingredients, and the employment of various mixing and manipulation techniques produce popular pastry doughs, such as puff, choux, and strudel pastries. It is the purpose of this article to outline popular pastry varieties and present some common small- and large-scale production methods.

Plain Pastry

Pie Crusts

Shortcrust pastry or piecrusts are prepared by cutting solid fat into the flour and salt, and gradually adding water to obtain the consistency for rolling the dough into the desired shape. A low-protein, pastry flour is used to prevent the development of gluten in the pie dough. Limiting the mixing step after the addition of water and limiting reworking of dough will also help to prevent gluten development that would result in a tough crust.

Medium-flaky crust is obtained by cutting the fat into lumps the size of rice or coarse cracked corn. Flakier crusts are obtained by chilling the water and sometimes the flour to 1.7–4.5°C prior to mixing, cutting fat into larger pieces and/or keeping the mixing step as short as possible. Chilling the dough before rolling also helps to keep the fat firmer. A mealy crust forms when the flour and shortening are mixed thoroughly. The dough should be at about 18 °C after mixing and may be held there for 3–4 h in order to distribute the moisture more evenly. The type of fat used also affects the flakiness or mealiness of the crust. Rolling of the dough should start from the center and continue in the direction that will produce the desired shape and thickness.

Many varieties of pie crust dough, with fat contents ranging from less than 50 to 75%, are used. Pie crusts can also be prepared with a combination of shortcrust dough and short pastry (pâte de sucre or flan pastry) or with short pastry alone. Pie crust dough can be used for two-crust, fruit-filled pies, single-crust, and soft-filled pies. The typical one- and two-crust pies are approximately 23 cm in diameter and serve six to eight people. Crusts are also used for baked meat or fish pies, quiches, tarts, and turnovers. Fruit-filled turnovers can be made from dough scraps.

In two-crust fruit pies, the bottom crust should be slightly thicker than the top in order to support the fruit filling. Placement of cooled fruit filling in the prepared pie crust allows it to bake adequately before the filling begins to boil. Two to four cuts should be made in the upper crust to vent the steam during baking. Crusts are baked at 281–232°C, reducing the moisture content to a low level.

Two types of machines are used to form pies. Pie crusts can be produced commercially on a small-scale basis using a pie press that shapes dough balls into pastry sheets. Alternatively, pies can be formed by automatic sheeting and cutting. The rotary pie machine mixes the dough, reduces its thickness and cuts it into 7.5 × 12.5-cm sections. These pieces are automatically cross-rolled into thin, round pie pastry sheets that are manually placed into the pie plates. The top crust is placed on top after the filling is added to the bottom crust. The rotary pie machine then finishes the pie by crimping, scaling, and trimming.

The straight-lined pie type is another example of a sheeting and cutting machine that is more completely automated than the rotary pie machine. Pie dough is divided in two and separately reduced, cut into 7.5 × 11.5-cm pieces and cross-rolled into the top and bottom round pastry sheets. The pastry is automatically placed into the pie plate, filled, topped with another cut pastry sheet, sealed, crimped, and trimmed.

Short Pastry

Short, pâte de sucre or flan pastry is a rich dough containing a large amount of fat and, unlike standard

pastry, eggs and sugar. This pastry is used for biscuits, tarts, some pies, and the bottom and sides of fruit flans and cheesecakes. If a nonsweet pastry is desired for meat, vegetable, or seafood dishes, other ingredients, such as Parmesan cheese, may be substituted for the sugar. Smooth blends of shortcrust and pâte de sucre doughs are often used for pie shells and cream rolls. Chocolate or cocoa may also be added to these blends.

Puff Pastry

Puff pastry is lighter, flakier, and more delicate than standard shortcrust or flan pastry. It contains a higher fat level and has a unique preparation method that is critical for preparation of a successful product. This pastry can be used for a wide variety of products, including turnovers, shells filled with whipped cream, custards or fruit, vol-au-vents, and sausage rolls, and is considered a staple in commerical bakeries.

The pastry is prepared with a high-protein flour (bread), water, salt and shortening. A firm, plastic shortening, equal to 50% of the dough weight and containing some moisture, is optimum. Other ingredients, such as eggs and acids (cream of tartar, vinegar, or lemon juice) can be used. There are three commonly used methods for mixing and handling the puff pastry dough – the French (roll-in), English (roll-in), and the Scottish (all-in) method.

The French method involves rubbing a portion of pastry fat into the flour to lubricate the gluten. A portion of the water, acid, and eggs is placed into the center of a ring made from the mixed flour and shortening. The dough is mixed well, and the procedure is repeated until all the ingredients, with the exception of the remaining fat, have been added. The dough is rolled into a rectangle, 1.25 cm thick with a thinner outside border, and the fat is rolled to the size of the thicker dough. After the fat is placed on the thicker dough, the thinner dough is folded over on the thicker dough, and the thinner dough is folded over, making a type of pocket. The fat and dough is then rolled into a rectangle. One half-turn of the dough is formed by folding one end of the dough two-thirds of the way down the rectangle and folding the opposite end to cover the first fold (see **Figure 1b**). The new rectangle is three layers of pastry fat separated by dough layers. The dough is relaxed, and the rolling procedure is repeated after turning the dough through 90° for a total of six half-turns. The French method of puff pastry preparation is the most popular but is not used by some, because it is complicated and difficult to produce under high-speed commerical manufacturing processes.

The English method is the most popular in the USA. The dough is sheeted into a rectangular shape, and the roll-in fat is spread uniformly over two-thirds of the area. Three-fold pastry preparation (**Figure 1**) is used to form three dough layers separated by two layers of fat.

The Scottish method is similar to pie-crust preparation, simple, and widely used commercially. All the pastry fat is broken into lumps (5 cm) and mixed loosely in the flour. The remaining ingredients are then added to form a lumpy dough. The rolling procedure is the same as the French method with the addition of one extra half-turn. After the final rolling, the dough is shaped and relaxed before baking. For maximum volume, puffed pastries should be baked at high temperatures (204–212°C). The Blitz method is a modification of the Scottish method that partially develops the gluten prior to adding the firm shortening.

Two mechanical mixers are commonly used in batch commercial pastry production. The low-speed, double-arm mixing machine with a large dough bowl and slow mixing produces a good-quality commerical puffed pastry. The Scotch pastry method must be followed when the high-speed mixer is used in large-scale, high-product-capacity operations. Careful timing is critical with these mixers to prevent overmixing that results in an intimate mixing of fat with the dough and formation of a short rather than a

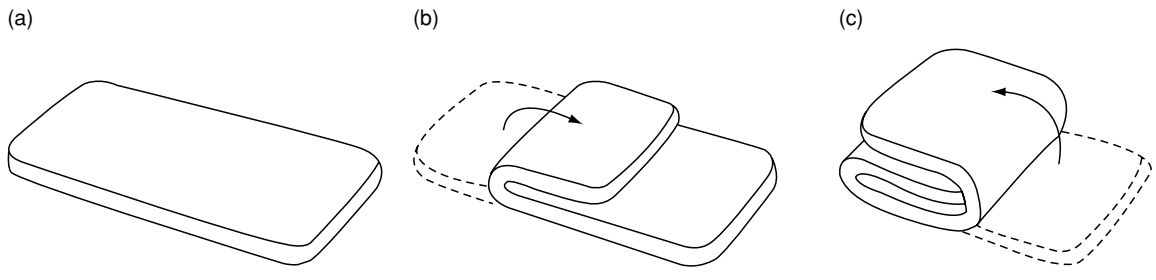

Figure 1 Three-fold pastry preparation: (a) the dough is rolled into a rectangle; (b) one end of the dough is folded two-thirds of the way down the rectangle: (c) the opposite end is folded to cover the first fold.

puffed pastry. After mixing the dough, any of the methods described in the commerical pastry preparation section can be applied. Continuous puff pastry dough-production equipment extrudes the dough and shortening into a double-layer continuous tube with the shortening in the center layer. This is flattened and reduced by a dough stretcher. The sheet is folded, stretched, and thinned. Pieces are cut into their final shape for pastry shells, cheese or savory sticks, napoleons (mile feuilles), turnovers, sugar crisps, etc. Products prepared with this continuous process are usually intended for wholesale distribution. Thus, their size and flakiness are limited to prevent breakage during shipping.

Choux Pastry (pâte é chou)

A wide variety of pastry products are made using choux paste: cream puffs, éclairs, French crullers, soup nuts, and decorative shapes used for pastry garnishing. Choux pastry differs from other pastries in that it is cooked before it is piped or spooned. It is composed of 150–200 parts eggs, 100 parts flour, 100 parts shortening (butter) and approximately 200 parts water. Flour is quickly stirred into a mixture of liquid, seasoning and fat, which is heated to boiling. The fat must be completely dispersed in the hot liquid to form a proper emulsion. Stirring continues until the smooth, gelatinized paste no longer sticks to the pan. The mixture is cooled, and the eggs are beaten into the choux mix one or two at a time, mixing well after each addition. Liquid may be gradually added to make the final paste the desired soft consistency. A small amount of chemical, fast-acting leavening can be added to this liquid to obtain the smooth consistency and maximum pastry volume. The paste is spooned or piped on to parchment-paper-lined pans and baked at 215–226°C until crisp. (*See* **Leavening Agents**.)

Choux pastry can be prepared using a continuous extrusion process. The extruder has groups of processing zones provided by varying the pitch of the screw. Throughout these zones, ingredient mixing, kneading, starch gelatinization, and comminuted/homogenization are accomplished. The final step involves extrusion of the dough through a die, forming the desired choux pastry shape. (*See* **Extrusion Cooking**: Principles and Practice.)

Strudel Pastry

The dough used to prepared strudel can be of the puff pastry type or can be made from water, seasoning, eggs, shortening or oil, and high-protein flour. Optional ingredients include sugar and lemon juice. The fat is mixed or cut into the flour mixture, and the liquid ingredients are added gradually. The dough is made into a ball, kneaded, and shaped into a rectangular form, relaxed, then rolled and gently stretched to obtain very thin, transparent dough. Oil is brushed on the thin layers. Home preparation by hand stretching is difficult. Commercial methods have been developed to prepare thin sheets. Strudel pastry and Fillo (phyllo) dough, which is similar to strudel, are frozen. These are sold in wholesale and retail markets and have wide applications for the home baker. Strudel filling is placed at one end of the pastry, and the dough is rolled over the filling as in the preparation of a Swiss roll. Relaxed strudel is baked at 218–233°C.

Yeast-leavened Pastry

Danish Pastry

Danish pastry is a rich pastry that combines the principles of puff pastry and fermented, sweetened dough. The dough contains high-protein flour (11.5–12%) that is often combined with up to 30% pastry flour for easier handling during lamination. Other ingredients include butter or margarine, yeast, sugar, shortening, milk solids, eggs (optional), salt, and flavoring. Fat containing moisture will help produce steam for leavening and flakiness. The total amount of fat can range up to 50% of the pastry dough. Sheeting and folding fat between layers of dough forms thick films of fat separating dough layers. Two types of Danish pastries are made in the USA. The European style is made from lean sweet dough that has a short shelf-life. The American style is more common and is made from a richer dough with a longer shelf-life.

There are two commonly accepted mixing procedures for the preparation of Danish pastry: conventional (three- or four-fold) or the short mixing time method, and the lamination or the long-mixing-time method, which is used for automated, high-speed sheeting systems. In the conventional three-fold method (Figure 1a–c), all the ingredients are combined with the exception of the rolled-in fat. A rectangle is formed by rolling the dough to a thickness of 1.25 cm. A large portion of roll-in pastry fat is evenly distributed over two-thirds of the dough, and the rectangle is folded in thirds, starting with the portion without fat. The dough is then rolled into a rectangle of 1.25-cm thickness and folded into four equal parts. After retarding, the dough is rerolled, and the procedure is repeated two more times. The four-fold or book-fold technique (Figure 2a–c) involves distributing fat over the center 50% of the dough and folding

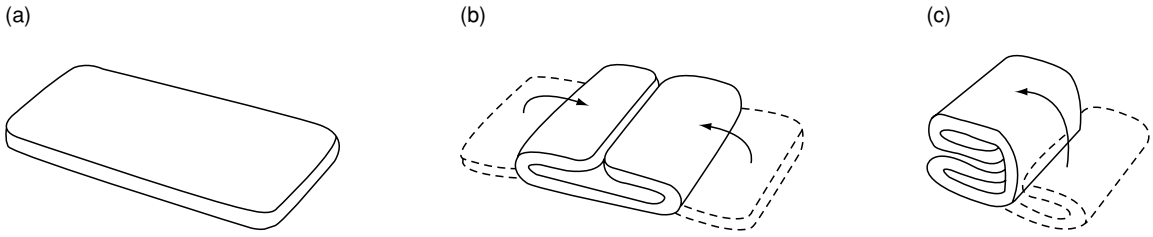

Figure 2 Four-fold pastry preparation: (a) the dough is rolled into a rectangle: (b) both ends of the dough are folded halfway down the rectangle; (c) one folded end is turned to cover the opposite fold.

the two ends of the original rectangle to the dough center. One end is folded over the other fold to line up with the far edge. The retarding and refolding steps are then repeated, similar to the procedure described for the three-fold method.

The gluten structure is developed during the laminating rather than during mixing. The commercial lamination method involves layering the shortening between two pieces of dough. This can be accomplished by extruding dough around the shortening, or high-speed pumping of the shortening between two continuous dough sheets. Automatic or overlapping of 45–60-cm dough pieces is followed by sheeting. This process is repeated two more times before cutting.

The retarded dough may be shaped into a wide variety of pastries, including crescents, sticks, rings, filled pockets, and rolls. Individual pastries are baked at 193–204 °C. Larger Danish products, such as coffee cakes, are baked at lower temperatures, 176–190 °C, to prevent over-browning before the pastry structure is set.

Croissants

The croissant is a popular, sweetened, yeast-raised product that is delicate and flaky. It has a medium-grain texture and the shape of a crescent. Dough composition and preparation techniques are similar to those of Danish pastries, with total fat contents ranging from 25 to 50%. The rolled in fat is a critical component for laminated yeast doughs that should have the same consistency as the dough. It provides the two-dimensional gluten framework that results in the characteristically flaky croissant. Additional ingredients are sugar, salt, whole eggs, yeast, and water. Dough (19°C) is mixed completely, without over-developing the gluten, for 1 min in a vertical high-speed mixer. The dough is extruded, and fat is extruded on top. It is then flattened, rolled and rerolled, and laminated for a total of 36 layers. Most of the gluten development occurs during the lamination step. Retarded dough is rolled and cut into triangles with slightly longer sides than the base. Filling is added, and the dough is rolled with four rotations, leaving the peak touching the baking sheet. The 'rolled' pastries are proofed and then baked at 163–204°C.

Toaster Pastry

Toaster pastries are convenience pastry products that are popular in the USA. These breakfast or snack pastries are made from a filled dough, formed into a shape and size that can fit into a toaster. The pastry dough is prepared from soft wheat flour, sugar, shortening, chemical leavening, salt, flavorings, and colors. It is baked just enough to set the dough and reduce the moisture content, thus extending the product shelf-life. Although many are shelf-stable, many new varieties are frozen. Browning is completed in the toaster.

Commercial Preparation of Pastry

Most pastry products evolved after long periods of small-scale, manual preparation followed by high-speed, automated production in this century. High-capacity production of pastry is made possible by elimination of manual dough manipulation and automation of the pastry production process. Processing time is shortened by elimination of roll-in steps, and reducing resting times between fold-in steps. Variations exist in the continuous production methods for the different pastry types such as pie, Danish, and puff pastries. However, common to all are the sheeting, depositing, lamination, and cutting steps.

An example of an automated pastry production system is presented in Figure 3. The dough is mixed and carried to the sheeter head, or three-roll laminating head, by the dough feeder and conveyer belt. The sheeter head unit consists of three rollers with adjustable speeds for producing perfect sheeted pastry. Two are feed rollers, one with deep grooves and the other with fine triangular grooves. The third roller has a smooth surface and is located underneath the feed rollers. Fat layers can be added to the first dough to

produce the flaky texture of pastries. A second sheeter head adds another dough layer over the fat. If the Scottish system is used, all the fat is incorporated into the dough, a fat extruder is not needed, and only one sheeter head unit is required.

Dusting flour boxes distribute small amounts of flour on the conveyor belt, to prevent sticking, and to the top of the dough sheets prior to cross-rolling. Conical cross-rollers travel across the belt width, thinning and spreading the dough sheet to the desired thickness. Further sheeting occurs at the two-roll sheeter, reducing dough thickness. Several systems can be utilized to obtain the desired flakiness by controlling the number of times the pastry is folded.

The book-fold method (Figure 2a–c) involves folding the dough sheet and then turning it through 90 °C and sheeting the dough, repeating the procedure to obtain the optimal flakiness. Another method involves continuous folding and sheeting of the dough. A third method uses a guillotine to cut the dough sheet into pieces (50 × 60 cm) and then stacks then with a retracting conveyor. The dough pieces are placed on another conveyor belt operating at a 90° angle to the first belt. The pieces are stacked five layers high by this process, after which the dough sheets are reduced in thickness. Another method utilizes a curling arm, or roll winder, which coils the dough sheet covered with extruded fat into five layers. A final technique uses a ring extruder that produces a very uniform, hollow dough cylinder, lined with fat. This method is particularly suited for long-shelf-life pastries. For all methods, the dough sheets can be reduced in size by pressing, cross-rolling, and running between a multiroller device. This multiroller allows the dough sheet to be manipulated when in contact with the small rollers, which press the dough on to the larger roller. The small rollers revolve individually as the whole group of small rollers also rotate together in a loop. The dough is allowed to relax when it is between the rollers and is not touching the large roller. A similar stretcher system with a larger number of small rollers, but without the bottom roller, has also been used. The final pastry production steps repeat the sheeting and reducing steps, depending on the necessary dough thickness and desired flakiness. Preparation of individual pastries of varying sizes and shapes depends upon the type of cutting, depositing and shaping equipment utilized.

Ingredient Functionality and Dough Characteristics

S L Andrews and J B Harte, Michigan State University, East Lansing, MI, USA

Introduction

Traditional pastry or pie crust is a simple dough made from four primary ingredients – flour, fat, salt, and water. Numerous pastry varieties have been developed by slightly altering ingredients, their amounts, mixing methods, and shaping. Common ingredient modifications include the amount or type of fat, the protein content of flour, the substitution of milk for water, use of chemical leavening agents and yeast, and the addition of other ingredients such as eggs, sugar, acid, and flavorings. It is the purpose of this article to outline pastry ingredient functionality and their proportions and desirable pastry characteristics. US and equivalent UK pastry terms are presented in **Table 1**.

Functionality of Ingredients

Flour

Flour is the main ingredient in pastry, and the type of flour used affects the characteristics of the pastry.

Table 1 US and equivalent UK pastry terms

US	*UK*
Standard plain pastry	Shortcrust pastry
Short pastry	Pâte de sucre or flan pastry
Cookies	Biscuits
French puff pastry	Flaky pastry
Scottish puff pastry	Rough puff pastry

Protein in flour yields gluten wherever the flour is dampened with water and manipulated. Gluten development increases as the flour's protein content increases and as the amount of added water increases. Gluten development can be minimized by incorporating fat and flour before water is added. This method insulates flour proteins from added water and limits gluten development. The extent of gluten distribution throughout pastry and the amount of gluten formed determine whether pastry is crumbly, with a tendency to be compact and tough, or tender and flaky. When dough is rolled and baked, gluten is denatured by heat, which contributes additional toughness. High-protein flours yield more gluten, which results in a more cohesive dough. In contrast, pastry flour and other low-protein flours do not yield as much gluten and tend to make a tender pastry which crumbles and cannot hold its shape. A mixture of high gluten or plain flour blended with a soft cake or pastry flour can be used to achieve the desired protein concentration.

In choux pastry a high-protein (12–13%) flour is used. During baking, egg and flour proteins in choux pastry coagulate, preventing steam and gas from leaving the pastry, and setting the pastry into the desired form. High-protein (13%) flour is also used in yeast-leavened Danish pastries. For croissants, a 12.5% protein flour is recommended. (*See* **Flour**: Analysis of Wheat Flours.)

Fat

Fat contributes tenderness, or shortness, to pastry. Depending on the type of pastry, the fat content can range from 25% to almost 75% of the dough. Fat tenderizes pastry by waterproofing flour particles. The polar groups in water have an affinity for the polar groups in both the protein and starch. Polar carbonyl groups and the double bonds in unsaturated fatty acid moieties make it possible for fat to unite with polar groups on the surface flour particles. The remaining portions of the fat molecule have no affinity for the flour or water and act as a mechanical barrier, preventing contact of the water and protein in the flour.

A fat's ability to interfere with gluten formation is known as its shortening power. Pure fats have more shortening power than do butter or margarine which contain 16% water. Even pure fats, such as lard, hydrogenated shortenings, and oils, exhibit different characteristics in a pastry product. Oil is more dense than lard, which is more dense than shortening. In addition, liquid fats have more spreading power and are able to coat flour more evenly and completely. The higher the ratio of liquid to crystals, the greater the covering power of the fat.

In addition to making pastry tender, fats also contribute desirable flakiness by separating the dough into layers or flakes. Oils, on the other hand, tend to coat each particle of flour. As a result, water contact with the flour is limited, little gluten is developed, and a tender but crumbly, or even greasy, pastry results. A flaky, tender pastry can be made with oil, but, because oil mixes so easily with flour, the mixing must be carefully monitored. Oil and flour should be mixed until the particles are the size of peas. Overmixing will cause particle size to decrease, resulting in a crumbly pastry.

Plastic fats, having the properties of both liquid and crystalline fats, tend to make a more flaky product which is tender. Lard is considered an excellent pastry fat because of its shortening action, desirable plasticity, and dispersibility which enhances flakiness. Selection of fat depends on a number of factors, including ambient temperature, method of processing, and desired crust characteristics (mealy or flaky). (*See* **Fats**: Uses in the Food Industry.)

Puff pastry dough contains up to 100 parts of a good-quality, high-protein flour, 58 parts of water, and two parts of salt. A firm, plastic, shortening, equal to 50% of the dough weight and containing some moisture, is optimum. Fat containing moisture will help to produce steam for leavening and flakiness.

Liquid

The liquid most frequently used in pastry is water, but liquid is often contributed by the addition of milk and eggs, and even fats such as butter and margarine which are 16% water. Liquid is needed to hydrate the flour, develop gluten, and provide cohesion to the dough. Without liquid, the flour particles would not adhere to form a dough. With insufficient liquid the dough crumbles and is difficult to handle. Too much liquid causes excessive gluten formation, producing a tough pastry. While too much liquid is undesirable in pastry doughs, liquid is essential in choux pastry for maintaining the desired soft consistency of the paste. Liquid in the form of water or milk is gradually added to produce the final paste consistency. If the paste is too thick, the baked volume will be low and the shell will be thick.

To promote flakiness, water used in pie dough mixtures should be chilled. This limits homogenization during dough mixing by creating hard fat particles. Ice water may also be used. Liquid is also necessary for leavening. When baked, liquid in pastry dough produces steam, leavening the product and separating the individual flakes. Fat containing moisture will also help to produce steam for leavening and flakiness.

Salt

Salt functions as a seasoning and is not required to produce a successful pastry product. A crust without salt will produce a flat-tasting crust. However, its omission does not affect the mechanical aspects of the pastry.

Other Ingredients

Eggs Eggs are incorporated into several pastries, including choux paste, short (pâte de sucre, or flan pastry), and croissant doughs. Eggs are optional ingredients in yeast-leavened Danish and puff pastry doughs. Egg yolks can function to lubricate the gluten, while the whites aid in baked pastry volume. Eggs contribute richness, structure, and increased keeping qualities. In choux pastry, for which 90–100 parts whole egg is beaten into a mixture of 60 parts high-protein flour (12–13%), 100 parts water, 40 parts shortening, and two parts seasonings to form a very thick paste, the primary functions of eggs are dough emulsification, leavening, and supplying moisture.

Acids Acids such as cream of tartar, vinegar, or lemon juice are used in some pastry formulations. Acids relax the gluten, thus improving the ease of rolling. If too much acid is added, the dough will be sticky and difficult to handle and roll. (*See* **Acids**: Natural Acids and Acidulants.)

Sugar Sugar helps to tenderize the dough, adds extra flavor, and promotes crust browning. Lactose, the simple sugar found in milk, also contributes to product browning. (*See* **Lactose**.)

Milk In some pastries, milk replaces water as the source of liquid. Milk adds crust color by providing lactose, which promotes Maillard browning during baking. Milk solids strengthen the interior cell structure, which helps to maintain pastry flakiness. Milk can also aid in producing a thin, smooth crust. (*See* **Browning**: Nonenzymatic.)

Yeast Yeast is used in croissant and Danish pastry doughs to provide leavening through the production of carbon dioxide. Danish pastry doughs may contain a high concentration of yeast to offset the growth-inhibiting effects of added sugar.

Proportions of Ingredients (by Weight)

For a traditional plain (shortcrust) pastry, 100 parts flour (average 115 g per cup) are used for each 42–59 parts fat. The optimal amount of plastic fats, such as lard, is 44 parts to 100 parts of flour. If less than 44

parts are used it may become difficult to mix in the water without overdeveloping the gluten. When liquid fat such as vegetable oil is used, 42 parts should be used to each 100 parts of flour. If more than 59 parts of fat are used, the pastry becomes crumbly and greasy. Within the recommended range, the smaller the proportion of fat, the greater the likelihood of developing excessive gluten. For each 100 parts flour, 2.5 parts salt are used for flavoring.

A minimal amount of water must be added to develop gluten (flakiness). If too little water is added, the pastry will be crumbly, but too much water will cause excessive gluten development and the pastry will be tough. A mixture of 31 parts water to 100 parts flour is sufficient to provide flakiness without promoting toughness. When a minimal amount of fat is used, careful measurement of liquid becomes even more important. A difference of as little as 2.5 parts water per 100 parts flour can cause a discernible difference in the tenderness of the pastry.

Pastry Characteristics

Tenderness and flakiness are two desirable characteristics of pastry products which can occur together or separately. Up to an optimum, tenderness increases as fat is increased, as a result of the shortening power or ability of the fat to coat the gluten strands, interfering with gluten structure. The fat can also function to coat the flour particles and prevent water from fully hydrating the flour, thus preventing gluten formation. Higher temperatures increase the ability of the fat to spread, coating the gluten and increasing tenderness. Keeping fat and water cold will serve to promote a flaky, tender pastry which is not greasy or too tender. A product which is too tender becomes crumbly and too hard to handle. Overmanipulation, including kneading of pastry dough, has the opposite effect. As the dough is kneaded, rerolled, or mechanically overmixed, the pastry becomes tough as a result of excess gluten formation. Toughness can also be caused by adding too much liquid, or by the presence of excess flour during rolling.

Flakiness results from partially hydrated flour or dough being layered between thin sheets of fat. Pastry layers are separated during baking as steam and, to some extent, air separates the layers. These fat layers must coat the flour sufficiently to produce layers, yet not enough to cause the pastry to crumble. Cutting fat into the flour in large particles promotes flakiness. Medium-flaky pastry is made by cutting fat into small lumps, while a mealy crust will form when the flour and shortening are mixed thoroughly. Use of cold water helps to promote flakiness in the final product. For long flaky pastry the fat is cut into larger lumps and the lumpy, sticky dough is rolled three times, turning three times for each roll. The harder fats do not spread as readily as softer fats and thus are more likely to have flour particles adhering to the fat. Optimum mixing time for desirable tenderness is longer when harder fats are used. Dough rerolling and folding increase flakiness. Increased gluten development can hold steam more efficiently and separate the dough into layers. The resultant increased toughness may be reduced by rolling small pieces of fat between the dough layers.

Dough Retardation and Relaxation

During dough mixing and handling, fat must remain cold enough so that it does not soften during preparation. This is especially true for roll-in fat products, such as puff and Danish pastries. Additional fat folded into the dough creates numerous layers of dough and fat. To prevent changes in fat properties that occur quickly at elevated temperatures, dough is retarded or relaxed at refrigerator temperature between sheetings. To prevent greasiness and decreased volume during baking, cooled pastry should reach ambient temperature slowly.

Leavening

In pastry, leavening occurs when heated liquid creates steam, and individual layers (flakes) are separated. Baking temperature is important to insure sufficient leavening. Too low a temperature will not allow the optimum production of steam for aeration, while an oven temperature that is too high will result in premature setting of the proteins and low pastry volume. Leavening also occurs as air expands during baking.

In yeast-leavened Danish pastry and croissant doughs, yeast is added for additional leavening from carbon dioxide. In choux paste, a small amount of chemical, fast-acting leavening – ammonium bicarbonate and baking powder (1:1) (14 g per 454 g extra liquid) – can be added to this liquid to obtain the smooth consistency and maximum pastry volume. In choux pastry, if eggs are used to soften the paste, the liquid and chemical leavening mixture is not needed. Leavening of the choux paste during baking occurs by expansion of the eggs; carbon dioxide is released from the chemical leavening agents, and steam is formed from heated liquids in the paste. Flour and egg protein coagulate to set the shape of the aerated pastries. (*See* **Leavening Agents.**)

PEACHES AND NECTARINES

C Blattný, Prague, Czech Republic

Introduction

Both peaches and nectarines originated from the same tree – the peach, whose botanical name is *Prunus persica* L. (rose family – Rosaceae). They are a typical stone fruit with the seed in a hard stone; soft pulpy flesh surrounds the stone and the surface is covered with a relatively thin skin. The peach and nectarine are closely related to other species of the genus *Prunus*: apricot, almond, plum, and cherry.

Origin and History

The peach is a native of China, where it was depicted in old paintings and mentioned in Chinese mythology and folklore as far back as the tenth century BC. The peach signifies long life and peach blossom has also been important in China for a very long time. There semiwild forms can be found in all native peach areas from south to north-west and north-east.

It is unclear how peach and nectarines spread to Europe. At least two or three ways are probable. First, when the Romans occupied Syria to the end of the first century BC and found the peach, they named it 'Persian apple.' It must have been important that peaches grow quickly from seed, and this permitted their rapid dispersal from China to the west. The second way was probably across Egypt to Rhodes and the third route was over Greece and the Balkans. Since the beginning of the second millennium peach and nectarines spread throughout Europe, especially in the south and south-east. France played an important role in the development of the peach – at the beginning of the seventeenth century about 30 cultivars of peach were grown there. During the following two centuries this number reached more than 350 cultivars. Also in Italy interest in peach and nectarine increased from century to century. Much archeological evidence of peach seeds has been found there along the central Donau in Hungary and Slovak republic. The Spaniards brought peaches to America (Mexico and Florida) in the sixteenth century. Peaches spread in America very quickly and, especially in California, the peach became the leading fruit grown in orchards.

Requirements of the Peach Tree

Peaches have different requirements according to their old native district. The hardiness, early or late blooming, and requirement of winter cold exposure (chilling) are most important. Most older cultivars need more than 950 h at around 6 °C. However it should also be emphasized that the peach tree is a warmth-seeking botanical species. It needs higher

temperatures in summer with strong intensive sunshine and relatively mild frost in winter – attributes of a mild climate. However, cultivars from south China are suitable for subtropical regions as they need less chilling.

The peach has very similar requirements for environmental conditions as the vine. The soil for peach should be warm, not too heavy, airy, pH 6–7.5, and $CaCO_3$ 3–5%. Selection of the rootstock for given conditions is important. The following seedlings are used in various countries: peach seedling (various types), peach × almond hybrids, almond seedlings, plums seedlings, *Prunus davidiana* (China), and peach × *P. davidiana* hybrids. Peach seedlings prevail: in some countries peach × almond are very often used.

Nectarine cultivars have greater environmental demands. They need warmer summers (without rain), as the fruit's skin tends to crack after rain.

The Fruit

Peach is one of the most variable of all tree fruit species. From the pomological point of view, the cultivars are divided into five groups:

1. True peaches – freestone or semifreestone with fuzzy skin
2. Clings – clingstone with fuzzy skin
3. Nectarines (smooth-skin peaches) – with fuzz-free skin and freestone
4. Brugnons – small clingstone nectarines
5. Peento – a special group of peaches with flat fruit (almost like dried figs) and exposed stone

This division is by no means accurate. It is necessary to emphasize that in some years when there is a cold and rainy summer, a stronger fusion of flesh and stone also occurs with freestone cultivars.

Cultivars of peach and nectarine differ in their height, width, and thickness. Both peaches and nectarines are round or oval-round, oval, oblong, or somewhat flat. The suture leading from the stem pit to the top of the fruit or behind it is a typical feature. The depth of the suture also differs between cultivars. Some have a small tip on the top, some have deeper ones, and a small number of cultivars have a small knoll (like Venus). The skin of true peaches and clings is fuzzy. This fuzz differs according to the cultivars – sometimes it is very fine, sometimes it is dense and very fuzzy. The skin is orange-yellow, white with red cheeks, or red with stripes, or plain red. The flesh is soft, sometimes too firm or too fibrous, yellow, orange-yellow, nearly white, green-white, or red. In old-type cultivars, which have only been selected to a limited degree, the flesh is often farinaceous. The color of flesh around the stone and under the skin is slightly darker and sometimes red.

Nectarines usually have a somewhat smaller fruit and a smooth shiny skin (like plums); the flesh is harder, more like a plum, and not melting like true peaches. The taste differs slightly from true peaches; however it is outstanding too. Greater consumer acceptance is attained of the fruit of nectarines which are more acidic than peaches. The color of the skin is often red to purple-red. In recent years an important development of white-flesh nectarine cultivars has occurred.

The stones of peaches and nectarines are conspicuous by their surface, with different deep branch-like grooves and pits. These characteristic shape, size, grooves, and color of the stone are peculiar to every single cultivar.

Regulations

Commission regulation (EC) no. 2335/1999 lays down marketing standards for peaches and nectarines.

Definition of Produce

This standard applies to peaches and nectarines grown from cultivars of *Prunus persica* L., to be supplied fresh to the consumer; peaches and nectarines for industrial processing are excluded.

Provisions Concerning Quality

The purpose of this standard is to define the quality requirements for peaches and nectarines after preparation and packing.

Minimum requirements Peaches and nectarines must be:

> intact, sound, produce affected by rotting or deterioration such as to make it unfit for consumption is excluded, clean, practically free of any visible foreign matter, practically free from pests, practically free from damage caused by pests, free of all abnormal external moisture, free of foreign smell and/or taste

Peaches and nectarines must have been carefully hand-picked. The development and ripeness of peaches and nectarines must be such as to enable them to withstand transport and handling and to arrive in a satisfactory condition at the place of destination.

Classification

- Extra class
- Class I
- Class II

Table 1 Classification of peaches and nectarines according to size

Diameter	*Size (code)*	*Circumference*
90 mm and over	AAAA	28 cm and over
80 mm – under 90 mm	AAA	25 cm under 28 cm
73 mm – under 80 mm	AA	23 cm under 25 cm
67 mm – under 73 mm	A	21 cm under 23 cm
61 mm – under 67 mm	B	19 cm under 21 cm
56 mm – under 61 mm	C	17.5 cm under 19 cm
51 mm – under 56 mm	D	16 cm under 17.5 cm

Provisions Concerning Sizing

Sizing is determined by circumference or maximum diameter of the equatorial section (Table 1).

Diseases

Peaches and nectarines are subject to attack by a cosiderable number of diseases. Viruses and *Mycoplasma* are the most significant. We will discuss only a few diseases here

- Peach mosaic (vector – eriophyoid mite *Eriophyes insidiosus*)
- Peach yellows and little peach (vector – leafhopper *Macropsis trimaculata*)
- Phony (distributed through the root system)
- X-disease (vectors – more species of the leafhoppers)

These diseases have various symptoms on the leaves, twigs, and fruits. All these diseases are transmitted with buds by propagation, therefore healthy budwood and rootstocks are the most important control measures (together with the fight against vectors). Affected trees have nearly no crop and usually die within a short period.

The fungus diseases leaf curl, brown rot, and mildew are troublesome:

- Leaf curl (*Taphrina deformans*) curls and deforms the leaves early in the season; their color changes to dark red or violet. It must be prevented by applying fungicides just before bud opening.
- Peach mildew (*Sphaeroteca pannosa*) appears in the form of a white powdery substance upon the leaves and fruits. Spraying with fungicides will commonly hold it in check.
- Brown rot (*Monilia fructicola*). Infection begins during flowering but fruit rot often occurs after harvest. Control with fungicide during vegetation and then immediate cooling after harvest are important.
- Gray mold (*Bothrytis cinerea*) occurs especially after a wet spring during storage if the fruit has been infected during gathering. Gentle harvest, undamaged fruit, and temperature about 0 °C during storage and transport are effective control measures.

Harvesting of Fruit

In the 1930s the harvesting season of peaches was about 3 weeks – mid-July to mid-August. Due to intensive breeding work, especially in the USA (and in France and Italy), the harvesting season is now extended to at least 2 months; in the most favorable environmental conditions it may be more than 3 months (mid-May to 3 September). As regards ripening, the cultivar Redhaven grown worldwide is taken as the reference. Most peach cultivars ripen in the midseason 2–3 weeks after Redhaven; more nectarine cultivars ripen before Redhaven; the canning clingstone cultivars have a shorter harvesting period before and 6 weeks after Redhaven.

The harvest differs according to the purpose of using the fruit. For fresh fruit the fruit has to be harvested 2–3 days before it will reach ripeness, with a fully developed flavor. This is called tree-ripe. Therefore it is sometimes recommended to repeat harvesting at least three times according to advancing ripeness. The grade of ripeness can be determined by skin ground color changes from green to yellow in most cultivars (exept for the white-flesh cultivar). This is called minimum maturity, and is used to harvest fruits determined for distant markets and long transport. The ideal time to harvest peaches is when they are beginning their ripening process, but are still firm. At this stage they withstand picking operations and hauling quite well and complete the ripening process in good condition. If picked too soon, potential tonnage is lost because peaches and nectarines grow considerably just before reaching maturity. If the harvest delay is too long, they begin to soften, bruise easily, and shelf-life is reduced. To satisfy consumers that the fruit is ready to eat it is necessary to initiate the ripening process at the right time before the fruit is put on the market. Nowadays detailed ripening protocols for different peach and nectarine cultivars from important international export districts have been developed. For home gardens usually the best time is when the yellow-fleshed cultivars change from yellowish-green to yellow or orange-yellow. White-fleshed cultivars are ready for harvest when the color changes to cream white.

The nearly ripe fruits of the best quality should be gathered and placed in the market boxes that are provided with special niches for each individual fruit to prevent bruising during transport. Rapid transport should take place in refrigerated trucks.

Cultivars destined for processing are usually picked all at once – true peaches by hand and clings with the help of fruit-shaking machines.

Postharvest Operations

Peaches and nectarines are transported from orchard to packinghouse and cooler as soon as possible after harvest. In the packinghouse the fruits of minimum maturity are sorted to eliminate fruits with visual defects, and to select outstanding nice colored and big fruits (for the extra class). Cleaning machinery to remove fuzz from peaches is often used in all major production areas. In the defuzzing operation the peaches are scrubbed with rotating brushes to remove the fuzz and then washed and rinsed with fresh cold water. Sizing segregates fruits by size or weight. It is very important to cool the fruit as quickly as possible to near 0 °C. Also longer chilling at 0 °C is recommend. When the fruits are stored at a higher temperature, between about 2.2 °C and 7.5 °C, chilling injury (internal breakdown) occurs. First the flavor is lost, then the flesh becomes mealy, wooly, or harder, and brown around the pit of the stone. Cultivars of peach and nectarine differ in their susceptibility to chilling injury; nectarines are less susceptible.

Sometimes during harvest or after 1–2 days, black spots or stripes occur on the skin. This is a result of abrasion combined with touch with metal – iron or copper. Therefore it is very important to handle fruit gently during harvest and postharvest hauling operations.

Supplying Fresh Fruit to Consumers

The fruits must be intact, sound, clean, practically free of any visible foreign matter, practically free from pests, free of abnormal external moisture and free of any foreign smell or taste. The fruits must have been carefully picked and sufficiently developed that the ripening process can continue in order to reach the degree of maturity proper to their cultivar characteristic, to withstand transport and handling, and to arrive at their destinations in satisfactory conditions. Usually they are classified to four or seven classes according to the diameter of the widest part of the peach and nectarine.

Use of fresh fruits

Peaches – and, to a certain extent, nectarines – belong to the most sought-after fruits, thanks to their delicious taste and the development of global trade. Most of the peach crop (usually about 60%; in some regions much more) is marketed as fresh fruit; for nectarines, nearly all of the crop is used fresh. Cultivars of true freestone peaches with white and orange-yellow melting flesh, thin skin with not too dense fuzz, and delicious taste, fully ripened are the best for eating fresh. On the market such cultivars are sold in four to five classes. Sliced fresh peaches or nectarines are eaten alone or in combination with other fruit in salads or cocktails. Canned or frozen fruit can be used in the same way. Dried fruits are usually eaten as an energy-giving snack. In homes and confectioneries peaches and nectarines can be used for baked goods, icecream, gelatine desserts, pies, juices, and sherbets.

Some sensitive individuals can experience difficulties caused by a thicker fuzzy skin of certain peach cultivars. This unpleasant characteristic can be solved by a defuzzing operation (with rotating brushes) or by developing large nectarines, as was done in the last decades, especially in the USA.

Processing

The main method of processing is canning, usually about 30% of the whole crop, while a small amount is dried in some regions. The fruits are further used for jams, jellies, juices, brandy and liqueurs, preserves, and other miscellaneous products.

Technological Requirements

Peaches are inspected, graded, halved, pitted, and peeled before canning, freezing, and drying. The shape of the fruit should be round or flattened round and almost uniform; the diameter should be at least 45 mm. The flesh should be soft but firm enough (not farinaceous), of yellow-orange color, and have a taste full of the aroma. The smaller the stones, the better – 8–9% of total fruit weight. Tannin content should not be more than 0.08%. True peaches and clings are used in the processing industry. Cling cultivars are better, as they have firm flesh from the skin to the stone. Therefore after pitting and peeling the flesh is equally firm and does not crumble. The cling cultivars withstand better mechanical harvesting with shaking machines, longer transport, and storage. A further advantage of clings is equal ripening and slower overripening than true peaches. For processing the optimal grade of ripeness has to be measured just before processing starts. Prematurely harvested and processed fruit is too hard and lacks intense taste and flavor. Peaches are usually canned in light to heavy syrup, less so in water or juicy pack. When freezing the syrup, a small amount of ascorbic acid (to prevent browning) is used. Peeled peaches must be sulfured for drying.

Recommended Cultivars

Nowadays grown cultivars have different origins. In earlier times cultivars from the Persian (Iran) region were a base for many old cultivars. But in the middle of the nineteenth century some Chinese clings were imported to America directly from China. Some from North China (with hard winters) required high chilling and some from South China required less chilling. From these Chinese imports accidental hybrids with cultivars grown in that time in the USA have been chosen. One such hybrid was introduced in the 1870s as the cultivar Elberta. It had become one of the most widespread cultivars in a short time and a parent of many new cultivars.

Some examples of worldwide cultivars (2000 AD) are:

- true peaches – freestone and semifreestone – yellow: Redhaven, O'Henry, Spring Lady, Rich Lady, Cresthaven, Maycrest, Springcrest, Elegant Lady, Royal Glory, Fayette; white: Maria Bianca, White Lady
- clingstones: Babygold 5, 7, Vivian, Harbinger, Andross, Loadel, Helford 2, Golden Queen
- nectarines – yellow: Redgold, Fantasia, Flamekist, Supercrimson, Venus, Armking, May Grand, Marycrest; white – Queen Giant, Silverking.

In many districts these has been a shift from middle and late cultivars to early-maturing ones. This resulted from the strong demand for the first peaches and nectarines harvested. This is reflected in the high prices of early peaches and nectarines. In recent years there has been an improvement in the size and color of early peach and nectarine cultivars. Many have firm, white flesh with a delicious flavor and taste. In the typical great peach district a peach cultivar now usually lasts less than 20 years before being replaced by new superior one. Elberta's (1870) longevity is a distinguishing feature. North American cultivars became popular in European districts (Italy, France, Spain, Hungary, and Yugoslavia) and also in South America and North Africa. New cultivars were selected that required less chilling in the USA around the year 1970. This allowed an important increase in peach growing in very warm regions – India, Peru, Thailand, Brasil, Israel, not just in the USA. In the last decade many new cultivars have been developed in all main peach- and nectarine-growing regions – for instance, in the USA about 250, France about 55, Italy about 90, China about 35, Mexico about 20, and in the whole world more than 500 new cultivars.

Table 2 Chemical composition of peaches and nectarines

	$g\,kg^{-1}$
Water	805.0–877.0
Protein	7.0–8.0
Total lipid	0.9–2.0
Sugar	70.0–150.0
Acids	6.0–12.0
Dietary fiber	14.0–20.0
Ash	4.0–5.0

Sugar is composed on average from 13% glucose, 15% fructose, and 72% saccharose. Organic acids fluctuate according to grade of ripeness: 42% citric acid and 58% malic acid.

Nutritional Value

The composition of peaches and nectarines is given in Tables 2, 3 and 4. When ripe, most modern cultivars of peaches and nectarines exhibit a well-balanced proportion of acids and sugars. The content of dietary fiber and mineral salts, principally potassium, is important. Vitamin content is relatively low. It is influenced by the cultivar, how it is grown, the environment, and ripeness grade. There is also a rich content of delicious aromatic substances present. All this contributes to the great popularity of peaches and nectarines.

Production

Worldwide production of peaches and nectarines is increasing. This trend is mainly based on a large

Manganese	0.4–1.1
Selenium	Traces

Table 4 Vitamin content of peaches and nectarines

Vitamins	
Beta-carotene	$0.58–4.40\,mg\,kg^{-1}$
Vitamin E	$7.00\,mg\,kg^{-1}$
Vitamin B_1	$0.17–0.50\,mg\,kg^{-1}$
Vitamin B_2	$0.40–0.53\,mg\,kg^{-1}$
Vitamin B_6	$0.18–0.30\,mg\,kg^{-1}$
Niacin	$6.00–9.90\,mg\,kg^{-1}$
Pantothenic acid	$1.40–1.70\,mg\,kg^{-1}$
Folate	$30.00–34.00\,\mu g\,kg^{-1}$
Vitamin C	$66.00–370.00\,mg\,kg^{-1}$

The content of beta-carotene (provitamin A) depends on the color of the cultivar (white, yellow, orange-yellow, red).

number of new more suitable cultivars and better cultivation methods (fertilization, irrigation, prevention of diseases and pests). These developments have led to the possibility of exploiting moderately favorable environmental conditions. Worldwide production increased over 20 years by more than 50% and in 1996–98 reached a volume of 11 146 million tonnes. The USA produced 1302 million tonnes, and Europe 3418 million tonnes, of which the most important are Italy 1447 million tonnes, Spain 894 million tonnes, Greece 648 million tonnes, and France 468 million tonnes. High production volumes have been registered in China: 2922 million tonnes, Turkey: 372 million tonnes, Argentina: 284 million tonnes, Chile: 278 million tonnes, South Africa 221 million tonnes, and Tunisia 221 million tonnes. The development of international trade was also a great contributory factor: it solved problems of rapid transport without losses, mainly due to standardization and refrigeration all the way from harvest to consumer.

Origin

Arachis hypogaea L., commonly known as peanut, groundnut, monkey nut, goober, or earth nut because the seed develop underground, is in the division Papiolionaceae of the family Leguminosae. The peanut is only one of a few hundred species of legumes that produces flowers above ground but develops the fruit below ground. Peanuts are native to South America and were cultivated in pre-Columbian native societies of Peru as early as 3000 BC. Peanuts probably originated in the region of eastern South America, where a large number of species are found growing wild. A Bolivian origin is suggested by the wide range in seed and pod morphology documented there. It has been suggested that *A. hypogaea* originated from a hybrid between *A. cardenasii* (nn) and *A. batizocoi* (K. & G.), as both parents occurred in reasonable proximity in Bolivia. Peanuts were widely distributed throughout South and Central America and the Caribbean region during the time of Columbus. Peanuts were probably brought to West Africa from Brazil in the sixteenth century and then to the African east coast and to India. Peanuts from widely

separated regions of the world were brought to Africa and it is regarded as a center of genetic diversity.

Production

Worldwide production figures for peanuts are estimated at slightly less than 30×10^6 t and peanuts are produced on a significant basis in more than 30 different countries. In recent years, India, China, and the USA, the three largest producers, accounted for approximately 65% of the world production. Production figures for the USA are relatively stable at about 1.6×10^6 metric tons. However, production from China and India have been about 10.9×10^6 t and 7.4×10^6 t, although recent estimates from India at 7.4×10^6 t are probably much higher than current production. Although cultivated for many centuries, the economic importance of groundnuts and groundnut oil has increased rapidly only in the past century.

Yield per hectare is highly variable, depending on environment, variety, disease, and other factors. Important increases in peanut yield occurred between 1960 and 1990 and these increases are due to improved technology and management of factors which reduce yield. Peanuts are a high-value crop and an important source of revenue to producers throughout the world, and especially in less developed countries. The exportation of peanuts is mainly from the USA, China, and Argentina, while less developed countries utilize peanuts produced within the country, and the majority of these are processed for oil. The percentage of peanuts crushed for oil is a function of the use of peanuts as edible products and the need for readily available, cheap cooking oil. On a world basis, more than 50% of the peanuts produced are crushed for oil. In India, 75–80% of the peanuts produced are crushed for oil, while in the USA only approximately 12% of recent production is crushed.

World production of peanut oil is estimated at 4.65 million metric tons (Table 1). Extraction methods (hydraulic press, expeller, and/or solvent extractor) may differ widely due to technological advances in some countries; however, residue may contain 1–7% oil and with inefficient equipment the percentage may be much higher.

Peanut Plant

The leaves of peanuts are alternate and pinnate, with three to four leaflets on long petioles (Figure 1). The leaflets, which are obovate and softly hairy, are normally about 3–5 cm long. Peanuts have a distinct main stem and variable numbers of lateral branches. There are two major types of peanuts based on growth habit of the plant – upright with erect central stem and spreading with numerous laterals. The upright type is suitable for mechanical production, and the spreading type is grown more often in less developed farming operations. The root system of peanuts is often expansive and may be found up to a depth of 2 m. Several strains of *Rhizobium* nitrogen-fixing bacteria are found in abundant nodules on main and lateral roots.

Flower, Fruit, and Seed

Peanuts have yellow flowers on axillary branches which are small (about 12 mm long). Depending on genotype, environment, and temperature, flowering starts at about 25 days after emergence and the most

Figure 1 Peanut plant.

prolific flowering occurs between 5 and 11 weeks after planting (Figure 2).

Under the best of conditions, fewer than 20% of the flowers produce mature fruit and with drought or heat stress the percentage may decrease to fewer than 15%. Genotypes which produce most flowers during the first 2 weeks of the flowering period produce greater numbers of pods. Peanuts are generally self-pollinating, although a small amount of cross-pollination may occur. About 7–10 days after fertilization, the receptacle thickens and elongates into a long carpophore bearing the fertilized ovules to the ground. The carpophore is commonly known as the peg, and the action of burying the immature pod is known as pegging. Growth of the peg is positively geotropic until it enters the soil – approximately 5–7 cm. The tip then turns horizontal and begins to develop into a fruit, commonly referred to as a pod, containing from two to four seeds and ranging in size up to 8.0×2.7 cm. The enlargement of the pod proceeds from base to apex and reaches maximum size about 3 weeks after the penetration of the peg into the soil. As the pod matures, the inner face of the shell becomes increasingly darker in color, associated with an increased tannin content, and becomes very dark brown on maturation. Seeds show large variations in size, shape and color, all of which are fairly stable for any given cultivar. Seed size, together with the seed mass, has been used extensively in agronomic classification of peanuts. Larger seed types are generally preferred for confectionery purposes; mostly small and medium-size seeds are used to produce oil.

Peanut Composition

Peanut composition is greatly affected by variety, environment, and maturity. The interaction of these factors with harvest date and handling determines the specific composition of an individual lot. Average percentages for peanut components are presented in Table 2.

Figure 2 Number of flowers of peanut plant as a function of time.

Oil

Peanut oil content is considered to average about 50% and the triacylglycerol content is generally in the range of 95%. Peanut oil is composed of mixed glycerides and contains a high proportion of unsaturated fatty acids, in particular, oleic (18:1) and linoleic (18:2). Additional fatty acids are palmitic (16:0), stearic (18:0), arachidic (20:0), 11-eicosenoic (20:1), behenic (22:0), and lignoceric (24:0). A comparison of fatty acid content with some other vegetable oils (Table 3) shows that peanuts are considered to have generally undetectable levels of linolenic acid. Peanuts contain higher levels of oleic acid than corn and soybean but lower levels than olive oil. However, peanut lines with high oleic acid concentration have recently become commercially available. The fatty acid profile from these peanuts is similar to that of olive oil.

Several years ago, research at the University of Florida examined approximately 500 peanut lines for fatty acid distribution and identified two lines with oleic-to-linoleic ratios of about 35. Using classical breeding techniques, commercial peanut varieties have been developed incorporating the high oleic acid trait. The developed lines do not have meaningful differences in oil content, flavor, color, or texture. Oxidative stability comparisons of high

oleic peanut oil versus normal peanut oil were made using extracted, neutralized, and bleached oil from isogenic peanut lines varying only in fatty acid composition. Oil from the high oleic line contained 76.3% oleic and 4.7% linoleic compared to 56.6% oleic and 24.2% linoleic in the normal peanut oil. Oxidative stability was found to be as high as 14.5 times greater for high oleic peanut oil depending on the method of measurement. Details of peanut oil composition and characteristics are provided in the section on vegetable oils.

Extraction of Peanut Oil

Peanut oil is held in cells in an extremely fine emulsion. Damage to cells results in the release of oil. Peanut oil is usually extracted by hydraulic press, expeller, and solvent extractor. These may be used separately or in combination. The oil in the residue from oil recovery by the three methods is about 7, 5, and 1%, respectively. The residue (press cake) from the hydraulic press and expeller is generally used for livestock feed, and that from solvent oil extractors may be finely ground into flour for human consumption, if the nuts were of good quality.

Proteins The total protein content of whole seed peanuts ranges between 22 and 30%. Total protein can be separated into four major fractions: albumins, arachin, nonarachin, or conarachin. The arachin and conarachin fractions represent about 63% and 33% of the total, respectively. The arachin fraction is rich in threonine and proline and poor in lysine and methionine, while the conarachin fraction is poor in phylalanine and tyrosine.

The arachin and conarachin protein fractions are complex in composition and structure. Gel electrophoresis of sodium dodecyl sulfate dissociated proteins showed that these two fractions each contained five different components having molecular weights between 20 and 84 kDa. Two-dimensional polyacrylamide gel electrophoresis of seed polypeptides resulted in the detection of at least 74 major and between 100 and 125 minor peptides among various peanut cultivars and breeding lines. Variation existed among the major polypeptides of the cultivars, as noted by isoelectric points between pH 4.4 and 8.0 and molecular weights between 16 and 75 kDa. There is genetic variability in the mechanism for peanut protein synthesis, indicating that there is a potential for the development of peanut cultivars possessing nutritionally desirable proteins by manipulating protein synthesis.

Nutritional value of peanut protein depends on the amount and kind of essential amino acids available during digestion (Table 4). Amino acid availability in peanuts and peanut products is enhanced by the processing they undergo before consumption. Antinutritive factors, including trypsin inhibitors, hemagglutinins, goitrogens, saponins, and phytic acid are present in raw peanuts, and heat treatment in blanching and roasting of peanuts destroys the trypsin inhibitor and hemagglutinin. Peanuts are generally considered to be deficient in lysine and methionine, thus their relative nutritive value is decreased in comparison with a reference protein. The protein efficiency ratio for peanut protein is generally considered to be 1.5–1.8 and these values are related to the limited availability of lysine and methionine.

Carbohydrates The carbohydrate content of peanut kernels is usually determined by difference from the proximate analysis. It has been found to range from 10 to 20% of the fresh weight. Defatted peanut meal contains about 38% total carbohydrate. The major components are starch, sucrose, and nonstarch polysaccharides. Defatted meal contains about 18% sugars.

The major sugars in peanut are sucrose, stachyose, raffinose, fructose, and glucose. Inositol, verbascose, arabinose, and galactose have also been reported in various studies. The total sugar content has been found to vary with genotype, maturity, growing conditions, storage conditions, and kernel size. Large kernels usually contain less sugar. Cooler growing conditions were found to produce more sugars and sugar content decreases with maturity. Sucrose is the predominant sugar, with the content ranging

Table 4 Amino acid composition of peanuts

[a]Data represent means from several sources.
[b]Essential amino acids.

from 2.7 to 3.5%. Stachyose is the next abundant, at levels of 1.5–2.5%. Other values found are 0.02–0.06% for raffinose and 0.01–0.04% for inositol. Fructose and glucose are usually present at less than 0.02%.

The sugar content is important for peanut flavor. Free sugars are noted to be precursors to roasted peanut flavors. When roasted, there is loss of some sugar content, with the greatest losses being sustained by fructose and glucose.

Vitamins and minerals The vitamin content of peanut seed is shown in Table 5. Peanuts have little or no vitamin A activity. Three forms of tocopherol (α, γ, β) have been found, with γ-tocopherol the highest and β-tocopherol the lowest. Peanuts are considered to be a good source of vitamin E, niacin, and folate.

Peanuts contain several of the minerals essential for human growth and development (Table 6). Recommended daily intake percentages of the quantities present are significant and constitute a good source of minerals.

Production and Handling Practices that Affect Quality

Maturity

Peanut maturation is extremely important in changes of biochemical components related to quality and shelf-life potential. Those facts have been demonstrated collectively in sensory studies to evaluate the relationship of maturity and flavor quality. Mature peanuts tend to have increased intensity of positive flavor descriptors, such as roasted peanutty and sweet aromatic, while immature peanuts are more commonly associated with negative terms, such as painty and fruity fermented. The term 'painty' is related to the common term 'rancid' and indicates the propensity of oil components in more immature peanuts to undergo enzymatic or autooxidation changes that result in decreased shelf-life. The degree of dark roast color is related to maturity level, with immature peanuts roasting darker because of higher free sugars and free amino acids. The relationship of high curing temperature to decreased sensory acceptability in immature peanuts has been demonstrated. Further, decreased sensory acceptability caused by high intensities of the off-flavor term 'fruity fermented' in sized lots was related to darker roast colored immature peanuts in the lot.

Maturity in peanuts is a complex concept because peanuts of all market types are generally marketed in various commercial seed sizes based on thickness, or on count per unit weight. The complexity arises in that all mature peanuts are not large and all immature peanuts are not small. Although size and maturity are positively related, the relationship is not absolute, and peanuts of very different maturity are found consistently in all commercial sizes. This fact is confounded even more in lots that are marketed on a count-per-weight basis wherein large and small seed may be mixed together to give the same count as seed of consistent uniform size. Peanut seed size distribution is affected by the environment in predictable ways. Soil temperature increases tend to shift the mean seed size down while cooler temperatures shift the mean size upward. Irrigation, harvest date, and soil temperature treatments generally produced significant differences among percentages of individual maturity classes in each commercial size. The distributions of maturity classes within commercial sizes are sufficiently different to suggest that flavor, roast color, shelf-life, and other quality factors would be affected in final roast products. Published data indicate that there are sensory differences in medium-grade-size peanuts harvested on a weekly basis over a 6-week period. In these studies, the percentage of immature peanuts in the seed sized lots progressively decreased with time. Roasted peanuts from earlier harvests had lower roast peanut impact and more bitter taste. Although shelf-life studies were not

conducted, the increase in percentage of mature peanuts in progressive harvests predisposes those lots to longer shelf-life.

Environment

The fact that growth, production, and handling practices affect quality, flavor, and shelf-life of peanuts and peanut products is implicit in data from numerous studies, years of manufacturing use, and the wide ranges of flavor and shelf-life observed in those countless situations. However, although studies report specific biochemical constituents and the effect of certain practices and conditions on changes in those compounds, the total effect on final product shelf-life resulting from all these processes must be extrapolated using established quantitative and qualitative relationships of specific constituents to shelf-life potential.

The role of environment on peanut yield has been consistently documented, but the effect on peanut quality factors potentially related to flavor and shelf-life has received little recent research attention. Higher soil temperatures tend to result in smaller seed size distributions, but studies on biochemical comparisons among years do not relate well to specific environmental conditions. Drought and temperature stress have been shown to affect some of the protein factors of peanuts. Soil temperature increases result in decreased concentrations of the free carbohydrates fructose, glucose, sucrose, raffinose, and stachyose in peanuts.

Harvest

When peanut plants are removed from the soil, the peanuts begin to dry, and the final natural processes related to potential flavor and shelf-life are initiated. When peanuts are harvested into inverted windrows, temperatures inside pods near the ground may reach 40–50 °C when air temperatures are no higher than 32 °C. Conditions that slow the drying process with associated high moisture may lead to fungus growth with resulting high free fatty acid values due to microbial lipase activity. Peanuts affected in this way are usually visibly damaged and may be removed electronically as part of the shelling process, or in less developed countries they may be removed by hand picking. Although off-flavors may not normally be thought of as factors that reduce shelf-life, usually the physical, physiological, and biochemical mechanisms that contribute to off-flavor development so disrupt the normal processes that shorter shelf-life should be anticipated. Obviously, processors will not knowingly utilize off-flavor peanuts in formulations, but knowledge or stipulation of growing and handling practices for purchased peanuts may contribute to the production and delivery of more stable products by the processor.

Maturity, as previously discussed, is a primary factor in total quality of peanuts, and the level of total crop maturity at harvest influences many of the handling and storage factors that follow. Moisture content decreases as peanuts mature on the plant, and at harvest, a wide range of moisture percentages are present. The range has variably been ascribed as 20–70% moisture at the time of digging. Given this, and the degree of biochemical and physical development of the various peanuts, it is readily discernible that differences in flavor and shelf-life are still being affected. Peanuts normally air-dry for some period of time before they are harvested. In mechanical harvest situations, peanuts usually dry to an average of 20–25% moisture before being picked and further dried.

The physical process of machine harvest has potential effects on the shelf-life of peanuts due to the force used to pick and transport peanuts into the machine. The physical damage in mechanical harvest, noted as cracked or broken pods, must inherently damage seed integrity, although relationships to quality reduction have not been investigated. Peanuts that are field-dried are subject to various environmental conditions which may affect quality. Harvested peanuts with a high percentage of immature pods will be difficult to dry to an overall safe storage level. High-moisture peanuts going into storage provide an increased opportunity for decrease in shelf-life potential.

Storage

Shelf-life potential may be maintained in storage of in-shell and shelled peanuts. In-shell peanuts are stored in bulk situations in many parts of the world, often at approximately 10% moisture content. In these situations, care must be given to ventilation and moisture control, because as the stored peanuts cool in response to ambient conditions that are usually cool, they dry further. The moisture that is lost must not be allowed to concentrate into the bulk lot because of obvious quality and microbial considerations. Adequate conditions of storage, especially ventilation, are critical to maintaining low levels of free fatty acids and total carbonyl compounds. Because of the removal of the shell, which is a normal protective barrier, shelled peanuts are somewhat more susceptible to quality/shelf-life deterioration. Shelled peanuts may be held in conditions of *c*. 0.5–5 °C and 55–70% relative humidity for periods of a year or more without quality loss.

Moisture content should be in the 7% range and slightly lower levels may impart additional protection. In peanuts stored at *c*. 6 and 9% moisture, the

higher moisture content resulted in reduced flavor quality and changes in amino acids, carbohydrates, and the phospholipid fraction of oil.

Consumption/Uses of Peanuts

Peanut Oil

Peanut oil is used as a cooking oil, especially in deep-fat frying; peanut oil is excellent since it has a smoke point of 229.4 °C. Degradation which may occur during frying results in the increase of free fatty acids and a decrease in smoke point. Crude peanut oil has a bland, slightly beany, nut-like flavor which is removed during refining to produce an oil that is odorless. Peanut oil develops few off-flavors or odors in use as a frying oil. Peanut oil is sometimes used in salad oil and in pourable dressings because of the length of time solids are held in suspension in the oil, although it solidifies from 0 to 3 °C. Refined peanut oil is widely used to prepare pastries, shortening (hydrogenation), oleomargarine, mayonnaise, salad dressings, and other food products. It is superior to oils from corn, soybean, cotton seed, olive, or safflower for making salad dressings to be stored below −12.2 °C.

Roasted Peanuts

Peanut roasting is a common practice in much of the world since roasting brings out the unique flavor. In western countries, particularly the USA, roasted and salted peanuts are one of the popular food items, produced on a commercial scale under a highly mechanized system with excellent quality control and packaging methods. In many European countries, peanuts are roasted and then coated with various flavors. A large portion of the US peanut crop is processed into roasted product for use in peanut butter, salted peanuts, and confections. Although the salted, roasted form predominates, oil-cooked, salted, unsalted, and low-calorie forms such as whole or mixed nuts are also popular.

A typical protocol for dry-roasted peanuts is exposure to 160 °C for 20–30 min. Seed coats are generally removed before applying oil and salt. In oil-roasting, blanched peanuts are immersed for 3–5 min in heated oil. After roasting the peanuts are then subjected to air cooling and salting with about 1.8–2.2% salt. Studies conducted to determine the effect of high-oleic-oil roasting indicated slight increases in shelf-life of normal oleic peanuts. Since peanut seed coats contain phenolics, including tannins, and the germs contain bitter saponin compounds, these are often removed before consumption. The current methods of blanching eliminate the skins and germs so that blanching always precedes oil-roasting, but often follows dry-heat roasting.

Peanuts have a high oil content and defatted peanuts have been developed to meet a specific consumer market. Partially defatted peanuts are obtained by hydraulic pressing to remove about 50% oil, followed by restoration of pressed kernels to their original size and shape by immersion in boiling water containing salt, species, or flavorings. Kernels are then dried and roasted. The pressure applied in the hydraulic press, the holding time, and the initial depth of peanuts in the compression influence the reconstitution of peanuts.

Peanut Butter

Although not a product accepted worldwide, peanut butter and products made from it are the most consumed form of peanuts in the USA, and notable consumption occurs in Canada and The Netherlands. Marketing introductions of peanut butter are still in progress in many European countries. Peanut butter is made by the fine grinding of dry roasted peanuts. Salt, hydrogenated oil, and sugar are usually added. Peanut butter may be made from any variety of peanuts but the blend of two parts Spanish or runner peanuts with one part Virginia peanuts is considered best for the most desirable consistency. Peanut quality, roasting techniques, manipulation of temperature, and grinding result in a wide range of colors, flavors, and consistencies of peanut butters on the market.

After grinding, oil separates from the solid particles unless a crystalline lattice is formed. Since crystals of fat are not present in the natural oil of peanut butter at ordinary temperatures, hydrogenated peanut oil, which is crystalline at these temperatures, is mixed uniformly with the product to provide such crystals. Generally, the incorporation is accomplished above the melting point of the hydrogenated peanut oil to insure more complete dispersion of the hydrogenated oil. In a satisfactorily stabilized peanut butter, crystallization of the added fat (hydrogenated peanut oil) takes place generally throughout the product before the oil–meal mixture can separate. *Trans*-fats infrequently associated with hydrogenated oil have recently been examined in commercial peanut butters and the work demonstrated unmeasurable quantities using current technology.

Confections

Peanuts (split, granulated, whole or ground peanut paste) are used in a wide range of other products,

including confections such as candy bars, dragées, hard-coated peanuts, peanut butter cups, peanut brittle, and a variety of other specialty applications. Shelf-life is important for confectionary products and is greatly affected by the product configuration, moisture content, and storage temperature.

Aflatoxin

Aflatoxin is a potentially carcinogenic compound produced by *Aspergillus flavus* and *A. parasiticus* which can invade peanuts, corn, cottonseed, and other commodities. In technologically advanced countries, control programs and testing programs are in place which significantly reduce the concentrations of aflatoxin over those found in developing countries. Aflatoxin contamination is usually found to be the most serious when drought conditions are present during the last few weeks of growth and pod development. Preharvest contamination is a significant economic problem for the peanut industry. Preharvest aflatoxin contamination in the crop is a problem when drought-type conditions predispose peanuts to insect damage by lesser corn stalk borer and other insects which are known carriers of fungus spores. Invasion of pods and infestation of seed often result in visible damage, and high levels of aflatoxin are characteristically found in damaged kernels. Preharvest invasion can occur with no obvious kernel damage and, although extensive studies have been conducted, the exact mechanism of fungal invasion is not yet known. Aflatoxin contamination is often highest in small, immature seed. Studies have demonstrated a relationship between the water activity-related physiological ability of the seed to produce phytoalexins and the water activity at which the fungus can best invade the seed. As the ability of the seed to produce phytoalexins decreases, there appears to be a point at which the fungus can grow in the seed before decreasing water activity terminates growth of the fungus.

Although generally less frequent, postharvest contamination may be a problem, especially when moisture accumulation and proper temperatures are present in harvest, transport, or storage.

Once the pods are field-dried and stripped from plants, they must be dried to moisture content less than 9% prior to storage. Peanuts stored at moisture content greater than 10% have increased risk for growth of *A. flavus*. Once dried to less than 9% moisture, peanuts can be stored for long periods with little loss of quality if kept under controlled storage conditions. Control of aflatoxin is best addressed during production by the appropriate irrigation of the crop through harvest time. In most contaminated lots, only a relatively small number of kernels is contaminated, and in many cases physical separation is the ideal method. This is based on the assumption that contaminated kernels are either discolored or shriveled. Methods include manual sorting, mechanical sorters, or electronic scanning, which examines each kernel separately and accepts or rejects it on the basis of reflectance. Action levels of aflatoxin in peanuts and other commodities are set and rigorously enforced within producing countries, and import regulations carefully control levels which may be imported.

Peanut Allergy

In recent years, concern for food allergies in general has increased, and concern for peanut allergy is no exception. For unknown reasons, peanut allergy is associated with a higher incidence of fatal food-induced anaphylaxis than any other food allergy. Immediate hypersensitivity to foods occurs in 6–8% of children and about 1% of adults. In the USA, a recent survey suggested that 0.7% of children are allergic to peanuts in varying degrees. Avoidance is the only current method of dealing with food allergy. Research potentials in dealing with peanut allergy will be discussed later.

Five peanut allergens have been identified by different research groups. Two major allergens, Ara h 1 (a vicilin) and Ara h 2 (a conglutin) are recognized by serum immunoglobulin E (IgE) of greater than 90% of peanut allergic individuals. Ara h 3 is recognized by serum IgE of about 40–45% of allergic individuals and is thus considered to be a minor allergen. Ara h 5 (a profilin) is also a minor allergen; IgE is recognized by about 13% of allergic individuals. Refined peanut oil (heat-processed) is not allergenic; however, oils contaminated with peanut protein may indeed produce significant allergic reactions in peanut-sensitive individuals. Cold-pressed oils are more likely to contain peanut proteins than hot-pressed oils.

Current research on peanut allergy is directed at testing an approved asthma drug, anti-IgE monoclonal antibody, against peanut allergy. Development and testing of a vaccine against peanut allergy are progressing towards human trials. A third area of research involves identification of enzymes involved in mediation of the allergic reaction and development of a test kit for individuals (especially children) to determine potential for peanut allergy.

PEARS

C Blattný, Prague, Czech Republic

Introduction

The genus of pear *Pyrus* has about 20 species. Cultivars of the common pear (mainly European and American) belong to *Pyrus communis*. The Asian cultivars belong to the sand pear *Pyrus serotina* = *P. pyrifolia*. The pear is a member of the rose family (Rosaceae).

Origin and History

The common pear came from Central Asia. It was well known and popular in ancient Greece. In the year 287 BC Theofrast, in his *Historia Plantarum*, described four cultivars of pears. The Romans took over the cultivation of pears from the Greeks. In the time of Vergil (50 years BC), Cato described 35 cultivars. The number of cultivars increased very quickly and by the end of the Middle Ages over 200 cultivars were described. But most of the outstanding dessert cultivars that are now widespread were selected out in the eighteenth and nineteenth centuries in France and in Belgium. Most of these old pear cultivars arose out of the selection of seedlings that grew as a consequence of random cross-breeding. Intentional or deliberate breeding led to new cultivars during the twentieth century, but a number of excellent cultivars from the eighteenth and nineteenth century have not been replaced. By the end of the twentieth century it is roughly estimated that 3000 cultivars of the common pear had come into being.

In China the cultivation of sand pear cultivars was known some centuries before Christ. Nowadays, many cultivars of the sand pear are widespread in East Asia. By the end of the twentieth century this sand pear had spread not only to North America, but also in smaller amounts to other continents. This species is also used for hybridization with the common pear, especially in the USA, as hybrids are less susceptible to the dangerous infectious bacterial disease fireblight.

Requirements of the Pear Tree

The pear tree, depending on the species and cultivar, has moderate to high demands of temperature (in winter as well as in summer) and length of vegetation period. Winter cultivars need warmer regions with a longer vegetation period to ripen properly and to attain better quality. Some of the cultivars do not tolerate extensive winter frost, e.g., Bartlett (Williams Christ). Fairly rich, warm, loamy soil, of sufficient depth and with a well-drained subsoil are suitable for the pear. Of all temperate climate fruit species, pear quality is the most influenced by soil properties and weather.

The trees that grow naturally from seeds (or grafts on pear seedlings) reach a height of up to 9 m with trunks of 30 cm or more in diameter. The cultivars of pears can only reproduce by being grafted on a rootstock – usually a pear seedling. In order to create smaller or dwarf trees the quince can be used as the rootstock. Most widespread vegetatively propagated clones of the quince are: quince A, quince C, from East Malling Research Station in England, French Provence Quince BA 29 C, and Le Page series C. In the USA a new hybrid Old Home × Farmingdale 333 (OH × F333) is now also recommended. Certain cultivars like Bartlett (Williams Christ) and Bosc are incompatible with the quince and require an interstem, e.g., cultivar Hardy or Old Home (used in the USA).

Many pear cultivars are self-sterile. They need the pollen of other cultivars to develop fruitfully. Some cultivars have relatively often parthenocarpic fruit (without kernels). Those fruits are usually longer and slimmer.

The cultivars of the Japanese-type Asian pear will pollinate each other. Chinese types need another cultivar for pollination, and when they bloom with the cultivars of the common pear, these cultivars could be very good pollinators for them.

As regards the sand pear's requirements of the environment, these are similar to the common pear, but it seems that suitable districts for peaches will also be best for most sand pear cultivars. *Pyrus betulaefolia* is recommended as standard rootstock for sand pear cultivars. The hybrid OH × F333 is also suitable.

The Fruit

The pear is a typical pome fruit closely related to the apple. The basic shape is pear-shaped and ranges according to the cultivar from bell-shaped, to egg-shaped, conical, globular and teardrop-shaped (Figure 1). Further differences are in size, color, texture, flavor, taste, ripening season, and possibilities for processing and cooling.

The flesh is usually firmer than that of apples; when fully ripe it softens and finally it melts. After

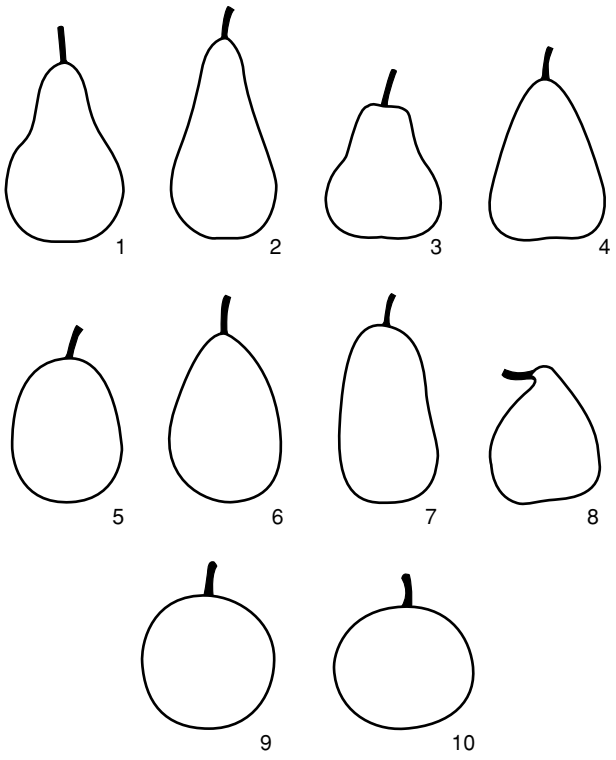

Figure 1 Different shapes of pear. 1, pear-shaped; 2, bottle-shaped; 3, bell-shaped; 4, conical; 5, egg-shaped; 6, teardrop-shaped; 7, cylinder-shaped; 8, fig-shaped; 9, globe-shaped; 10, flat globe-shaped

overripening the flesh quickly melts due to hydrolysis of pectin and total disorganization of enzymes. At optimal grades of ripeness, the fruit of the best dessert cultivars melts like butter. The skin is smooth and its color varies from yellow, yellow green, to brown (maybe russet) and also almost red. Only two cultivars are bright dark red: Max Red Bartlett and Red Anjou. The flavor and taste of cultivars differ greatly – some are spicy like muscat. There is another conspicuous difference between pears and apples. In the center of a pear around the core and along the vessels from the stem to the core, the gritty cells called stone cells are present. The more gentle the cultivar, the fewer small stone cells are present. However, very small stone cells in a very small number are always present in the best dessert cultivars, e.g. Bartlett (Williams Christ). The number of stone cells is not only influenced genetically by also by the quality of the soil, especially for winter cultivars. Most modern dessert cultivars of the common pear have large heavy fruit: medium weight 150–180 g, heavy weight 200–400 g, giant weight up to 750 g.

Asian pears are also called Oriental pears, Chinese pears, and Japanese pears. The Asian pear cultivar differs in its flesh texture – when eaten ripe they remain pleasantly firm, crisp, and juicy like apples but with a different and distinctive texture. They do not change texture after being picked and stored like common pears. Most Asian pears are sweet, flavorful, and low-acid. They are round or flat fruit with yellow or green skin, with bronze-colored and russeting skin or they are pear-shaped with either smooth or russeted skin.

Diseases and Pests

Diseases

Some virus and *Mycoplasma* diseases are relatively widespread. We will only discuss a few here. Ring pattern mosaic gives striking light-green or greenish-yellow rings and a line pattern in the leaves. Yellow veins and red mottle are typical with chlorotic banding of the tertiary and final veins. Both diseases suppress growth in a number of pear cultivars. The disease stony pit occurs wherever pears are grown. The fruits of diseased trees become pitted and deformed with many gritty cells in the tissue near pitty areas. Fruits with many pits are woody and difficult to cut. Either only a few or all of the fruits of diseased trees may develop symptoms, depending on the susceptibility of the cultivar. An affected fruit may have one or a number of pits and is not suitable for eating. The content of dry matter, ash, potassium, calcium, and mallic acid is higher in diseased fruits then in comparable healthy ones. The content of monosaccharides is less. The affected fruits cannot be used to produce sherry and brandy. Very sensitive cultivars are Bosc, Doyenné du Comice, while Bartlett in the USA is relatively resistant.

Fireblight, a bacterial disease, is the greatest problem limiting production of pears in the USA. Fireblight seldom affects Europe. Leaves and young terminal shoots infected by bacteria *Erwinia amylovora* wilt, die, and blacken. Further infection of branches and trunk results in the development of cankers and finally the death of the tree. Recommendations for decreasing the danger of fireblight are:

1. Select tolerant, better resistant cultivars. In the USA recommended hybrids between common and Asian pears include: Moonglow, Kieffer, Seckel, Waite, and Maxim.
2. Control of the vector – green apple aphids (*Aphis pomi*).
3. Avoid any practice that encourages excessive and soft terminal growth.
4. Prune out and burn the infected portion of the tree (better in winter) and avoid overfertilization.

Pear scab is a disease caused by the fungus *Venturia pirina*. The infection starts at blossom time and occurs on the blossoms, more so on the leaves than on the fruits. Infection of young pear fruits may cause the pear to be lop-sided and sometimes cracked. Then the scab spots spread on the whole fruit, especially on that of the susceptible cultivar. After very late infection, small scabs occur which then develop into so-called storage scabs. Spraying during infection time (May–July) is one of the best control measures.

During longer storage some pathological and physiological disorders can occur:

- blue mold rot (*Penicillium expansum*) – after mechanical injury
- gray mold rot (*Botrytis cinerea*) – infection during blossoming or through wounds of mature fruits
- senescent scald – dark brown skin discoloration
- superficial scald – diffuse brown skin discoloration
- freezing injury – translucent, water-soaked appearance of tissue
- bitter pit – brown, corky lesions in the flesh
- watery breakdown – rapid enzymatic flesh breakdown
- carbon dioxide injury – browning of interior walls of carpels and adjacent core tissue
- low-oxygen injury – core browning

Control measures

- effective preharvest disease control procedures
- careful handling during harvesting and postharvest preparation for market to minimize mechanical injuries
- prompt cooling to 0 °C
- maintenance of proper temperature (−1 °C to 0 °C) during storage and transport
- use of postharvest chemical treatments
- use of the controlled atmosphere

Pests

Codling moth (*Laspeyresia pomonella*) larvae feed on the fruits to the core and enlarge an exit hole which they plug with frass. They can have two to three generations and they are the most dangerous pests to apples and sometimes can be pernicious to pears. Spraying when females lay their eggs (June, July) is a good control measure.

Pear midge (*Contarinia pyrivora*) can cause considerable damage to young fruits. The attacked fruitlets become deformed and enlarged, and are later black in the center and full of white maggots, and they crack, decay, and fall down in a short time. They hibernate in the soil. Spraying just before the blossoming can decrease the damage.

Pear leaf midge (*Psylla pyricola*) in some districts is an important pest, resembling a miniature cicade. The psyllas suck on the leaves which margins roll. Maggots produce a honeydew that collects in droplets on the leaves, branches, and the fruit. It is an excellent medium for sooty molds. The crop is usually lower and unsellebled. Another danger to pear psylla is in its transmission of *Mycoplasma*.

Harvesting

The pear has to be gathered from the tree before full ripeness, usually when the basic green color changes to yellowish green. It is very important to determine the correct time for the crop. Prematurely harvested fruits do not ripen but they stay hard permanently and become leathery. Therefore the best time for gathering is when the fruits attain normal size, which is optimal for the cultivar, at the time when the stem parts readily from the branch if the fruit is slightly lifted. Then it is important to get the fruit quickly to cool storage. Overripe fruits soften so quickly that they are nearly useless.

To harvest fruits of Asian pears one must hold them lightly in the palm and pluck them using an upward twisting motion to remove the fruit from the spur. A pulling motion can result in damage as the stalk may be removed from the fruit. The skin of Asian pears is much more susceptible to abrasion and friction marks than common pears. Smooth surface containers such as polystyrene trace should be used to gather fruit. Fruit should be placed into trays with the stem end upward, preferably in single layers.

Chill Storage

Only a very small number of common pear cultivars can endure longer preservation in chill storage (Bosc, Anjou, Doyenné du Comice) if they do make it to the fresh market. These cultivars can be stored in controlled atmosphere (1–2% O_2 + 0–1% CO_2) at 1 °C for up to 4 months (Bosc and Doyenné du Comice) or 6 months (Anjou) while maintaining their capacity to ripen and attain good flavor and texture. Some winter cultivars can be stored in cooler places for some months until spring, but their quality is much lower (Diel, Comtesse de Paris, Nelis). For chilling it is necessary to have optimal temperature −1–0 °C, optimal relative humidity 90–95%, and for ripening, optimal conditions are 15–22 °C and 90–95% relative humidity. This basic schedule for ripening must be introduced after each longer cool storage of all pear cultivars to help the development of flavor and optimal texture of the flesh.

Some of the Asian pear cultivars, e.g., Shinseiki, Hosui, Kosui, Nijisseiki, have an adequate storage life. If fruits are harvested at the recommended maturity, a storage life of 12–20 weeks and subsequent shelf-life of 10–15 days can be expected, depending on the cultivar.

Important World Cultivars

- Common pear
- Summer – Bartlett (= Williams Christ), Dr J. Guyot, Clapp's Favourite, Santa Maria, Max Red Bartlett
- Autumn – Doyenné du Comice, Bosc, Conference, Fondante de Charneuses, Elisabeth, Luise Bonne, Boussock, Hardy, Lucas
- Winter – Diel, Comtesse de Paris, Anjou, Red Anjou, A. Lucas, Passe Crassane, Nelis
- Sand (Asian) pear (recommended in the USA)
- Early – Shinseaki
- August – Hosui, Kosui, Nijisseiki (Twentieth Century), Yo Inashi
- Late – Shinko, Olympic (Korean Giant)
- Sand (Asian) pear (widespread in China)
- Ya Li, Tse Li

Supplying Fresh Fruit to the Consumer

The fruit must be intact, sound, clean, free of any visible foreign matter, free from pests, free of abnormal external moisture, and free from any foreign smell or taste. The fruit must have been carefully picked and sufficiently developed so that the ripening process can continue in order to reach the degree of maturity appropriate to the cultivar, to withstand transport and handling, and to arrive at the destination in a satisfactory condition. Usually fruit is classified into three or four classes according the diameter of the widest part of the pear fruit.

Use of Fresh Fruit

The time to ripeness for consumption varies according to the cultivar: summer cultivars – up to 2 weeks; autumn cultivars – 2–8 weeks; winter cultivars up to 16 weeks. It is greatly influenced by the grade of ripeness during gathering and by storage temperature.

Dessert cultivars of the common pear, when eaten at the right stage of ripeness (the flesh should melt like butter) are delicious fruits. The fruits are used in various cookies, fruit salads, desserts, and gelatine dishes.

A small warning: it should be mentioned that some sensitive people can experience flatulence after eating fruits of the common pear, especially fruits which are not fully ripened.

The Asian pear cultivars are refreshing, very juicy, crispy like apples and, as with common pears, they go well with salads.

Processing

Pears are less often used for processing, compared to apples, due to their relatively low acid content and, above all, to a rapid ripening process which leads to the already-mentioned melting disintegration and liquefaction of the fruit. Selected pear cultivars are outstanding raw material for canning. They must, however, fulfill strict conditions:

1. The shape of the fruits is one of the decisive determinants of industrial preparation, since a suitable shape facilitates basic processing – peeling, halving, and removal of the core. The most suitable is a longish pear form with a wider stem part (for instance, the parthenocarpic fruits of the Bartlett (Williams Christ)). Cultivars that are too round have their core situated too high, which causes difficulties for machine coring. Fruits that are bottle-shaped, that crack, and that are too small are unsuitable.
2. The flesh should be white or faintly yellowish.
3. The skin should be firm, not too thick, clearly demarcated from the flesh, and easily peelable.
4. For factory processing, pears must be of the prescribed size and shape. Fruits of a uniform size and shape reach most uniformly technologically required ripeness. This degree is attained when the basic green color of the skin changes to yellow. Accurate appraisal of the degree of ripeness heralded by the changing color of different cultivars calls for an experienced eye. Many manufacturers use penetrometric methods to measure the firmness of the flesh, i.e., the pressure needed to push a special needle to a certain depth of the fruit. In areas of great production of cultivars destined for canning, for instance the summer Bartlett (Williams Christ) it is possible to employ long-term storage at temperatures -1 to $0\,^{\circ}C$ for 9–12 weeks, or at temperatures $+1\,^{\circ}C$ for 6–8 weeks to extend the processing season. The relative humidity must be 90–95%. The ripening process must follow this chill storage. Similar conditions can be also used for further canning of suitable cultivars like Clapps Favourite, Elisabeth, or Kieffer. The fruits are canned in syrup. To prevent browning of the flesh it is recommended to plunge the peeled halves in a solution of ascorbic or citric acid.

- Sweetening – the same requirements as for canning are applied.
- Drying of pears is relatively widespread in some regions. Pears suitable for drying should be of medium size (3 cm length), typically pear-shaped, slimmer in the stem part, the skin thinner, and the flesh with a small number of stone cells. Dried fruits should have a cinnamon color. Pears should be fully ripe with the highest content of sugar. They are dried whole, halved, or divided into small pieces, with the skin on or peeled.
- Pears are not frequently frozen. The requirements are the same as for canning.
- Brandy – due to the delicious flavor of some cultivars, e.g. Bartlett (Williams Christ), pear brandy is the mildest of the fruit brandies.
- Perry is a famous light alcoholic drink (like light wine) made from special perry cultivars. This drink was produced and beloved in Roman times. It is a drink of choice particularly in Normandy, the UK, Austria, Switzerland, and the USA. The special perry cultivars are highly fertile, with small fruit, and they should have a high content of sugar and acids and a rich content of tannins. Unfortunately, the production of those cultivars declined strikingly during the twentieth century.

Production

The pear is a popular fruit in temperate regions. Their production over the last 10 years in individual countries has developed differently. Worldwide it is increasing – in 1996–98 it reached 14 034 million tonnes, while in 1989–91 it was only 9529 million tonnes. It especially rose in China, by 245%, and amounted to 6401 million tonnes in 1996–98, that is, 45% of world output. The increase can also be observed in South America and Africa – in Chile by *c*. 500%, in Ecuador by 300%, in Argentina by 225%, in Morocco by 430%, in Algeria by 310%, in Tunisia by 210%, and in Egypt by 350%. Even in other warm regions production also increased, for instance, in Lebanon by 390% and in Turkey by 140%.

The changes are the result of the development of international trade which has facilitated refrigerated transport of high-quality dessert cultivars over long distances. Particularly profitable is the supply of the winter market either from southern countries of the northern hemisphere or from countries of the southern hemisphere. Among the largest exporters of pears we find now Argentina and Chile – not only Italy, France, and The Netherlands, as it was some years ago. The decrease in pear output in European countries is chiefly connected to the increase in the cultivation of apples and peaches to replace the pear.

Table 1 Chemical composition of pears

	$g\,kg^{-1}$
Water	775–869
Protein	4–5
Total lipid	3–4
Sugar	124–158
Acids	1–5
Dietary fiber	15–28
Ash	3–4

Sugar is composed on average from 54% fructose, 13% glucose, 15% saccharose, and 18% sorbit. Organic acids fluctuate according to the cultivar. In dessert cultivars malic acid, prevails citric acid is about 10% of

Table 2 Mineral salt content

Mineral salt	$mg\,kg^{-1}$
Calcium	100.0–160.0
Iron	2.0–3.0
Magnesium	60.0–80.0
Phosphorus	110.0–150.0
Potassium	1100.0–1300.0
Sodium	0.0–20.0
Zinc	1.2–2.3
Copper	0.9–1.1
Magnesium	0.4–0.8
Selenium	0.0–10.0

Table 3 Vitamin content

Vitamin	
Beta-carotene	0.15–0.30 mg kg^{-1}
Vitamin E	4.30–5.00 mg kg^{-1}
Vitamin B_1	0.20–0.50 mg kg^{-1}
Vitamin B_2	0.30–0.40 mg kg^{-1}
Vitamin B_6	0.15–0.18 mg kg^{-1}
Pantothenic acid	0.62–0.70 mg kg^{-1}
Folate	70.00–140.00 µg kg^{-1}
Vitamin C	40.00–50.00 mg kg^{-1}

Nutritional Value

The composition of the pear is given in Tables 1–3. Pears contain a good quantity of sugars (rapidly assimilated fructose, glucose, saccharose, and sorbit), as well as pectin, tannin, mineral salts, organic acids, some vitamins, and dietary fiber. There is also a rich content of delicious aromatic substances present. All this contributes to the great popularity of pears.

PEAS AND LENTILS

G Grant and M Duncan, Rowett Research Institute, Bucksburn, Aberdeen, UK
R Alonso and F Marzo, The Public University of Navarra, Pamplona, Spain

Background

Peas and lentils are potentially rich sources of macro- and micronutrients and bioactive factors. This overview deals with the nutritional properties of the seeds, possible physiological responses (detrimental or beneficial) of animals to the constituent bioactive compounds, and the effects of processing on nutritional quality.

Peas (*Pisum* spp.) and lentils (*Lens* spp.) have been cultivated since around 6000–5000 BC, making them amongst the earliest of the developed legume crop plants. They are highly adaptable and can flourish in a wide variety of habitats and environmental conditions. As a result, they are grown in most regions of the world and provide a staple source of dietary protein and energy for a significant proportion of the population.

Much of the world output of peas and lentils continues to be produced by traditional agricultural methods, whereby they may be grown as part of a crop rotation system or as secondary crops. Large-scale intensive cultivation and industrial processing of these legumes as foodstuffs do, however, occur in some regions. Nonetheless, peas and lentils have been at a commercial disadvantage to seeds such as soyabean in that they do not contain significant amounts of oil. This has limited their commercial value. Protein and starch are the primary products of cultivation of these seeds, whereas with soyabean, they are essentially byproducts of vegetable oil production and therefore comparatively inexpensive. However, food production will need to increase greatly to meet the requirements of a rising world population. This is most likely to be met through use of food sources that grow well in a wide range of environments, in particular those that are adverse to soyabean production. Peas and lentils are good candidates for further development in this regard. Furthermore, since many legume seeds contain bioactive compounds that have been linked to health-promoting effects, peas and lentils may have significant health benefits in addition to being ready sources of protein and energy.

Composition

Although peas and lentils are highly adaptable, their actual composition varies greatly according to region, climate, cultivar, and husbandry. The carbohydrate levels may range between 525 and 740 g kg^{-1}, protein between 156 and 355 g kg^{-1}, and lipid between 6 and 61 g kg^{-1} (**Table 1**). Intensively grown peas and lentils have been developed and selected for yield and thus are less variable in composition. In general, these contain around 240–280 g protein per kilogram, 570–610 g of carbohydrate, about 100 g of lipid,

Table 1 Comparison of general composition and nutritional value of raw legume seeds

	Peas	*Lentils*	*Soyabeans*

and 250–300 g of total dietary fiber. The protein and lipid levels are far lower than those in raw soyabean but are similar to the amounts found in other cultivated legumes, such as kidney beans. Carbohydrate levels in peas and lentils are about double that in soyabean, and the dietary fiber content can be two to three times greater.

The levels of individual amino acids in peas and lentils also vary greatly according to region, climate, and cultivar. Again, those in intensively cultivated varieties are more consistent (Table 2). The average amino acid profile of peas is close to the MIT (Massachusetts Institute of Technology) recommended amino acid pattern for humans, but that of lentils may be slightly deficient in the sulfur amino acids and possibly tryptophan (Table 2). However, when compared with the requirements for rats, the most widely used experimental animal, both seeds are deficient in a number of amino acids. The sulfur amino acids are limiting, being present at 47–56% of the requirements of rats. (*See* **Amino Acids**: Properties and Occurrence.)

Pea proteins are readily extractable in neutral or alkaline aqueous conditions. They are mainly of the globulin type, with the 7S globulins (vicilin) tending to predominate over the 11S globulins (legumin). Lentil proteins are also mainly of the globulin type, with legumin being the more prominent form. However, lentil proteins tend to be poorly soluble under neutral or alkaline aqueous conditions if whole seed meal is extracted. In contrast, solubility is high if the lentils have been dehulled. This may be a result of the removal of tannins present in the hulls. The globulin proteins of both seeds generally have low contents of the sulfur amino acids. In contrast, the levels in albumin (water-soluble) fractions from these seeds are quite high, owing to the presence of sulfur amino acid-rich proteins such as the trypsin/chymotrypsin inhibitors.

Protein digestibility values for peas and lentils *in vivo* are around 79–84%. This is similar to the values obtained *in vitro* (80–84%) with activated pancreatic extracts. However, digestibility values *in vitro* are around 65–70% if purified digestive enzymes are used. This discrepancy *in vitro* is likely to be a result of slow or poor digestion of vicilins by the pure enzymes. A similar difference was noted with phaseolin from kidney bean. It was highly resistant to pure proteolytic enzymes but readily degraded when incubated with rat intestinal tissue plus contents. Enzymes or factors, in addition to pepsin, trypsin, and chymotrypsin, were shown to be necessary to facilitate digestion of this protein. The nature of these components is unknown. However, if additional factors are crucial to promote degradation of legume globulins, there is no guarantee that all animals will possess them. There could therefore be

considerable species differences in ability to digest legume globulins. (*See* **Protein**: Quality.)

Purified radiolabeled pea legumin and vicilin are digested by rats almost as effectively as casein (97.4, 97.1, and 98.5%, respectively). Equally, isolated lentil globulins are readily degraded (99%) by rats. The globulins do not therefore appear to be inherently resistant to proteolysis *in vivo*. Digestibility values obtained with raw meals or crude protein extracts are much lower. This is likely to be a result of interference with proteolysis by the seed matrix or seed components, such as protease inhibitors. This would not be a problem with protein isolates prepared from peas or lentils.

Utilization of Raw Legumes

Weight gains and net protein utilization values obtained with young rats fed raw peas or lentils as the sole source of dietary protein (approximately 400 g per kilogram of diet) are low. This is mainly a result of reduced food intake and increased fecal dry matter and N and urinary N excretion. Supplementation of diets with methionine improves food intake, *N* retention, and weight gain, but the overall nutritional quality remains below that of high-quality protein (Table 3).

Inclusion of raw peas at 150–450 g per kilogram of diet severely impairs food intake and growth by weanling pigs. The effects are much less marked in pigs over 5–6 weeks old, and supplementation of diets with tryptophan or methionine greatly improves performance. The maximal inclusion levels recommended are 100 g per kilogram of diet for weaner pigs, 200 g kg^{-1} for grower pigs and 350 g kg^{-1} for finishers. The growth of chicks is severely retarded by inclusion of up to 200 g of raw pea meal in their diet. Supplementation with methionine, cystine, and tryptophan improves performance but only to a limited extent. Older birds appear more tolerant of peas, and with laying hens, up to 330 g kg^{-1} can be incorporated into the diet without any significant adverse effects. Addition of supplementary methionine and lipid to the diet allows this incorporation to be increased to around 440 g per kilogram of diet. Fecal dry matter and N outputs by human subjects are increased by intake of 130 g of lentils per day, but urinary N output is slightly decreased.

Possible Health Benefits

Peas are hypocholesterolemic for rats, pigs, and humans. The mechanisms remain unclear but may be linked to fiber and saponins in the seeds. With rats, the effect may be partly a result of reduced lipid deposition by the animals. Lentils are hypocholesterolemic for rats but not apparently for pigs or humans, at least at the dietary inclusion levels studied.

Bioactive Factors

Peas and lentils contain a number of potentially bioactive components such as protease inhibitors and lectins that may influence body metabolism in a negative or positive manner (Table 4).

Trypsin/chymotrypsin Inhibitors

Peas and lentils contain Bowman–Birk-like trypsin/chymotrypsin inhibitors that inhibit the activity of these digestive enzymes *in vitro* and *in vivo*. These inhibitors are of a relatively low molecular weight (around 8–10 kDa) and are double-headed in that they inhibit two enzyme molecules simultaneously. The original Bowman–Birk inhibitors (BBI) were isolated from soyabean and were found to inhibit

[a]Trypsin and chymotrypsin inhibitor is given as the number of grams of enzyme that would be inhibited per kilogram of meal.
[b]α-Amylase inhibitor is expressed as inhibitor equivalents using pure kidney bean α-amylase inhibitor as standard.
[c]Lectin levels are given as hemagglutinating units (U) per kilogram of meal based on the ability to agglutinate rabbit blood cells or as g kg^{-1} based on recoveries obtained during purification of lectin.
Data from Trowbridge (1974) *Journal of Biological Chemistry* 249: 6004–6012, Savage (1988), Savage and Deo (1989), Liener (1991) *Journal of the American Oil Chemists Society* 56: 121–129, Anderson and Wolf (1995) *Journal of Nutrition* 125: 581–588, Huisman and Jansman (1991) *Nutrition Abstracts and Reviews (Series B)* 61: 902–921, Alonso *et al*. (1998) *Food Chemistry* 63: 505–512, Alonso *et al*. (2000) *Journal of Agricultural and Food Chemistry* 48: 2286–2290, Alonso *et al*. (2001) *Nutrition Research* 21: 1067–1077, Cuadrado *et al*. (1999), Grant (1999), and Grant *et al*. (1999).

only trypsin and chymotrypsin in combination. However, in other legume seeds, variants capable of inhibiting two molecules of trypsin or chymotrypsin are also present. This heterogeneity in the reactivity profiles of BBI-like inhibitors makes it difficult to quantify the amounts present in the seeds or seed products. Therefore, for comparison purposes, the amount of each enzyme inhibited by a known amount of product is usually given. Alternatively, enzyme inhibitory units are calculated from the same data.

Trypsin and chymotrypsin inhibiting activity in peas and lentils varies greatly between cultivars (Table 4). Assuming that the mix of inhibitor variants leads to an average profile of one molecule trypsin and one molecule chymotrypsin inhibited per molecule inhibitor, available data suggest that peas contain 0.4–2.8 g of BBI-like inhibitor per kilogram and lentils 0.15–1.4 g kg^{-1}. This is comparable with the levels found in many other legumes. Soyabean has 3.2–3.7 g of BBI per kilogram. However, it also contains 4.5–9.0 g per kilogram of Kunitz trypsin inhibitors. Thus, the total trypsin inhibiting activity in soyabean is far higher than that in peas or lentils.

BBI are highly resistant to proteolysis *in vitro*. Nonetheless, native BBI and BBI-type inhibitors seem to be readily degraded *in vivo*, although ^{125}I-BBI seems to be highly resistant to proteolysis *in vivo*. Native inhibitors have limited effects on digestion and absorption of dietary protein and growth of animals, even when they are included at high levels (≤10 g kg^{-1}) in the diet. However, BBI or BBI-like inhibitors interfere with cholecystokinin-mediated control over pancreas function and trigger hypersecretion of pancreatic trypsin, chymotrypsin and α-amylase in rats, chicks, quails, and humans. In rats, chicks, and quails, this leads to pancreas enlargement, mainly as a result of hyperplasia and hypertrophy of the acinar cells and, in the long term, may lead to tissue dysfunction and disease. The effects of the inhibitors are, however, species-specific. Thus, they induce pancreas growth in young rats, mice, hamsters, guinea-pigs, and chickens but have little or no effect on the pancreas of young pigs, cattle, monkeys, or dogs.

Pancreatic enlargement is evident in rats fed pea diets, although the increase is usually much less than observed in rats given an equivalent intake of raw soyabean. Pancreatic growth was not apparent in rats fed lentil meal, although an inhibitor-enriched fraction of lentil meal did cause enlargement.

Consumption of soyabean BBI by experimental animals appears to significantly reduce the incidence and severity of liver, colon, and mammary cancers that develop as a result of treatment with chemical carcinogens or radiation. The mechanisms by which this occurs, however, remain unclear. BBI acting through localized effects on gut endocrine cells may induce the release of a number of hormones, growth factors, or peptides that interfere with tumor cell metabolism. Alternatively, bioactive fragments of BBI absorbed from the gut may be the main protective agents. The BBI-like inhibitors of field bean have also been shown to have cancer-preventing properties. It is thus possible that pea and lentil inhibitors will have a similar protective effect. (*See* **Trypsin Inhibitors**.)

α-Amylase Inhibitors

α-Amylase inhibitors inhibit the activity of salivary and pancreatic amylase *in vitro* and *in vivo*. They can impair the growth and metabolism of animals when given at high levels in the diet but may have beneficial uses in treatment of obesity or diabetes. They are generally present in very high amounts in *Phaseolus* species (kidney beans, 4.3 g of inhibitor per kilogram). However, the levels in peas and lentils are very low (Table 4) and unlikely to contribute significantly to the effects of these legumes on metabolism.

Lectins

Lectins are defined as carbohydrate-binding proteins/glycoproteins other than enzymes that are present in most plant materials. They are highly resistant to proteolytic degradation *in vivo* and survive passage

through the gastrointestinal tract. If appropriate carbohydrate receptors are present on gut epithelial cells, lectins bind to them and may be taken up systemically. As a result, lectins can potentially interfere with and modify many aspects of gut and systemic metabolism. Individual lectins vary greatly in their effects *in vivo*, but most species appear to be responsive to dietary lectins. (*See* **Hemagglutinins (Haemagglutinins)**.)

Lectins can be separated into eight general categories on the basis of their carbohydrate-binding specificity: complex, fucose, galactose, *N*-acetylglucosamine, mannose, mannose/glucose, mannose/maltose, and sialic acid. Some, such as soyabean agglutinin (galactose-specific), alter gut and pancreas metabolism in rats, in particular causing rapid growth of these tissues, without affecting systemic systems. A few, including kidney bean lectin (complex specificity), have additional effects on systemic hormone balance and lipid and muscle metabolism and can be very deleterious if consumed in high amounts. Others, such as pea and lentil lectins (glucose/mannose-specific) appear to have little or no effect on the body metabolism of rats.

The sensitivity of animals to lectins may, however, vary with species, age, period of exposure, gastrointestinal bacteria, diet composition, and dietary history. Thus, the glucose/mannose-specific jack bean lectin (Con A) has no effect on mature germ-free rats but has limited effects (causes small intestine and pancreas enlargement) in specific pathogen-free rats. It is, however, highly deleterious to rats carrying a salmonella infection, to suckling guinea-pigs, and to quails. The glycoconjugates expressed on the gut surface of very young animals differ greatly from those in mature counterparts; in particular, a high proportion of mannose residues are present. This is also evident in rats with a pathogen infection. In these circumstances, lectins that would not normally affect the gut may be able to bind to it and elicit changes in body metabolism.

The levels of lectins in peas and lentil are low compared with that in soyabean (Table 4) and very low by comparison with kidney bean (15–30 g kg^{-1}). Furthermore, in studies with mature rats, these lectins have no significant effects on metabolism. This would suggest that they are unlikely to cause problems. However, in view of the data with Con A and the number of factors that influence the sensitivity of an animal to lectin, one cannot exclude the possibility of specific circumstances where these dietary lectins have profound effects.

Young chicks do not do well when raw peas are added to their diet in low amounts but will tolerate quite high dietary inclusions if they are a few weeks old. During this period, the gut develops from its very immature form at hatching to its adult form. The gut may be susceptible to the action of pea lectin at the early stages of the maturation period.

Antigenic Proteins

Native 11S globulins (glycinin) and 7S globulins (conglycinin) of soyabean induce very adverse immune reactions in preruminant calves and newly weaned piglets, leading to gut damage, scouring, and poor performance. Pea globulins partially survive gut passage and can trigger some immune responses in preruminant calves. However, the degree to which this occurs is very much lower than that observed in soyabean-fed animals.

Lentils have been linked to allergy problems in a small number of pediatric patients. A number of possible allergens have been identified, including subunits of vicilin. The incidence of intolerance to pea proteins seems to be low.

Phytate

Phytic acid is often the main reserve of phosphorus in legumes. However, it also chelates with minerals and metals, such as calcium, magnesium, zinc, and iron, forming insoluble salts that are not readily absorbed by animals or humans. In particular, it can severely impair availability of zinc and iron. Phytate can also complex with proteins and may thereby reduce digestibility or enzyme activity.

Mineral uptake by pigs and chickens fed with soyabean-based diets is slightly impaired. Addition of phytase, a phytate-degrading enzyme, to the diet appears to counteract this effect, leading to an improvement in mineral uptake and better overall performance by the animals. However, the efficacy of this treatment can be very variable.

Phytic acid levels in peas and lentils are lower than those in kidney beans (11–17 g kg^{-1}) and soyabean (Table 4). None the less, they can still affect mineral metabolism, since iron absorption from a pea protein-based infant formula is significantly enhanced after enzymatic degradation of phytate.

Pea and lentil phytate can clearly have adverse effects on mineral uptake and body metabolism. However, in many cases, their impact is likely to be minimal because the mineral content of the diets is well above the requirements. Pea and lentil phytate, however, may cause significant problems if mineral intake, particularly of zinc and iron, is close to or below requirements.

Dietary phytic acid may have health-promoting properties. It can inhibit α-amylase, limit carbohydrate digestion, and lower blood glucose. There

are also indications that it is hypocholesterolemic and protective against colon cancer. However, the amounts required are quite high. It is unclear whether a normal physiological intake of peas or lentils would provide sufficient phytate to have a significant health-protective effect. (*See* **Phytic Acid**: Nutritional Impact.)

Tannins

Tannins are present in a wide array of plant crops. Legume condensed tannins are oligomers of variously substituted flavan-3-ols, and their antinutritional effects have recently been comprehensively reviewed. These compounds can reduce enzyme activity in the gut, impair gut morphology, lower nutrient (protein, carbohydrate and lipid) digestion and absorption, reduce mineral uptake, and greatly stimulate excretion of endogenous N. Thus, at high dietary intakes, they can adversely affect animal performance.

In contrast to the antinutritional effects, dietary flavan-3-ols have also been suggested to have important roles in disease prevention, particularly of cardiovascular diseases and some forms of cancer. They may act as antioxidant and free radical scavengers, inhibit tumor initiation and promotion, and have antibacterial and angioprotective properties.

The tannin contents of peas and lentils tend to be higher than that in soyabean (Table 4). However, the levels are comparable with those in many other legume seeds. Lentils contain moderate amounts of catechins and proanthocyanidin dimers and trimers, whereas pea samples tend to have low amounts. The compounds may have health-protective effects. However, since questions still remain as to how effectively these compounds or products derived from them are absorbed from the gut and distributed throughout the body, it is difficult to assess whether a normal intake of peas or lentils will provide sufficient flavanols to have a significant beneficial effect. (*See* **Tannins and Polyphenols**.)

Saponins

Triterpenoid saponins, found in leguminous plants, are composed of a triterpene aglycone linked to one, two, or three saccharide chains of varying size and complexity. The levels in peas and lentils are similar to, or slightly lower than, those in soyabean (Table 4) and other legume seeds. They may reduce weight gain if consumed at very high levels. However, at the levels present in peas, lentils, and soyabeans, they are considered to have no significant antinutritional effects. Saponins, however, may have beneficial effects. They have been found to be hypocholesterolemic in a number of species, owing in part to their ability to facilitate adsorption of bile acids to dietary fiber. Evidence of their efficacy in humans is not conclusive. It has also been suggested that saponins may have anticarcinogenic or antioxidant properties. (*See* **Saponins**.)

Fiber

Peas and lentils contain high levels of crude and total dietary fiber (Table 1). The fibers have a high binding capacity for bile acids *in vitro* and also promote fermentation in the hind-gut and production of butyrate *in vivo*. As with other dietary fibers, pea and lentil fibers are generally considered to be beneficial. However, the specific effects of these dietary fibers on metabolism remain unclear. Inclusion of pea or lentil fibers in diets appears to lower postprandial blood triglyceride levels without affecting cholesterol concentrations. However, other studies suggest that pea fibers can influence cholesterol levels in humans. Equally, studies show that pea fibers reduce or delay starch absorption and reduce the blood glucose peak, whereas others show no effect on blood glucose. This variability may be a result of differences in the test meals used or the nutritional/health status of the subjects. Pea fibers are used in the treatment of hypercholesterolemic patients. However, they are not used alone but given as part of a mixture of dietary fibers. (*See* **Dietary Fiber**: Properties and Sources.)

Starches

Legume starches in general tend to be less digestible or more slowly digested than corn starches. This slow release means that their glycemic index is low. They can thus be useful in diets for those with impaired carbohydrate tolerance. Lentils have been found to have beneficial effects on blood glucose profiles of diabetic patients. This is due, at least in part, to the slow release property of the constituent starch combined possibly with the effects of the fiber. (*See* **Starch**: Structure, Properties, and Determination.)

Vitamins and Minerals

Peas and lentils contain significant amounts of important vitamins and minerals. The levels of most are fairly similar in both seeds. However, lentils appear to contain higher levels of ascorbic acid, folic acid and vitamin B_6 than peas but have considerably less vitamin A. (*See* **Vitamins**: Overview.)

Effects of Processing

Various processing methods are routinely used in the preparation of peas and lentils for consumption. These include dehulling, soaking, germination, cooking, autoclaving, extrusion, and fermentation.

In general, dehulling or soaking seems to have limited effects on the levels of bioactive factors or the nutritional quality of the seeds. Dehulling of lentil increases the solubility of lentil proteins, and soaking slightly reduces trypsin inhibitor and phytate content. Germination lowers phytate and slightly reduces trypsin inhibitor, tannin and polyphenol levels in peas, and lowers trypsin inhibitor and phytate in lentil. Nonetheless, it may also increase levels of nonprotein amino acids. Natural fermentation also reduces the levels of bioactive compounds and slightly improves the starch and protein availability from legumes. The efficacy of this treatment is, however, extremely variable, partly because the environmental factors responsible are unknown.

Cooking, autoclaving, or extrusion treatment of peas fully inactivates trypsin inhibitors and lectins, has limited effects on phytate and polyphenols, but greatly reduces tannin concentrations. Starch digestibility is significantly increased, but protein digestibility is improved only to a limited extent (Table 3). The effects of cooking on lentils appear similar, with the exception that the reduction in tannins and polyphenols may be more pronounced than that observed with peas. Prolonged thermal treatment (cooking, autoclaving, or extrusion) can adversely affect nutrient availability from peas and lentils.

Thermal treatment of peas and lentils clearly improves the nutritional value of the constituent proteins (Table 3). With rats, this is evident only after supplementation of the diet with methionine to bring the sulfur amino acid content up to the requirements for rats. The human need for sulfur amino acids is much lower than that of rats and could be met from the levels present in peas and possibly lentils (Table 2). For humans, the biological value of cooked peas or lentils alone may thus be close to that found for the supplemented diets in rats.

Pea-based diets are hypocholesterolemic for rats. This property is retained even after extrusion treatment of the seeds. Some lentil proteins retain their antigenicity, even after cooking.

Digestibility of Heat-treated Globulins

The moderate digestibility of raw legume proteins has mainly been attributed to the presence of antinutritional factors in the seeds and the refractory nature of the proteins. However, although heat-treatment abolishes the activity of the main antinutritional factors, it appears to have remarkably little effect on the digestibility of pea or lentil proteins. In addition, pea and lentil globulins have a very high digestibility *in vivo*, once isolated from the seeds. The proteins are thus not inherently indigestible.

It is possible that interactions between nonprotein components of the seed matrix and the constituent proteins may be preventing digestion of a proportion of the proteins. Heating may not abolish these interactions. Alternatively, globulin-like proteins from some heat-treated legumes have been shown to be less digestible than counterparts from raw seeds. This may be due to the formation of large protein multimers that are not readily accessible to digestive enzymes. Any beneficial effects of heat treatment of seeds on protein availability may be negated, in part, by the development of these poorly digestible multimers of the globulin proteins. This merits further study.

Summary

Peas and lentils are potentially good sources of dietary protein and carbohydrate and micronutrients. They contain a range of bioactive compounds that may be detrimental to consumers. However, some of the bioactive compounds may also be beneficial for health. Thermal treatment greatly improves the nutritional quality of the seeds. Both raw and processed seeds have hypocholesterolemic properties.

PECTIN

Contents

Properties and Determination

L Flutto, Danisco, New Century, KS, USA

Introduction

Pectin is a high-molecular-weight carbohydrate polymer which is present in virtually all plants where it contributes to the cell structure. The term pectin covers a number of polymers which vary according to their molecular weight, chemical configuration, and content of neutral sugars, and different plant types produce pectin with different functional properties. The word 'pectin' comes from the Greek word *pektos* which means firm and hard, reflecting pectin's ability to form gels.

The gelling properties of pectin have been known for centuries, but the isolation of commercial pectin only started at the beginning of the twentieth century. In this document we highlight the chemistry, origin and production, and the functional properties of pectin.

Chemistry

The Homogalacturonic Acid Backbone

Pectin consists of a chain of galacturonic acid units which are linked by α-1,4 glycosidic bonds. The galacturonic acid chain is partly esterified as methyl esters. Pectin molecules can have a molecular weight of more than 200 000, corresponding to a degree of polymerization up to 1000 units (**Figure 1**).

Though the esters are the most significant components on the galacturonic acid backbone, other chemicals, such as acetyl, can be important in specific pectin types. Commercial pectin can also be partly

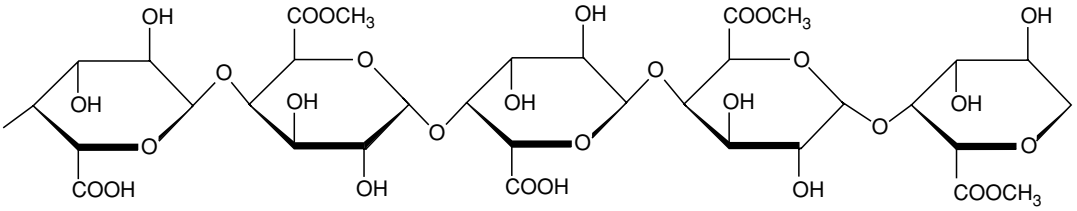

Figure 1 Pectin consists of long sequences of anhydro galacturonic acid completely or partly esterified with methanol.

Table 1 Classification of pectins

High-ester pectin (HE)	No amidation Conventional LE	DA < 25% Amidated LE

DE, degree of esterification; DA, degree of amidation.

amidated with ammonia to form galacturonamide units in the molecular chain.

Some neutral sugars are also included in the homogalacturonic backbone. This is the case for rhamnose but also specifically in apple pectins for xylose.

The percentage of galacturonic acid of the whole molecule is defined as the galacturonic acid content (% GA), which is set at a minimum of 65% in the definition of pectin as a food additive.

The percentage of esterified or amidated galacturonic acid units of the total number of galacturonic acid units in the molecule are respectively defined as the degree of esterification (DE) and the degree of amidation (DA) (Table 1). Regulations limit the DA to a maximum of 25%.

Esterification Pattern

In addition to the number of components on the backbone, their position is of significant importance to the functional properties of pectin. The distribution of esters is of special importance as it affects the local electrostatic charge density of the polymer and so its interaction with other charged molecules, whether ions such as calcium, proteins, or other pectin molecules.

In apple pectin subjected to a mild extraction process, the ester distribution is reported to be almost random, while citrus pectin tends to have a somewhat blockwise distribution.

Neutral Sugars

Pectin always contains varying amounts of neutral sugars such as D-galactose, L-rhamnose, L-arabinose, and D-xylose. Some of these neutral sugars are constituents of side chains to the galacturonan backbone. However, 1,2-linked L-rhamnose is present in the main polygalacturonic chain where it forms 'kinks' in the molecular chain. Xylose is also a very important neutral sugar in apple pectin where it is attached in the homogalacturonic backbone.

It is well documented that neutral sugar side chains are concentrated in relatively short segments of the galacturonic backbone, described as 'hairy regions.' The part of the molecule free of side chains is described as the 'smooth region.' (Figure 2).

Chemical and Physical Properties

Solubility Pectin is soluble in water, but insoluble in most organic solvents. The solubilization rate in water is related to the degree of polymerization and the number and distribution of methyl-ester groups. The pH, temperature, and ionic strength of the solution are of great importance to the rate of pectin dissolution. The calcium content of the water used to dissolve the pectin is of special relevance as it is common that a high-water hardness will translate into an incomplete dissolution of pectin.

Rheology of pectin solutions Pectin solutions are viscous but pectin is not an especially effective viscosifier compared to other gums such as guar gum.

Dilute pectin solutions are almost Newtonian, and they are only slightly affected by the presence of calcium. However, solutions with more than 1% pectin exhibit pseudoplastic behavior and are strongly affected by calcium. There is a continuum in texture starting with water through thixotropic solutions with yield value to stiff gels depending on the pectin type and concentration, level of calcium, and pH.

Stability High-ester pectins are stable at pH levels of 2.5–4.5. Above a pH level of 4.5, β-elimination will occur, depolymerizing the galacturonic acid chain. This mechanism requires an esterified carboxyl group next to the glycosidic bond to be cleaved (Figure 3), so low-ester pectins are more stable at higher pH values.

The pectin molecular structure is quite resistant to heat. At pH around 3.5 pectin is only marginally depolymerized at high temperatures. The heat-stability

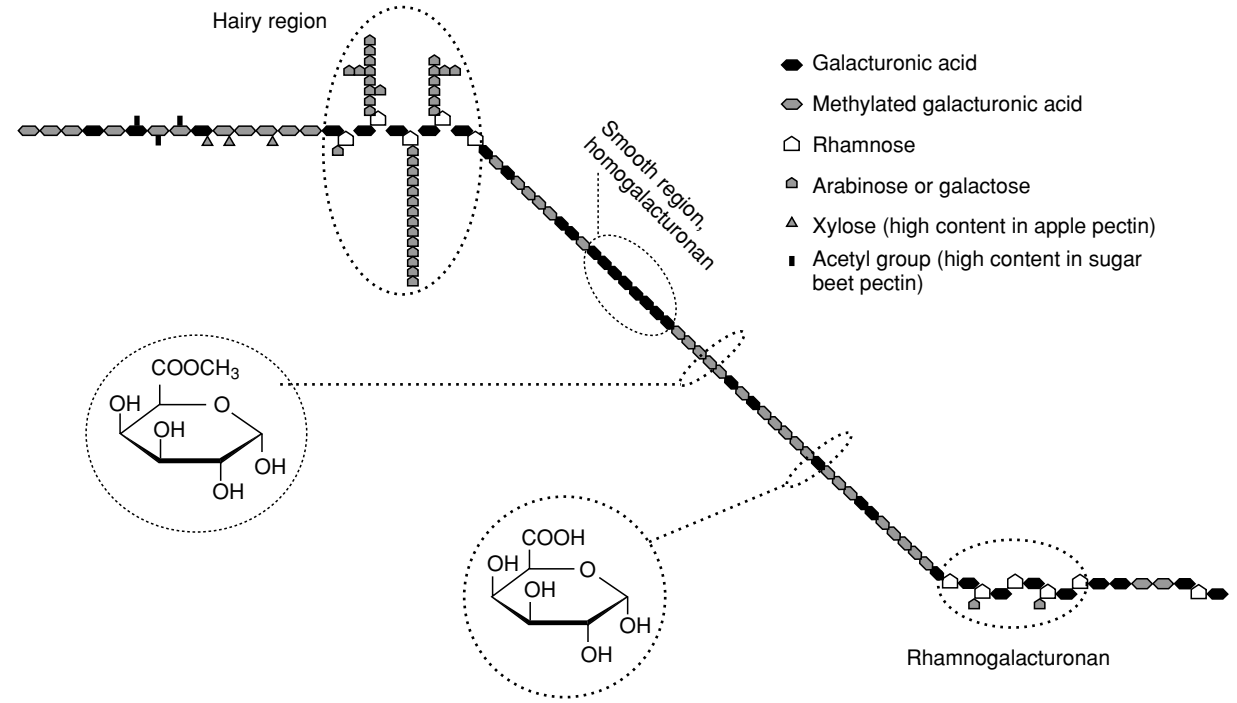

Figure 2 Primary and secondary structure of pectin.

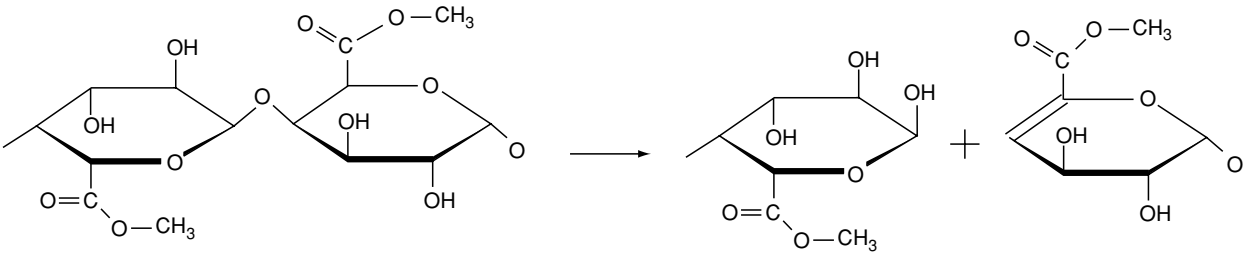

Figure 3 β-elimination mechanism.

of pectin is greatly improved when the water activity of the system is lowered through the addition of sugar.

Origin and Production

Pectin is a natural component of plants, predominantly in the form of pectic substance or protopectin, which is not soluble in water. The pectic substance is an essential part of the plant cell wall structure, acting as a cement for the cellulosic network and a hydrating agent. The exact nature of the pectic substance is not completely understood. It is, however, generally recognized that it is a complex structure in which pectin is attached to other cell wall components such as cellulose, hemicellulose, and proteins by covalent bonds, hydrogen bonds, and/or ionic interactions. In the plant the residual carboxyl groups are partly neutralized with cations of calcium, potassium, and magnesium which are present in the plant tissues.

Pectin is today commercially produced mostly from apple pomace and citrus peels by an extraction process followed by separation, purification, isolation, and then drying, milling, and standardization (Figure 4).

Functional Properties

Pectins are used in a broad variety of food and pharmaceutical products. Their principal properties are gel formation with both high- and low-ester pectins, viscosity build-up, and protein stabilization with high-ester pectins. As methods develop for obtaining a better understanding of the pectin molecular structure, it is likely pectin will be attributed new functional properties in the future.

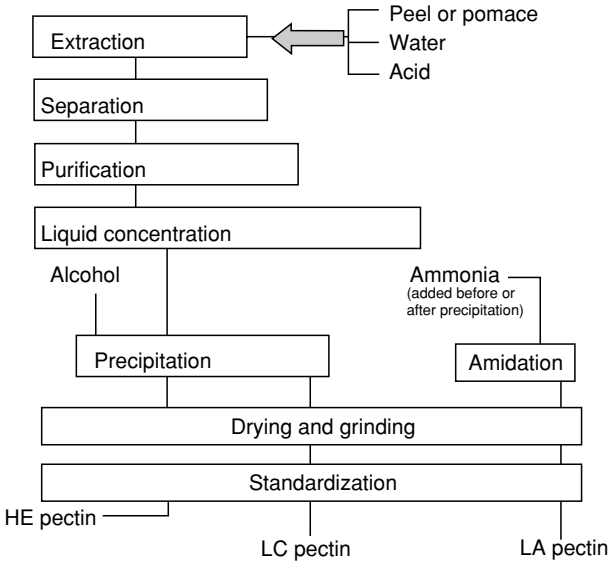

Figure 4 Pectin manufacture flow sheet. HE, high-ester; LC, low ester conventional; LA, low ester amidated.

Gelling of High-Ester Pectins

The ability of pectin to form gels in specific conditions has long been used in the production of jams and preserves. The separation of high- and low-ester pectins in accordance with the 50% esterification rule proves somewhat arbitrary when dealing with gelling mechanisms. It is clear that the dominant factor in the gelling of pectin is highly dependent on its degree of esterification but the complex network structure is most often the result of a combination of several mechanisms. The statement that high-ester pectins will gel with sugars and acid, while low-ester pectins gel with calcium, is certainly valid but certainly calcium can alter the gelling of high-ester pectins, just as pH and soluble solids will affect low-ester pectin gelling.

Gelling Mechanism

It is generally accepted that a high-ester pectin gel is formed by the cross-linking of the polymer in junction zones, in which mainly hydrogen bonds but also hydrophobic attractions between the methyl-ester groups play a part. Calcium bridges may also participate, especially if the esters are distributed in blocks, leaving large parts of the molecule as free acids.

Gelling will occur upon cooling of a media where favorable conditions are met. Cooling is necessary to decrease molecular movement and permit the formation of intermolecular interactions.

As the pectin chains carry negative charges they will tend to repel each other. This repulsion will depend on the charge density of the molecule which can be directly correlated to the pH of the medium and the frequency of free galacturonic acids of the polymer. The higher the pH and the lower the degree of esterification, the higher the charge density and hence the stronger the repulsion.

This repulsion, but more importantly the impossibility of forming hydrogen bonds between ionized pectin chains, are the reasons why a low pH is required for high-ester pectin gelling. At a low pH, typically below 3.6, the repulsion is low enough for the distance between the pectin chains to be reduced sufficiently and hydrogen bonding can occur. In order to achieve sufficient hydrophobic interactions to stabilize the molecular network, the water activity of the system also has to be decreased. Sugars are usually added for this purpose.

So, typically, high-ester pectins will only form gels when the pH is below 3.6 and soluble solids are above 55% (Figure 5).

Upon storage of a cooled gel, it is typical that the texture will still develop into a stronger final gel. This corresponds to a slow reorganization of the network involving the creation of new junction zones or an enlargement of the existing junctions between the pectin molecules.

Parameters Influencing Gelling

The gelling and final gel structure of high-ester pectins is influenced by a great number of parameters, the main ones being the pectin concentration, the degree of esterification, molecular weight, acetylation and branching of the pectin molecule and the pH, ionic strength, water activity, sugar type, and cooling rate of the gelling medium.

Pectin concentration The concentration of high-ester pectin will increase the final gel strength of the system due to the increase in the number of junction zones, increasing the number of chains with elastic activity. An increase in molecular weight would have the same effect. In addition to this expected effect, the gelation rate is also increased with increasing pectin concentration and a power law can be calculated between the two parameters.

Degree of esterification The degree of esterification of the galacturonic acids affects both the charge density of the polymer and the number of sites for hydrophobic interaction. As pectin molecules with a high degree of esterification are less charged, they can form gels at a higher pH and will also start gelling at a higher temperature.

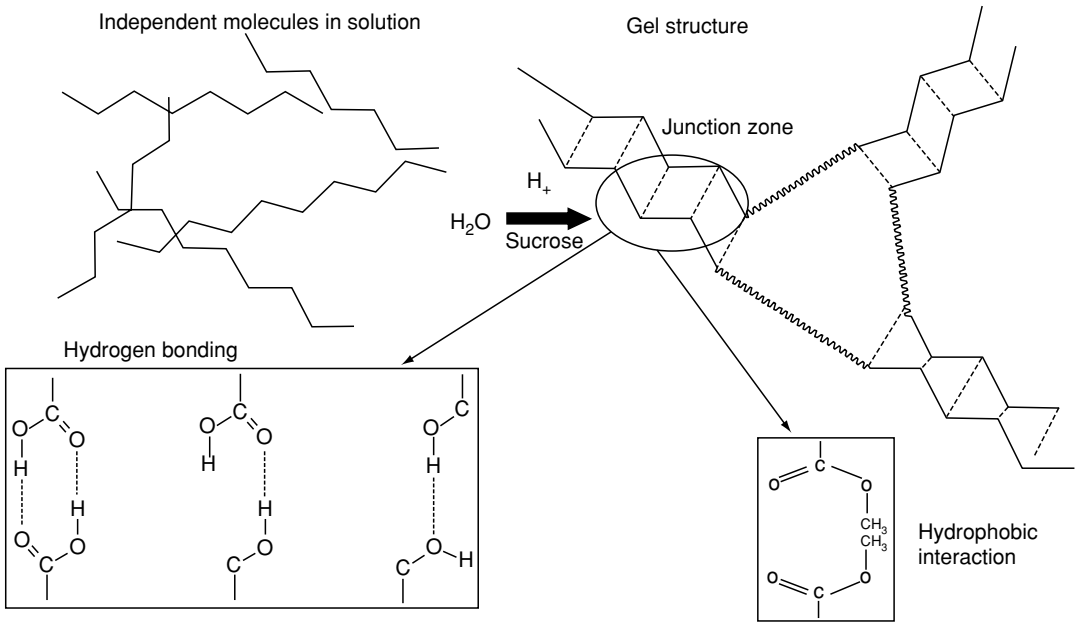

Figure 5 High-ester pectin gels through hydrogen bonding and hydrophobic interactions in an acidic water and sugar matrix.

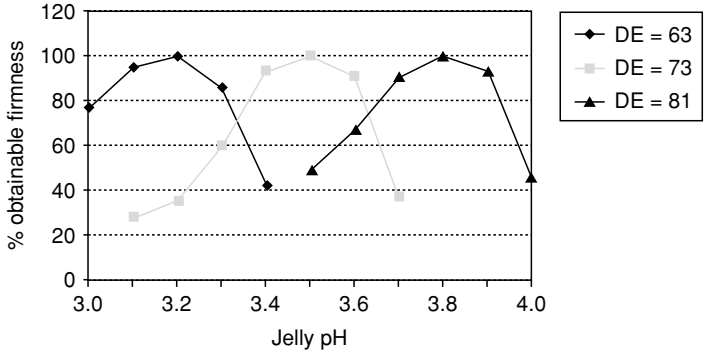

Figure 6 High-ester pectin: the degree of esterification (DE) determines the optimal pH for the gelation.

This last effect forms the basis for the classification of high-ester pectins into rapid-set, medium-rapid-set, slow-set, and extra-slow-set pectins as the degree of esterification is decreased from more than 70% to 50% (Figure 6).

The distribution of the ester groups on the backbone will also affect pectin gelation, as a marked blockwise distribution of esters will result in a significant contribution of calcium gelling. This contribution of calcium gelling will significantly increase the gelling temperature of the pectin (Figure 7).

Acetylation and branching Acetylation sharply decreases the gelling ability of pectin as the size of the acetyl groups does not allow the pectin chains to come close enough for interaction between the molecules.

The effect of neutral sugars on high-ester pectin gelling can be twofold and would need to be studied more extensively. Neutral sugars present on the pectin molecule could result in steric hindrance of intermolecular interaction and thus decrease the ability of the pectin to form gels. However, they could also participate in gelling through hydrophobic interaction and contribute to an increased cohesion of the gel.

pH and ionic strength of the gelling system The lower the pH, the lower the repulsion between the pectin molecules and, thus, the easier it will be for them to interact. This means that a low pH will lead to faster gelling in high-ester pectins. However, below a critical level, the gel strength will be reduced as the gelling is too fast to obtain a well-organized polymer

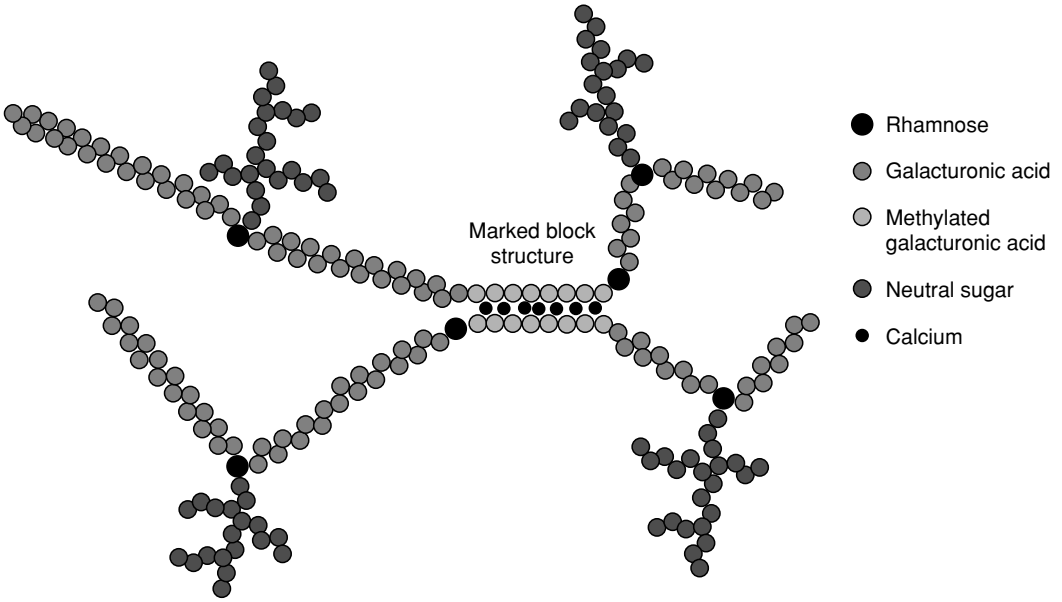

Figure 7 Participation of calcium gelling in high-ester pectin gelation.

network and precipitation can occur. The optimum pH for gelation is controlled by the degree of esterification of the pectin as well as the soluble solids content of the medium (Figure 6).

Through their effect on the neutralization of the pectin molecule, cations present in the system will affect gelling. High ionic strength shifts the optimum pH range towards higher values. This is particularly visible with sodium ions. However, with ions such as calcium or potassium that can bridge high-ester pectin molecules in areas with a low density of ester, there is a possible increase in junction zones. This effect can become significant for high-ester pectin with marked blockwise distribution of ester groups (Figure 7).

Water activity and sugar types Water activity and sugar types will both affect the way hydrophobic interactions can develop between the pectin molecules. As water activity is reduced, the hydrophobic interactions are easier to form, causing faster gelling to occur and the final gel strength to be increased.

The commonest way of reducing water activity in a food system is through the use of sugars. The effect of sugars on hydrophobic interaction and so on gel structure will be specifically linked to their molecular conformation and their interaction with the neighboring water molecules (Figure 8).

Influence of cooling rate and storage temperature Cooling decreases molecular movement and allows polymer molecules to interact at close distances. As the cooling rate is increased, the gelation rate is also increased. However, during rapid cooling and with a low storage temperature, gelling can actually become very slow, reflecting the difficult development of hydrophobic interactions in these conditions. With an intermediate cooling rate and temperature range, hydrogen bonds and hydrophobic interactions together can contribute to the build-up of a network with the highest elasticity.

Properties of high-ester pectin gels Due to the nature of the molecular interactions involved in high-ester pectin gelation, gels made with these pectins will typically not be thermo-reversible or shear-reversible. When submitted to mechanical stress, the broken gel will then show a high level of syneresis.

Gelling of Low-Ester Pectin

Low-ester pectin has traditionally been used for gelling food products when the conditions required to achieve a gel with high ester pectin were not met. Recently however, low ester pectins have also found applications in high sugar and low pH systems because of their specific texture characteristics.

Though the same base mechanism applies, low ester conventional and amidated pectin differ in their gelling properties and offer a broad range of functional properties.

Gelling mechanism The gelation of low-ester pectins is the result of ionic linkage through calcium bridges between carboxylic groups from two pectin

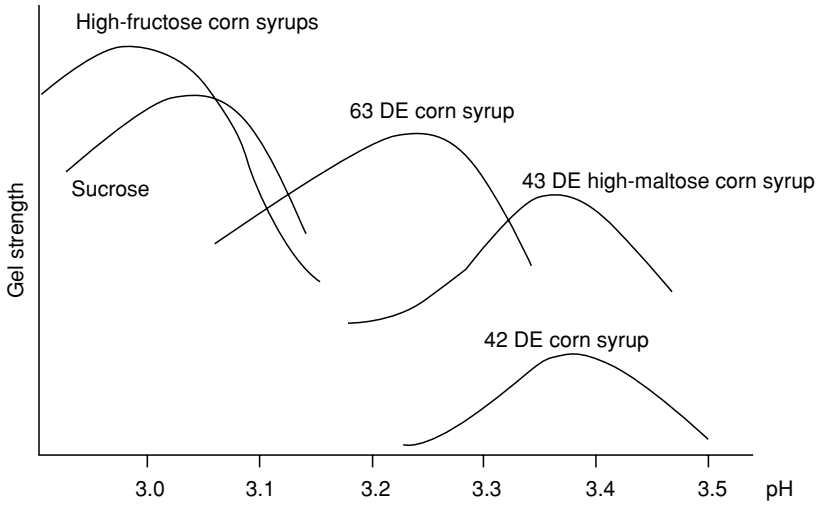

Figure 8 Effect of various sugars on high-ester pectin gel strength. DE, dextrose equivalent.

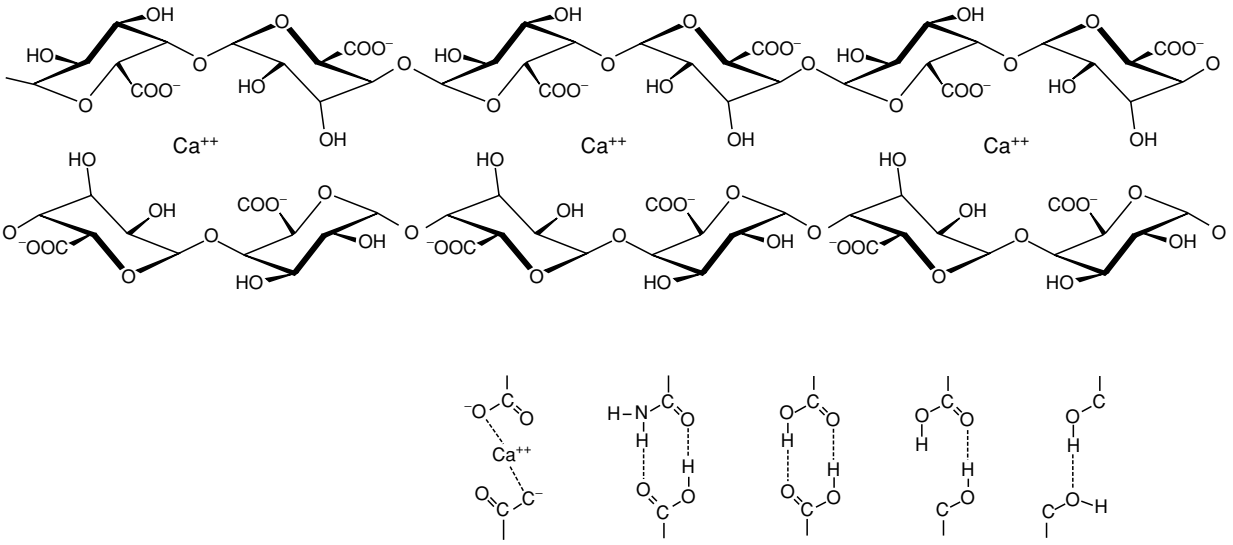

Figure 9 Eggbox model. Schematic overview of established low-ester pectin gel mechanism, showing calcium-induced junction zones. Inset shows detail of the various types of possible hydrogen bonding that participate in the junction zone, together with the calcium chelation (far left).

chains with the participation of hydrogen bonding. The linkage generally takes place upon cooling a pectin and calcium system. The most commonly accepted model of association is the eggbox model (Figure 9). In this model, pectin chains could be bridged by calcium ions, which incorporate in their coordination shells two polyanion oxygen atoms from one pectin molecule and three from another chain. Even though a number of positive ions can bridge pectin molecules, especially magnesium and potassium, calcium is particularly effective in complexing with carbohydrates, largely because its ionic radius (0.1 nm) is big enough to coordinate with many oxygen atoms and because of flexibility with regard to the direction of its coordinate bonds.

The exact calcium requirements to obtain a gel highly depend on the degree of esterification of the pectin, the recipe, and process parameters such as the rate of cooling. An increase in ionic strength, increase in pH, or decrease in the degree of esterification lowers the amount of calcium required to achieve sol–gel transition. An optimum calcium level can be defined for a given pectin in specific conditions. Above this optimum level, pregelation will occur, i.e., gelling will occur at too high temperatures to obtain a coherent gel structure (Figure 10).

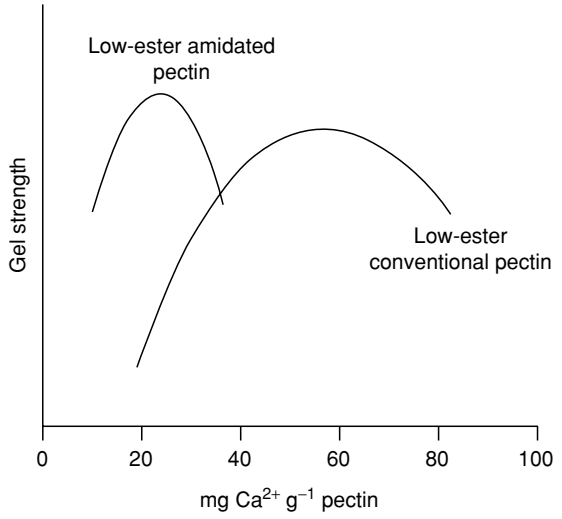

Figure 10 Influence of calcium on low-ester pectin gels.

Gelling is dependent on the length of the junction zones, that is, the number of galacturonic acid units involved in electrostatic bonds with calcium. The bonds are stable when at least seven consecutive carboxyl groups from each chain are involved. If the junction zones formed with calcium become too long, a pectin precipitate may be formed. This may occur with pectin with a very low degree of esterification when large amounts of calcium are available.

The presence of ester or amide groups prevents the formation of junction zones in the interjunction segments of the molecules, making them more flexible. Side chains also prevent aggregation of the pectin molecules through steric hindrance.

The typical high-ester pectin gelling mechanism with hydrogen bonds and hydrophobic interactions can also contribute to the final texture of low-ester pectin gels, especially at low pH and with high soluble solids concentration.

Parameters Influencing Gelling

Although the availability of calcium is a critical factor in the gelation of low-ester pectins, other parameters in relation to the pectin molecule and media have a significant influence on gelling and the final structure obtained. The main parameters are the number and distribution of ester and amide groups as well as the molecular weight of the pectin molecule and the pH, ionic strength, and water activity of the gelling system.

Influence of esterification Because calcium bonds can only occur in esterification-free zones, gel strength increases with a decreasing degree of esterification. For low-ester pectin with an average DE above 30%, the distribution of the esters may be of significant importance as it will control the length of possible junction zones and influence the gelling temperature, the final gel strength, and texture.

Influence of amidation The amidation of pectins was developed in the 1940s as a means of modifying the functional properties of low-ester pectins in order to achieve better gelling control. The exact mechanism by which the amide groups intervene in the gelation remains to be fully explained. However, it is generally accepted that amidation increases the gelling power of low-ester pectins due to the possibility of hydrogen bonding involving amide groups. Gels made with amidated pectins are firmer and require less calcium; they are also more thermo-reversible than ones made with low-ester conventional pectins.

Influence of molecular weight As for any polymer gel, the length of the polymer governs the number of junction zones required to achieve a coherent network. Low-ester pectins with a high molecular weight will exhibit a higher gelation rate, lower calcium requirements for gelling, and an overall more cohesive and elastic gel structure with a reduced tendency towards syneresis.

Influence of pH At low sugar content, as the pH is decreased, the pectin molecules are neutralized with protons, decreasing the probability of junction zones forming with calcium. This translates into higher calcium requirements and a looser gel texture at a low pH.

On the other hand, when the water activity of the system is decreased by the addition of sugars, the high-ester pectin gelling mechanism will start to play a significant part in the gelling and the calcium requirements will then be decreased when the pH is lowered. In usual food systems, availability of natural calcium will also be increased at a lower pH and thus may reduce the need for extra calcium addition (Figure 11).

Influence of ionic strength An increase in gel strength can be observed at a higher ionic strength. This is usually explained by the neutralization of the polymers by the extra ions, which allows the chains to be closer, leading to a more organized and cohesive gel.

Influence of water activity As the solids level increases, calcium requirements decrease. However, for most pectins, a higher solids level accelerates gelling, and increases the setting temperature and the final gel strength. It also reduces the optimum calcium window, thus increasing the risk of pregelation.

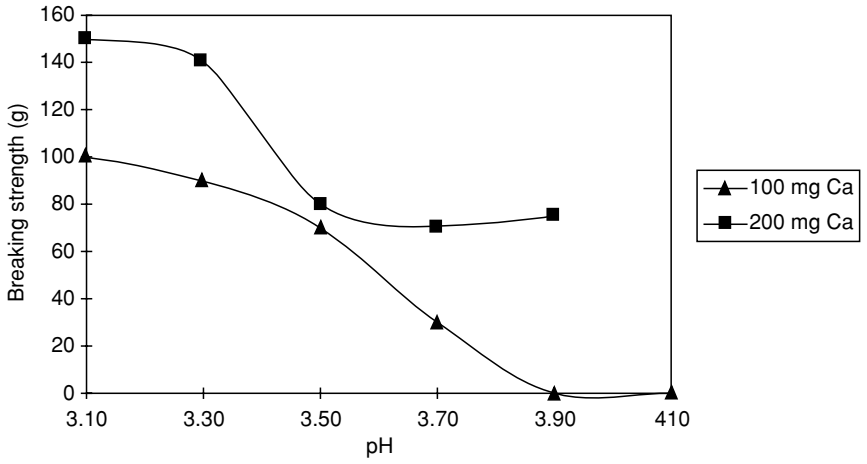

Figure 11 pH influences on Ca-curves in low-sugar system (31% soluble solids), with high reactive amidated pectin. Triangles, 100 mg Ca; squares, 200 mg Ca.

In practice, this leads to a choice of pectin with a higher degree of esterification (less calcium-reactive) at a higher solids level.

Properties of Low-Ester Pectin Gels

The properties of low-ester pectin gels are very dependent on the type of pectin used (conventional or amidated) along with the procedure and formulation employed to make the gel. Typically, they are thermoreversible and show a high degree of thixotropy. In specific conditions it is however possible to obtain heat-resistant or very brittle gels with no shear reversibility.

Protein Stabilization with High-Ester Pectins

In acidified conditions, casein and, more generally, food proteins will tend to agglomerate and sediment if the viscosity of the system is low enough. In these conditions the proteins are also very sensitive to dehydration and can easily become sandy after heat treatment. With the rapid development of acidified dairy beverages worldwide, now expanding with other protein sources such as soy, the need for effective protein stabilizers in a low-pH environment is growing strongly. High-ester pectin has proven to be a very useful stabilizer in these conditions.

Mechanism It is generally accepted that, at sufficient pectin concentrations, the adsorption of the carboxyl blocks of the pectin molecule to the protein surface will stabilize the protein system through steric repulsion (Figure 12). So, the presence of blocks of free carboxyl groups on the galacturonic backbone has an important influence on the protein-stabilizing property of pectin.

Due to the lower proportion of carboxyl groups, high-ester pectin has a weaker electrostatic interaction with protein than low-ester pectin but proves to be more effective. Indeed, it seems to be important that significant parts of the pectin molecule do not interact with the protein surface in order to achieve the steric repulsion effect. It is also the key to minimizing interactions between pectin and cations available in the system.

Both the DE of the pectin and the distribution of the esters on the polymer affect its stabilization properties. Excessively large blocks of carboxyl groups will tend to interact with the ions present in the system, such as calcium, rather than with the protein – an interaction which will lead to an increase in viscosity or even gelation.

Conditions Most food proteins (isoelectric point around 5) can form complex coacervates with anionic polysaccharides such as pectin (isoelectric point around 3.5) in the intermediate-pH region, where the two macromolecules carry opposite net charges: pH above the isoelectric point of the polysaccharide but below that of the protein.

In the case of pectin–protein interaction, the strength of the complex will depend on several factors, such as the distribution of the carboxyl groups on the galacturonic acid backbone, but also on the three-dimensional protein structure and the distribution of ionizable groups on its surface. The whole interaction will also depend on several system parameters such as pH, ionic strength, presence of sugars, or fat.

Through its role in the ionization of both the protein and pectin molecules, pH is the most significant factor affecting electrostatic pectin–protein interactions. It

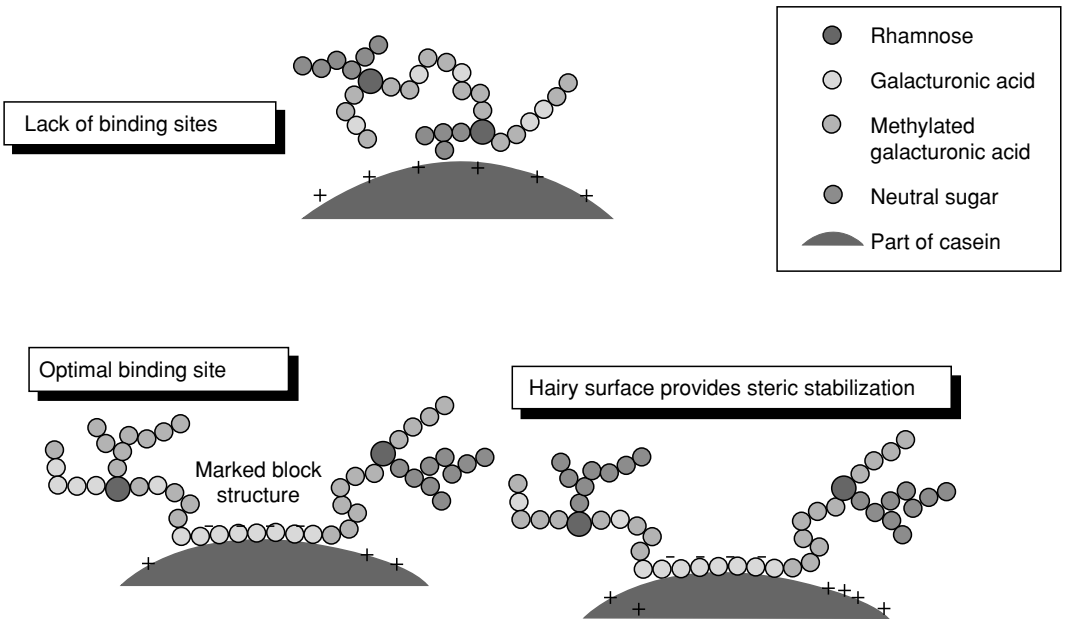

Figure 12 Theoretical picture of interaction between pectin and protein.

also plays a very significant role in the protein structure and how proteins interact in a complex system such as milk.

The optimum pH range for interaction between high-ester pectin and casein is 3.6–4.5. At a lower pH, the block structures of the high-ester pectin will not be sufficiently ionized for proper protein binding as the pH is too far below the pKa of the pectin. Above the isoelectrical point of the protein, the protein–polysaccharide complex is very weak or nonexistent and the electrostatic protein–protein repulsion is dominant. It is, however, clear that this repulsion is not sufficient to stabilize the proteins.

Conclusion

Pectin exhibits a wide range of functional properties and enjoys a very good public image as a natural product derived from fruit. Today it is widely used as a textural ingredient and stabilizer in a variety of food applications, and there is little doubt that its usage will grow as new functionalities are revealed.

natural component of plants, pectin is a desirable texturizing and stabilizing agent for use in all kinds of processed foods available today. In this chapter, we take a brief look at the most important food uses of pectin and its key properties in each system.

Function in Foods

Pectin is traditionally used for its gelation properties, with more than a third of the pectin commercially available being utilized by the jam and jelly industry. Pectin is used to 'set' or gel jams, jellies, and preserves. The pectin holds fruit pieces suspended within the gel structure, trapping water between cross-linked pectin molecules. The result is a gelled food that is shelf-stable. However, in more complex applications such as fruit preparations for dairy products, pectin is used to impart specific rheological properties during the manufacturing and storage of the fruit preparation, as well as during blending with the dairy product and all during the shelf-life of the finished product. Pectin is also widely used for its unique protein stabilization properties in acidic conditions. The general acceptance of pectin as a natural material and a soluble food fiber has made it desirable for use in a variety of applications (Table 1).

Jams and Jellies

Jams, jellies, and preserves can be divided into two categories. Traditional products have a solids range usually above 60%. Reduced sugar products have a soluble solids content in the range of 25–55%.

High-ester pectins are used in the production of jams, jellies, and preserves with soluble solids above 60% and a pH below 3.6. As high-ester pectin gels are not shear-reversible, it is of utmost importance that the jars be filled at a temperature above the setting temperature of the pectin in order to avoid a broken gel and syneresis. Various high-ester pectins used in recipes with different soluble solid contents will have different optimum pHs (Figure 1).

The choice of pectin will also be dependent on the type of product made. A fast-setting pectin is preferred for preserves where fruit pieces have to be suspended evenly throughout the container. By contrast, a slow setting pectin is used for jellies in order for air bubbles to escape prior to gelling, resulting in a fully transparent product. The size of the packaging will also influence the choice of pectin, with fast-setting pectin recommended for larger jars, as the cooling rate is slower, and a quick gelling is necessary to keep the fruit pieces in place. It is important, however, to note that for very large containers (several kilograms to several hundred kilograms), it is necessary to cool down the product before filling as the cooling rate is too slow in the center of the product, and the pectin is degraded when exposed to high temperatures for an extended time. In this case, a slow-set pectin or even a low-ester pectin is required to allow for cooling prior to filling without breaking the gel network. When filling in small packages and especially in food-service single-serve packages, the use of a slow-set pectin is also required as the filling time can be quite long. The temperature of the product in the holding tank before the packaging line will need to be reduced to avoid pectin degradation in time and insure consistent gelling from the first to the last package of the batch. Low-ester pectins are used when conditions for gelling a high-ester pectin are not met. Typically, this is the case when the sugar content is reduced below 60%. They are, however, also used in high-soluble-solids formulations when a

pH	3.2		3.2		3.2	
Filling temperature (°C)	40–50		45–55		55–65	

Procedure (regardless of targeted soluble solids)

1. Dry-blend the low-ester pectin (the locust bean gum if present) and sugar I, and add the blend to 80 °C hot water I, agitating vigorously
2. Mix fruit, sugar II and water II and heat the blend to approx. 80 °C
3. Add the pectin solution, agitating continuously
4. Evaporate to the desired content of soluble solids
5. Add preservatives and adjust pH with citric acid
6. Add flavoring
7. Cool to filling temperature and fill

spreadable texture is desired. These pectins gel in the presence of calcium ions, which is the main factor controlling the gelling. The soluble solids level and pH are only secondary parameters, but they have an influence on the gelling temperature and the texture.

As the soluble solids are decreased, the greatest challenge for the manufacturer is to keep an even distribution of fruit pieces. Indeed, the main influence of the soluble solids level will be on the viscosity of the jam at high temperatures during the process.

The choice of a low-ester pectin is therefore mostly based on the solids level. The use of low-ester amidated pectins with increasing calcium reactivity is usually recommended when the soluble solids are decreased. This insures a faster set with an even distribution of fruits. In low-brix formulations, the addition of calcium may be required to supplement the calcium brought by the fruits and the water and to insure a fast and homogeneous gelling.

To further avoid the flotation issues, a combination of low-ester amidated pectin and conventional pectin is commonly used. The low-ester conventional pectin forms a network at a higher temperature than the amidated counterpart and helps to keep the fruit well distributed. Other gums such as locust bean gum or guar are also often used in combination with a low-ester pectin to provide viscosity in low-solids formulations (Table 2).

A rapidly growing category in jams and jellies field is products where refined sugars have been replaced by fruit-juice concentrates. These products usually have between 40 and 50% soluble solids and rely on low-ester pectin gels. The only difference with standard reduced sugar recipes is in the ionic balance, as the fruit concentrates add a significant amount of calcium, as well as magnesium and potassium, to the formulation. This influences the choice of pectin as well as the amount of calcium to be added to the product. It is important to position the product on the flat part of the calcium curve and use a pectin with a broad tolerance to calcium in order to obtain a consistent texture, despite the usual variations in calcium content of the natural raw materials (Figure 2).

Fruit Preparations

The fruit preparation industry constantly juggles between retaining the identity of the fruit, perfect fruit

distribution throughout large totes, unique formulations able to accommodate fruits with a varying calcium content, and the texture and flavor of the final dairy product in which the fruit preparations are used. These challenges, combined with the pressure on manufacturers to develop new fruit preparations quickly and the need to create process-friendly formulations, call for the use of highly functional and versatile stabilizers. Pectin has found a natural application in these systems and is widely used.

Use of Pectin in Fruit Preparations

Pectin is used in fruit systems for various purposes. However, fruit preparations should only be thickened and not fully gelled. This requires pectin capable of giving fruit preparations a high degree of thixotropy.

The texture of the fruit preparation can be controlled by various parameters, as outlined in Table 3.

Use of a High-ester Pectin

When more than 55% soluble solids are used, a high-ester pectin with a typical dosage of 0.3% can successfully impart viscosity and control syneresis in a fruit preparation.

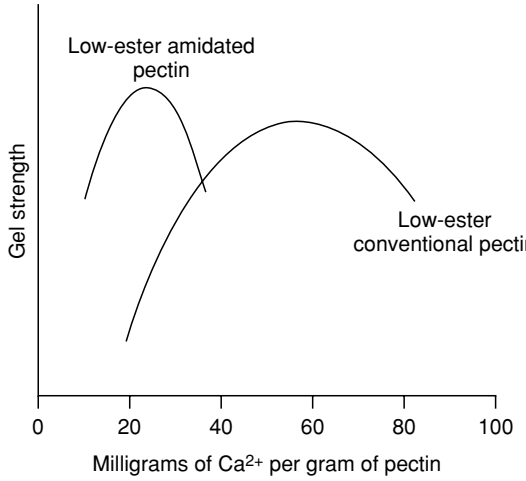

Figure 2 Low-ester-pectin calcium curves.

It is also possible to use a high-ester pectin with less than 55% soluble solids in order to yield a special texture. In these cases, a high-ester pectin typically gives the fruit preparation a high degree of shine and smoothness, although higher dosages are necessary.

Special high-ester pectins developed for their interaction with casein can also be used to obtain a high degree of texture carry-through in the white mass. At a usage level of 1–2%, the pectin gives the fruit preparation the required texture and significantly increases the viscosity of the finished stirred yogurt. It also helps maintain a constant viscosity and reduce syneresis during the shelf-life of the dairy product (Figure 3).

Use of a Low-ester Pectin

Conventional and amidated low ester pectins are widely used in fruit systems. While conventional pectins require a slightly higher dosage and high level of calcium, special ones have extreme processing flexibility and can be used with great success in a broad variety of formulations from 30 to 50 Brix with various pH values. It is common to include low ester conventional pectin in fruit on the bottom formulations. Low-ester amidated pectin can prove more economical with the possibility of lower dosages, although it tends to be more sensitive to calcium variations (see Figure 2). When the calcium level is adjusted, it is possible to achieve an excellent fruit suspension with a high level of shear reversibility. This allows low viscosity during pumping for maximum fruit identity.

Calcium Addition for Texture and Postreaction Control

When using a low-ester pectin, it is usually necessary to add calcium salts to obtain the full texture. The necessary quantity will depend on the calcium source, pH, soluble solids, fruit type, and content of the preparation. Specific calcium salts should be selected according to the speed of release and labeling considerations. Calcium chloride, -lactate, and -citrate is

Table 3 Parameters influencing the texture of fruit preparations

Choice of pectin	High-ester, low-ester conventional, and low-ester amidated pectins perform differently and allow a variety of textures
Pectin dosage	A higher pectin dosage results in a thicker texture
Calcium level	The calcium level needs to be adjusted with consideration for a possible reaction in the white mass; higher calcium levels usually increase viscosity, but pregelation can occur if too much calcium is added
Soluble solids	Higher soluble solids usually result in a shorter texture
Filling temperature	Lower filling temperatures usually result in a more fluid texture
Use of other hydrocolloids	Locust bean gum, guar gum, xanthan gum and starches can be successfully used in combination with pectin to achieve specific textures

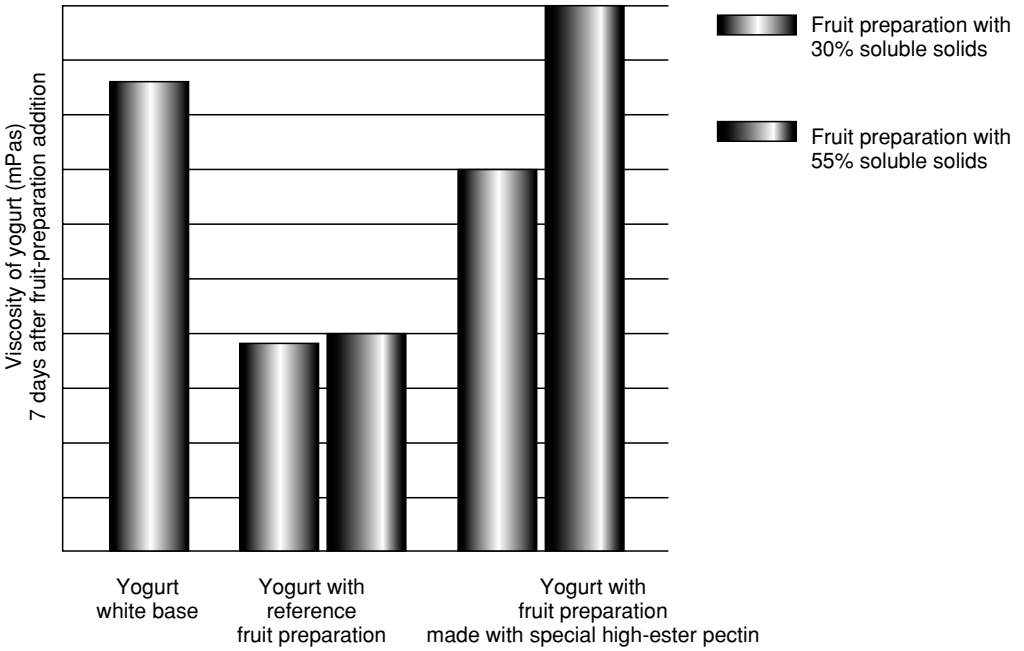

Figure 3 Use of a special high-ester pectin in a fruit preparation to increase the viscosity of yogurt.

most commonly used to supplement the calcium contained in the fruit.

If the calcium content of the fruit preparation is too low, the pectin present in the fruit preparation may react with the calcium of the yogurt, resulting in a grainy texture (stirred yogurt) or a gelled preparation (fruit on the bottom). To avoid this type of postreaction, it is highly recommended that the appropriate amount of calcium is added to the fruit preparation.

Bakery Fillings

In principle, bakery fillings are a form of fruit preparation. However, they deserve a separate paragraph as the demands on these products are fairly specific. Applied on or inside the dough, they usually need to be heat-resistant and have a level of water activity low enough to minimize water transfer from the filling to the dough. This is especially important for long-shelf-life cookies and cereal bars, which tend to be where there is greatest demand. As is the case for fruit preparations for the dairy industry, the trend is for the bakeries to outsource the production of fillings and transport them in larger containers.

Most bakery fillings have a high solids content typically between 60 and 80%. Thus, a high-ester pectin seems a natural choice also because these gels are thermally irreversible. However, high-ester pectin gels are completely nonthixotropic and lose their entire structure after pumping. So, pure high-ester pectin gels, which require cooling prior to filling and mechanical pumping at the bakery, are not adequate for packaging in large containers. High-ester pectin gels would be destroyed by such processes and show syneresis and a very poor bake stability.

High-ester pectins may, however, be used successfully for cold gelation systems, also called delayed setting systems. These are gel systems in which all the gelling conditions for a high-ester pectin are met, with the exception of the pH, which is kept too high. This viscous syrup can then be shipped to the bakery, where the acid is then added upon depositing the filling on the dough.

For other types of bake-stable fillings, specific low-ester pectins can prove ideal. Even if low-ester pectin gels are typically characterized as being thermally reversible (a property used in glazes), they can be made bake-stable by using an optimized formulation. Low-ester conventional pectins are usually preferred, as they show a higher bake stability due to a stronger binding with calcium. The choice of the correct calcium salt as well as its dosage is the key to both the texture of the filling and its heat stability. In very high solids formulations, the use of pectin in combination with alginate can prove useful in improving the filling appearance and its bake stability.

Glazes and Bakery Decor

Glazes are widely used to cover fruit tarts and other types of cakes where they not only add consumer appeal but also extend shelf-life by forming a

barrier to dehydration and microbiological contamination. The high transparency and shine of pectin gels make the use of this hydrocolloid an ideal choice for this application. In some specific applications, it is possible to use combinations of pectin with alginate or carrageenan.

Contrary to most bakery fillings, in glazes and bakery decorations, the heat reversibility of the system is usually of paramount importance. These products are most often sold to bakery shops in concentrated form and reheated and diluted with water before application. The gel must then form quickly and keep for several days, even on fruits with a high water content. In industrial applications, the gel has to be so completely reversible such that the product can be sprayed. Clearly, these requirements are best met with low-ester amidated pectins.

The use of specific calcium sources with controlled release together with calcium sequestrants is necessary to control the gelling of a low-ester pectin and secure an optimum performance after reheating.

Confectionery

Pectin is widely used in traditional confectionery items such as 'pâte de fruit,' or Zefir. However, it is also an important textural agent in a number of other confectionery articles, where its superior flavor release, high transparency, and clean bite are sought after.

Jelly candies typically have a soluble solids content of between 75 and 80% and a pH of around 3.5. Due to the high solids level, it is important to use a very slow setting high ester pectin and include buffer salts in the formulation to avoid any pre-gelling before depositing.

The standard process usually involves making a pectin solution with the buffer salts, heating the sugars and fruits when present, and mixing in the pectin solution before cooking to reduce the water level and obtain the desired solids content. Immediately before depositing, acid, color, and flavorings are added. Pectin jellies can be deposited in starch or rubber molds or in large trays for further cutting. It is also possible to use pectin on jet cooking equipment where all the ingredients are mixed together, and the pectin actually dissolves at a very high temperature (around 140 °C) with all the solids present. This procedure usually requires the use of specific pectins with particular dissolution properties.

In most cases, the pectin chosen for confectionery will be an extra-slow setting type to guarantee a low setting temperature. Even with this type of pectin, the gelling temperature of the system is usually around 80 °C, and the depositing temperature needs to be above this level if the full gelling potential of the pectin is to be used. This is a major difference from the commonly manufactured gelatine candies, which have a much lower setting temperature. Another significant difference is the speed of gelation, as pectin jellies can be demolded quickly after depositing since a firm gel is obtained very quickly. As with all high-ester pectin gels, typical pectin jellies are not thermally reversible.

The buffer salts commonly used with pectin in confectionery include sodium citrate and sodium potassium tartrate. The latter tends to give the jellies a somewhat firmer texture.

High-ester pectin is also often used in combination with other ingredients such as gelatine, starch, or agar to give intermediate textures. In the case of gelatine candy, pectin is also used in small amounts to increase the melting point of the confectionery pieces in warm climates, thus insuring a better appearance throughout their shelf-life without significantly affecting the texture.

In specific candy pieces where a neutral flavor such as vanilla is used, the use of a low-ester pectin is necessary in order to obtain a gel at a higher pH. As with high-ester pectins, it is usually necessary to reduce the setting temperature. In these systems, calcium sequestrants such as sodium hexametaphosphate are used. Turkish delight is one such traditional candy based on a low-ester pectin gel with or without the addition of starch.

High- and low-ester pectins are also widely used for confectionery fillings, which are then either enrobed usually with chocolate or, for example, panned into jelly beans.

Fruit Beverages and Soft Drinks

Pectin is used as a viscosifier in beverages and soft drinks, and high-ester pectins may be used as a mouthfeel improver. This use has been widely developed for juice drinks with a reduced juice content or sugar-free soft drinks.

Low-concentration pectin solutions can be considered Newtonian and show a low viscosity. This is of great relevance for the use of pectin in fruit beverages and soft drinks as the concentration used rarely exceeds 0.5%. Indeed, the clean mouth feel imparted by pectin compared with the tendency towards a slimy mouth feel with some other gums could be related to the low viscosity of pectin solutions at the shear rate applied in the mouth. This property makes pectin an ideal choice when trying to replace the mouth feel lost by the reduction in sugar content.

As most juice beverages and soft drinks contain calcium, pectin with a high degree of esterification is

usually recommended to minimize the calcium sensitivity of the pectin and avoid any risk of gelling. A slight gelling of the product changes the rheology of the solution, resulting in undesirable pseudoplastic behavior. For this reason, the most commonly used pectin is of the rapid setting type. Pectin manufacturers usually offer rapid-set pectins standardized to a viscosity instead of gelling properties, so as to guarantee a consistent performance in a beverage application.

Yogurt Drinks and Other Acidified Protein Beverages

From being largely restricted to certain regions or addressed to specific consumer groups, acidified protein drinks today have become a highly esteemed and popular food world-wide. Aided by the increased focus on health benefits, the market for acidified beverages with proteins is currently enjoying rapid growth.

Perfect stability and a consistent mouth feel are essential to consumers, so the use of stabilizers is necessary in order to prevent any defects such as sedimentation, whey separation, and grainy mouth feel.

At a low pH, the positive net charge of the protein clusters in an acidified drink is insufficient to prevent aggregation of the proteins, and the drink therefore suffers from severe sedimentation of protein aggregates and separation. This lack of physical stability is even more pronounced if a shelf-stable, postpasteurized product is desired as the unprotected proteins are denatured by the heat treatment. Although specific structural details vary, the same general stability issues occur with various protein sources such as casein, whey, soy, or other plant-derived proteins.

The stability problem can be avoided by adding a stabilizer such as a high-ester pectin. With its controlled block structures of nonmethylated galacturonic acid units, high-ester pectins can bind to the protein surface as the blocks are negatively charged at a pH of 3.6–4.5, a typical level in acidified beverages. Bound to the proteins, the long pectin molecules protect them from reaggregation through steric stabilization. Even with a postpasteurized drink, this stabilization can produce a shelf-stable product and prevent unwanted sedimentation and serum separation.

Yogurts and Other Dairy Products

The gelling of low-ester pectins with calcium ions is often used to set dairy products, but low-ester pectins are also used to reinforce the texture of other types of gel network such as the protein network in yogurts and fermented dairy products. Recently, the trend towards low-fat or non-fat dairy products has increased the need to use textural ingredients and stabilizers to restore a pleasant mouth feel and avoid common defects such as syneresis.

Low-ester pectins can be dissolved in neutral milk and are commonly used in the manufacture of gelled neutral dairy desserts. Giving a softer texture with more body and a high level of creaminess than widely used carrageenan, pectin is preferred in premium creamy formulations where the extra cost of pectin can be justified. It is also used when carrageenan is not desired on the label. In addition, pectin is the main component of a variety of regional home-made desserts formulations such as Fruche in Japan. Fruche is a fruit and pectin solution sold in a pouch, which the consumer can mix with milk. After half an hour in the refrigerator, the gelled product can be consumed as a refreshing dessert. In Europe, pectin is often seen in dry mix blends for home-made desserts.

Whether the effect of low-ester pectins on the texture of fermented dairy products comes through gelation with calcium or interaction with proteins is not quite clear. However, low-ester pectin is already widely used on its own or together with gelatine or starch to add texture to yogurts and other fermented products.

Owing to the high level of calcium present, the usage level of the pectin must be low in order to avoid an excessively strong reaction between the pectin and the calcium, resulting in a sandy product. The maximum recommended usage level is around 0.25%. Interestingly, high-calcium-reactive pectins usually show a better performance than their low-calcium-sensitive counterparts. Amidated pectins are usually preferred, even if conventional low-ester pectins do prove useful in specific recipes for syneresis control.

Pectin can also be used in combination with carrageenan for mousse products, where gelatine is not desired. Pectin provides a much better gelation after the mousse mix is whipped, leading to a more sliceable texture compared with carrageenan alone.

Other Applications

Pectin is used in a great number of other applications. For example, it is used in tomato-based products such as barbecue or taco sauce as an alternative to starch. Usually, low-ester conventional pectins are used to thicken the sauce and ensure a nonmelting texture when the sauce is poured over hot food.

PELLAGRA

D A Bender, University College London, London, UK

Introduction

Pellagra is a nutritional disease due to deficiency of the vitamin niacin and the essential amino acid tryptophan. The clinical features of pellagra are dermatitis, diarrhea, and dementia; it is commonly known as the 'disease of the four Ds,' since it is also fatal – the fourth 'D' is death.

During the first half of the twentieth century, pellagra was a major problem of public health in the southern USA, with some 87 000 deaths attributed to the disease between 1900 and 1950. Through the 1950s to 1980s, it continued to be a problem in southern Africa and parts of India, but improvements in food availability and general nutritional status have led to more or less complete eradication of pellagra as an endemic nutritional deficiency disease.

There have been a few reports of outbreaks of pellagra among refugees in southern Africa when rations have been inadequate to meet the demand, and individual cases have been reported among alcoholics and people with Crohn's disease and other gastrointestinal diseases that impair nutrient absorption.

Pellagra may also occur as a result of a variety of (relatively rare) conditions affecting tryptophan metabolism and as a side-effect of a number of drugs that inhibit tryptophan metabolism. In alcoholics, it is not clear whether pellagra is the result of an impairment of tryptophan and niacin metabolism directly attributable to alcohol, or whether it reflects general undernutrition among people who obtain a considerable proportion on their energy needs from alcohol, and hence have a low intake of (nutrient rich) foods.

The first full description of pellagra was given by Casal in 1735, working in Spain; he called it '*mal de la rosa*' – the red disease. The name pellagra was coined by Frapolli in 1771, from the Italian '*pelle*' for skin and '*agra*' for rough, thus describing the most striking feature of the disease, the roughened appearance of the skin, resembling severe sunburn in areas exposed to sunlight. Casal recognized that the underlying cause of pellagra was nutritional, associated with the limited diet of many in central Spain at the time, although he did not associate it with the then recent introduction of maize from Central America.

The spread of pellagra largely followed the introduction of maize as a dietary staple, and by the nineteenth century, it was a major problem around the Mediterranean, in the Balkans, and in the Ukraine, as well as the southern USA and southern Africa. In South Africa, pellagra became a problem following the outbreak of rinderpest in 1897, which killed most of the cattle, leading to a marked deterioration in the diet of people who had previously had ample supplies of milk and meat to supplement their maize-based diet. In the USA, it was the social and economic upheaval of the Civil War, which led to large numbers of subsistence farmers living on a diet based very largely on maize.

The other region where pellagra was a major problem is the Deccan plateau in India, where the dietary staple is jowar (a variety of millet, *Sorghum vulgare*), rather than maize.

Although Casal had described pellagra as a nutritional disease, at the beginning of the twentieth century it was generally assumed to be due to an infectious agent. The nutritional basis of the disease, and the interaction between deficiencies of both niacin and tryptophan, was established mainly by Goldberger and coworkers in the USA between 1913 and 1948. A 'pellagra-preventing factor' isolated from protein-free yeast extract was shown in 1937 to be nicotinic acid, and either nicotinic acid or its amide, nicotinamide, was shown to prevent or cure the disease in both man and experimental animals. The name niacin was coined when it was

decided to enrich foods with the vitamin, since it was considered that nicotinic acid would be unacceptable as a food additive, because of its chemical (but not metabolic) relationship with nicotine. In the USA, 'niacin' is commonly used to mean nicotinic acid, and the amide is niacinamide; elsewhere, 'niacin' is used as a generic descriptor for nicotinic acid and/or nicotinamide.

Other early studies showed that feeding additional protein, and especially the essential amino acid tryptophan, would also prevent or cure pellagra, suggesting that it was a protein-deficiency disease rather than due to a lack of a vitamin. It was not until 1947 that the problem was resolved, when it was shown that tryptophan is a metabolic precursor of the nicotinamide moiety of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). The coenzymes can be formed in the body either using preformed dietary niacin or by *de novo* synthesis from tryptophan.

The reason a maize-based diet predisposes to pellagra is that the proteins of maize are particularly poor in tryptophan, so that a diet in which there are few other sources of protein provides insufficient tryptophan for nicotinamide synthesis. Other cereals, such as wheat, barley, rye, rice, and millet, contain enough tryptophan to meet the requirement for niacin synthesis.

Although maize proteins are poor in tryptophan, the other cereal associated with pellagra, jowar, provides a minimally adequate amount of tryptophan to meet requirements. However, the proteins of jowar are considerably richer in leucine than most other proteins, and a diet based largely on jowar provides a considerable excess of leucine. There is a considerable body of evidence that this amino acid imbalance can be a precipitating factor in the development of pellagra when the dietary intake of preformed niacin is extremely low, and the intake of tryptophan is only marginally adequate. Leucine inhibits kynureninase, and hence reduces the rate of oxidative metabolism of tryptophan, resulting in reduced formation of NAD. In addition, leucine competes with tryptophan for tissue uptake, and thus has a further inhibitory effect on the rate of tryptophan oxidative metabolism and NAD synthesis.

All cereals contain preformed niacin. However, this is largely present as a variety of nicotinoyl esters, collectively known as niacytin, which are not hydrolyzed by digestive enzymes to any significant extent, so that most of the niacin present in cereals is nutritionally unavailable. A small proportion of the niacin present as niacytin (up to about 10%) may be biologically available as a result of nonenzymic hydrolysis by gastric acid.

Interestingly, pellagra has not been a problem in Central America, the original home of maize. This is because of the traditional way in which it is prepared. Rather than milling the grain, it is steeped overnight in limewater (calcium hydroxide solution), then squeezed to form the dough from which tortillas are made. This alkaline treatment results in hydrolysis of most of the nicotinoyl esters, so releasing free nicotinic acid, which is nutritionally available. Although maize spread to many countries following its discovery, it was generally milled like other grains rather than being treated in the traditional Mexican manner.

Clinical Features of Pellagra

Dermatitis

Exposure of the skin to modest amounts of sunlight results in a severe sunburn-like dermatitis in sufferers (pellagrins). Mechanical pressure can cause similar lesions, especially around the wrists and ankles. The skin in the affected areas is red and slightly swollen at first, and then becomes rough, thickened, cracked, and dry, with scaling, a shiny surface, and brown pigmentation.

The cause of this photosensitive dermatitis in pellagra is unknown and cannot be attributed to the known metabolic functions of either tryptophan or the nicotinamide nucleotide coenzymes. There is some evidence that there is increased metabolism of the amino acid histidine in the skin in pellagra, resulting in a lower than normal concentration of both histidine and an intermediate in its metabolism, urocanic acid, both of which are believed to have a role in absorbing ultraviolet light, and so minimizing damage to the skin from exposure to sunlight. Treatment of pellagrins with niacin both clears the dermatitis and also increases the concentration of histidine and urocanic acid in the dermis.

The skin lesions of pellagra may be due to secondary zinc deficiency when tryptophan intake is inadequate or its metabolism is disturbed; they resemble the lesions seen in acrodermatitis enteropathica, which is due to a failure to secrete the intestinal zinc-binding ligand, which is believed to be picolinic acid – a tryptophan metabolite. There is some evidence that some pellagrins have a poor zinc status, and the zinc depletion associated with excessive alcohol consumption may be a factor in the development of pellagra among alcoholics.

Diarrhea

Although diarrhea is common in pellagrins, it is not a constant feature of the disease, and indeed in some

cases, there may be chronic constipation. The cause of both the diarrhea and the constipation is almost certainly general nutritional deficiency, resulting in atrophy of the intestinal mucosa and the intestinal musculature.

Dementia

The psychiatric disturbances of pellagra range from mild hallucinations with some psychomotor retardation, through confusion with increasing hallucinations, to severe dementia and anxiety psychosis, with melancholia, intermittent stupor and possibly epileptiform convulsions. In many ways, this resembles schizophrenia, but the dementia of pellagra can be differentiated from schizophrenia and the organic psychoses by the sudden lucid phases that alternate with the most severe mental symptoms.

Although the cause of the psychiatric disturbance in pellagra remains to be firmly established, it is likely that it is largely due to deficiency of tryptophan, as a precursor for the neurotransmitter serotonin (5-hydroxytryptamine), rather than a direct result of inadequate supply of the nicotinamide nucleotide coenzymes in the brain.

The Equivalence of Dietary Tryptophan and Niacin

The nicotinamide ring of the coenzymes NAD and NADP can arise either from preformed dietary niacin or by *de novo* synthesis from quinolinic acid, an intermediate in the oxidative metabolism of tryptophan. For an adult in nitrogen balance, the amount of tryptophan available for oxidative metabolism is about 99% of the dietary intake, since new synthesis of protein is balanced by catabolism of tissue proteins, releasing their tryptophan for metabolism. A variety of studies have shown that under normal conditions, 60 mg of tryptophan are equivalent to 1 mg of preformed dietary niacin, and it is usual to express the total niacin intake in terms of niacin equivalents – the sum of preformed niacin plus 1/60 of the tryptophan. On this basis, average Western diets provide more than enough niacin to meet requirements from tryptophan alone, ignoring preformed niacin. Indeed, reanalysis of dietary records of people who died from pellagra in the USA during the first half of the twentieth century shows that their intake of preformed niacin and tryptophan was (marginally) adequate to meet requirements, suggesting that some other factor may have been involved in precipitating the disease.

Complicating Factors in the Etiology of Pellagra

Deficiency of Vitamins B_2 and B_6

The enzyme kynurenine hydroxylase in the oxidative pathway of tryptophan metabolism is a flavoprotein, and hence its activity is impaired in riboflavin (vitamin B_2) deficiency. The enzyme kynureninase is pyridoxal phosphate-dependent, and its activity is impaired in vitamin B_6 deficiency. This means that deficiency of either vitamin B_2 or B_6 will reduce the rate of oxidative metabolism of tryptophan and hence the rate of formation of quinolinic acid and NAD. If the intake of tryptophan is anyway marginal, this could well precipitate pellagra.

Mycotoxins

A number of mycotoxins cause DNA damage, and activate poly(ADP-ribose) polymerase as part of the DNA repair mechanism. This enzyme uses NAD as the source of ADP-ribose, releasing nicotinamide. While, theoretically, this nicotinamide could be reused for synthesis of NAD, the enzymes involved (nicotinamide phosphoribosyltransferase, nicotinamide deamidase, and nicotinic acid phosphoribosyltransferase) are all more or less saturated with their substrates at normal tissue concentrations. This means that the additional nicotinamide released by poly(ADP-ribose) polymerase cannot be used for NAD synthesis but will largely be methylated to *N*-methylnicotinamide and excreted. Exposure to such mycotoxins may therefore be a factor in the etiology of pellagra, depleting the body of nicotinamide. The one report of an outbreak of pellagra in Mexico was associated with a shipment of maize that had suffered considerable fungal damage.

Estrogens and Progestagens

Through the first half of the twentieth century, when pellagra was a major problem in the southern USA, there was a twofold excess of women over men among those affected. In a number of reports of more recent outbreaks, there is a similar sex ratio between the menarche and menopause. There is no difference in the numbers of males and females affected among either prepubertal children or adults aged over about 40 years. This suggests that estrogens and/or progestagens may have a pellagragenic effect. Estrogen metabolites are competitive inhibitors of kynureninase, and the administration of progesterone results in reduced activity of kynurenine hydroxylase, although *in vitro*, neither progesterone nor its conjugates affects the activity of kynurenine hydroxylase.

When the intake of preformed niacin is low, and that of tryptophan is marginal, the impairment of tryptophan metabolism by estrogens and progesterone may be sufficient to precipitate pellagra more commonly in women than men.

Non-nutritional Pellagra

Pellagra can occur as a result of impairment of tryptophan metabolism due to a variety of diseases that affect the tryptophan oxidative pathway, or as a result of drugs that inhibit one or more enzymes of the pathway, despite an apparently adequate intake of tryptophan. General malabsorption associated with gastrointestinal disease; there have been a number of case reports of pellagra among people with Crohn's disease. In most cases, the condition responds well to supplements of nicotinamide.

Carcinoid Syndrome

Under normal circumstances, about 1% of the daily intake of tryptophan is metabolized by way of 5-hydroxytryptamine in the central nervous system and gut, with the remainder being oxidized by way of kynurenine, and thus available for NAD synthesis. A carcinoid is a tumor of the enterochromaffin cells of the gastrointestinal tract, which forms 5-hydroxytryptamine from tryptophan. The carcinoid syndrome occurs when the tumor has metastasized, usually to the liver, and in extreme cases as much as 60% of the daily intake of tryptophan may be metabolized by way of 5-hydroxytryptamine. The result is a considerable reduction in the rate of oxidative metabolism through kynurenine, and hence a considerable reduction in the synthesis of NAD from tryptophan, resulting in the development of pellagra in a significant proportion of patients.

Hartnup Disease

Hartnup disease is an inborn error of metabolism affecting the membrane proteins that transport the large neutral amino acids (including tryptophan). The same proteins are involved in the absorption of free tryptophan from the gastrointestinal tract into the bloodstream, from the bloodstream into tissues, and in the reabsorption of amino acids from the urine. The result of the defect is a considerable reduction in the amount of dietary tryptophan that is absorbed, as well as a considerable loss in the urine. Thus, despite an apparently adequate intake, there is a deficiency of tryptophan (and other large neutral amino acids), resulting in the development of pellagra.

Inborn Errors of Tryptophan Metabolism

A number of inborn errors of metabolism affecting enzymes of the tryptophan oxidative pathway have been reported, all of which result in the development of pellagra. Such conditions include much reduced activity of tryptophan dioxygenase, the first enzyme of the pathway; low or undetectable activity of kynureninase and kynurenine hydroxylase; and increased activity of aminocarboxymuconic semialdehyde decarboxylase, the enzyme that competes with the nonenzymatic cyclization of aminocarboxymuconic semialdehyde to quinolinic acid, the precursor for NAD synthesis.

Drug-induced Pellagra

A number of drugs can precipitate pellagra, despite an apparently adequate intake of tryptophan. The best-documented such drug is the antituberculosis drug isoniazid (isonicotinic acid hydrazide), although two antiparkinsonian drugs, Benserazide and Carbidopa, are also associated with niacin depletion. These drugs have an indirect effect on tryptophan and niacin metabolism. They are hydrazine derivatives that act as carbonyl-trapping reagents and therefore cause depletion of vitamin B_6 by forming inactive adducts with the metabolically active form of the vitamin, pyridoxal phosphate. Among other effects, this results in impaired activity of kynureninase, and hence a reduced rate of tryptophan oxidative metabolism and NAD synthesis. Although the pellagra responds to supplements of nicotinamide, it is more usual to give supplements of vitamin B_6, at least in combination with isoniazid, in order to minimize the other metabolic effects of vitamin B_6 depletion.

Pellagra has also been reported among cancer patients treated with a variety of chemotherapy agents that cause strand breaks in DNA. This activates poly(ADP-ribose) polymerase as part of the DNA repair mechanism, and so depletes tissue NAD. Indeed, this is the mechanism of action of these drugs; they deplete NAD in the tumor cells to such an extent that there is severe impairment of energy-yielding metabolism, leading to cell death. It has been suggested that patients treated with such chemotherapeutic agents should receive supplements of niacin to protect against the development of pellagra.

PEPPERS AND CHILLIES

B Pickersgill, The University of Reading, Reading, Berkshire, UK

Introduction

Pepper and chilli have been used to designate many different plants and plant products. This article is concerned principally with *Capsicum* peppers, whose fruits are consumed as a pungent spice or condiment (chilli or cayenne peppers), or as a nonpungent vegetable or source of color and flavor (sweet or bell peppers, paprika, pimentos). Several species of *Capsicum* were domesticated in the American tropics, but *C. annuum* has outstripped all others in global importance. The basic structure of the fruit is similar in all types of *Capsicum*. However, variation in thickness of the fruit wall and thickness of the cuticle affects ways in which the fruits are harvested, handled, and processed. The domesticated peppers vary even more strikingly in the characteristics most valued by humans: color, aroma, and pungency. Their fruits have significant nutritional value, as well as medicinal properties related to their pungency. World production of both spice and vegetable peppers has increased steadily throughout the last two decades.

Pepper, Chilli, Pimento, and Malagueta

The European discoverers of the Americas often named the novel plants they encountered on the basis of real or perceived similarities to those with which they were already familiar. The confusion thus begun in the names associated with *Capsicum* still persists.

'Pepper' is derived from a Greek word originally used for black and white pepper, but subsequently applied to genera belonging to seven different families (**Table 1**), all of which have pungent fruits or seeds. 'Chilli' comes from one of the indigenous languages of Mexico, where *Capsicum* has been consumed for more than 5000 years. The Spanish spelling of this word is 'chile'. In the USA today 'chile' tends to be used for the plant and its fruit, but 'chili' for a cooked dish containing *Capsicum* and various other ingredients. 'Chile powder' thus signifies ground fruits of *Capsicum*, but 'chili powder' also includes garlic, onions, cumin, and other spices.

'Pimento' is derived from the Latin word for pigment, and in medieval times signified spices in general. Pimento is still used as an alternative name for allspice (**Table 1**), but when applied to *Capsicum*, 'pimento' or 'pimiento' in English usage is usually restricted to large red nonpungent fruits, sold canned or used in processed foods.

The name 'malagueta,' used throughout much of Latin America for an extremely pungent small-fruited *Capsicum*, has also been borrowed from an Old World spice and is used for two unrelated genera in the American tropics (**Table 1**).

Botanical Background

Capsicum belongs to the family Solanaceae, which also includes tomato, eggplant (aubergine), and potato. (*See* **Potatoes and Related Crops**: Fruits of the Solanaceae; **Tomatoes**.) *Capsicum* contains about 20 species, all confined to the Americas until Columbus' discovery of the New World. In the Americas, human selection produced much variation in the fruits. Many of these variants were formerly regarded as distinct species, but now only five domesticated species are generally recognized: *C. annuum, C. frutescens, C. chinense, C. baccatum*, and *C. pubescens*. Each was domesticated independently, but contains a similar range of variation in fruit characters.

The bell peppers, paprikas, and pimentos, together with most of the Mexican chillies, are all included in *C. annuum*. This is now the most widespread, and economically the most important, of all the cultivated species of *Capsicum*. There is disagreement over whether *C. frutescens* is or is not a species distinct from *C. annuum*. If it is considered distinct, then the

Table 1 Botanical identities, geographic origins, and uses of plants for which the names pepper, pimento, and malagueta have been used

Scientific name	*Common names*	*Origin*	*Uses*
Anacardiaceae (mango, cashew, pistachio family)			
Schinus molle	Pepper tree, pink peppercorn	Andes	Condiment
Annonaceae (custard apple family)			
Xylopia aethiopica	Guinea pepper, African grains	Tropical Africa	Spice
Xylopia spp.	Malagueto, pimenta de macaco (monkey pepper)	Tropical America	Condiment
Myrtaceae (clove, guava, eucalyptus family)			
Pimenta dioica	Jamaica pepper, pimento, allspice	Caribbean	Spice
Piperaceae (pepper family)			
Piper nigrum	Black, white, green pepper(corns)	India	Condiment
Solanaceae (potato, tomato, tobacco family)			
Capsicum spp.	Red pepper, chilli pepper, capsicum, aji, malagueta	American tropics	Spice and condiment
Capsicum annuum (nonpungent cultivars)	Sweet, bell, green or red pepper, pimento, mango (USA)	Mexico	Vegetable
Rutaceae (citrus family)			
Zanthoxylum spp.	Szechuan pepper, Chinese prickly ash	Far East	Condiment in Chinese cookery
Zingiberaceae (ginger, cardamom, turmeric family)			
Aframomum melegueta	Melegueta pepper, grains of paradise, guinea grains	West Africa	Spice, especially for alcoholic drinks

cultivar 'Tabasco', which is the main ingredient of tabasco sauce, belongs in *C. frutescens*. In Mexico and Central America, wild forms of both species are often lumped together as bird pepper (also known as chile piquin or chiltepin).

The most common cultivated pepper of the West Indies and much of South America is *C. chinense*, which is closely related to *C. annuum* and *C. frutescens* but has a distinctive aroma and flavor. Habanero and Scotch Bonnet types (the latter named from the shape of the fruit) are now finding specialty markets in some developed countries. Nonpungent forms of *C. chinense* are grown commercially in Amazonia, where *C. annuum* does not succeed, and may prove suitable for other parts of the humid tropics.

The remaining two domesticated species are virtually unknown outside the Americas. *C. baccatum* is widespread in Andean South America and southern Brazil. The rocoto, *C. pubescens*, is another Andean species, easily recognized by its dark seeds.

Morphology and Anatomy of the Fruits

The fruit of *Capsicum* is a berry, which is unusual in being hollow, not filled with pulp as in tomato. In wild peppers, the very pungent small red fruits are so palatable to birds that ripe fruits are rarely found. As the fruits ripen, an abscission layer develops between the base of the fruit and the calyx, so birds can readily remove mature fruits from the plant. In domesticated peppers, this abscission layer does not develop, so the fruits remain on the plant until harvested by humans. Domesticated peppers may have much larger fruits than wild peppers, and may be pungent, mild, or nonpungent. Size and pungency are genetically independent characters, so small nonpungent fruits and very pungent large fruits can and do occur. Fruits of domesticated peppers have various shapes, described by local names such as girl's finger, dog's penis, fish eye, and friar's hat. In some European countries, sweet peppers always have pointed fruits, while in others, 'blocky' types that can be stood on the stylar end and stuffed from the stalk end are preferred.

In all *Capsicum* fruits, an outer wall or pericarp surrounds an inner cavity that contains the seeds. Fruits that are used fresh have a thick pericarp, whereas fruits that are used dry or after grinding have a thinner pericarp. Water loss from the pericarp is retarded by an impermeable outer cuticle, which is indigestible and may be tough, but accounts for the relatively long shelf-life of the vegetable peppers. The cuticles of pimentos are removed before canning, but cuticles of bell peppers are not usually removed, so human selection for palatability has produced thinner cuticles in bell peppers than in pimentos. When the fruits are used dried, those that lose moisture quickly without becoming wrinkled or unattractive in appearance are preferred. These fruits thus also often have thin cuticles.

A layer of so-called giant cells immediately under the inner epidermis of the pericarp gives the inner surface of the fruit wall a characteristic blistered appearance which may help to distinguish fragments of *Capsicum* pericarp from other contaminants in the ground spice. The function of the giant cells is not known, but they are not associated with pungency.

In small-fruited chilli peppers, there are two chambers, or carpels, separated by an inner wall, or septum. The seeds are attached to a spongy tissue called the placenta that develops from the septum. Large fruits are often formed from more than two carpels, and therefore have additional septa. The septa are better developed at the stalk end of the fruit, and often fail to reach the tip, so most of the seeds are borne on a hemispherical placenta at the stalk end of the single cavity in the fruit.

Special Characteristics

Quality of pepper fruits, and of the products made from them, depends on their color, aroma, and pungency. Hot peppers also have certain well-known pharmacodynamic effects. Nutritionally, both hot and sweet peppers are valuable sources of vitamins.

Color

The middle layer or mesocarp of the fruit wall is responsible for the color of both ripe and unripe fruits. The cells of the mesocarp contain plastids, which in the unripe fruit usually contain chlorophyl. The quantity of chlorophyl varies in different cultivars. Occasionally chlorophyl is absent and the unripe fruits are creamy white. Immature fruits may also contain sap-soluble, purple anthocyanin pigments. As the fruit ripens, both chlorophyl and anthocyanin usually disappear. Chloroplasts are converted to chromoplasts, and additional chromoplasts form *de novo*. There is a relationship, not yet fully understood, between chlorophyl content of the unripe fruit and carotenoid content of the ripe fruit. Immature fruits that lack chlorophyl may ripen red, but the red is deepest in fruits that are dark green when unripe. (*See* **Chlorophyl; Colorants (Colourants): Properties and Determination of Natural Pigments; Ripening of Fruit.**)

As a red pepper ripens, total carotenoids increase 35-fold and are sequestered within fibrils in the chromoplasts. About half of this increase represents *de novo* synthesis of red pigments. These consist of three ketocarotenoids: capsanthin (30–60% of total carotenoids present), capsorubin (5–15%), and cryptocapsin (about 5%). They are unusual in containing the cyclopentanol ring, unlike red carotenoids of fruits such as tomato (which accumulates lycopene). Lycopene is thought to be an intermediate in the biosynthesis of capsanthin and capsorubin (Figure 1).

Although the carotenoid pigments are formed in the chromoplasts, the quality and quantity of these pigments, which determine the different colors of the mature fruit (Table 2), are controlled by genes located on the chromosomes, not in the plastids. Fruits of the yellow color series cannot synthesize red carotenoids. In *C. annuum*, yellow-fruited plants carry a deletion of the DNA that codes for the enzyme capsanthin-capsorubin synthase, which catalyzes the final step in the production of capsanthin and capsorubin. Recessive alleles of other nuclear gene(s) reduce the quantities of pigments in the fruits, but we do not know where or what these blocks to pigment synthesis may be. Chocolate-brown fruits, such as those used in the famous Mexican sauce mole, are homozygous recessive for an allele of another nuclear gene, which prevents chlorophyl breakdown in the ripe fruit. The combination of red carotenoids and green chlorophyl appears as brown.

Breakdown of the red pigments in harvested fruits, or in powders produced by drying and grinding these fruits, is not prevented by blanching, but is retarded by antioxidants. This suggests that pigment breakdown is not due to enzyme action, but may involve two other processes: an autoxidative degradation which is accelerated by heat, and an autocatalytic destruction in light which involves direct absorption of light energy.

Aroma

Droplets of volatile oil in the mesocarp cells produce the characteristic aroma of the pepper fruit. These droplets increase in quantity as the fruit ripens. The oil is a mixture of methoxypyrazines, aliphatic alcohols, and esters, in which the most important constituent is 2-methoxy-3-isobutylpyrazine. This has one of the lowest odor thresholds of any compound examined, being detectable at levels of 2 parts in 10^{12} parts water. Methoxypyrazines have also been reported from other vegetables such as raw potato and French bean, but at much lower levels than in *Capsicum*. (*See* **Sensory Evaluation**: Aroma.)

The aliphatic alcohols and esters seem to be responsible for the fruity and floral components of the aroma. Although aroma is a valued attribute of fresh chillies, and the different aroma and flavor properties of different chillies are usually well-known to habitual consumers, little is known about differences in composition of the volatile oil either within or between different species of *Capsicum*.

Pungency

Some botanists have used pungency of the fruits to distinguish *Capsicum* from allied genera. The biological significance of pungency is not known, but the sensory effect is produced by a group of vanillyl amides collectively known as capsaicinoids (Table 3), amongst which capsaicin and dihydrocapsaicin

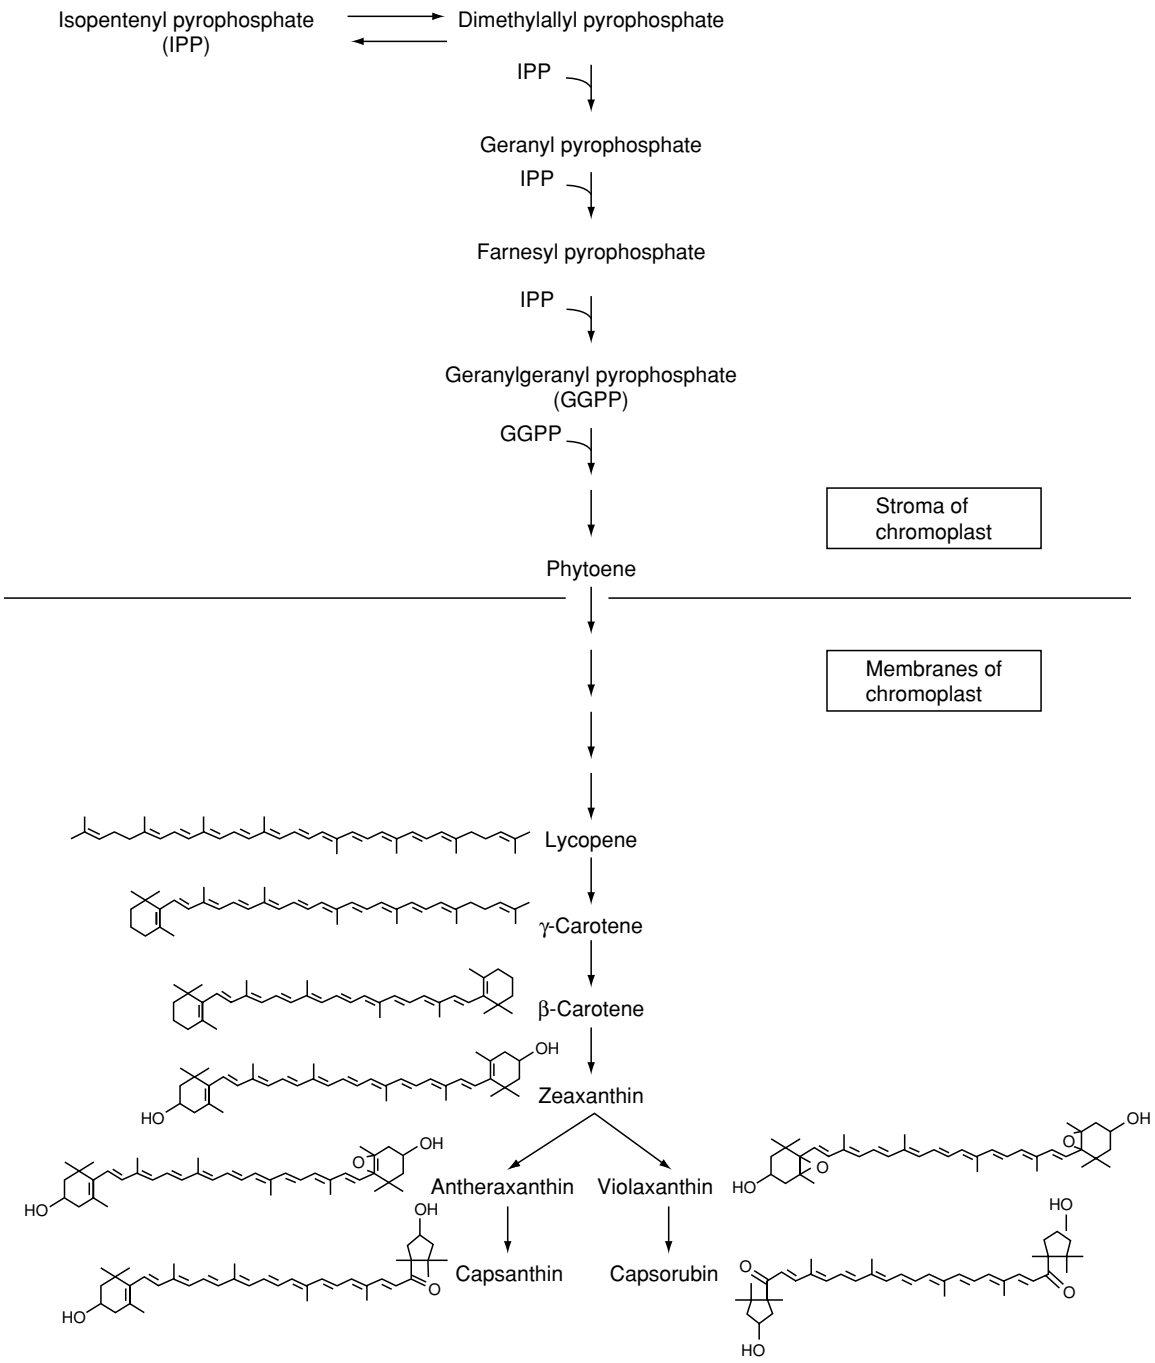

Figure 1 Biosynthesis of carotenoid pigments in fruits of *Capsicum*. Modified from Camara B, Hugueney P, Bouvier F, Kuntz M and Monéger R (1995) Biochemistry and molecular biology of chromoplast development. *International Review of Cytology* 163: 175–247, with permission.

predominate. Capsaicin is insoluble in cold water but soluble in alcohol, acetone, ether, and similar solvents. It is one of the most pungent compounds known, detectable by taste at dilutions of 1 in 15–17 million. Pungent compounds are also present in other plants, for example, ginger and black pepper (Table 3). The capsaicin molecule has three characteristic features: the vanillyl group, the acid–amide linkage, and the alkyl side-chain. Change in any one of these decreases pungency. Piperine from black pepper lacks the vanillyl group and has a short side-chain with a bulky substituent. Its pungency is more than two orders below that of capsaicin. Gingerols and shogaols, from ginger, have a vanillyl group and a long alkyl

chain, but lack the acid–amide bond and thus are also much less pungent than capsaicin. The length of the alkyl side-chain has been varied experimentally in synthetic analogs of capsaicin. Pungency appears first in compounds with a six-carbon side-chain, peaks with the nine-carbon side-chain, then gradually declines as chain length increases. The synthetic nine-carbon analog, *N*-vanillylnonamide, has been used as a substitute for capsaicin.

Biosynthesis of capsaicinoids is thought to involve one pathway from phenylalanine to vanillylamine, and one from valine or leucine to their respective isoacids, followed by condensation of vanillylamine with the activated fatty acids. Two capsaicinoid-like compounds (capsiate and dihydrocapsiate) have been identified from a nonpungent Japanese cultivar of *C. annuum*. These compounds have an ester moiety in place of the amide moiety of capsaicin and

Table 2 Effects of pigment quality and quantity on color of the ripe fruit in *Capsicum*

Pigment quantity	*Pigment quality*	
	Red pigments present	*Red pigments absent*
Normal	Red	Orange-yellow
Slightly reduced	Tangerine	Lemon yellow
Trace amounts only	Pink	Cream

Table 3 Structure and pungency of capsaicinoids compared to pungent principles of ginger and black pepper

Name	*Structural formula*	*Threshold pungency (10^5 Scoville units)*

Substituted piperidine (from black pepper)		
Piperine		1.0

dihydrocapsaicin, hence do not taste pungent. It is not known whether they are intermediates in the biosynthesis of capsaicin and dihydrocapsaicin.

Continuous light has been reported to induce formation of capsaicinoids during postharvest ripening of nonpungent *C. annuum*, and cells isolated from sweet pepper stem callus will synthesize capsaicin *in vitro* under appropriate conditions. The nonpungent mutant, at least in *C. annuum*, may therefore involve some change in a regulatory or switch mechanism affecting the pathway of capsaicin biosynthesis, rather than a simple block in this pathway.

Although many secondary metabolites of the Solanaceae (such as nicotine) are produced wholly or partly in the roots, this is not true of the capsaicinoids. Experiments in which tomatoes were grafted on to hot pepper rootstocks, and vice versa, showed that capsaicinoids are produced only in the fruits. They usually appear about 2 weeks after flowering and reach a plateau 4 weeks after flowering. Temperature, particularly night temperature, seems to affect both the formation and accumulation of capsaicinoids. Capsaicinoids are synthesized in the epidermal cells of the placenta, in the inner compartment of the endoplasmic reticulum. They are translocated across the cell membrane, through the cell wall, and accumulate in cavities beneath the cuticle covering the placenta. This may cause the cuticle to crack and the capsaicinoids to spread over the seeds and inner wall of the fruit, leading to the widespread, but erroneous, belief that pungent peppers have pungent seeds and pungent fruit walls.

For a long time, pungency of *Capsicum* was assessed organoleptically by the Scoville test, which was simple and convenient but not accurate or reproducible. A specified weight of *Capsicum* was combined with a specified volume of alcohol, diluted with sugar solution to the threshold of taste, and the reciprocal of the dilution was the measure of pungency in Scoville heat units (150 000 Scoville units = 1% capsaicinoids). The major techniques now used for separating and quantifying the various capsaicinoids are gas chromatography, high-performance liquid chromatography, and high-performance thin-layer chromatography. There is still no simple nonorganoleptic test that can be applied in the field. (*See* **Chromatography**: Thin-layer Chromatography; High-performance Liquid Chromatography; Gas Chromatography.)

Pharmacodynamic Properties

Capsaicinoids are responsible for many pharmacodynamic as well as organoleptic properties of *Capsicum*. Hot peppers stimulate saliva flow and may overcome loss of appetite. They also stimulate gastric juices, thereby aggravating stomach ulcers. They increase peristalsis, thus having a laxative action (which has benefited archeologists studying food remains in prehistoric feces). Hot peppers increase perspiration, which may partially explain their popularity in hot climates. Chilli-containing foods reputedly reduce risks of thromboembolism and significantly lower both liver and serum triglycerides. Capsaicinoids induce coughing and sneezing, inflame the skin, and have an irritating effect on mucous membranes of the eyes and nose. This was exploited in the past by some Amerindians, who punished their children by holding them over the smoke of a fire on to which dried chillies had been thrown, and exploited more recently by manufacturers of certain aerosols sold for use against 'muggers.'

The burning and pain associated with hot peppers result from pungent capsaicinoids acting on sensory neurons known as nociceptors. Repeated exposure leads to desensitization. Experimenters who desensitized their tongues to capsaicin found that their taste thresholds for other pungent compounds, such as ginger and mustard, also increased, but their ability to perceive tactile stimuli or basic tastes, such as sweet, salt, sour, or bitter, was not affected. Capsaicin apparently acts via a receptive site in the nociceptor. This site seems also to be involved in the perception of temperatures which are dangerously high (perhaps explaining why pungent foods are perceived as 'hot'). Capsaicin kills the nociceptor, or destroys its peripheral terminals. This has been exploited in the topical use of capsaicin as an analgesic to treat conditions such as shingles and rheumatoid arthritis.

Nutritional Value

Hot peppers are traditionally valued for adding interest to bland, starchy foods and for masking off-flavors in meat and other stored products. Both hot and sweet peppers are also excellent sources of vitamins, particularly vitamins A and C. Carotene (provitamin A) is deficient in many tropical diets. Green peppers have a β-carotene equivalent of 180 μg per 100 g; red peppers contain 4770 μg of carotenoids per 100 g. (*See* **Retinol**: Physiology.)

Fresh peppers are perhaps even more important as a source of vitamin C. The Hungarian chemist Szent-Györgyi won the Nobel Prize for his isolation of vitamin C, first from the adrenal gland, later from paprika and lemon. Fresh paprika fruits contain up to 340 mg per 100 g, i.e. more vitamin C per unit weight than citrus. Much of this is lost when peppers are dried (paprika powder contains only 30–60 mg per 100 g), but about two-thirds is retained in canned *Capsicum* fruit. (*See* **Ascorbic Acid**: Physiology.)

Harvesting, Handling, and Processing

Green bell peppers and fresh green chillies are picked when the fruit has reached its full size but the seeds are not yet fully mature. This is usually about 1 month after flowering, or 70 days after planting. Fruits are picked by hand at 7–14-day intervals over a harvesting period of about 3 months. They are usually picked with calyx and fruit stalk attached, since bacteria and fungi may infect the scar left by removal of the calyx and cause postharvest rots. Harvested fruits can be stored for up to 14 days, preferably under cool humid conditions (7–10 °C and 95% relative humidity). Ventilation may be advisable to remove accumulating ethylene, which would accelerate fruit ripening. Ripe peppers are harvested 2–3 weeks later than green peppers but are handled in the same way. Since the grower has to wait longer before harvest, ripe fruits usually command higher prices than green peppers.

Sweet peppers may also be marketed as dehydrated flakes. Stalks, calyces, placentas, and seeds are removed mechanically and the pericarp is diced, sprayed with sulfite-bisulfite solution and dried by hot air. Pimentos for canning have the tough outer cuticle plus the underlying epidermis removed by roasting or by treatment with lye, then are cored to remove placenta and seeds and canned either whole or diced.

The quality of *Capsicum* powders depends on their color and flavor, which are influenced by how the fruits are harvested and handled. Paprika is always made from red-fruited cultivars. The genotype influences both the quantity of pigment present and how well it is retained after harvest. Traditionally, fruits are harvested when fully ripe and dried in the open air for 3 weeks or more. The red pigments increase for the first 25 days of after-ripening, then remain constant until about 40 days after harvest, when they start to break down. Mechanical harvesting requires that 80–90% of the fruits mature simultaneously. In Hungary, plants are cut by machine at ground level and laid in the field to dry and after-ripen. Artificial drying in hot air is also widely used, but if temperatures exceed 80 °C, fruit color starts to deteriorate. Stalks, calyces, placentas, and seeds are separated from the dried fruits because they would dilute the color, but at least 5% of cleaned seeds are then re-added to facilitate grinding (the precise percentage depends on the intended grade of the final product). The seeds contain fat, and carotenoids are fat-soluble, so adding ground seeds helps to disperse the color evenly, though the fat may become rancid during storage. (*See* **Drying**: Theory of Air-drying.)

Pungent fruits are handled in much the same way as paprika. Grinding is done mechanically, formerly in the importing countries, but costs are high and grinding of chillies is particularly unpopular because of the cough- and sneeze-provoking effects of the dust, so grinding is increasingly left to the producing countries. The ground powder is fumigated to control microorganisms and stored under dry, cool, dark conditions to minimize breakdown of the red pigments. (*See* **Fumigants**.)

Oleoresins are extracted from dried and ground fruits. If the seeds are ground with the fruits, fat from the seeds dilutes both color and pungency, and hence quality, of the oleoresin. However, if the seeds are removed, the cost of production is increased and the yield of oleoresin is decreased. Acetone and ethylene dichloride are frequently used solvents. The extract is distilled to remove the solvent, leaving the concentrated oleoresin.

Global Distribution, Products, and Commercial Importance

Capsicum is adapted to tropical or subtropical climates, but can be grown in temperate climates in glasshouses or under protected cultivation. The Food and Agriculture Organization (FAO) production yearbooks do not distinguish between *C. annuum* and other species, or between pungent and nonpungent peppers. Over the last two decades, total world production of chillies and green peppers (presumably including also ripe fruits of sweet pepper and pimento) increased from about 7 million to nearly 17 million tonnes. Over half of this is produced in Asia. China alone produces over 40% of the world total.

Data in the FAO trade yearbooks combine, under the heading pimento, information for capsicum, cayenne, chillies, paprika, and red pepper. The confusion surrounding the name chilli has already been discussed. Capsicum is a similarly confusing term, which may be used for the nonpungent vegetable peppers, but may also be used for some mildly pungent dried fruits, e.g. Ancho, that are larger than most fruits known as chillies. Applied to the oleoresin, capsicum signifies the most pungent, rather than the least pungent, of the commercial grades. Cayenne is usually made from small-fruited peppers, grown in various parts of the world, and is usually very pungent. However, in the USA cayenne is made from locally grown, large-fruited cultivars and is less pungent. Paprika comes mainly from Hungary, Spain, and the USA and is usually, though not always, nonpungent. Ground red pepper and crushed red pepper have similar names, but ground red pepper is usually milder than crushed red pepper. Red pepper may also refer to ripe fruits of some sweet peppers.

The FAO trade yearbook shows that, in 1997, North America and Europe were net importers of over 100 000 t of 'pimento.' Asia and Africa were net exporters. China contributed about 40% of Asia's exports, thereby earning over US$72 million, while India contributed a further 30% and earned approximately US$40 million.

Oleoresins are valued by some commercial food processors for their greater hygiene (less contamination by microorganisms, insects, or rodent droppings) and more precise standardization of pungency. They are used mainly in the USA and the UK, but elsewhere do not seem to be replacing pepper powders. Three different oleoresins are produced commercially: oleoresin paprika, oleoresin red pepper (or oleoresin chilli), and oleoresin capsicum. Oleoresin capsicum is used mainly in the pharmaceutical industry but also in the production of some foods and beverages, such as ginger ale. One kilogram of oleoresin capsicum replaces approximately 20 kg of cayenne. Oleoresin red pepper is made from less pungent fruits, such as the long, thin peppers much grown in Asia. One kilogram of oleoresin red pepper replaces about 10 kg of red pepper. Oleoresin paprika is used for coloring salad dressings and oleomargarines, partly because it retains its color longer than annatto. One kilogram of oleoresin paprika replaces 12–15 kg of paprika powder.

Probably less than 10% of total global production of hot peppers is for export. The remainder is grown for local use. Mexico leads the world in chilli consumption at 15 g per head per day. Sweet peppers are eaten less regularly than hot peppers but are consumed in larger quantities (up to 20 g per meal). At these levels of intake, *Capsicum* adds considerably more than spice to the diet of some of the world's poorest people.

Introduction

Peptides consist of chains of amino acids linked to each other by amide bonds, also known as peptide bonds. They form a heterogeneous group of compounds, because of the large number of different naturally occurring amino acids and the high potential variability in the order and number (chain length) of residues making up the peptide.

The number of amino acids that a peptide contains is indicated by a prefix, e.g., di-, tri-, tetrapeptide; the term 'oligopeptides' or 'low-molecular-weight peptides' refers to peptides with 10 or fewer residues, while 'polypeptides' is used for peptides with higher molecular weights. Although the transition point from polypeptide to protein is not well defined, proteins are normally considered to have at least 100 residues (mol wt > 10 000). By convention, peptides are referred to by the first three letters of the amino acids making up the chain or by one-letter abbreviations. Also by convention, the amino acid with the free amino group is referred to as the *N*-terminus and is represented on the left, while the amino acid with the free carboxyl group is referred to as the *C*-terminus and is represented on the right. (*See* **Amino Acids**: Properties and Occurrence.)

The *N*-terminal amino group and the *C*-terminal carboxyl group on peptides react chemically in the same way as the α-amino and α-carboxyl groups on free amino acids, and they can be used for detection and quantification purposes.

The acid–base behavior of peptides is dependent upon the free α-amino group on the *N*-terminal residue, the free α-carboxyl group on the *C*-terminal residue, and the ionizable R groups located at intermediate positions.

In the presence of carbonyl compounds, certain peptides take part in the Maillard reaction, leading to the formation of melanoid pigments that contribute to the development of undesirable coloration in foodstuffs. Conversely, there are also lysine-containing peptides that retard browning reactions with glucose, and these may be appropriate for fortifying the lysine content of sugar-containing foods to be cooked. (*See* **Browning**: Nonenzymatic.)

Peptides also play a very important role in determining the rheological properties of foods. Hydrolysis of proteins to peptides during processing (fermentation, ripening, and cooking) of foods may modify food texture.

Peptides in Foods

Peptides are naturally present in foodstuffs. Most simple peptides are the result of partial hydrolysis of protein polypeptide chains. On the other hand, nonprotein peptides have also been recorded in foods. Such peptides usually differ in structure from the peptides derived from proteins, and these structural variations may protect them from the action of peptidases.

The tripeptide glutathione, present in the cells of all higher animals, is an example of a nonprotein peptide. It contains a glutamic acid residue linked by an unusual peptide bond involving its γ-carboxyl group. Glutathione plays a role in the active transport of amino acids, acts as an antioxidant for lipids and as an activator for certain enzymes, and is a coenzyme of glyoxalase. Other nonprotein peptides include the dipeptides carnosine, anserine, and balenine, which are present in vertebrate muscle and contain a β-amino acid (β-alanine) bound to L-histidine or 1-methyl-L-histidine. These histidine dipeptides are present in differing proportions in the muscles of different species and therefore are a mean of determining the source of the meats used in meat or of identifying marine fish species.

Peptides may also be present in foods because they have been used as additives (e.g., sweeteners, flavor enhancers, or bulking agents for light beverages) to improve food quality. Some peptides produced by the enzymatic hydrolysis of proteins possess better functional properties than the parent proteins and consequently are used by the food industry for a variety of purposes.

Peptides have lower molecular weight and less secondary structures, as well as higher number of ionizable groups and exposure of hydrophobic groups than native proteins. These facts imply that solubility, surface activity, foaming, and emulsifying properties may be different from that of the intact protein.

Enzymatic hydrolysis has been reported to enhance the emulsifying capacity of different proteins. Peptides with an inhibitory effect on autoxidation of linolenic acid and hence potentially useful as antioxidants have been found in fermented foods and in protein hydrolysates. Moderately large peptides have

pronounced bulking properties and large peptides act as foam stabilizers; because of these interesting functional properties, enzymatic hydrolysates of soya bean proteins have been used in beverages. Hydrolyzed hydrophobic proteins from gluten (zeins, gliadins) have been prepared with a view to increase solubility and diversify their functional properties.

Analysis of the peptides of enzymatic hydrolysates of trypsin can be used to confirm the presence of nonmeat proteins such as soyabean proteins in meat products. Tryptic peptides of the caseins from milks of different species are distinct and may be used to detect blends of milks. The presence of the casein glycomacropeptide is also useful in detecting adulteration of powdered milks with rennet whey.

Organoleptic Properties

Peptides are tasteless or bitter, with the exception of certain dipeptides of glutamic acid and aspartic acid, which are sweet. Others, like the lower alkane members in the series of methyl esters of L-aspartyl-α-amino-cycloalkane carboxylic acid and a series of L-aspartyl-D-alanyl tripeptides, are sweet but turn bitter or tasteless when the size of the *C*-terminal amino acid ring increases. There is, thus, an important relationship between size and flavor in these peptides. Peptides belonging to L-aspartyl D-alanyl amides are strong sweeteners and may be used as good sugar substitutes. (*See* **Sensory Evaluation**: Practical Considerations.)

Foods may also contain peptides with a flavor similar to that of monosodium glutamate, termed umami taste or relish, which are able to mask the bitter taste produced in foods by bitter peptides or other bitter substances. This group includes hydrophilic peptides, in particular acid peptides that balance flavor in foods.

Warmed-over flavor in cooked–stored–recooked meat has also been related to the higher hydrophobic peptide content in such meats as compared to cooked meats. However, low-molecular-weight peptides play an important role in the flavor formation and intensity of meat, beef broth, and dry cured ham.

Bitter peptides form as a result of proteolytic reactions that take place in foods. These bitter peptides have been identified in soyabean and casein hydrolysates as well as in foods, like cheese, that undergo fermentation of ripening processes with marked proteolytic activity. The bitter taste has been related to the hydrophobic amino acid content and to chain length. An overly high proportion of hydrophobic amino acids gives rise to bitterness; however, above a given molecular weight bitter flavors are no longer perceptible, even though hydrophobic amino acids are present. Proteins do not have a bitter taste even when they contain hydrophobic amino acids, yet hydrolysis of such proteins may indeed yield bitter peptides. Bitter flavors in di- and tripeptides have been observed to increase when the hydrophobic amino acid is located on the *C*-terminal residue and the basic amino acid is on the *N*-terminal residue. Enzymatic activity is extremely important in the development of bitter flavors in foods. Trypsin does not degrade bitter peptides, although peptidases may break down bitter peptides to nonbitter lower-molecular-weight peptides and amino acids.

Bitterness is the most frequent flavor defect limiting cheese acceptability. It has been attributed to the formation and accumulation of bitter peptides derived from casein. During cheese manufacture rennet or rennet substitutes and microbial proteases are the principal agents hydrolyzing the caseins and are thus thought to be responsible for the occasional appearance of bitter taste. The use of rennet substitutes may give rise to the appearance of bitter peptides; for instance, commercial chicken pepsin produces an objectionable level of bitterness in cheese. On the other hand, cheeses made from goats' or ewes' milk are less susceptible to bitter flavor defects than cheeses made from cows' milk.

Aged cheeses, in particular hard cheeses, require long ripening periods in which to acquire the desired organoleptic characteristics. Proteases have therefore been used to accelerate the ripening process and lower costs. However, the proteases give rise to bitter peptides that limit cheese quality. In recent years a considerable amount of work has been carried out on peptidases that break down the bitter peptides derived from the caseins to smaller, nonbitter peptides. The combined use of proteases and peptidases may be an effective means of shortening ripening times, while preventing the development of bitter flavors. (*See* **Cheeses**: Chemistry and Microbiology of Maturation.)

Bitter peptides that contribute to bread flavor form during the fermentation and baking of bread dough as a result of the action proteolytic enzymes on the protein fraction in the flour (gliadins and glutelins).

Analytical Procedures

Spectrophotometric Methods

The *N*-terminal α-amino groups on peptides react quantitatively with reagents such as ninhydrin to form colored derivatives or with *o*-phthalaldehyde and fluorescamine to form fluorescent derivatives. These reactions are useful in making quantitative determinations of peptides in foodstuffs and for detection during chromatographic analysis. Due to the

peptide bond, peptides also take part in reactions which free amino acids do not undergo, like the classic biuret reaction. This reaction consists of the formation, in an alkaline medium, of a colored complex with a transition metal (e.g., copper or nickel) that can be measured quantitatively by spectrophotometry. This reaction is utilized in quantifying peptides. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

The peptide content can also he determined by assaying the aromatic amino acids tyrosine and tryptophan, which is readily achieved by measuring absorbance at 280 nm or by measuring the color reactions of these amino acids with certain reagents like Folin-Ciocalteu's reagent. Another analytical method for determining the high-molecular-weight peptide content is by precipitating the peptides with acid dyes (amino black, orange G) and measuring the excess dye remaining in solution. These methods are useful in determining the total peptide contents of foodstuffs, but their drawback is that they provide no information on how many or which peptides are present. For this, other techniques such as chromatography or electrophoresis are needed.

Chromatographic Methods

Paper chromatography and thin-layer chromatography have conventionally been used to separate peptides, particularly for the fractions isolated by gel permeation chromatography (GPC) and ion exchange chromatography (IEC), but they are lengthy, time-consuming procedures with low resolving power and low reproducibility.

Gel filtration chromatography on open Sephadex columns with different pore sizes (G-10, G-25, and G-50) using water or saline or acid buffers as solvents is used extensively in the fractionation of peptides. Detection is performed by measuring absorbance of the column eluate with an ultraviolet detector at 280 nm, the absorbance wavelength for tyrosine and tryptophan, or at 214 nm, the absorbance wavelength for most amino acids and the peptide bond. Peptides elute in fractions according to their molecular weight. Small peptides must normally be separated from the amino acids; gel filtration on columns prepared by hydroxypropylation (Sephadex LH-20), ion exchange on diethylaminoethyl (DEAE)-cellulose or DEAE-Sephadex with Cu^{2+} complexes, or ligand exchange columns with a stationary phase modified with Cu^{2+} are used for this purpose. Ion exchange chromatography on DEAE-cellulose or on Aminex A-5 is normally used for the separation of high-molecular-weight peptides, employing saline buffers as eluent. Detection is carried out at 280 nm or in the visible region after derivatization with ninhydrin.

These methods are now most often used as preparatory techniques for subsequent high-performance liquid chromatographic (HPLC) or electrophoretic analysis of the peptide fractions. (*See* **Chromatography**: Principles.)

High-performance Liquid Chromatography

Because of its versatility, short analysis times, high resolution, and effective separations, and because it is well suited to automation procedures, HPLC is the most widely used method of peptide analysis. Practically all known mechanisms have been employed in the chromatographic separation of peptides, e.g., separation based on molecule size (GPC), on charge (IEC), on hydrophobicity (reversed-phase and interaction chromatography), and even on combinations thereof; of these, however, reversed-phase chromatography is most commonly used to separate mixtures of peptides from foodstuffs (Figure 1). It affords the possibility of changing the stationary phase, the pH, the ionic strength of the aqueous buffer, or the type of organic modifier, of using different gradient shapes, and of working at a variety of temperatures, making this method suitable for analyzing highly different peptides. Moreover, the option of using microcolumns makes it possible to detect quantities on the order of picomols and has been an important step toward HPLC–mass spectrometry coupling. (*See* **Chromatography**: High-performance Liquid Chromatography; Combined Chromatography and Mass Spectrometry.)

Reversed-phase chromatography Reversed-phase columns with pore sizes of 6–10 nm are highly appropriate for separating small peptides. Columns with pore sizes of 30–50 nm give the best results when separating large peptides (mol wt 4000), because the molecules are able to pass freely through the pores, thus permitting greater access to the alkyl chains and increasing column efficiency and load capacity.

The mobile phase is commonly a mixture of water and an organic solvent, normally acetonitrile, methanol, or 2-propanol, although other organic solvents such as methoxyethanol, ethanol, butanol, or tetrahydrofuran are also used. Gradient elution is normally required for reversed-phase HPLC of peptides.

Because of their high polarity, peptides do not interact sufficiently with the hydrophobic chains of the stationary phase in reversed-phase chromatography. On the other hand, they do interact with any free silanol groups in these phases. Salts or strong acids must be added to the stationary phase to block the silanol groups. In order to reduce the polar nature of the peptides, chromatography should be carried

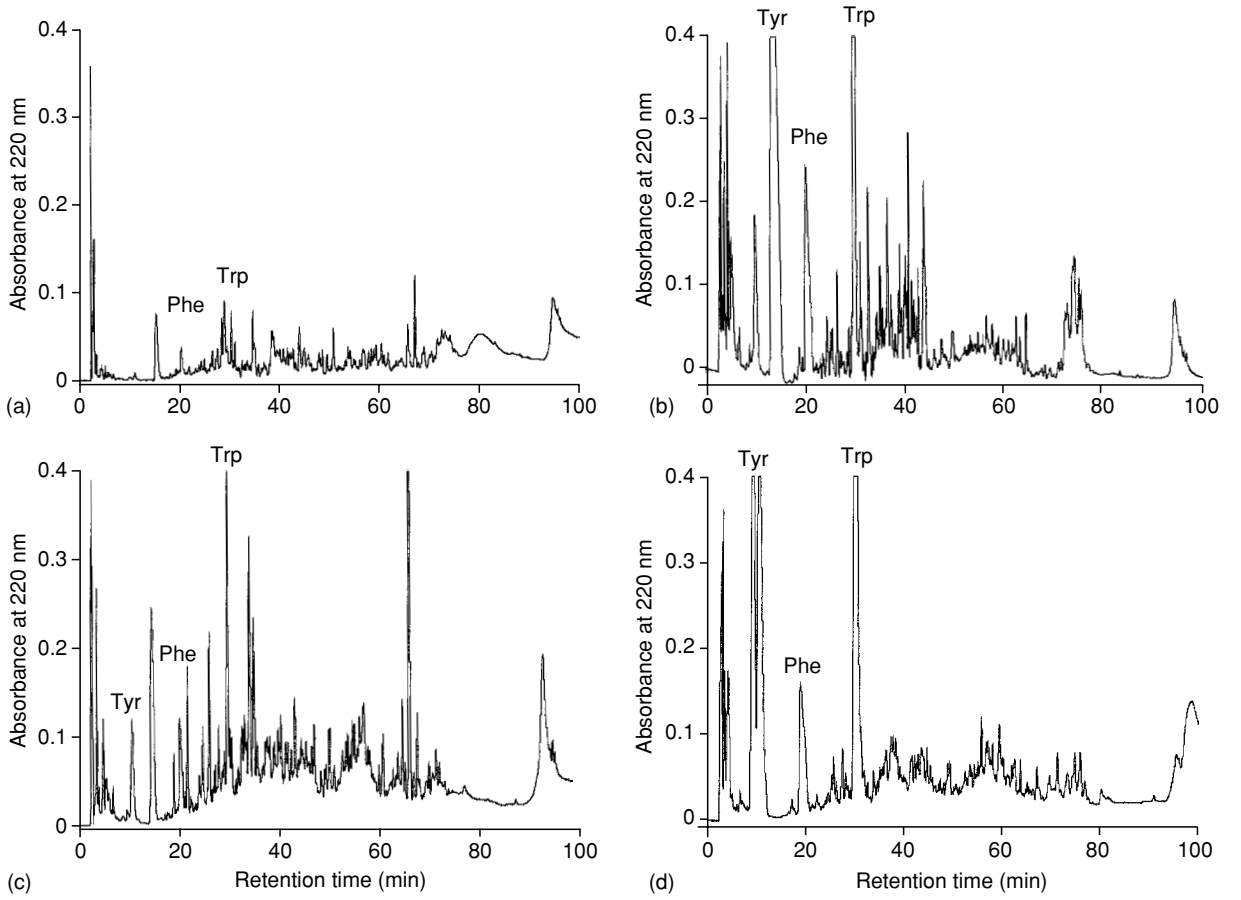

Figure 1 Chromatogram of the peptides of the water-soluble fraction from commercial (a) Vidiago, (b) Cabrales, (c) Beyos, and (d) Peral cheeses. Column: Ultraspher ODS. Solvent: TFA/acetonitrile/water. Gradient elution. Detection at 220 nm. From González de Llano D, Polo C and Ramos M (1995) Study of proteolysis in artisanal cheeses: high performance liquid chromatography of peptides. *Journal of Dairy Science* 78(5): 1018–1024 with permission.

out at a pH of less than 3, so that the carboxyl groups on the acids amino acids (aspartic acid and glutamic acid) are not in their dissociated form. However, at this pH the basic amino acids histidine, lysine, and arginine are charged and must be blocked by forming ion pairs. The selectivity of the chromatographic system can be modified depending on the pH and on the type of ion-pairing reagent used. Trifluoroacetic acid has been widely employed as the ion-pair reagent for peptides.

Ion exchange chromatography IEC has also been used in peptide separations. Two types of ion exchangers are utilized: cationic exchangers to separate neutral and basic peptides, and anionic exchangers to separate neutral and acid peptides. Peptide separations have been carried out on polymeric cationic exchange resins (polystyrene/divinylbenzene copolymers), and indeed automatic peptide analysers, similar to those used in amino acid analysis, have been designed, with postcolumn detection using ninhydrin.

Size exclusion chromatography (SEC) High-performance SEC has most commonly been applied to protein separations, though on occasion it has also been used to separate peptides from foodstuffs. The stationary phase may be inorganic, such as silica or alumina. The disadvantage of inorganic materials is that their active surfaces adsorb charged molecules and hence they must first be deactivated, for instance using organosilanes. Organic materials such as glycerol methacrylate, sulfonated styrene divinylbenzene, and polyesters with surface hydroxyl groups have also been used.

The different separation mechanisms referred to above (reversed-phase HPLC with small or large pore sizes, IEC, and SEC) are complementary, and the best separations are sometimes achieved by combining the various methods.

Detection Peptides are detected in amounts ranging from 100 to 1000 ng by absorbance at between 200 and 230 nm. Detection of peptides containing aromatic

amino acids (phenylalanine, tyrosine, and tryptophan) may be performed at 254 nm; tyrosine- or tryptophan-containing peptides can also be detected at 280 nm. Rapid-scanning ultraviolet/visible detectors based on diode array technology have proved an extremely useful aid in identifying peptides that contain aromatic residues. Wavelengths of the spectrum maxima, convexity interval, and wavelength of the second derivative spectrum maxima, all over in the 190–340 nm range, allow identification of the aromatic amino acids that form the peptides, as well as identification of HPLC coeluted compounds such as the cinnamic derivatives detected in the peptide fractions of wines.

Since numerous solvents and even other sample components may absorb light in the range 200–230 nm, formation of derivatives detectable at higher wavelengths that are more specific for given chromophores is commonly employed. To this end, phenyl isothiocyanate and dansyl chloride are frequently used in peptide analysis as derivatizing agents. Peptides may also be detected using a fluorescence detector to detect either the natural fluorescence of certain amino acids in the peptide sequence or the fluorescence of derivatives formed artificially using such reagents as fluorescamine and *o*-phthalaldehyde. Other reagents used lately for derivatization of peptides are naphthalene-2,3-dicarboxaldehyde, 3-(4-carboxy-benzoyl) 2-quinolinecarboxaldehyde, and 6-aminoquinoyl-*N*-hydroxysuccimidylcarbamate.

Following the significant advances made in liquid chromatography/mass spectroscopy coupling in recent years, mass spectrometry has turned into a detection system that holds great promise for peptide analysis, since it is capable of furnishing structural information and quantitative data that are otherwise difficult to obtain.

The greatest advance in the analysis of peptides has been the coupling with spectrometric techniques, both for identification and for characterization. Their high accuracy, sensitivity, and, in some instances, tolerance to solvents make mass spectrometers ideal detectors for analyses of HPLC-separated peptides. Presently, electrospray ionization and matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry – soft ionization methods – provide the suitable means to determine accurate mass on peptides and proteins with high sensitivity (subpicomol range). Furthermore, both methods are suitable for the creation of peptide ions for analysis using tandem mass spectrometry and collision-induced dissociation methods. Mass spectrometry in conjunction with database searching plays an increasingly important role in the characterization of food peptides.

Electrophoretic Techniques

Despite the important advantages afforded by HPLC in the analysis of hydrophobic peptides, electrophoresis can be useful, because insoluble peptides can be solubilized with detergents. Although a number of different supports have been employed, polyacrylamide gel electrophoresis (PAGE) and sodium dodecyl sulfate–PAGE (SDS-PAGE) have been widely used in the study of peptide formation from proteins during food processing. Another developed method of peptide analysis that may be used either an alternative or a complement to HPLC is capillary electrophoresis. This technique has extremely high resolving power and allows the separation of peptides differing in only a single amino acid; it is simple, fast, and appropriate for quantitative analysis, and only small amounts of sample are required. Peptide separation by CE is now almost a routine technique in food analysis. Moreover the application of two analytical techniques (HPLC-CE, SEC-CE) and coupling mass spectrometry to HPLC have acquired great importance for characterization of complex peptide samples. (*See* **Electrophoresis**: General Principles.)

Determination of Amino Acid Composition and Sequence in Peptides

The amino acid composition of peptides is generally assayed by carrying out acid hydrolysis with 6 mol l^{-1} hydrochloric acid, followed by determination of the individual amino acids by HPLC. Various types of HPLC have been employed to separate the amino acids, but reversed-phase chromatography on C_{18} columns is most commonly used. Detection of the amino acids normally involves derivatization, since maximum absorbance of amino acids is located in a region of the spectrum (214 nm) in which many other compounds also absorb. The most frequently used derivatizing agents are dansyl chloride, phenyl isothiocyanate and *o*-phthalaldehyde.

Peptide sequencing is normally performed by degradation of the *N*-terminal amino acid using phenyl isothiocyanate, Edman's reagent. The terminal amino groups react with the isothiocyanate, forming a phenylthiocarbamylic derivative. When treated with acid in an organic solvent, cyclization takes place and phenylthiohydantoin amino acid is formed; this can be separated from the rest of the chain, which remains intact. The process can be repeated.

The usefulness of Edman degradation in the sequencing of low-molecular-weight peptides is limited, because of the low repetitive yield in the successive sequencing cycles. For such peptides the best results are obtained by coupling sequential Edman degradation with detection by means of

dansylation or by the double coupling method using 4-*N*,*N*-dimethylaminoazobenzene-4′-isothiocyanate and phenyl isothiocyanate.

Mass spectrometry has also become a powerful tool for the sequencing of small amounts of peptides and proteins. Tandem mass spectrometry and ion source collision-induced dissociation produce information specific to the amino acid sequence and the specific covalently modified amino acid. A new method, referred to as protein ladder sequencing, for the *N*-terminal sequencing of peptides utilizes multiple steps of partial Edman degradation chemistry prior to the analysis of the reaction mixture by MALDI-TOF mass spectrometry.

PESTICIDES AND HERBICIDES

Contents

Types of Pesticide

R Pleština, World Health Organization, Geneva, Switzerland

Introduction

Humans have always had to cope with disease, discomfort, and great economic loss caused by pests. Some methods for pest control date back to ancient times. What may be called the 'pesticide revolution' dates back to the early 1940s when dichlorodiphenyltrichloroethane (DDT) was first used as an insecticide. Since that time, in a variety of pest-control activities around the world, both in agriculture and in public health, chemicals continue to play a significant role, and this trend will be sustained for many years to come. Although pesticides are poisons, the majority of people recognize the advantages of their use in view of the benefits they bring to the control of disease vectors and nuisance pests, and particularly to the increase in food and fiber production. Research

on alternatives has produced few materials to take the place of these chemicals. Although the use of pesticides has more or less stabilized, or is even declining in the developed world, it continues to increase in the developing countries owing to development and buildup of pest resistance, because of an increase in the need for food, feed, and fibers, in addition to a limited and constantly decreasing per capita availability of arable land. (*See* **Insect Pests:** Insects and Related Pests; Problems Caused by Insects and Mites.)

There is little doubt that the principles promoted by the concept of integrated pest management will reduce excessive use of pesticides. However, it should be stressed that integrated pest management does not exclude pesticide use, and pesticide treatment should be considered as a supplement to basic sanitation; like drugs, pesticides should always be used with discretion and in conjunction with other measures in order to achieve effective pest control.

Definition and Classifications

The term 'pesticide' is defined in many different ways, each having some specific feature. Most of them, however, define pesticide as a pest-control agent aimed at killing or repelling a pest. The most widely accepted definition is that given in the *International Code of Conduct on the Distribution and Use of Pesticides* (FAO, 1990) which reads as follows:

> Pesticide means any substance or mixture of substances intended for preventing, destroying or controlling any pest, including vectors of human or animal disease, unwanted species of plants or animals causing harm during or otherwise interfering with the production, processing, storage, transport, or marketing of food, agricultural commodities, wood and wood products or animal feedstuffs, or which may be administered to animals for the control of insects, arachnids or other pests in or on their bodies. The term includes substances intended for use as a plant growth regulator, defoliant, desiccant, or agent for thinning fruit or preventing the premature fall of fruit and substances applied to crops either before or after harvest to protect the commodity from deterioration during storage and transport.

Similarly, classifications of pesticides are numerous, depending on the criteria used and their use. Thus, based on the pest they control, pesticides may be grouped as insecticides, fungicides, herbicides, rodenticides, repellents, etc., and based on the chemical structure of the active ingredient, they may be grouped as organophosphates, carbamates, organochlorines, etc. There is also a clear distinction between agricultural and public health pesticides or household pesticides. By formulation, the products may be grouped as liquids, solids, or gases. In addition, there are persistent and degradable pesticides. One classification does not exclude another; all of them are used to make a classification according to the hazard that pesticides pose to humans, and this arises from their intrinsic toxic property. Thus, the World Health Organization elaborated *The WHO Recommended Classification of Pesticides by Hazard* and *Guidelines to Classification 1992–1993* (Table 1). (*See* **Fungicides**.)

This document was approved by the 28th World Health Assembly in 1975 and has since gained wide recognition in a number of Member States and by pesticide registration authorities. Although the classification takes into account acute oral or dermal toxicity, whichever is higher, it also considers any irreversible effect that might be recognized. For practical reasons, a number of pesticides classified as Class III (slightly hazardous) are listed in a separate table as 'Unlikely to present acute hazard in normal use.' *Guidelines to Classification* is prone to frequent revision, based on documented scientific evidence.

Needs and Present-day Use

The costs and benefits of pesticides are currently being evaluated, on the one hand, for their ability to reduce the cost of food and feeds, and to decrease the spreading of vectorborne diseases, and, on the other hand, for the potential impact that pesticides may have on human health and the environment. All of these aspects should not, however, be considered

Table 1 WHO recommended classification of pesticides by hazard

Class	*LD50 for the rat (mg per kilogram of body weight)*			
	Oral		*Dermal*	
	Solids[a]	*Liquids*[a]	*Solids*[a]	*Liquids*[a]
Ia (extremely hazardous)	5 or less	20 or less	10 or less	40 or less
Ib (highly hazardous)	5–50	20–200	10–100	40–400
II (moderately hazardous)	50–500	200–2000	100–1000	400–4000
III (slightly hazardous)	Over 500	Over 2000	Over 1000	Over 4000

[a]The terms 'solids' and 'liquids' refer to the physical state of the product or formulation being classified.
From WHO (1992).

separately from the costs which must be paid to ensure the correct use of pesticides.

It has been estimated that if pesticides were not used, the potential loss of food production would be 45% (30% attributed to pests, including weeds and diseases before harvest, and 15% as a postharvest loss). In addition, in over 100 countries, more than 4×10^8 clinical cases of vectorborne diseases currently exist. For some of these diseases, control of vectors remains the main control measure, and for others, pesticides are considered to be an essential part of disease control. The use of pesticides in the control of household pests should not be neglected, regardless of whether they are used in the control of vectors of diseases or to control nuisance pests. This aspect of pesticide use is of great importance, as pesticides intended for this kind of application are available to the general population.

Although the exact figures for the global use of pesticides, either according to intended use (agriculture, public health, household) or according to regional or country use, are not available, it is certain that the quantities of pesticides used are steadily growing, albeit less in the developed countries than in developing countries, and this trend may continue for some years. A few highly developed countries show a decline in the quantities used as more efficient compounds are applied, and the trend to organic farming increases. (*See* **Organically Farmed Food**.)

In western Europe and North America, herbicides are the most represented groups of pesticides, whereas in the tropics, insecticides are used more than other groups of pesticides. This fact gives rise to ever-growing concern, mainly attributable to the indiscriminate use and frequently to the misuse of pesticides. This concern is supported by the fact that, although only about 20% of pesticides are used in developing countries, they account for the majority of total deaths caused by pesticide poisonings.

Evaluation of the Risk and Testing Procedure

In general pesticides, in common with drugs, are among the most carefully studied chemicals, and this makes the toxicological evaluation of active material possible and meaningful.

According to the widely accepted *International Code of Conduct on the Distribution and Use of Pesticides*, pesticide manufacturers are expected to ensure that each pesticide is adequately and effectively tested in accordance with sound scientific procedures and good laboratory practice. Generated toxicological data and use patterns are then meticulously evaluated by competent international or national institutions, and results made available to the relevant national authorities in order to allow them to introduce the necessary legislation for their regulation, including registration. (*See* **Legislation**: Contaminants and Adulterants.)

In many countries, registration procedures are elaborated upon in great detail, offering possibilities, for preparing precise precautionary measures for their production, transport, storage, and use. Unfortunately, in many areas, the implementation of carefully prescribed safety measures is lacking, and pesticides are greatly misused.

The activities of the WHO in the safety assessment of pesticides were initiated soon after its foundation, and a number of expert committees have been devoted to the toxic hazards arising from pesticides used in public health programs. Subsequently, the experts also became concerned with the safety aspects of pesticides used in agriculture. The evaluation of pesticide residues in food started in 1963 in collaboration with the Food and Agriculture Organization (FAO). Since then, the Joint Meeting of Pesticide Residues in Food (JMPR) has evaluated a large number of pesticides. The main objectives of the WHO Expert Group on Pesticide Residues (the WHO component of JMPR) are consistent with those of the International Programme on Chemical Safety and include the formulation of guiding principles for exposure limits such as acceptable daily intake (ADI) for pesticide residues in food. Tolerances for these substances in air, water, soil, and the working environment are recommended by other WHO expert groups. (*See* **World Health Organization**.)

Although the requirements for toxicological data needed for health-risk assessment vary considerably from country to country, they comprise short- and long-term toxicity studies in several species of experimental animals, data on absorption, distribution, metabolism and excretion of a pesticide, carcinogenicity, reproduction, and genotoxicity, and other special studies for particular classes of compounds.

Evaluation of data is an extremely complicated process, and results are not always equivocal. This is particularly so because extrapolation of animal data to humans is mainly based on the introduction of a safety factor and, when possible, on pharmacokinetic extrapolation. Whenever applicable, observations on humans following occupational and/or accidental exposure are incorporated within the health-risk evaluation process.

Biological Activity of Pesticides

The inherent toxicity of a pesticide to humans is the same regardless of its use, either in agriculture or

vector control activities, or when it is consumed as a residue in food. The difference in untoward effect might occur as a result of the differences in the route and extent of exposure; these influence the dose absorbed, which is most decisive in producing an ill effect.

Of more than 800 chemicals used as pesticides, over 100 have become obsolete or their use has been discontinued because of inefficacy or an unacceptably high risk to human health and to the environment.

Pesticides are, by nature, toxic to some degree to several forms of life, including mammals. However, some of them are such potent toxins that they are considered to be extremely hazardous chemicals. Like other biologically active substances, the active material of a pesticide has to come into contact with its target (such as a cell or an enzyme) in sufficient concentration before it can exert an effect. Therefore, the physical characteristics of the active material, its penetration ability, stability, distribution, persistence, and degradation in the body, etc., considerably influence the likelihood of appearance of untoward effects in humans. These characteristics vary considerably not only from one pesticide to another but also among various preparations of the same active material.

Diversity of chemical structures among pesticides leads to the diversity of the biological effects produced both in pests and in humans; only some of these are sufficiently well understood, and these groups will be described briefly. Several examples of various classes of pesticides are listed in Table 2.

Anticholinesterases

Anticholinesterases are frequently powerful poisons for both insects and mammals. Some of these compounds are too toxic to be used as pesticides (e.g., war gases), while others may have beneficial effects and are used as drugs in clinical practice.

The primary effects of anticholinesterase insecticides, both in insects and in humans, are attributable – entirely or in part – to the inhibition of an enzyme, acetylcholinesterase, in nervous tissue, which leads to the accumulation of acetylcholine, an important chemical transmitter of nerve impulses. If this happens, complex nervous system functions no longer behave normally, causing disturbances in glands, muscles, and parts of the brain.

There are two main groups of anticholinesterase insecticides: organophosphorus compounds (esters, amides or thiol derivatives of phosphoric, phosphonic, phosphorothioic, or phosphonothioic acids) and monomethyl carbamates (methyl N-substituted esters of carbamic acid).

Organophosphorus compounds can be grouped into two categories: those which can act on cholinesterases directly without being modified, and those which first have to be transformed in the body and are therefore called indirect inhibitors. This difference has great importance in the assessment of the hazard. After overexposure to direct inhibitors, signs and symptoms usually appear fairly quickly. Indirect inhibitors produce a more delayed and prolonged action, and when symptoms appear, although exposure might have ceased, they may develop further to cause a critical illness.

Monomethyl carbamate insecticides are all direct inhibitors of cholinesterases. As a rule, they are readily absorbed from the gut, rapidly metabolized, and rapidly excreted. The inhibition of the enzyme by carbamates is very short, rarely exceeding several hours. Therefore, the symptoms of carbamate poisoning, although they may be of rapid onset and severe, are shorter in duration than after poisoning with organophosphorus compounds.

Chlorinated Hydrocarbons

Organochlorine pesticides are more persistent in the environment than most other synthetic organic pesticides. For this reason, and because some insects have developed resistance to this class of compounds, their use is steadily decreasing. They are efficiently absorbed by the gastrointestinal tract, but some of them are also readily absorbed through intact skin.

Although the mechanism of action is not yet fully understood, the major toxic action of this group of chemicals is on the nervous system, both central and peripheral. They act by altering the electrophysiological properties of the cell membranes (particularly nerve axons) disturbing sodium and potassium ion exchange through the membrane. As this is a reversible process, organochlorine insecticides, which vary considerably in toxicity, have little or no obvious effect when dosages are small, even if exposure to them is of a very long duration. It should be borne in mind, however, that many of these insecticides or their degradation products are soluble in fat and can be stored in the body fat, where they remain apparently without effect if not mobilized.

However, their persistence, both in humans and in the environment, has caused public concern, since, in certain situations, they may pose health and environmental problems. In view of the extreme range of toxicities within the group, it is impossible to generalize further. This is particularly so because organochlorine compounds differ considerably in their stability in the environment in different climatic conditions.

Table 2 Examples of some chemical classes of pesticides

Chemical class of compounds	*ISO name*	*Structural formula*	*Primary use*	*Mode of action in mammals*	*Acute oral toxicity for rats (LD50; mg kg^{-1})*	*WHO classification by hazard*
Organo-phosphorus	Parathion		Insecticide	Inhibition of cholinesterases	13	Extremely hazardous
	Dichlorvos		Insecticide	Inhibition of cholinesterases	56	Highly hazardous
	Malathion		Insecticide	Inhibition of cholinesterases	2100	Slightly hazardous
Monomethyl-carbamates	Aldicarb		Insecticide	Inhibition of cholinesterases	1	Extremely hazardous
	Propoxur		Insecticide	Inhibition of cholinesterases	95	Moderately hazardous
Chlorinated hydrocarbons	Dieldrin		Insecticide	Disturbance of sodium (Na^+) and potassium (K^+) ion transport in nervous membranes	37	Highly hazardous

Continued

	DDT		Insecticide	Disturbance of Na^+ and K^+ transport in nervous membranes	113	Moderately hazardous
Pyrethroids	Permethrin		Insecticide	Disturbance of Na^+ and K^+ transport in nervous membranes	500	Moderately hazardous
	Deltamethrin		Insecticide	Disturbance of Na^+ and K^+ transport in nervous membranes	135	Moderately hazardous
Substituted phenols	Dinoseb		Herbicide	Electron transport inhibition	58	Highly hazardous
	DNOC		Insecticide	Electron transport inhibition	25	Highly hazardous
Bipyridinium compounds	Paraquat		Herbicide	Excessive production of superoxide	150	Moderately hazardous

Continued

Triazines	Atrazine		Herbicide	Nonspecific (irritant)	2000	Slightly hazardous
Chlorophenoxy	2, 4-D		Herbicide	Nonspecific	375	Moderately hazardous
Dithio-carbamates	Maneb		Fungicide	Nonspecific (irritant)	6750	Slightly hazardous
Coumarins	Brodifacoum		Rodenticide	Reduction of clotting power of the blood	0.3	Extremely hazardous

Pyrethrins and Pyrethroids

Pyrethrum is one of the oldest natural insecticides in use in the world today, and it has one of the best safety records of all insecticides. It is a mixture of several esters, called pyrethrins, which are extracted from flowers belonging to the genus *Chrysanthemum*. Natural pyrethrins are unstable to light and are therefore unsuitable for residual application, particularly in agriculture. This led to the development of several classes of related synthetic compounds which have a higher stability to light and a high insecticidal activity. They are known as pyrethroids. In general, pyrethroids can be toxicologically divided into two classes on the basis of signs of toxicity: those causing mainly tremor and prostration (T syndrome) and those causing choreoathetosis and salivation (CS syndrome).

For both groups, the main biological activity is mediated through the effect on sodium channels along the axon membrane of the nerves, in both insects and mammals. The effect on the sodium-exchange disturbance is fully reversible, the duration of which is different for the two classes of pyrethroids: compounds belonging to the group causing the T syndrome produce a considerably shorter effect on the sodium 'gate' openings than those belonging to the CS group.

Being highly lipophilic, pyrethroids readily pass through cell membranes and are absorbed into the body by all routes following exposure. However, the ratio of the toxic dose by the oral route to that of intravenous injection is very high; this is because of rapid detoxification, mainly by cleaving of the ester bond by esterases.

Present-day evidence indicates that doses of a pyrethroid likely to be encountered both in the workplace and through food consumption would not lead to any serious untoward effects, although reversible transient effects on the skin may be recorded and may be used as a warning response of inadvertent exposure.

Nitro- and Chlorophenols

Among dinitro compounds, the most toxic is dinitroorthocresol (DNOC), applied mostly as a winter wash for fruit trees. This and similar compounds are readily absorbed not only through the lungs and gastrointestinal tract but also through intact skin. Since DNOC is eliminated more quickly from laboratory animals than from humans, animal experiments are of limited value for the assessment of hazard. These compounds are strong metabolic stimulators, exerting a common biochemical action which affects energy at the cellular level, stimulating end metabolic processes independently of their physiological stimulator, which is the thyroid gland.

The major effects observed with excessive overexposure to these chemicals indicate a general effect on the nervous system. As the liver and kidney accumulate high concentrations of nitro- and chlorophenols, they are often also adversely affected. The major mode of action in the acute toxic effects involves uncoupling of the energy conservation process.

In animals and humans, increased basic metabolism leads to hyperpyrexia, tachycardia, hyperventilation, dehydration, and, ultimately, depletion of carbohydrate and fat stores. In the case of a single large exposure, symptoms develop rapidly, and if death occurs, it will probably take place within 24–48 h with characteristically fast rigor mortis. A high environmental temperature might aggravate the hazards from exposure. In nonfatal cases, recovery is complete, but the skin remains stained yellow for a long period of time.

Bipyridinium Compounds

The best-known representative of this class of compounds is paraquat, a widely used herbicide of moderate acute toxicity. However, paraquat deserves special attention as it produces striking lung injury in many species regardless of its route of entrance, most probably because it accumulates in lung tissue in both experimental animals and humans.

Both its herbicidal and toxicological properties are caused by the ability of the parent cation to undergo a single electron addition, forming a free radical which reacts with molecular oxygen, producing a superoxide anion. The oxygen radical damages the cell, presumably through lipid peroxidation.

So far, a large number of paraquat poisonings have been reported, the majority being accidental or suicidal and very few resulting from occupational exposure. Acute fulminant poisoning may lead to death within a few days, and more protracted cases may last for several weeks, even months, resulting in fatal, irreversible pulmonary fibrosis.

The response to treatment of paraquat poisoning, even if started soon after the accident, is not very promising, and the mortality rate remains high.

Anticoagulants

Pesticides with hemorrhagic effects are widely used as rodenticides, exerting their action by disturbing the blood clotting mechanism through inhibition of synthesis of vitamin-K-dependent factors and by decreasing prothrombin production. Some have also been used as drugs in human medicine.

As the desired harmful effect in rodents is achieved only following repeated ingestion of small amounts of these compounds, this reduces the hazard to man, and safety records are remarkable. The existence of a very effective antidote (vitamin K_1), needed in case of poisoning, makes these compounds even safer. Owing to the development of rodent resistance to many existing anticoagulants, there is a present-day trend to develop new rodenticides of a similar or entirely different mode of action.

Fumigants

Fumigants have little in common either in their chemical structure or in their mode of action. The only common characteristic is that all have a relatively high vapor pressure, and, as a rule, they are highly toxic to both pests and humans. Handling requires great skill, and strict safety rules must be followed, including the wearing of specific personal protective clothing (gas masks with specific cartridges). Many countries have therefore posed restrictions on the availability of these fumigants. To this group belong the frequently used hydrogen cyanide, phosphine, methyl bromide, chloropicrin, and some others. (*See* **Fumigants**.)

Miscellaneous Pesticides

Diversity of pesticide structure and biological activity does not allow any further meaningful grouping according to their mode of action. Therefore, several more common classes of pesticides, which do not belong to any of the above-mentioned groups, are outlined below.

Inorganic and organometal pesticides, in particular those containing arsenic, mercury, thallium, and fluorine, were extensively used in the past. Those insecticides containing some types of arsenical active material are considered today to be the only insecticides showing sufficient evidence for carcinogenicity in humans. Therefore, their use today is restricted worldwide or banned. However, numerous pesticides with active ingredients containing zinc, copper, tin or sulfur are still widely used and are considered to be irreplaceable in the control of many plant pests and diseases. As a rule, the toxicity of most of these is rather low, and the health hazard they pose is frequently outweighed by the benefit they bring. (*See* **Heavy Metal Toxicology**.)

Those *pesticides derived from plants* which are still in use are entirely unrelated chemically and toxicologically. They range in toxicity from practically harmless (such as pyrethrins) to highly hazardous (such as nicotine). Several groups of chemicals extracted from some tropical plants (Endod, Neem) are known to be biologically active against various pests, as learned by experience. However, the evidence of safety for humans and beneficial species is still lacking.

Insect growth regulators disturb the metamorphosis of insects by interfering with juvenile hormones needed for proper functioning of this process. Their action is slow and toxicity for humans negligible as the mode of action is specific to insects. Some are even recommended for use in drinking water for control of mosquito breeding sites.

Biopesticides (e.g., *Bacillus thuringiensis* H14) are very useful tools in pests control, both in agriculture and in public health, and have been in operational use for many years. However, research into the genetic manipulation of the bacteria has been intensified, particularly regarding the incorporation of the gene responsible for toxin production into other organisms. The safety aspects of these mutants should be studied carefully.

Health Hazard Arising from Pesticides

A terminological distinction should be made between *toxicity*, which is an innate capacity of a chemical to cause damage, and *hazard*, which is a qualitative term expressing the potential that a pesticide can harm health. Thus, the most toxic pesticides may be handled with little hazard if sensible and disciplined adherence to good practice become routine, and vice versa. Therefore, toxicity and hazard are not synonyms because hazard is a function of two other variables besides toxicity: the extent of contamination and duration of exposure. This can be expressed in the form of an equation:

$$\text{Hazard} = K_1 \text{ toxicity} \times K_2 \text{ contamination} \times K_3 \text{ time}$$

(K_1, K_2, and K_3 are selected measures for a given parameter, e.g., reciprocal value of LD50 (median lethal dose), amount of active ingredient and duration of work.) If any of the three variables on the right-hand side of the equation equals zero, the hazard is also zero.

The toxicity variable can never be zero (by the definition of a pesticide), but it can be acceptably low by selecting a pesticide of favorable mammalian toxicity versus insect toxicity. The toxicity of the active material also depends on the ability of the body to detoxify and/or excrete the active material. If these mechanisms fail, hazard from exposure to an insecticide is increased. Thus, disease of the liver or kidney – the two organs which are mainly responsible for metabolism and excretion of foreign compounds – place an individual in a higher risk group.

The magnitude of the hazard will also be reduced by a reduction in contamination when the pesticide is

applied by an experienced and well-trained operator who is properly equipped and properly protected. To exert a biological action, the active material must reach a sensitive tissue or organ, and it must therefore enter the body by some route. The speed of its action depends largely on the speed with which the active material reaches the blood system. Thus, exposure to volatile insecticides by the respiratory route produces an effect without much delay because the active material, which comes in through the alveolar system, is quickly absorbed into the blood circulation. Insecticide absorption is much influenced by the solvent. Regardless of the kind of compound, the speed of onset of signs of poisoning is faster if the dose is large and oral, and slower if the dose is small and dermal. There are three important routes of entry: oral (gastrointestinal), respiratory (inhalation), and dermal (through intact skin).

The longer the working time, the higher the risk, provided that the two other variables remain unchanged. It is therefore essential to limit the duration of exposure, depending upon the toxicity of the formulation used. It is preferable that work with pesticides be shared if more trained workers are available. In this way, total exposure is reduced and risk diminished.

Assessment of all of the parameters mentioned is essential for those concerned with the safe use of pesticides, as they are crucial in posing specific limitations of availability and use of a particular pesticide in agriculture, public health, or household use.

Diagnosis and Treatment of Pesticide Poisoning

In cases of acute poisoning, placing a correct diagnosis may be very difficult, even for the very experienced clinician, unless the illness is undoubtedly associated with recent exposure (occupational or accidental). This is particularly so because the signs and symptoms vary considerably both in intensity and sequence of appearance. Laboratory tests available are limited, and treatment should never be delayed pending the results of these tests.

Following excessive exposure to anticholinesterases (organophosphorus compounds or monomethyl carbamates), signs and symptoms develop very quickly, and these include nausea, headache, glandular hypersecretion (salivation, lacrimation), muscular weakness, vomiting, and cramplike abdominal pain with diarrhea. Blurred vision caused by an effect on the ciliary body is very indicative of poisoning. In severe cases of poisoning, paralysis of the diaphragm may occur, leading to respiratory depression, coma, and death.

Acute poisoning by chlorinated hydrocarbons is rare nowadays, unless they are swallowed accidentally or with suicidal intent. Signs and symptoms include apprehension and excitement, dizziness, hyperexcitability, disorientation, headache, and convulsions. In some instances, the onset of symptoms may be delayed, and remission of acute symptoms may occur in 1–3 days.

Clinical cases of poisoning with pyrethroids are extremely rare, and limited observations do not permit a detailed description of signs and symptoms in humans. However, from the studies on experimental animals and on the basis of the similarity in mode of action, one may expect similar signs and symptoms to those of organochlorine pesticides.

Acute poisoning with nitro- or chlorophenols resembles the signs and symptoms developed in a thyrotoxic crisis, with increased body temperature being the leading sign.

The peculiarity of paraquat poisoning is usually a delayed effect on the lungs with the development of fatal fibrosis. Without clear evidence of exposure, early diagnosis is virtually impossible.

As anticoagulants disturb clotting mechanisms, laboratory tests may help in clarifying obscure signs of bleeding in an otherwise healthy person.

The management of poisoning includes three essential procedures: (1) alleviation of life-threatening effects, (2) removal of nonabsorbed material, and (3) antidotal or supportive treatment. Any delay in the prompt institution of treatment can prove fatal. Rapid implementation of first-aid measures, removal of the source of contamination, and transport to a hospital, if indicated, may save life.

The sequence of procedures which should be strictly observed is as follows:

1. Check respiration, and make sure that the airway is clear.
2. Give artificial respiration if spontaneous breathing is inadequate.
3. Check the need for decontamination, and proceed if required.
4. Give antidote if available.
5. Collect evidence of exposure.
6. Transport to a medical care facility.

As a rule, emergency treatment starts in the field, continues during transport, and ends in a health center or in a hospital.

Emergency treatment in the field should be directed first towards alleviation of the life-threatening effects. All efforts should be made to maintain normal respiration, and a prerequisite for this is a clear airway.

In cases of serious poisoning with anticholinesterase insecticides, atropine is a drug of choice, to be

given a soon as possible. To save life, it must be given by injection. Oral application may mask the clinical picture and is not recommended.

As soon as the diagnosis of organophosphorus compound poisoning is made, a first injection of 2–4 mg of atropine sulfate should be given intramuscularly, or intravenously in very severe cases. The effects of intravenous atropine application begin within 3–4 min and are maximal about 8 min after injection. Overatropinization is not as dangerous as underatropinization. Persons with manifest peripheral symptoms should also be given 1–2 g of a soluble salt of pralidoxime. Patients poisoned with carbamates must not be given an oxime.

For intoxication with organochlorine compounds, there is no specific antidote. Treatment is aimed at controlling the symptoms, especially hyperactivity and, in some instances, convulsions. Artificial ventilation may be required. Anticonvulsant treatment with barbiturates, diazepam, or paraldehyde should be given in sufficient dosage to calm the patient and prevent convulsions.

The principal management of intoxication by conventional or second-generation anticoagulant rodenticides is administration of phytomenadione (vitamin K_1). In addition to vitamin K_1, a seriously ill patient should initially be given a transfusion of carefully matched whole blood (as little as 50 ml may be effective); transfusions may be repeated daily until the patient's prothrombin time has returned to normal. Prolonged observation of patients affected by second-generation anticoagulants (coumarin derivatives) is required because these compounds are metabolized slowly, and repeated therapy may be indicated.

For intoxication with paraquat, no antidotes currently exist, and management essentially relies upon (1) the use of adsorbents to prevent absorption from the gut and (2) the removal of absorbed paraquat from the body, although these are rarely effective in severe poisoning. One liter of a suspension of Fuller's earth (about $300\,g\,l^{-1}$) or bentonite (about $70\,g\,l^{-1}$) should be administered orally as soon as possible. Activated charcoal may be more effective in adsorbing paraquat and should be used if it is available. In an emergency, use of ordinary soil may be beneficial if these adsorbents are not available. Administration of oxygen is contraindicated in acute poisoning because paraquat is more toxic in the oxygenated lung, and the use of oxygen should be delayed for as long as possible.

If a number of patients are found to be exhibiting symptoms suggestive of poisoning by a pesticide (or other chemical) without a history of exposure, the possibility of the cause being gross contamination of a food item or of drinking water, and being unrelated to any chemical, should be considered.

Types, Uses, and Determination of Herbicides

A M Au, Department of Health Services, State of California – Health and Welfare Agency, Berkeley, CA, USA

Introduction

The major function of herbicides is to prevent or control weed growth in the field. Some herbicides are nonselective, that is, they kill a wide variety of

plants, both desirable and undesirable. Other herbicides are selective – they kill certain kinds of plants while permitting others to survive. Selectivity of herbicides enables a desired crop to grow and produce free of competition from weeds. This article focuses on the classification of herbicides based on mode of action, the methods of application, safety implications, specific examples of uses, stability in the environment, and the analysis of residues in foods.

Classification Based on Mode of Action

Herbicides can be classified in different ways: by chemical name, by chemical characteristics of the compound, by toxicity, or by mode of action. There are two major categories of herbicides classified by mode of action: contact herbicides and translocated herbicides.

Contact herbicides affect only the part of the plant that they touch. Absorption through foliage is minimal. The application, therefore, must be made in sufficient quantity to cover the foliage thoroughly. Examples of contact herbicides are diclofop, dinoseb, diquat, and paraquat. Certain contact herbicides, like diquat and paraquat, are deactivated by soil particles. They must be mixed with clear water and applied directly to the vegetation.

At the molecular level, not all contact herbicides act in the same manner. For example, diquat and paraquat generate phytotoxic free radicals that interfere with the lipid metabolism of the plant and lead to ultimate death, whereas diphenyl ether herbicides cause chlorosis and necrosis resulting from the inhibition of the photosynthetic process. The biochemical mechanism of action of organic arsenicals such as cacodylic acid is not known.

Unlike contact herbicides, systemic herbicides can be translocated to other parts of the plant. They alter the normal biological function of the plant by interfering with certain biochemical reactions. Thus, when applied to foliage or soil, they enter the plant and translocate to their site of action. Examples of translocated herbicides are atrazine, glyphosate 2,4-dichlorophenoxyacetic acid (2,4-D) and simazine. Systemic herbicides, like contact herbicides, also have diverse modes of action at the molecular level. Chlorinated aliphatic acid herbicides, such as trichloroacetic acid (TCA), modify protein structure, causing chlorosis and necrosis in plants. Amide herbicides (e.g., alachlor, metachlor) interfere with both protein and nucleic acid synthesis. Carbamates inhibit protein synthesis only. The phytotoxic activities of thiocarbamates and dithiocarbamates appear to stem from the ability of these compounds to inhibit lipid synthesis. Phenoxy herbicides (e.g., 2,4-D), on the other hand, apparently stimulate protein and RNA synthesis. These stimulations accelerate plant growth and, in turn, contribute to the death of the plants. Unlike the other translocated herbicides listed above, triazine herbicides block photosynthesis as the primary mode of action.

Methods of Application

Uniform and precise application of herbicides to the field is essential. Common herbicide carriers are liquid formulations containing emulsifiers. Since most herbicides are organic compounds that are not readily soluble in water, they are frequently distributed as dry granules.

Liquid herbicides are usually dispensed by sprayers. Large ground sprayers mounted on mobile units such as tractors can apply herbicide over areas as large as a hectare. Recirculating sprayers distribute the herbicide solution horizontally above the crop. Solution not lost in tall weeds is caught in a basin and pumped back to the spray tank for reuse. Most herbicides can be applied to foliage or to the soil by sprayers and granule applicators as broadcast treatments or bands.

There are three basic types of application methods for the distribution of either granular or liquid herbicides. These are ground-operated application, aerial application, and manual application. Most of the application devices can be adapted for use via ground-operated or aerial-operated methods, depending on the vehicle on which the device is mounted. Handheld sprayers, such as backpack sprayers or small plot sprayers, are examples of manual applicators.

Granular herbicide formulations can be applied by drop-type applicator, centrifuge spreaders or pneumatic systems. The drop-type applicator consists of rollers rotating over an orifice in the hopper. The flow of the herbicide granules is controlled via a metering mechanism. The maintenance of this type of applicator is cumbersome. In the centrifuge spreader system, herbicide granules are distributed into the field by two counterrotating disks. In the pneumatic system, the herbicide granules are kept in a hopper, and the flow of granules is controlled by a ground-driven fluted roller coupled to a low-volume, high-pressure airstream. The granules eventually reach the spreader nozzles via two flexible delivery chutes which provide the control necessary for the adjustment and positioning of the treatment.

Recently, because it appears to be cost-effective and environmentally beneficial, the wiper application method (first conducted in 1909 by Mahanay) was reintroduced as an application method for wipe-on herbicides. There are a wide variety of wiper applications, including the Rope-wick, carpet roller,

continuous belt, rotary wiper, and Rogueing glove application. The Rope-wick device is a rig consisting of a series of short, exposed nylon ropes, each end of which is connected to a reservoir of herbicide solution. The solution passes into the ropes by both capillary action and gravitational flow. As the applicator moves through the weed-infested field, the chemical on the soaked wicks is rubbed on to the tops of the tall weeds but not on to lower-growing crop. Spray drift is eliminated. The carpet roller, as the name suggests, is a tractor mounted with a nylon carpeted roller soaked with liquid herbicide through a delivery system from a herbicide reservoir. The design is such that herbicide will only be in contact with the tall weeds without contacting the desired crop. A continuous belt consists of a V-belt, with sponges glued on to it, passing through a herbicide-containing reservoir. An adjustable pressure wheel removes excess herbicide from the sponges prior to its application on to the weeds. This helps prevent herbicide from contacting the crop. A rotary wiper applicator consists of flexible arms that allows wiper rotation around stationary objects to avoid injury to tree trunks. A glove equipped with absorbent pads that has continuous loading of herbicide solution from a reservoir is known as the Rogueing glove application.

A relatively new way of applying herbicide is through a sprinkler system. Liquid herbicide is pumped into the system and sprayed in a manner similar to a water sprinkler system.

Aerial spraying, using small aircraft or helicopters, can cover a large field in a shorter time period. Sprayers similar to those used in the ground operation can be mounted on to the aircraft for application to large areas.

Considerable research has been conducted by chemical companies to devise controlled-release formulations, a technology which has been demonstrated to be safe and effective in the drug industry. The three controlled-release systems are: (1) the chemically bound system, in which the herbicide is bound to a polymer; (2) the microencapsulation system, where the herbicide is coated by a polymer; (3) the matrix encapsulation system, where the herbicide is dispersed within a polymer matrix. This technology renders safer herbicide handling, reduces environmental pollution, and enhances herbicide selectivity.

The treatment of seeds with herbicides is another area of research currently under investigation. Certain herbicides can be applied to certain crop seeds prior to planting. Once planted in the soil, the herbicide moves swiftly away from the seed to the surrounding area to inhibit weed growth. This approach is economical and convenient to use. It also has a lesser tendency to pollute the environment.

Safety Implications

Ideally, herbicides are chemicals designed to cause injury only to undesirable weeds. Due to the biological differences between plants and animals, herbicides have low acute toxicity towards humans. However, most chemicals tend to have more than one metabolic effect on different living organisms. It is such unexpected secondary or side-effects of chemicals that cause major concern. Before the approval for marketing of any herbicide by the government, chemical companies must conduct extensive studies on the effectiveness of new herbicides. In addition, studies on metabolic fate and toxicity to animal species and plants are conducted to insure that the herbicide is safe to be used in the field. The cost of these testing procedures is tremendous. The specific requirements for herbicide registration depend upon the law of the country in which they are used but, in general, herbicides may not be used without registration by some governmental agency that carries out extensive reviews of the studies and tests performed by the chemical companies. It is also the duty of the vendor to provide users with information about all precautions and safe handling procedures of the herbicide. Adherence to those instructions by users is of utmost importance for the avoidance of harmful exposure.

The health effects of herbicides and their environmental impacts have been a major concern of the public. The health and safety issues associated with herbicide use affect not only consumers, but also farmers, formulators, applicators, and field workers, as well as the users of home and garden products. Groundwater contamination by agricultural chemicals has been an issue worldwide and will continue to be important in the years to come. Restrictions on the use and banning of certain herbicides are on the rise. Development of biodegradable herbicides with low residue levels combined with improved delivery systems can help protect the environment.

Depending on the conditions, exposure to herbicides at a high concentration can be fatal. Precautions in handling herbicides should be strictly followed to avoid unnecessary exposure. Safety training of all personnel designated to handle herbicides is imperative, and refresher safety training should also be conducted periodically to keep personnel up-to-date on all safety issues.

Equipment for application should be inspected frequently to insure that it is functioning properly. Malfunctioning equipment should be repaired prior to usage. Emergency procedures covering spillage or accidental poisoning should be established and strictly followed. There should be health surveillance programs for workers to monitor and insure worker

well-being. Personal protective equipment and clothing should be checked for leaks periodically and should be kept clean. Good record-keeping of herbicide inventory and application is necessary to account for usage.

In order to avoid inhalation of herbicides during application, workers should wear respirators. There are many different kinds of respirators, namely the chemical cartridge respirators, powered air-purifying respirators, canister respirators, supplied-air respirators, and self-contained breathing apparatus. There are also certain herbicides that can be absorbed by the skin; users should handle these with due caution and should wear appropriate protective clothing, including face shields.

Care should be given in the storage and transport of herbicides to minimize spillage. In case spillage occurs, proper decontamination should be performed immediately. Maintenance of all equipment for dispensing herbicides should be done routinely. Warnings should be given in advance to alert others of possible herbicide drift during application, and warning signs and restricted-entry signs should be posted to prevent others from entering the treated areas.

Specific Examples of Uses

Weeds are usually defined as undesirable plants. Weeds are often the primary concern of farmers, because they cover many millions of productive acres that could be used to grow beneficial crops. In the past, farmers controlled weeds by manually removing them from the crops. The ancient Romans killed weeds with salt. With farms of small size, manual weed control, such as hand hoeing and pulling, mowing, burning, and machine tillage, is feasible. However, with large farms such labor is extensive and costly. As the size of the farms increased and synthetic herbicides were introduced, farmers began to rely on herbicides to control weeds.

Generally, there are three different types of treatment for the application of herbicides. They are preplanting, preemergence, and postemergence treatments. Preplanting treatment takes place prior to planting; preemergence treatment is done after planting but preceding the crop or weed emergence; and postemergence treatment is performed after the emergence of the crop or weeds.

2-4-Dichlorophenoxyacetic acid (2,4-D) was one of the first synthetic herbicides introduced to control broad-leafed weeds in cereal crops and pastures. 2,4-D is an effective systemic herbicide and is selective for broad-leafed plants but not grasses. It can be used as either a pre- or a postemergence herbicide for corn, but only as postemergence for sorghum. 2,4-D is highly versatile and is used on a variety of crops such as wheat, barley, oats, rice, and sorghum. During the Vietnam war, Agent Orange, a 50: 50 mixture of 2,4-D and 2-4-5-Trichlorophenoxyacetic acid (2,4,5-T), was used extensively over the terrain in Vietnam as a defoliant to clear the way for US troops. 2,4,5-T is usually contaminated with dioxin, a highly toxic chemical compound and known carcinogen. It is due to this notorious contaminant that Agent Orange has been blamed for various illnesses and reproductive problems among those who came in contact with the defoliant in Vietnam.

Paraquat is used as a preemergence treatment for sugar beet. Simazine, on the other hand, is used both as a preplant and as a preemergence treatment for corn. *S*-ethyl dipropylthiocarbamate (EPTC) is incorporated into the soil as a preplant treatment for potatoes.

Herbicides have made it possible to grow more food on less land with less labor and at lower cost. Herbicides are also used to control aquatic weeds which impede water flow in irrigation canals and drainage systems, interfere with fishing, or promote insect-breeding grounds.

Stability in the Environment

For herbicides to exert their effects on weeds, they must be relatively stable in the treated environment. However, the stability of the chemical creates a burden on the environment, especially for those herbicides that find their way into aquifers and contaminate drinking water sources or remain on the crops at the time they reach consumers. In order to insure that the newer generation of herbicides do not linger on after accomplishing their task, research is directed towards synthesizing biodegradable compounds. The ideal herbicide is one that degrades to harmless chemicals after it performs its function and therefore does not persist in nature. Carbamates are one such class of chemicals specifically designed with that goal in mind.

Analysis of Residues in Foods

There is increasing awareness among consumers of the hazard of chemical contamination of food and drinking water. There is particular concern over the implications of food contamination by herbicide residues. Analysis for herbicide residues in food requires methods that identify not only parent structures, but also their metabolites and degradation products in a variety of food matrices. Certain food crops are perishable and therefore cannot wait for lengthy analysis to establish the suitability for consumption. Thus, rapid analytical technology is needed. Multiresidue

methods, which can detect the presence of many herbicides at once, are the methods of choice for determining the presence of a multiple number of herbicides and their degradation products in a food sample.

An analytical process consists of several major steps: the sample preparation, the extraction, the clean-up, the determinations, and the confirmation. These steps are common to the determination of other agrochemical residues, including pesticides, and are discussed in detail in the following article. The basic operation of sample preparation is to separate physically food or plant parts and to chop and blend them. The essence of the extraction process is to remove the target herbicide from the other components in the sample matrix. The main function of the clean-up procedure is to remove interfering constituents, usually by selective partitioning into organic solvents followed by an adsorption or size exclusion chromatographic purification step. The determination step includes separation of the purified samples through thin-layer chromatography, gas chromatography, or liquid chromatography techniques followed by the detection procedure using a variety of specific detectors for the targeted compound. For confirmation purposes, the analyte is further subjected to mass spectrometric analysis. Recently, successful attempts have been made in using gas chromatography–mass spectroscopy (GCMS) as a primary screening method. The GCMS screening technique provides simultaneous results for both the detection and the confirmation of the targeted compound in the sample matrix. This one-step procedure will be the method of choice as it offers both rapid and definitive data. (*See* **Chromatography**: Thin-layer Chromatography; Gas Chromatography; **Mass Spectrometry**: Principles and Instrumentation.)

Improvements to existing analytical technology are well underway to reduce the time- and solvent-consuming extraction and clean-up steps. Supercritical fluid extraction, which is based on the solvent properties of gases such as carbon dioxide at its critical pressure and temperature, can selectively remove the targeted compound from the complex food matrix in a short time. Through such approaches the recovery of the compound can be easily accomplished.

The use of antibodies as analytical tools is a common practice in clinical laboratories. Antibodies have been recently developed for identifying and quantifying herbicides. Antibodies can be isolated from the plasma of an immune-challenged animal or from a hybridoma cell line. An antibody that is specifically generated from a compound will have high selectivity towards that compound even in the midst of other interfering components and can bind to it tightly to form a complex. Therefore, by attaching a tracer to the antibody molecule, one can quantify the amount of antibody complex present, which is also an indication of the amount of the compound in the sample. A variety of tracers are available, for example radioisotopes, fluorescent molecules, and so forth. One of the disadvantages of the immunoassay is that the length of time to generate the specific antibody is relatively long. Typically, it takes approximately a year to develop. However, once it is generated, the immunoassay can be performed in less than half an hour. The triazine immunoassay is now available commercially, and, like most immunoassays, it is specific, sensitive, rapid, and cost-effective. (*See* **Immunoassays**: Principles.)

One of the modes of action of herbicides is by inhibiting photosynthesis. The Hill reaction is one of the processes in the photosynthetic pathway; therefore, a screening technique based on the inhibition of the Hill reaction can be a useful tool in detecting herbicides like triazines and carbamates.

Residue Determination

S Nawaz, Central Science Laboratory, Sand Hutton, York, UK

Background

Continued population growth has led to an increased demand on the world's natural resources. Pesticides are widely used to help increase the yield and improve

the quality of crops. Pesticides are categorized according to their mode of action and include insecticides, herbicides, fungicides, acaricides, nematicides, and rodenticides. Pesticides are also used as plant growth regulators and for public-health purposes. Global sales of pesticides during 1996 were estimated at over US$30 billion. Herbicides, insecticides, and fungicides accounted for 48, 28, and 18%, respectively, of the total sales (see Table 1). There are over 900 chemicals registered for plant protection purposes in the European Union (EU) alone. In addition to the existing pesticides, there are an ever increasing number of new chemicals being granted approval.

As pesticide use can leave undesirable residues, various national and international authorities regulate the use of pesticides and set maximum residue levels (MRLs) in crops. An MRL is the maximum concentration of a pesticide and/or its toxic metabolites legally permitted in food commodities and animal feeds. If pesticides are properly applied at the recommended rates, and crops are only harvested after the appropriate time intervals have elapsed, residue levels are not expected to exceed MRLs. The residue levels in foods derived from commodities that comply with the respective MRLs are also intended to be toxicologically acceptable. In the EU, the regulation of the agrochemical industry, and the setting of MRLs is currently being harmonized across all member states by the EC. In the USA, the Environmental Protection Agency is responsible for such regulation. The Codex Alimentarius Commission (FAO/WHO) has published tables of MRLs which have official status across the world and are used to aid international trade. The monitoring of the residues in foods is often at the microgram per kilogram level or lower and has to be supported by strict analytical quality-control standards, so that the analysis produces unequivocal, precise, and accurate residue data. Before samples are analyzed, the analyst has to demonstrate that the intended analytical method can achieve adequate specificity, sensitivity, linearity, accuracy, and precision at the relevant analyte concentration and in appropriate matrices. The calibration solutions must be prepared using certified reference standards. Residue analyses normally include the metabolites, isomers, and other related compounds included in the MRL definition. Many methods can determine a large number of residues in a single analytical run; these multiresidue methods are in common use and help reduce the total cost of analysis.

Sampling

A representative sample consists of a large number of randomly collected units. It is not always possible to collect large samples because of the cost of transportation and the practicalities of sample handling in the laboratory. Monitoring of pesticide residues for MRL compliance involves analysis of a composite sample, made up of a number of individual units. Recent research has shown that pesticide residues in individual units of fruit and vegetables can exhibit an extremely skewed distribution, and this is likely to add to the difficulty of taking a representative sample. The guidelines for obtaining composite samples for MRL compliance monitoring are published by the Codex Alimentarius Commission and are summarized in Table 2. In addition to checking for MRL compliance, residue analyses are also carried out to investigate other issues such as cases of misuse or the deliberate poisoning of wildlife or domestic animals. In such instances, a more targeted sampling regime may be adopted, and a qualitative analysis may suffice.

Sample Preparation/Subsampling

Samples should be analyzed without any delay, as some pesticide residues may degrade rapidly. If

Table 1 Major classes of chemicals used as pesticides

Type of chemical	*Examples and their primary uses*
Benzimidazole	Benomyl (F), carbendazim (F), thiabendazole (F)
Bipyridylium	Diquat (H), paraquat (H),
Carbamate	Aldicarb (I, N), carbaryl (I), carbofuran (A, I, N)
Dithiocarbamates	Mancozeb (F), ziram (H), thiram (H)
Organochlorine	DDT (I), lindane (I), endosulfan (I)
Organophosphorus	Chlorpyrifos, malathion (I, A), parathion (I)
Pyrethroids	Permethrin (I), cyfluthrin (I)
Substituted phenyl ureas	Diuron, linuron, monolinuron (H)
Triazine	Atrazine (H), simazine (H)

A, acaricide; F, fungicide; H, herbicide; I, insecticide; N, nematicide.

Table 2 Codex guidelines for collection of representative samples

Sample type	*Minimum weight of sample (kg)*
Small or light products (e.g., berries, peas, spinach)	1
Medium sized products (e.g., apples, carrots, potatoes)	1 (at least 10 units)
Large size products (e.g., melons)	2 (at least 10 units)
Dairy products (e.g., cheese, butter)	0.5
Meat, poultry, fish	1
Oils and fats	0.5
Cereals and cereal products	1

immediate analysis is not possible, storage of samples at −20 °C may help minimize the degradation process. Typically, a 20–50-g portion (subsample) is required for analysis. In order to obtain representative subsamples, it may be necessary to grind/mill and thoroughly mix the whole sample, so that any residues present are evenly distributed. This process is especially important because residue levels can exhibit a high degree of variability between individual units. Some pesticides are known to degrade during the processing of fruit and vegetable samples at ambient temperature. Milling frozen food samples in the presence of excess solid CO_2 (dry ice) has been shown to minimize the losses of most pesticide residues during the process.

Domestic mills (e.g., coffee grinder) as well as more specialized mills are used to grind samples of cereals, nuts, and pulses. Manual methods, such as cone and quarter or mechanized devices such as the riffle divider can be used to obtain representative subsamples from such samples. Samples of animal tissues are minced and mixed thoroughly before subsampling. For pesticides (e.g., organochlorines) that accumulate in the fatty tissue of animals, visible layers of fat may be removed for direct analysis. Preparation of homogenous fruit and vegetable samples prior to subsampling may be carried out using domestic food processors and blenders. However, larger specialized mechanical bowl choppers are more suitable for large samples, and heavy-duty choppers may be required to process frozen samples.

Extraction

The extraction step involves the quantitative transfer of pesticide residues from the food matrix into solvent(s). The efficiency of extraction process depends on the physicochemical properties of the solvent(s) and analytes. Important factors include pH, polarity, temperature, sample/solvent ratio, presence of water, and degree of analyte/matrix binding. Most extraction procedures employ organic solvents in the presence of water. The presence of water is critical for extraction of pesticides from cereals and cereal products, as it helps reduce the binding between residues and matrix. Samples of cereals, nuts, pulses, fruit, and vegetable samples are extracted by simple homogenization with an organic solvent. The most commonly used solvents include ethyl acetate, acetone, acetonitrile, hexane, methanol, and dichloromethane. For multiresidue extraction methods, it is not possible to establish the optimum extraction conditions for all residues with differing physical and chemical properties so the choice of solvent polarity is usually a compromise. Although the presence of water may aid the extraction process, most polar pesticides are partitioned into the water phase if the organic solvent used is not water-miscible. Addition of anhydrous sodium sulfate prior to extraction can overcome this problem. The analysis of nonpolar pesticides in fatty products involves extraction of fat using nonpolar solvents such as hexane, *n*-pentane, or light petroleum. After the evaporation of the solvent, the fat is redissolved in an organic solvent prior to the clean-up and determination steps.

Other methods used for residue extraction include soxhlet, where samples are exposed to solvent vapor that is condensed and vaporized repeatedly to exhaustively extract analyte(s). Supercritical fluid extraction (SFE) methods use a gas under high pressure and above the *critical* temperature to extract the residues. This technique is more widely used for samples with low moisture content (cereals) where sample/analyte binding is more common.

For residues that are not suited to multiresidue extraction methods, dedicated extraction methods may be used for single or small groups of closely related pesticides. These methods utilize physical and chemical properties of analyte and solvent to carry out selective extraction of the analyte from matrix. A number of pesticides are normally analyzed using single residue methods and include formetanate, fluazifop, 2,4-D, formetanate, propamocarb, and maleic hydrazide.

Clean-up

Sample extracts not only contain the target analyte(s) but may also contain coextractives, such as plant pigments, proteins and lipids. These coextractives may have to be removed prior to instrumental analysis to avoid possible contamination of instruments and to eliminate compounds that interfere during the determination step. To achieve low detection limits, sample extracts may also require a concentration step, which can be incorporated in the clean-up procedure. Clean-up procedures can lead to losses of residues and increases in the cost of analysis, and can reduce the sample throughput. Therefore, a number of methods utilize minimal clean-up and instead rely on the selectivity of the detector(s).

A number of analytical procedures employ liquid–liquid extraction for clean-up of sample extracts by selective partitioning of analytes between two immiscible solvents. This technique is commonly used during the analysis of fatty samples. Liquid–liquid extraction is not easy to automate and requires the use of large amounts of solvents. (*See* **Analysis of Food**.)

Adsorption chromatography is used in many residue laboratories for the clean-up of sample extracts. This process involves either:

- retention of analyte(s) on a chromatographic column while the coextractives are unretained: (the analyte(s) are then selectively eluted from adsorption medium); or
- retention of coextractives on a chromatographic column while the analyte(s) are unretained.

A number of materials are available for adsorption chromatography, including alumina, florisil, cellulose, diatomaceous earth (celite), carbon (charcoal, graphite), silver nitrate, and silica. Alumina and silica are effective for the clean-up of fatty samples for organochlorine (OC) pesticide residue analysis. Silver nitrate is used for the removal of sulfur-containing intreferences. Carbon has a high affinity for plant pigments and is particularly suitable for the clean-up of green leafy vegetable extracts with a high chlorophyl content.

Chemically modified silica sorbents are widely used for the clean-up of sample extracts. These materials are prepared by the reaction of silanol groups on silica surfaces with silane reagents to form esters containing required functional groups. These sorbents are used in cartridges, disks, membrane filters, and impregnated fiber tips. Some chemically modified silica and other sorbents used for clean-up of sample extract are given in Table 3.

Gel-permeation chromatography (GPC) or size-exclusion chromatography separates molecules on the basis of their molecular size. Large molecules (e.g., lipids, pigments, and polymeric coextractives) elute faster than smaller molecules such as pesticide residues. The reproducibility, suitability to automation, and compatibility with a wide range of pesticide/matrix combinations make GPC a popular clean-up method in many laboratories worldwide. The disadvantages of the technique include the use of large quantities of solvents, limited sample throughput, and incomplete separation of high-molecular-mass pesticides from coextractives. (*See* **Chromatography**: Principles.)

Table 3 Examples of sorbents used for clean-up of sample extracts

Nonpolar	*Polar*	*Ion exchange*
Octadecyl (C18)	Florisil	SCX benzenesulfonylpropyl
Octyl (C8)	Diol (2OH)	PRS sulfonylpropyl
Ethyl (C2)	NH_2 aminopropyl	Water's Oasis™ divinylbenzene: vinylpyrrolidione copolymer
Polypropylene	Silica	SAX trimethylaminopropyl

Chromatography and Determination

The final stage of the pesticide residue analysis procedures involves the chromatographic separation and instrumental determination. Where chromatographic properties of some pesticides are affected by sample matrix, calibration solutions should be prepared in sample matrix. The choice of instrument depends on the physiochemical properties of the pesticide(s) and the sensitivity required. As the majority of pesticides are relatively volatile, gas chromatography (GC) has proved to be an excellent technique for pesticide determination and is by far the most widely used. A typical chromatogram from a multiresidue method is shown in Figure 1. (*See* **Chromatography**: Gas Chromatography.)

Most residue methods employ splitless injection of 1–3 μl of the sample extract. Cold on-column injection is employed when the pesticides are likely to breakdown in a hot injection port. A wide range of GC column types are used for residue analysis, and the choice depends on the physicochemical properties of the analytes. Fused silica capillary columns are most widely used during analysis of pesticides (see Table 4). Typical capillary columns are 25–30 m long with an internal diameter range of 0.1–0.5 mm and a stationary phase of 0.1–10 μm thickness. Nonpolar stationary phases are used for the separation of nonpolar pesticide residues such as OC and pyrethroids. Similarly, more polar pesticide residues (e.g., methadimophos) are separated on relatively polar columns. The conventional semiselective detectors are widely used for residue analysis. Electron-capture detectors (ECDs) are utilized for halogenated pesticides (OCs and pyrethroids). Nitrogen phosphorus detectors are used for organophosphorus (OP) and nitrogen-containing pesticides. Flame-photometric detectors (FPDs) are used for OP and sulfur-containing pesticides, while atomic emission detectors can be used for a wide range of pesticides.

Gas chromatography–mass spectrometry (GC–MS) has been the predominant technique for the confirmation of pesticide residues in the past. Relatively inexpensive bench-top instruments have made the technique more widely available for routine screening in recent years. The resolving power of GC coupled with the specificity of mass spectroscopy provides the most effective means of pesticide residue analysis. A number of ionization techniques are available for GC–MS instruments and include electron impact (EI) and chemical ionization (CI). EI impact ionization

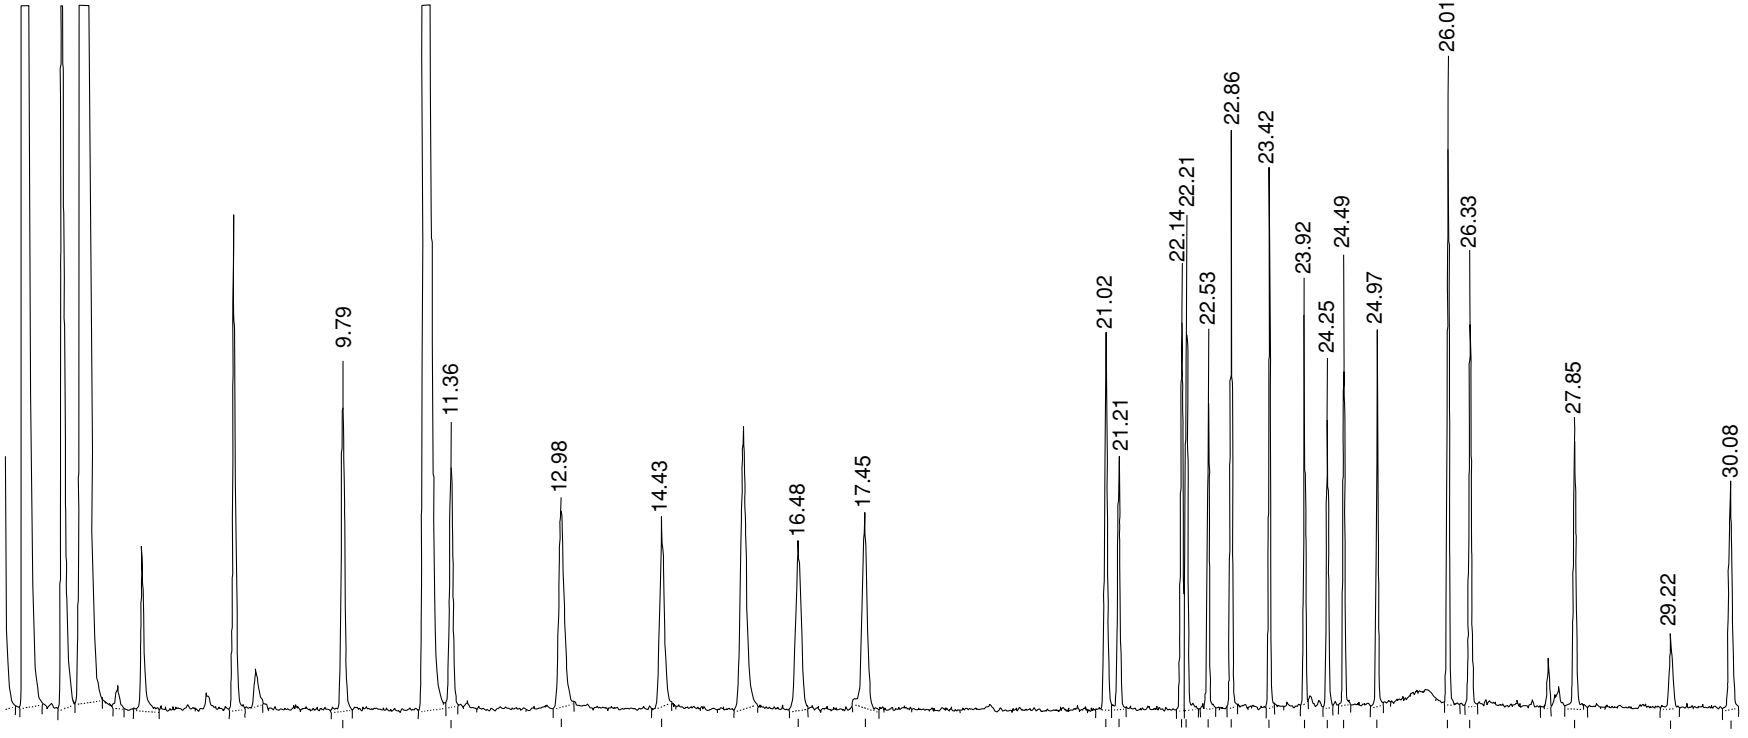

Figure 1 Chromatogram (GC–FPD) obtained from an injection of cauliflower matrix matched calibration solution containing 0.3 ng of each of following pesticides (and their retention times in minutes): heptenophos (9.79), ethoprophos (11.36), monocrotophos (12.98), dimethoate (14.43), fonofos (16.48), diazinon (17.45), parathion-methyl (21.02), malaoxon (21.21), fenitrothion (22.14), pirimiphos-methyl (22.21), malathion (22.53), parathion (22.86), pirimiphos-ethyl (23.42), mecarbam (23.92), methidathion (24.25), tetrachlorvinphos (24.49), profenofos (24.97), ethion (26.01), triazophos (26.33), pyridaphenthion (27.85), azinphos-methyl (29.22), and pyrazophos (30.08).

Table 4 GC stationary phases commonly used for pesticide analysis (listed in increasing order of polarity)

Stationary phase	*Typical uses*
100% methyl silicone (DB1)	Nonpolar pesticides
5% phenyl, 95% methyl silicone (DB-5)	Multiresidue screening
35% phenyl 65% methyl silicone (DB-35)	EPA method 608
50% phenyl 50% methyl silicone (DB-17)	Polar organophosphorus pesticides
14% cyanopropylphenyl 86% methyl silicone (DB1701)	Organochlorine pesticides
50% cyanopropylphenyl 50% methyl silicone (DB-225)	Polar pesticides
Poly(ethylene) glycol (DB-wax)	Polar pesticides

leads to a greater degree of fragmentation of molecules compared with CI. Hence, CI provides a greater sensitivity, but EI provides more spectral information. The detection systems most widely utilized in residues analysis are based on either the quadrupole or ion-trap principle. The quadrupole instruments have limited sensitivity in the scan mode compared with the ion-trap instruments. However, by operating in the selected ion mode, adequate sensitivity can be achieved on quadrupole detectors. A small quadrupole mass selective detector can typically detect over 100 pesticides in food extracts at the relatively high levels (typically 0.2 mg kg^{-1}) using full scan spectra, reducing to lower levels (typically 0.01 mg kg^{-1}) in the selected ion mode. The ion-trap detectors have a higher inherent sensitivity, and this allows screening of clean sample extracts for a wide range of pesticides at low levels (typically 0.05 mg kg^{-1}) in full scan mode. The major advantage of the ion-trap instruments is that the characteristic ions can be selected and then further fragmented to provide added specificity (MS–MS). (*See* **Chromatography**: Combined Chromatography and Mass Spectrometry.)

High-performance liquid chromatography (HPLC) is increasingly being used for the determination of pesticide residues, as it is especially suited to the analysis of nonvolatile, polar, and thermally labile residues that are difficult to analyze using GC. The resolution achieved on HPLC can be comparatively low, and therefore, the use of selective detection systems may be necessary for reliable residue analysis. Ultraviolet (UV) spectroscopy is the most common choice for detection of (OP) residues in environmental samples (e.g., soil, water). Although UV detection is not a very selective technique, it is commonly used for screening purposes due to its low cost, simplicity, and wide application range. Elimination of interferences and optimized chromatography are essential prior to detection in order to enhance the selectivity of UV-based methods. The use of diode array detectors can further enhance the selectivity of UV-detection procedures. Fluorescence detection offers a greater selectivity and sensitivity than UV. Pesticides with inherent fluorescence include dimethoate, ethoxyquin, azinphos methyl, phosalone, thiabendazole, and carbendazim. With the exception of thiabendazole and carbendazim, this technique is not widely used in pesticide residue analysis, as methods based on inherent fluorescence have a poor sensitivity compared with other methods available. Precolumn and postcolumn reaction systems can be employed with HPLC methods, which can help improve the chromatographic separation and detection of analytes. A number of pesticides (e.g., *N*-methyl carbamates, glyphosate, and phenylurea herbicides) are analyzed after derivatization to enable fluorescence detection. The electrochemical detectors are used for a number of pesticide residues (e.g., captan) in relatively clean samples.

The on-line combination of HPLC and mass spectroscopy (HPLC–MS) offers a high sensitivity and specificity, and its use in the field of pesticide residues analysis is growing. There are a number of ionization techniques used to interface HPLC with MS analyzers, of which the most widely used are electrospray and atmospheric pressure chemical ionization. The HPLC–MS methods use soft ionization techniques which typically produce protonated or deprotonated pseudomolecular ions. Therefore, the chromatographic data do not provide structural information except when the ions produced are subjected to successive fragmentation (MS^n). (*See* **Chromatography**: High-performance Liquid Chromatography.)

Derivatization

Some pesticide residues require derivitization to enhance the extractability, clean-up or subsequent chromatographic resolution and determination steps. For example, pesticides with hydroxy groups are not suited to GC analysis, and such an analysis may be possible only after derivatization to esters. Furthermore, esters of certain functional groups can enhance the detection process, e.g., pentafluorobenzyl derivatives produce a high response on the ECD.

Dithiocarbamate pesticides break down to carbon disulfide (CS_2) during analytical procedures. These residues are determined after treatment of samples with acidic tin (II) chloride. Any dithiocarbamate residues in the sample break down to produce CS_2 gas, which can be trapped in the reaction chamber. An aliquot of the gas (headspace) in the reaction chamber is analyzed for CS_2 using GC–FPD. Alternatively, the gas produced can be absorbed into a 2,2,4-trimethyl

pentane, and an aliquot of the liquid layer is then analyzed using GC. This approach is more robust and more amenable to GC–MS analysis compared with the headspace procedure.

Some pesticides containing sulfur may oxidize to form sulfoxide and sulfone derivatives before or during analysis. These products are also toxic and are included in the residue definition for the monitoring purposes. These residues are analyzed after complete conversion of the pesticide and its sulfoxide to the corresponding sulfone and thus enable combined measurement of the pesticide, its sulfoxide, and sulfone residues. The conversion step involves the treatment of sample extracts with potassium permanganate in the presence of 2-methyl propan-2-ol. The sulfone formed is then extracted into an organic solvent and analyzed by GC.

Other Techniques

Enzyme-linked immunosorbent assay (ELISA) methods are used for rapid screening of an individual or a group of closely related pesticides. These methods require little or no sample clean-up, require no expensive instrumentation, and are suitable for field use. ELISA methods are especially suitable for residue analyses that are not possible using multiresidue methods. ELISA kits are available for a number of pesticides, including 2,4-D, aldicarb, carbendazim, thiabendazole, chlopyrifos, diazinon, endosulfan, and metalaxyl.

Confirmation

For regulatory purposes, it is essential that pesticide residues be unequivocally confirmed using MS. However, if an MS method is not available, the sample extract is reanalyzed using a different chromatographic column and/or a different detection system to confirm the initial results.

Emerging Techniques

There are continued improvements in the design of instruments available for residue analysis. The use of GC injectors capable of injecting large volumes can enable determination at low levels. The use of fast GC, which utilizes an improved design for heating the columns, can enable faster chromatographic runs and thus enable quicker analysis. Improvements in GC instrumentation have enabled precise control over temperature and gas flow rate. The use of electronic pressure control devices can enable more reproducible chromatographic runs, thus improving the quality of data. These advances, coupled with more sophisticated software, can enable more reproducible chromatography, with a typical retention time variation of 0.01 s. Improvements in MS instruments will continue to enhance the selectivity of methods.

Toxicology

C K Winter, University of California Davis, CA, USA

Background

The use of agricultural chemicals, collectively known as pesticides, in the past several decades has led to significant reductions in crop losses resulting from insects, weeds, and plant diseases throughout the world. The toxicological properties that pesticides possess also present the potential for impacts upon human health and upon the environment. As an example, agricultural workers involved in the mixing, loading, and/or application of pesticides as well as those working in fields previously treated with pesticides face potential health risks resulting from excess exposure to the pesticides. Consumers are routinely exposed to pesticide residues in their foods, and the potential dietary risks from pesticide exposure have been the subject of considerable government study, regulation, and societal concern.

This review focuses upon the toxicology of the various types of pesticides used, how pesticide residues in foods are regulated, and the magnitude of potential risks faced by consumers from pesticide residues in the food supply.

Pesticides

Classification

The US Federal Insecticide, Fungicide, and Rodenticide Act defines a pesticide as 'any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest, any substance or mixture of substances intended for use as a plant regulator, defoliant, or desiccant, and any nitrogen stabilizer....' Under this broad definition, it is clear that a variety of pesticide types exist to control a wide number of different types of pests. A commonly held perception is that pesticides refer primarily to agricultural chemicals that control insects (insecticides). According to the US definition, however, pesticides also refer to chemicals that control plant diseases (fungicides) and weeds (herbicides) as well as a variety of other 'pests' (Table 1). For the purposes of consistency, all types of pesticides, including herbicides, will be considered under this broad umbrella in this article.

Pesticide Use

According to the US Environmental Protection Agency (EPA), approximately 2 billion kg of chemicals were used as pesticides in the USA in 1997. It should be noted that the majority of pesticide use was not for agricultural purposes. For example, 53% of pesticide use (by volume) involved chlorine or hypochlorites used for disinfection of potable and wastewater pools. 'Conventional' pesticides, defined as those developed or produced exclusively or primarily for use as pesticides, accounted for the remaining 47% of pesticide use by volume; 77% of this total was for agricultural uses, and 12% represented industry/government/commercial use, with the remaining 11% resulting from home and garden use.

Figure 1 shows the relative amounts of a variety of pesticide types used in US agriculture in 1997. Nearly half of the total volume of agricultural pesticide use came from herbicides and plant growth regulators (213 million kg), followed by sulfur/oils (65 million kg) and fumigants/nematicides (63 million kg). Agricultural insecticide use in 1997 was approximately 37 million kg, and 26 million kg of fungicides were used for agricultural purposes.

In terms of trends, total agricultural pesticide use, in terms of kg applied, has decreased slightly since 1979, with the largest drops in use representing insecticides, sulfur, and oils. The use of herbicides has been relatively steady.

Toxicity

Hundreds of different pesticide active ingredients are presently registered by the EPA, and nearly 300 pesticides are considered to have the ability to leave residues on food crops. Some of the more common classes of pesticides and some representative examples are given in Table 2. A comprehensive review of the toxicity of all pesticides is clearly beyond the scope of this article, and those interested in more specific and/or detailed pesticide toxicity information are encouraged to consult articles cited in the Further Reading section.

Table 1 Pesticide types and targets

Pesticide type	*Pest controlled*
Acaricide	Mites
Algacide	Algae
Bacteriocide	Bacteria
Defoliant	Leaves
Fungicide	Fungi
Herbicide	Weeds
Insecticide	Insects
Molluscicide	Snails
Nematicide	Nematodes
Rodenticide	Rodents

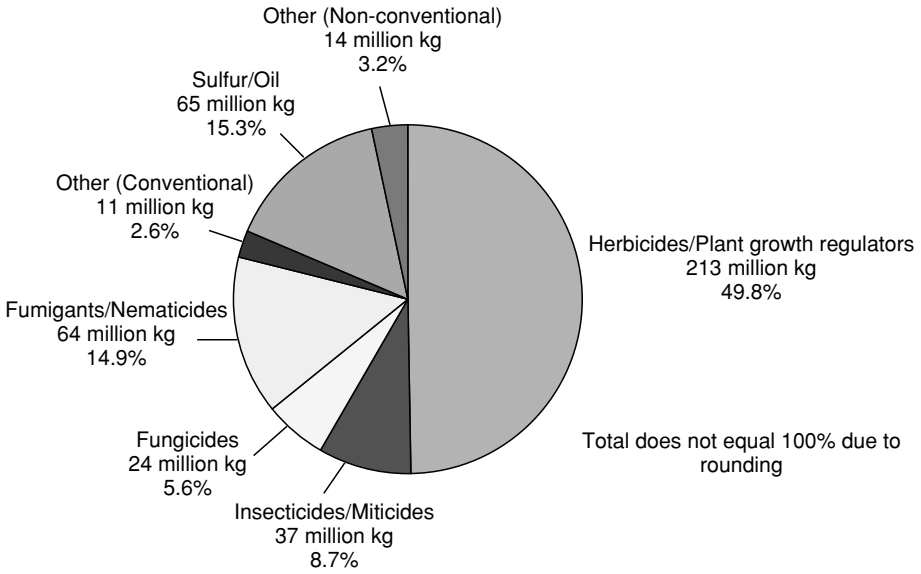

Figure 1 Agricultural use of pesticides in the USA, 1997.

Table 2 Common pesticide classes and representative examples

Pesticide	*Examples*
Insecticides	
Chlorinated hydrocarbons	Dicofol, methoxychlor, DDT, aldrin, chlordane
Organophosphates	Parathion, malathion, chlorpyrifos, azinphos-methyl
Carbamates	Aldicarb, carbaryl, carbofuran
Pyrethroids	Permethrin, cypermethrin
Herbicides	
Triazine	Atrazine, simazine, cyanazine
Phenoxy	2,4-D, 2,4,5-T, MCPA
Quaternary ammonium	Paraquat, diquat
Benzoic acids	Dicamba
Acetanilides	Alachlor, metolachlor
Ureas	Linuron
Fungicides	
Inorganic	Sulfur
Ethylenebisdithiocarbamates	Maneb, mancozeb, zineb
Chlorinated phenols	Pentachlorophenol

Insecticides Insecticides are represented by a variety of different chemical classes involving a variety of mechanisms of toxic action on insects as well as mammals such as humans. Examples of mechanisms of action include metabolic interference of the nervous or muscle systems, desiccation, and sterilization. Common types of insecticides include the chlorinated hydrocarbons, organophosphates, carbamates, and pyrethroids.

The first major synthetic class of insecticides, the chlorinated hydrocarbons, was developed during the 1930s and 1940s. Representative members of this insecticide class include DDT, aldrin, dieldrin, and chlordane. The chlorinated hydrocarbons are very potent nerve toxins to insects, and their initial use led to significant improvements in insect control. Their high insect potency, combined with generally low mammalian toxicity, provided excellent selectivity and insect control that was further enhanced by their high environmental persistence. In subsequent years, however, their resistance to environmental decay, coupled with their widespread continuing use, resulted in environmental build-up and food-chain magnification that resulted in significant environmental and ecological damage. Today, very few chlorinated hydrocarbon insecticides remain registered for use in the USA, because of environmental concerns, although their use may still be significant in many areas of the world. Many recent studies have also associated chlorinated hydrocarbon insecticides with potential adverse effects on human and nontarget organism fertility and reproduction arising from enzyme-inducing or estrogenic properties of the chemicals.

Historically, many of the uses of chlorinated hydrocarbon insecticides were replaced by the organophosphate and carbamate insecticides. In contrast to the chlorinated hydrocarbon insecticides, the organophosphates and carbamates break down quite rapidly in the environment following application. They also have a far greater acute toxicity in mammals. The organophosphates and carbamates are derived as esters of two very different chemical families but share a common mechanism of toxicological action

in both insects and mammals that involves inhibition of cholinesterase enzymes that can disrupt the nervous system.

A newer class of insecticides, the pyrethroids, are synthetic derivatives of pyrethrins (natural extracts from chrysanthemums) that are made to be more light-stable than their natural predecessors and thus more effective as insecticides. The pyrethroids were introduced in the 1970s and have broad-spectrum activity against many insects while possessing a much lower mammalian toxicity than the organophosphates or carbamates. The pyrethroids are frequently used in agricultural pest control, but their use is still limited by their environmental lability, relatively high cost, and their tendency to lose effectiveness through the development of insect resistance.

Herbicides Several different types of herbicides exist (Table 2), and each type has its own mechanism of toxic action on weeds. Since weeds and mammals differ dramatically in terms of metabolic function, herbicides targeting specific metabolic pathways in weeds frequently have little effect, and therefore a low relative toxicity, in mammals including humans.

The timing of herbicide application may determine significantly whether the potential exists for consumers to be exposed to herbicide residues in foods. Some herbicides (preplant herbicides) are applied before a crop is planted, whereas others (preemergent herbicides) are applied after planting but prior to the appearance of weeds, and others (postemergent herbicides) are used after the weeds have germinated. Some herbicides have broad-spectrum activity that makes them toxic to most types of plant life, including the crop being produced. One such example is glyphosate. Recent developments in genetic engineering have led to the development of varieties of soy, corn, and cotton that are resistant to glyphosate, meaning that glyphosate applications made while the crop is growing will control weeds without affecting the crop.

Other herbicides, such as the phenoxy herbicides (2,4-D, MCPA) are more selective in their toxicity; they are toxic to broad-leaf plants but not to narrow-leaf plants such as grasses. Some epidemiological studies have suggested links between agricultural worker exposure to phenoxy herbicides and certain types of cancer.

Fungicides A wide number of different types of fungicides are available for use in agriculture (Table 2). Fungicides control molds and other plant diseases by interfering with the growth and/or metabolic processes of fungal pests. In addition to improving crop yields, fungicides may provide human health benefits by reducing the production of mycotoxins (naturally occurring toxins produced by fungi living on the food crop) such as aflatoxins and fumonisins.

Pesticides suspected as carcinogens The potential carcinogenic (cancer-causing) effects of many pesticides have generated considerable public concern and regulatory scrutiny. Although the consumption of foods containing pesticide residues has not been correlated with the development of human cancers, some epidemiological studies have linked the occupational use of specific pesticides with the development of cancers. Most pesticides considered as carcinogens, however, owe their status as suspected carcinogens to the results of long-term animal toxicology studies in rodents such as rats and mice.

The carcinogenic potential of pesticides and other chemicals is typically determined through long-term animal bioassay studies. In these studies, animals are frequently given a high dose (the maximum tolerated dose, or MTD, that may cause considerable toxicity but does not reduce life expectancy), a lower dose (commonly one-half to one-fourth of the MTD), and a control (zero) dose. Relatively high doses of chemicals are given to the animals to maximize the potential to identify toxicological effects such as tumor production.

The amounts of pesticides that cause cancer in animal studies frequently exceed the amounts that humans are exposed to from the diet by several orders of magnitude. It has been argued that many pesticides considered to be carcinogens receive such classification because of the high doses used in the long-term animal studies and that the results of such studies may not be applicable to human exposure to much lower levels of the pesticides. As an example, it is well established that high-dose toxicity may lead to increased rates of cell proliferation that in itself is linked to the development of cancer in laboratory animals. Human exposure at lower levels of exposure would not be expected to trigger such a response and, as a result, would not be expected to lead to the development of cancer.

Long-term animal studies are also prone to inconclusive and/or contradictory results among different test animals and under different conditions. As a result, the EPA has developed a weight-of-the-evidence evaluation scheme based upon results of any human data and animal testing to determine the likelihood of a pesticide to be carcinogenic. A list of several pesticides considered by the EPA to be 'probable' carcinogens is provided in Table 3. Some pesticides may receive classification a 'possible' carcinogens, whereas many others are considered noncarcinogens.

Table 3 Some pesticides considered to be 'probable' carcinogens by the US Environmental Protection Agency

Pesticide	*Pesticide type*
Acetochlor	Herbicide
Aciflourfen sodium	Herbicide
Alachlor	Herbicide
Amitrol	Herbicide
Cacodylic acid	Herbicide
Chlorothalonil	Fungicide
Creosote	Wood preservative
Cyproconazole	Fungicide
Fenoxycarb	Insect growth regulator
Folpet	Fungicide
Heptachlor	Insecticide
Iprodione	Fungicide
Lactofen	Herbicide
Lindane	Insecticide
Mancozeb	Fungicide
Maneb	Fungicide
Metiram	Fungicide
Oxythioquinox	Insecticide
Pentachlorophenol	Fungicide
Pronamide	Herbicide
Propargite	Insecticide
Propoxur	Insecticide
Terrazole	Fungicide
Thiodicarb	Insecticide
TPTH	Fungicide
Vinclozolin	Fungicide

Regulating and Monitoring Pesticide Residues in Foods

The use of pesticides does not necessarily imply that food residues will occur. Many pesticides are applied to nonfood crops, whereas others such as broad-spectrum herbicides could damage or eliminate a crop if misapplied. The timing of the pesticide application is another important factor; many pesticides are applied to food crops prior to the development of edible portions of the crop, whereas other pesticides used on food crops may not result in residues, because of rapid environmental degradation between the time of application and the time of harvest.

Pesticide residue regulation In cases where the use of a pesticide on a food crop may present the potential to leave a residue in the USA, a maximum permitted allowable residue level, or tolerance, is established. Tolerances are specific to combinations of pesticides and commodities; it is possible for the same pesticide to have different tolerance levels established on different commodities, and several different pesticide tolerances for distinct pesticides may be established on the same commodity.

Although it may seem counterintuitive, pesticide tolerances are not based upon safety but rather represent the maximum expected residue of a pesticide on a particular commodity resulting from the legal use of a pesticide. The maximum levels are determined from the results of controlled field studies performed by the pesticide manufacturer using the 'worst legal case' conditions such as the maximum recommended application rate, maximum number of applications per growing season, and harvesting at the minimal anticipated time following harvest. Pesticide manufacturers typically petition the EPA to establish the tolerances at or slightly above the highest levels determined from the controlled field studies. As such, the values selected for tolerances are determined solely on the basis of agricultural practices but not as a result of human health risk assessments. Pesticide tolerances therefore should be considered to represent enforcement tools to determine whether pesticide applications may have been made in accordance to legal requirements; in cases where residues exceed the established tolerances, it is likely that such residues resulted from misapplication of the pesticides. Such a finding, however, rarely constitutes an 'unsafe' residue according to standard toxicological criteria. Pesticide tolerances, therefore, should be viewed as enforcement tools but not as standards of safety.

Before the EPA grants a tolerance, human health risk assessments are performed to determine the conditions for acceptable pesticide use. Such conditions include the listing of commodities on which a specific pesticide may be used, the target pests controlled by the pesticide, application requirements, and the acceptable interval between application and harvest. In the EPA's assessment of acceptable levels of consumer exposure to pesticides, it considers potential human exposure from all registered (and proposed) uses of the pesticide. If the resulting risk is deemed to be excessive, the EPA will not allow tolerances to be established for specific commodities. If the risks are considered to be acceptable, the tolerances are established, as discussed in the preceding paragraph.

The processes that the EPA uses to determine the acceptability of dietary pesticide risk are quite complicated and subject to ongoing evolution to meet the needs of new regulations, improved toxicology testing, and advances in computational methods.

The first step in evaluating the consumer risks from pesticide residues involves making estimates of the amount of consumer exposure. The maximum legal exposure to the pesticide is frequently calculated by assuming that (1) the pesticide is always used on all food items for which it is registered and/or proposed for registration, (2) all residues on the food items will be present at the established or proposed tolerance levels, and (3) there will be no reduction in residue levels resulting from postharvest effects such as washing, cooking, peeling, processing, and

transportation. This approach leads to the calculation of the theoretical maximum residue contribution (TMRC). Although studies have indicated that the TMRC values may overestimate the actual consumer exposures by factors of 100–100 000, the TMRC provides a starting point from which to estimate consumer risks.

In practice, the TMRC is compared with established toxicological criteria such as the reference dose (RfD) or the acceptable daily intake (ADI) that represent, following analysis of animal toxicology data and extrapolations to human health, the daily exposure levels that do not constitute an appreciable level of risk. In cases where the EPA determines that exposure to a pesticide at the TMRC is below the RfD or ADI, the risks for the pesticide are typically deemed to be negligible, and the EPA allows tolerances to be established for the pesticide on specific commodities. For pesticides that are considered as potential carcinogens, the EPA also requires that the quantitative carcinogenic risk to the pesticide be below one excess cancer per million using models that calculate possible human risks from low levels of exposures to potentially carcinogenic pesticides. Such models are developed from the results from long-term studies on animals given high doses of the pesticides. In cases where the exposures at the TMRC exceed the RfD or ADI, or in cases where the carcinogenic risks at the TMRC exceed one excess cancer per million, the EPA may adopt a refined risk assessment that more accurately expresses exposures. Such refinements may include adjustments of actual pesticide use, the use of more realistic pesticide residue data, and consideration of postharvest effects that may significantly reduce residue levels prior to consumption. In cases where the refined exposure estimates are below the RfD or ADI and where the carcinogenic risks at the refined exposure estimates are below one excess cancer per million, the EPA will typically allow tolerances to be established.

The processes by which the EPA determines human risks from pesticide exposure became more complicated following the passage and adoption of the Food Quality Protection Act (FQPA) of 1996. It is clear that the new requirements of FQPA will require scientists to develop improved methods for assessing risks to pesticides and that once such methods are adopted, the regulatory requirements may be much more stringent and may lead to reductions in the amounts and types of pesticides that may be used on food crops.

Prior to FQPA, the EPA allowed tolerances to be established on a chemical-by-chemical basis and considered only exposures resulting from dietary pathways. FQPA now requires the EPA to establish tolerances only when the risks posed by pesticides represent a 'reasonable certainty of no harm.' In determining what constitutes this 'reasonable certainty of no harm,' the EPA must now consider the *aggregate* exposure to pesticides from dietary, drinking water, and residential sources as well as the *cumulative* exposure from pesticides possessing a common mechanism of toxic action. As such, the EPA may consider the risks from entire families of chemicals rather than the risks from individual chemicals. Another important provision of FQPA is the so-called $10 \times factor$, which requires the EPA to consider applying an additional 10-fold uncertainty factor in cases where infants or children may be more susceptible to the toxicological effects of pesticides than adults. The application of the full $10 \times factor$ would result in a subsequent reduction in the RfD by a factor of 10.

Internationally, many countries adopt the Codex Alimentarius maximum residue limits (MRLs), which, like the US tolerances, exist primarily as enforcement tools to determine if pesticide applications are made following good agricultural practices. Although many US tolerances and Codex Alimentarius MRLs are identical, there are many cases in which the US tolerances are more restrictive and many others in which the Codex Alimentarius MRLs are more restrictive.

Pesticide residue monitoring *Authority* In the US, the Food and Drug Administration (FDA) has the primary responsibility for enforcing tolerances in domestic and imported foods. Domestic food samples are frequently collected near the source of production or at the wholesale level, whereas imported food samples are typically taken at the point of entry into the US. The types and quantities of samples taken by FDA are determined by a variety of factors such as regional intelligence on pesticide use, the dietary importance of specific foods, information on the amount of foods that enter interstate commerce, and pesticide use patterns. Samples are analyzed using multiresidue methods capable of detecting over 200 individual pesticides.

The US Department of Agriculture (USDA) also has a role in pesticide residue monitoring, as it is responsible for the monitoring of meat, poultry, and egg products. It also conducts the Pesticide Data Program (PDP), which collects residue data on fruits, vegetables, and processed foods. Findings from the USDA's PDP are considered to be more representative of the actual food supply than those collected from the FDA's regulatory monitoring programs and are commonly used by EPA to aid in its risk-assessment efforts.

US monitoring of pesticide residues also occurs at the state level. The largest state pesticide regulatory and monitoring program exists in California, and

several other states, including Texas and Florida, have significant pesticide-monitoring programs.

Residue findings The most recent FDA pesticide monitoring residue data are available for 1999. During that year, FDA analyzed 9438 food samples for pesticide residues. More samples were taken from imported foods (6012 samples, or 63.7%) than from domestic foods (3426 samples or 36.3%).

The results of FDA's 1999 monitoring of pesticide residues in imported foods are shown in Figure 2. Overall, 65.0% of the samples showed no detected residues, and violations were identified in 3.1% of the samples. Figure 3 shows the comparable results from domestic foods where 60.2% of the samples showed no detectable residues, and violations were present in 0.8% of the samples.

Pesticide residue violations commonly take one of two forms. The most common form of a violative residue results when residues of a pesticide are detected on a commodity for which no tolerance has been established. This type of violation may result from application of the pesticide to the wrong commodity, uptake from soil contaminated from a prior use of the pesticide on a different commodity, or drift of a pesticide from an adjacent field. The other type of violation results when residue levels are detected in excess of the established tolerance. In 1999, 90% of the import violations occurred where residues were detected on commodities for which tolerances were not established, and only 10% of the violations represented residues in excess of the tolerance. For domestic samples, 69% were detected on commodities for which tolerances were not established, and the remaining 31% of violations occurred when levels exceeding tolerances were detected. Fruits and vegetables were responsible for the highest percentages of residue detections and the greatest number of violations from both imported and domestic foods.

Results obtained from California's 1997 Marketplace Surveillance Program were quite similar to those of the FDA's 1999 monitoring. This program analyzed 5660 samples in 1997, with 62.2% of those originating from California, 6.7% from other US states, and the remaining 31.1% from other countries. The majority of samples (62.1%) showed no detectable residues, whereas 36.7% of the samples contained legal residues. Violations were detected in 1.2% of the samples, and only 12% of the violations represented residues detected in excess of tolerances. The violation rate from imported foods was 2.4%, and the violation rate for domestic foods was 0.7%.

The USDA's PDP analyzed 9125 food samples for pesticide residues in 1999. Foods analyzed included apples, cantaloupe, cucumbers, grape juice, lettuce, oats, pears, spinach, strawberries, sweet bell peppers, tomatoes, winter squash, and corn syrup. Most of the samples (8637) were from fruits and vegetables, with lower numbers of samples collected for oats (332) and corn syrup (156). The majority of samples (79%) was of domestic origin. Overall, 36% of the samples contained no detectable residue, whereas

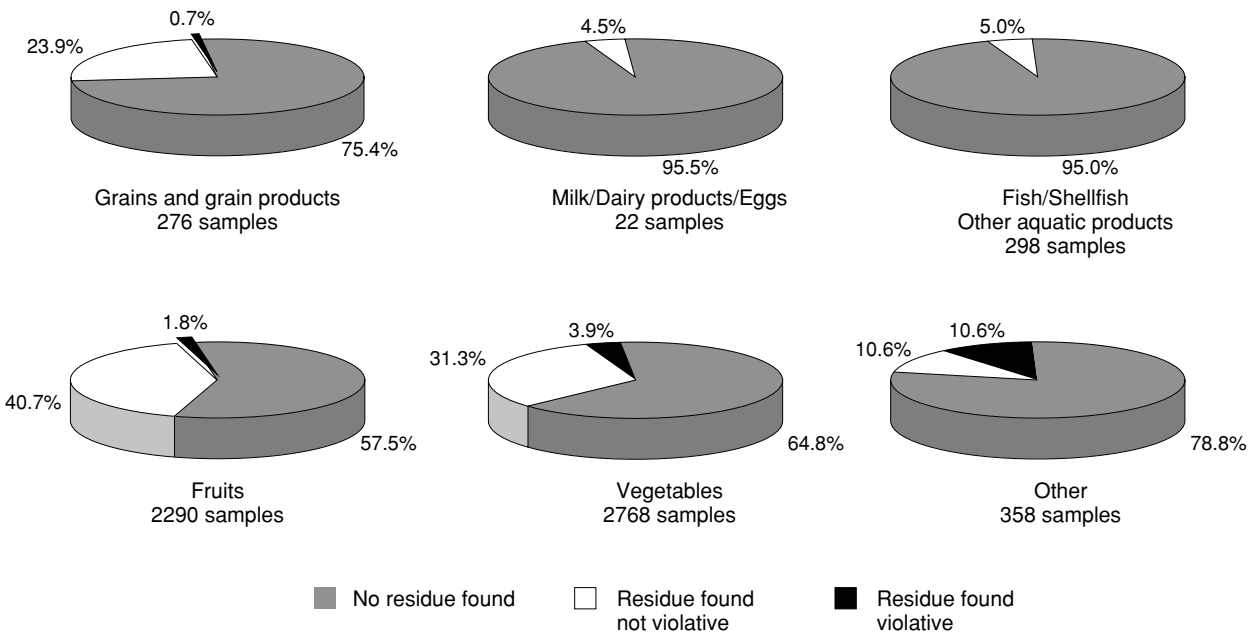

Figure 2 Results of US Food and Drug Administration monitoring of imported foods for pesticide residues, 1999.

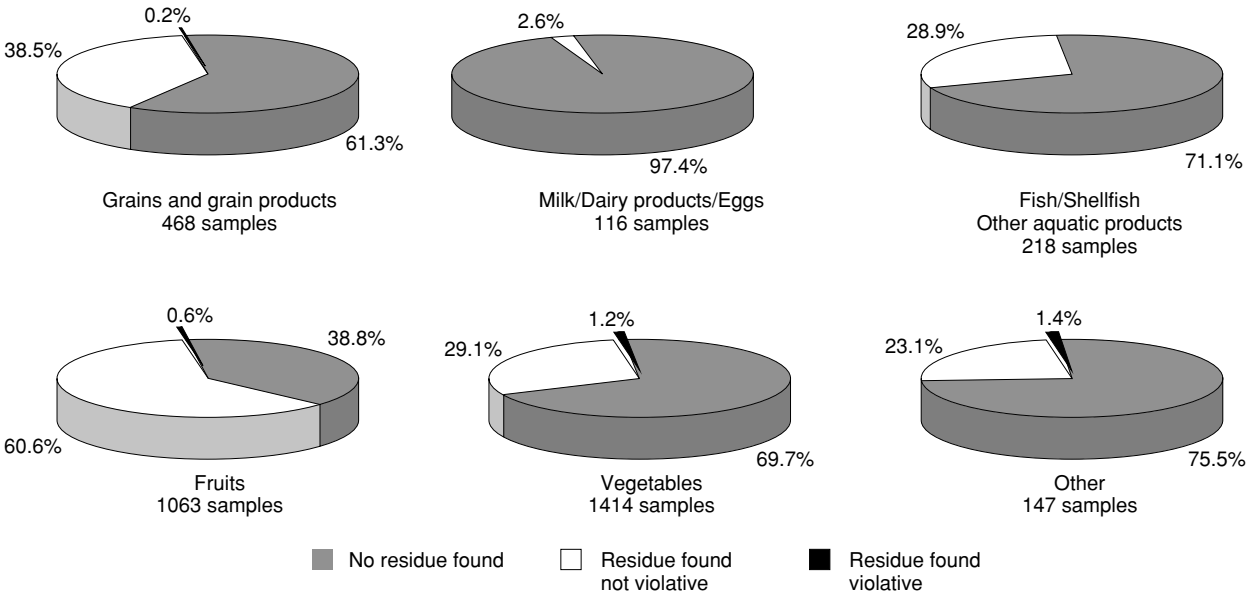

Figure 3 Results of US Food and Drug Administration monitoring of domestic foods for pesticide residues, 1999.

26% contained one residue, and 35% contained more than one residue. Residues exceeding the tolerance level were detected on 0.3% of the samples, and residues of pesticides were detected on commodities for which no tolerances of the pesticides were established on another 3.7% of the samples.

Dietary Risks from Exposure to Pesticides in Food

A common method used to discuss the potential human health risks arising from the consumption of pesticide residues in the diet is to report on the results of regulatory monitoring programs, as has been done in the previous paragraphs. Results indicate that a large percentage of food samples contain no detectable residues and that violation rates are relatively low, particularly for foods grown in the US. Frequently, the recitation of such findings is used as justification for a lack of significant human health risks resulting from pesticide residues in foods.

The problem with adopting such an approach is that it ignores the important, yet confusing, fact that pesticide tolerances are *not* safety standards but rather represent the maximum legal residues expected when pesticides have been used according to directions. Taking this a step further, violative residues should not be considered to be *unsafe* residues in most cases but merely represent cases in which pesticides have been misapplied or have been transported to commodities for which they are not registered. Although cases of pesticide misuse have historically resulted in a small number of incidents of acute poisoning of people consuming tainted foods, it can be reasonably argued that the vast majority of violative pesticide residues do not represent significant health threats to consumers based upon common toxicological and risk assessment criteria.

A more accurate approach for estimating human dietary risks from pesticides is to use exposure data derived from market basket surveys rather than regulatory monitoring data. The FDA, for example, performs its Total Diet Study annually. This study uses a market basket approach, with each market basket containing more than 250 individual food items. Foods are collected by FDA inspectors from three cities in each of the four geographical regions of the USA and are prepared for table-ready consumption prior to analysis for pesticide residues. By combining analytical results from estimates of typical consumption rates of the various food items or their components, it is possible to estimate the typical daily exposure of members of the general population to specific pesticides as well as to break the population down further into subgroups defined by factors such as age, gender, and geographical location.

Although the FDA no longer makes its dietary pesticide exposure estimates from its Total Diet Study available to the public, results reported from the 1991 Total Diet Study indicate that, for most pesticides in a variety of different population subgroups, the typical daily exposure estimates represent only a small fraction (often less than 1%) of the corresponding RfDs or ADIs. To put this into some level of perspective, it should be noted that typical RfDs are derived by first identifying the highest level of exposure to a pesticide that causes no noticeable

signs of toxicity in laboratory animals and then dividing that level by an uncertainty factor (usually 100) that presumably covers potential variability resulting from the animal to human extrapolation and from interhuman variability. Exposure at a level of 1% of the RfD represents an exposure 10 000 times below the level that does not produce noticeable effects in the animals. Such findings provide an illustration of why the majority of health professionals consider the typical human health risks from pesticides in the diet to be much lower than food safety risks posed by such factors as microbiological contamination of foods, nutritional imbalance, environmental contaminants, and naturally occurring toxins. The risks from pesticides in the human diet are clearly not zero, since consumption of tainted foods has caused documented human illnesses throughout the world, and concerns remain regarding potential long-term effects of dietary pesticide exposure.

It is also clear that the potential health benefits resulting from pesticide use should be considered. Pesticide use has resulted in increases in production of a wide variety of food crops, which translates into greater availability and lower consumer costs and thus a greater potential consumption of agricultural products. Epidemiological studies have clearly indicated that diets rich in consumption of fruits, vegetables, and grains may significantly decrease one's risk of heart disease and certain types of cancer. The US National Academy of Sciences, among other scientific bodies, has concluded that the theoretical increased risks from pesticide exposure resulting from increases in consumption of fruits, vegetables, and grains were greatly outweighed by the health benefits of these foods.

PH – PRINCIPLES AND MEASUREMENT

D Webster, Formerly of University of Hull, Hull, UK

Background

pH measurements have been, and continue to be, widely used as a rapid, accurate measure of the acidity of fluids of all sorts. There are two methods for measuring pH: colorimetric methods using indicator solutions or papers, and the more accurate electrochemical methods using electrodes and a millivoltmeter (pH meter). The development of the glass electrode, which is convenient to use in a variety of environments, and the development of the pH meter have enabled the widespread application of pH measurement and control to take place. The determination, and hence the control of pH, is of great importance in the food industry.

Basic Theory

In water, molecules (H_2O) are in equilibrium with hydrogen ions (H^+) and hydroxide ions (OH^-) (eqn (1)).

$$H_2O \rightleftharpoons H^+ + OH^-. \quad (1)$$

This ionization is of great importance in the chemistry of aqueous systems, as it enables water to give or take H^+ ions, as required, by other dissolved substances.

Applying the law of mass action to eqn (1):

$$[H^+][OH^-]/[H_2O] = \text{constant}, \quad (2)$$

where [ ] indicates the concentration in units of moles per cubic decimeter (mol dm^{-3}).

In pure water and dilute solutions, the concentration of the undissociated water may be considered constant, hence $[H^+][OH^-] = K_w$, where K_w is a constant called the ionic product of water.

The ionic product varies with temperature, but at about 25 °C, its value is 10^{-14} mol^2 dm^{-6} (K_w (0°C) = $10^{-14.9}$, $K_w(25°C) = 10^{-14.0}$, $K_w(60°C) = 10^{-13.0}$). This means that in pure water, the ionization is very small. As the concentrations of H^+ ions and OH^- ions are equal in pure water, and as $[H^+][OH^-] = 10^{-14}$ mol^2 dm^{-6} at 25 °C, $[H^+]$ (or $[OH^-]$) = 10^{-7} mol dm^{-3}.

To be strictly correct, eqn (1) should be written as eqn (3):

$$2H_2O \rightleftharpoons H_3O^+ + OH^-, \quad (3)$$

where the H^+ ion is attached to a water molecule to form the oxonium ion (H_3O^+). However, the symbol H^+ will be used throughout this article.

When, in a solution, there are an equal number of H^+ and OH^- ions, the solution is said to be neutral, when there is an excess of H^+ ions (> 10^{-7} mol dm^{-3} at 25 °C), it is acidic, and when there is an excess of OH^- ions ([H^+ < 10^{-7} mol dm^{-3}), it is basic or alkaline.

pH Scale

Although concentrations of H^+ and OH^- ions in acidic and alkaline solutions can be expressed in these molar concentrations, a much more convenient method was introduced by Sörensen in 1909. He proposed the use of the H^+ ion exponent pH, defined by the relationship $pH = -\log_{10}[H^+]$. (This may also be expressed as $[H^+] = 10^{-pH}$). To be strictly correct, this equation is $pH = -\log_{10}([H^+]/[1])$, as a logarithm must be dimensionless. From this, it can be seen that pH does not have units – the often-used expression 'pH unit' is wrong.

Using the pH scale, a change of 1 corresponds to a 10-fold change in the H^+ ion concentration, a change of 2 corresponds to a 100-fold change, etc. The pH scale has the advantage that all solutions from 1 mol dm^{-3} acid to 1 mol dm^{-3} alkali can be expressed by positive numbers from 0 to 14. Thus, at 25 °C, a neutral solution, which has $[H^+] = 10^{-7}$ mol dm^{-3}, has a pH of 7, a 1 mol dm^{-3} solution of a strong (completely ionized) acid such as hydrochloric acid, which has $[H^+] = 1 = 10^0$ mol dm^{-3}, has a pH of 0, and a 1 mol dm^{-3} solution of a strong (completely ionized) alkali acid such as sodium hydroxide, which has $[OH^-] = 1$ mol dm^{-3}, hence $[H^+] = K_w/[OH^-] = 10^{-14}$ mol dm^{-3}, has a pH of 14. pH values below 0 and above 14 occur in solutions of strong acids and alkalis of strengths greater than 1 mol dm^{-3}.

As K_w varies with temperature, pH measurements should be made at about 25 °C. The pH of a neutral solution at 0 °C is 7.45 ($K_w = 10^{-14.9}$, $[H^+] = \sqrt{10^{-14.9}} = 10^{-7.45}$ mol dm^{-3}, and at 60 °C, the pH is 6.5 ($K_w = 10^{-13.0}$, $[H^+] = \sqrt{10^{-13.0}} = 10^{-6.5}$ mol dm^{-3}).

To measure pH values, Sörensen used the electrochemical cell:

$$Pt, H_2(g) \mid \text{Solution X} \mid \text{Salt bridge} \mid Hg_2Cl_2 \mid Hg.$$

This representation indicates a hydrogen electrode (hydrogen gas passed over a platinum metal electrode) in a solution X and a calomel electrode (metallic mercury in contact with calomel (Hg_2Cl_2), in contact with a chloride ion solution) separated by a salt bridge (which allows ionic conduction to occur, but prevents solution X and the chloride ion solution from mixing). For such a cell, the difference in electromotive force (emf) ($E_1 - E_2$) between two cells in terms of the H^+ ion concentrations $[H^+]_1$ and $[H^+]_2$ of the two solutions is given by the equation

$$E_1 - E_2 = (RT/F)\log_e([H^+]_2/[H^+]_1), \quad (4)$$

where R is the gas constant, T the temperature, and F the Faraday constant. If $[H^+]_2$ is 1 mol dm^{-3}, E_2 will have a definite value, E^0. Therefore, $E_1 - E^0 = (RT/F)\log_e(1/[H^+]_1)$, or $E_1 = E^0 + (RT\log_e 10/F)p_sH_1 = E^0 + 0.05916\, p_sH_1 V$ (at 25 °C) (p_sH is used here for Sörensen's pH). Sörensen assumed that $[H^+]_1 = \alpha_1 M_1$ where α_1 is the degree of dissociation of the acid in solution 1, and M_1 is its molality. $E^0 = 0.3376$ V at 18 °C.

After this initial work of Sörensen, it was realized that the emfs of cells depend on activity rather than concentration, and other assumptions were incorrect. Sörensen and Linderström-Lang (1924) proposed $p_aH = -\log_{10} a_{H^+} = -\log_{10}[H^+]y_{H^+}$, where a_{H^+} is the activity, $[H^+]$ is the concentration of the H^+ ion in mol dm^{-3}, and y_{H^+} is the activity coefficient of the H^+ ion on the molarity scale. (To be strictly correct, a ratio of concentrations, as earlier, is needed here to give a dimensionless quantity.) These p_aH values can be shown to be related to the original p_sH values by the relationship:

$$p_aH = p_sH + 0.04. \quad (5)$$

Operational Definition of pH

In the previous section, some of the problems of the theory of pH were discussed. Careful study has shown that the numbers obtained depend, in a complex manner, on H^+ ion activity of electrolytes in solution, and it became clear than an operational definition of pH and a standard scale were needed to unify the great variety of pH measurements being made by research scientists and by industry and commerce. Hence, we now have an operational definition that has been endorsed by the International Union of Pure and Applied Chemistry. This definition is

$$pH(X) = pH(S) + (E_S - E_X)F/RT\log_e 10, \quad (6)$$

where E_x is the emf of the galvanic cell.

$$\text{Reference electrode} \,|\, \text{K Cl solution} \,|\, \text{Solution X} \,|\, H_2(g), \text{Pt}$$

and E_s is the emf of the same cell with solution X of unknown pH(X) replaced by solution S of standard pH(S).

In practice, a glass electrode is almost always used in place of the platinum/hydrogen gas electrode. The reference electrode is usually mercury/mercury(I) chloride (calomel), silver/silver chloride, or thallium amalgam/thallium(I) chloride. The standard reference pH is that of an aqueous solution of potassium hydrogen-phthalate of molality $0.05\,\text{mol}\,\text{kg}^{-1}$ at 25 °C. This has a pH of 4.005.

Food and pH

There are many instances when the food scientist needs to measure or control pH. For example, pH control is vital in the clarification and stabilization of fruit and vegetable juices, in the use and control of enzymes and microorganisms, in the preparation of foods by the fermentation of fruit or cereals, in the control of the texture of jams and jellies, and in the stability of the color and flavor of fruits.

The properties (e.g., emulsification and foaming ability) of many colloidal systems are affected by pH – these include proteins, pectins, and gums, all of which occur in foods. Chemical reactions that can occur in foods, particularly hydrolysis, are catalyzed by hydrogen ions, and therefore can be controlled by controlling the pH of the system. (*See* **Colloids and Emulsions**.)

Hydrogen ions affect the rate of growth of molds, yeasts, and, particularly, bacteria. Usually, there is a pH value at which optimum growth occurs, above and below which growth is inhibited. The relationship of pH to sterilization by heat is of particular significance during the canning of foodstuffs. (*See* **Canning**: Principles; **Spoilage**: Bacterial Spoilage; Molds in Spoilage; Yeasts in Spoilage.)

pH is a rough measure of the maturity of fruit. Young fruits initially have a pH close to that of the plant, but this rapidly decreases as the acidity increases. The pH of acidic fruits such as lemons and limes is about 2.0, and that of mildly acidic fruits about 4.0. These values can be compared with vegetables, which have pH values of 5–6. The pH ranges of a number of fruits and other foods is listed in Table 1. (*See* **Ripening of Fruit**.)

Buffer Solutions

Buffer solutions are of prime importance in pH determinations, as they are the standards for both colorimetric and electrochemical methods of determining pH.

Buffer solutions are solutions that resist a change in H^+ ion concentration (pH) when an acid or alkali is added to them. They are made up of a weak acid or weak base and its salt.

The equilibria in a solution of, say, a weak acid and its sodium salt are shown in eqns (7) and (8):

Table 1 pH values of some foods

Food	*pH*
Limes	1.8–2.0
Lemons	2.2–2.4
Gooseberries	2.8–3.0
Plums	2.8–3.0
Pickles	3.0–3.4
Grapefruit	3.0–3.4
Oranges	3.0–4.0
Rhubarb	3.1–3.2
Cherries	3.2–4.0
Pineapples	3.4–3.7
Pears	3.6–4.0
Apricots	3.6–4.0
Tomatoes	4.0–4.4
Bananas	4.5–4.7
Cheese	4.8–6.4
Carrots	4.9–5.3
Spinach	5.1–5.7
Potatoes	5.6–6.0
Peas	5.8–6.4
Tuna	5.9–6.1

Chicken	6.2–6.4
Drinking water	6.5–8.0

$$HA \rightleftharpoons H^+ + A^- \quad (7)$$

$$NaA \rightleftharpoons Na^+ + A^-. \quad (8)$$

As HA is a weak acid, equilibrium (eqn (7)) at moderate concentration will lie over to the left, i.e., as undissociated acid HA. The equilibrium of the sodium salt (eqn (8)) is a source of A^- ions. If acid (i.e., H^+ ions) is added to this weak acid and salt solution, the H^+ ions will be removed as they will combine with the A^- ions to form undissociated HA. If base (i.e., OH^- ions) is added, the OH^- ions will be removed as they will combine with the H^+ ions to form water and the equilibrium (eqn (7)) will move to the right to supply the H^+ ions required. Hence, the concentration of H^+ ions in the solution (i.e., the pH) will not change significantly. This is the buffer effect.

Common buffer solutions are made from potassium hydrogenphthalate with hydrochloric acid or sodium hydroxide (for pH 3–5), potassium dihydrogenphosphate with sodium hydroxide (for pH 6–8), and boric acid with sodium hydroxide (for pH 8–10).

Biologically, the buffer effect is often more important than the absolute value of pH. For example, buffer chemicals affect the way in which enzymes and microorganisms respond when the pH is changed. Juices from plant tissue have the ability to buffer pH changes to a greater or lesser degree, owing to the presence of organic acids, acid–salt systems, proteins, and acid phosphates.

Measurement of pH

Colorimetric Methods

Determination of pH using the color of acid–base indicators is a very simple technique that can be carried out rapidly and reproducibly. Approximate pH values can be obtained very quickly using pH papers. Under optimum conditions, accurate values of pH can be obtained by colorimetric methods. No doubt, these methods will be used for many years to come, but must become less favored with the advent of portable, cheap, easy-to-use electrochemical pH meters. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Color change of acid–base indicators Indicators are natural or artificial dyestuffs that are weak acids or bases (acids and bases that are only partially dissociated) and have different colors in their acidic and basic forms.

If the indicator is written as HIn and it dissociates (eqn (9))

$$HIn \rightleftharpoons H^+ + In^-, \quad (9)$$

the equilibrium (or ionization) constant is

$$K_{In} = [H^+][In^-]/[HIn], \quad (10)$$

and

$$[H^+] = K_{In}([HIn]/[In^-]). \quad (11)$$

Using $pH = -\log_{10}[H^+]$,

$$pH = pK_{In} + \log_{10}([In^-]/[HIn]); \quad (12)$$

pK_{In} is $-\log_{10} K_{In}$ and is called the indicator constant. The ratio $[In^-]/[HIn]$ determines the color of the indicator in the solution, and eqn (12), therefore, directly relates the color to the pH of the solution.

Eqn (12) shows that when $pH = pK_{In}$, the concentration of the indicator in each form is equal (i.e., $[HIn] = [In^-]$), and that at all pH values, both the acid (HIn) and basic (In^-) forms of the indicator are present in the solution. Our eyes are unable to detect the color of less than about 10% of one form of the indicator in the presence of the other, and the solution will appear to be the 'acid' color when $[In^-]/[HIn] < 1/10$, and the 'alkaline' color when $[In^-]/[HIn] > 10$. Therefore, the solution will be the color of the acid form of the indicator until $pH = pK_{In} - 1$, when the color will appear to change until it is that of the alkaline form of the indicator from $pH = pK_{In} + 1$. That is, the color changes over approximately 2 in terms of pH. In practice, the range for the color change is about 1.6–2 in terms of pH; this corresponds to a 40–100-fold change in the H^+ ion concentration. By choosing indicators with appropriate pK_{In} values, the whole of the pH range may be covered – a selection of some common pH indicators is given in Table 2.

Colorimetric Measurements of pH

Indicator papers For approximate determination of pH values, indicator papers may be used. Of particular value are 'nonbleeding' indicator papers. These contain dyestuffs strongly bound to the cellulose, so that the dye does not bleed into the test solution. These indicator papers are available, covering very narrow pH ranges, enabling moderately accurate pH values to be obtained very cheaply, conveniently, and quickly.

Comparison method This is carried out by adding similar quantities of an indicator to the test solution and a reference solution, and if the two solutions have the same color, they are assumed to have the same pH. The accuracy of the method, therefore, depends on the accuracy of the pH of the reference solution.

The indicator used must have a color at the pH of the test solution intermediate between the acidic and basic forms.

The approximate pH of the solution is first detemined using a 'universal,' or full-range, indicator, when an appropriate indicator for the measurement can be chosen. A quantity of the test solution is measured into a tube and a measured amount of indicator added. Tubes of buffer solutions covering the pH range of the indicator are treated in the same way. The colors of the tubes are viewed through the length of the tube against a white background. The accuracy of the method will depend on the differences of pH of the buffer solutions. These are typically 0.2, and the pH of the unknown solution can then be measured to within ± 0.1.

The Lovibond Comparator The need to use buffer solutions is eliminated by using a Lovibond 2000 comparator, in which the color of the test solution is compared with colored glasses. Standard colored glass rings are fitted into a disk that can be rotated and the colored glasses compared with the test solution. For accurate results, the sample solution and discs must be viewed against north daylight or in white light. Indicator discs for 14 different indicators are available. Special disks are available for the determination of the pH of blood.

With the Nesslerizer attachment, the solution is viewed through the depth of the liquid instead of through its thickness. The proportion of indicator therefore can be considerably reduced, resulting in a significant gain in accuracy, particularly when unbuffered or slightly buffered solutions are being tested.

Sources of error There are a number of possible sources of error when making colorimetric measurements.

1. *Slightly buffered solutions*. As indicators are weak acids or bases they will change the pH of the solution if it is unbuffered or only slightly buffered. Samples of relatively pure water, and solutions of a salt of a strong acid and strong base are the most frequently encountered solutions of this type. It is recommended that an appropriate pH meter is used for such solutions.
2. *Salt effect*. As discussed earlier, equilibrium constants depend on the activities of the components rather than concentrations, and it is only in very dilute solutions that activity equals concentration. Buffer solutions normally used have ionic strengths of up to 0.2 M. If the solution under test has a lower ionic strength than the buffer, the determined pH will be too small. The salt correction that must be applied is also affected by the types of ion present and the indicator used.
3. *Effect of colloids*. Colloid particles in the solution may preferentially absorb either the acid or the alkaline form of the indicator, giving totally erroneous results.
4. *Effect of proteins*. pH values obtained in the presence of proteins are unreliable. The effect of a protein on the determination depends on both the type of protein and the indicator used. Usually, the effect is greater when the protein is on the acid side of its isoelectric point.
5. *Effect of finely divided particles*. Chemical reactions may occur between the indicator and particles in the solution, giving erroneous results.
6. *Colored solutions*. Color comparison is not possible if the test solution is colored.
7. *Nonaqueous solvents*. Literature data on indicators apply to aqueous solutions; the indicator equilibria, hence the color, will be different in other solvents. The color of an indicator in, say, a water–alcohol mixture should be taken as only a rough guide to the true pH.

Table 2 Some pH indicators and their color changes and ranges

Indicator	*Color in acid solution*	*Color in alkaline solution*	*pH range*	pK_{In}
Thymol blue (acid)	Red	Yellow	1.2–2.8	1.7
Bromophenol blue	Yellow	Blue	2.8–4.6	4.0
Methyl orange	Red	Yellow	3.1–4.4	3.7
Methyl red	Red	Yellow	4.2–6.3	5.1
Litmus	Red	Blue	5.0–8.0	
Bromothymol blue	Yellow	Blue	6.0–7.6	7.0
Phenol red	Yellow	Red	6.8–8.4	7.9
Thymol blue (base)	Yellow	Blue	8.0–9.6	8.9
Phenolphthalein	Colorless	Red	8.3–10.0	9.6
Universal[a]	Red, orange, yellow	Green, blue, violet	3.0–11.0	
Full-range[a]	Red, orange, yellow	Green, blue, violet	1.0–14.0	

[a]These are mixtures of indicators; they give a continuous color change over a wide pH range.

Electrochemical Method

In order to measure pH by the electrochemical method, the emf of a reference cell is determined (see earlier). In this cell, the potential of one electrode (the hydrogen electrode) changes with pH, and the potential of the second, reference, electrode does not. Historically, the hydrogen gas electrode was used as the pH electrode, but the discovery by Cremer in 1906 that the potential difference across a glass membrane depends on the H^+ ion concentration on either side of it led to the development of the glass electrode. This is the electrode that is now always used for measuring pH.

Glass electrode In its simplest form, the glass electrode consists of a thin glass bulb containing a solution of constant pH, usually hydrochloric acid or a phosphate buffer with potassium chloride. In this solution is an electrode, usually silver coated with silver chloride.

The exchange of ions in the glass membrane for H^+ ions in the solutions on either side of it to form silanol ($\equiv$Si-OH) layers is the major factor in determining the pH response of the electrode, and special sodium and lithium glasses are used. As this surface layer is crucial to the correct functioning of a glass electrode, the pH-sensitive tip is stored in a pH 7 buffer solution, preferably containing $0.1\,\text{mol}\,\text{dm}^{-3}$ potassium chloride. As it is most important that the tip does not dry out, commercial electrodes are supplied with a storage teat containing the buffer plus potassium chloride solution.

Glass electrodes give a good linear response in the pH range 2–9, and up to pH 14 if the salt concentration in the test solution is not too high.

Combination electrodes Historically, the separate glass and reference electrodes were placed side by side in the test solution. Such electrodes are still available but are now used for special applications. Almost all pH measurements are made with combination electrodes in which the glass and reference electrodes are combined together. Although there are many details that vary from one electrode to another, the basic design is as shown in Figure 1. The glass membrane is at the bottom and is surrounded by the reference electrode. This is usually a silver/silver chloride electrode (silver wire coated with silver chloride in saturated potassium chloride solution), and the reference–test solution junction is at a porous glass frit near the bottom of the electrode. The potassium chloride in the reference cell slowly bleeds through the frit into solutions being tested and must be topped up, when necessary, through the filling hole near the top of the electrode.

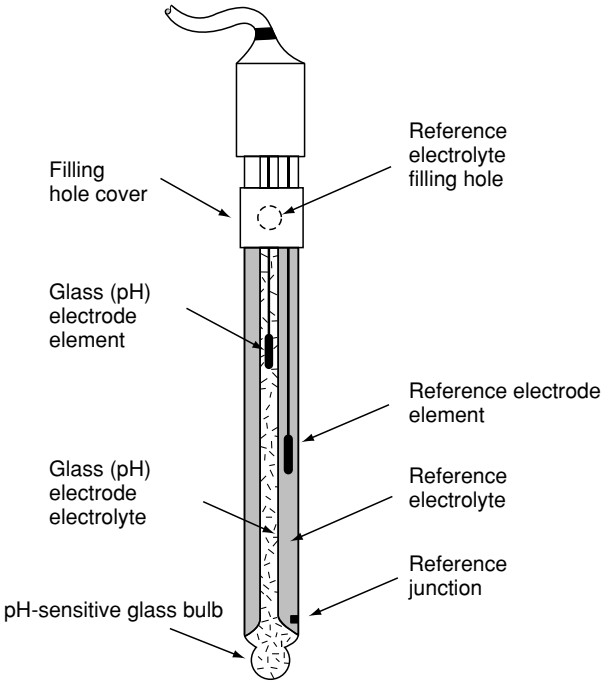

Figure 1 Combination pH electrode. Reproduced from pH: Principles and Measurement, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

For many purposes, this electrode is perfectly satisfactory, but under adverse conditions, the positive flow of reference electrolyte is reversed, and the sample solution contaminates the reference cell. This can be avoided by using a double-junction reference system in which the reference cell is connected through a glass frit with an intermediate electrolyte, which is in turn in contact, through a glass frit, with the test solution. Such an electrode also eliminates clogging owing to precipitation of silver chloride at the glass frit. Also, the intermediate electrolyte can be changed if that being used reacts with the test solution at the glass frit junction.

Special glass electrodes

Amplified electrode The major experimental difficulty in measuring the emf of a pH cell is the high electrical resistance of the glass membrane, commonly 10–500 MΩ. This requires a high-impedance millivoltmeter and short, screened connections to the electrode. One solution to this problem is a glass electrode with a built-in amplifier (Hanna Instruments), where the high-impedance circuitry is in an integrated circuit encapsulated at the top of the electrode together with a mercury battery. This electrode is ideal for industrial pH measuring and monitoring

as long, unshielded cables can be used from the electrode to the pH meter.

Other electrodes pH glass and combination electrodes of many types are available; these include electrodes in plastic bodies (for durability), microelectrodes for small volumes of test solution, electrodes resistant to proteins, and flat electrodes for pH measurement at surfaces.

pH meters A pH meter is a high-impedance millivoltmeter that is designed to convert millivolts to pH. There are many types available at a range of prices. Temperature compensation is important, and many meters have a temperature probe facility for this purpose. Many meters contain microprocessors and are very easy to use.

To make a pH measurement, it is necessary to calibrate the meter first. This is done by using two buffer solutions that, ideally, span the pH of the test solution. After rinsing the electrode, this is placed in the test solution and the pH read from the meter.

Accurate pH measurements can be made without difficulty on test solutions containing dissolved acids, bases or salts. If, however, the sample is virtually pure water (e.g., tap, rain, or boiler-feed water) pH measurements are unreliable. This is because (1) the glass electrode requires a long time to stabilize in a low-ionic-strength solution; (2) the solution has a low buffering capacity and is therefore susceptible to drift as atmospheric carbon dioxide is absorbed; (3) the low conductivity of the solution allows the pick-up of electromagnetic noise; and (4) there is electrical noise created at the reference junction. Special low-conductivity electrode buffer kits have been developed (Russell pH Ltd) for such measurements. In these kits, the glass electrode is of extremely low resistance, and the calibration errors are reduced by using a buffer of low ionic strength.

Very small, portable pH meters are now available. A good example is the Piccolo (Hanna Instruments). This meter weighs only 100 g and uses an interchangeable amplified electrode in a plastic container. It has a built-in temperature sensor that compensates for temperatures from 0 to 70°C, and it measures pH in the range 1–13 with an accuracy and resolution of ± 0.01.

PHENOLIC COMPOUNDS

M Murkovic, Graz University of Technology, Graz, Austria

Background

Polyphenols play an important role in plants as well as in foods. The main uses of polyphenols in foods are as colorants and antioxidants. A large amount of research on polyphenols has focused on their antioxidant properties, since they are thought to have positive effects on chronic degenerative diseases (cataracts, age-related macular degeneration, central neurodegenerative diseases, and diabetes mellitus), cardiovascular disease, and cancer. Polyphenols are also used as antioxidants in the food industry to increase shelf-life, which can be limited due to deterioration because of oxidation reactions, especially fat oxidation. Not only is oxidized food a problem because of the resultant rancid aroma. It can also have implications on human health, since increased exposure to free radicals can also increase the risk of these degenerative diseases.

The several thousand polyphenols that have been described in plants can be grouped in several classes. Distinction between these classes is drawn first on the basis of the number of constitutive carbon atoms and then in the light of the structure of the basic skeleton. In addition, besides simple soluble forms mainly found in vacuoles, there are also polymerized forms of varying solubility like the tannins or the completely insoluble lignins. The groups of polyphenols dealt with in this chapter comprise anthocyanins,

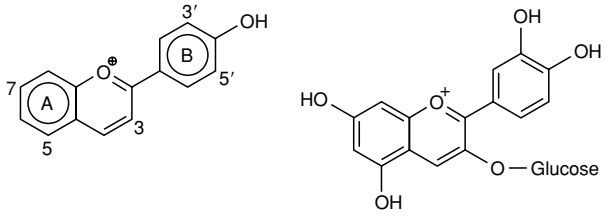

Figure 1 Structure and possible positions of hydroxylation and methoxylation of anthocyanidins (cyanidin-3-*O*-glucoside).

flavan-3-ols, isoflavones, flavones and flavonols, hydroxybenzoic acids, and hydroxycinnamic acids.

Anthocyanins

Anthocyanins are the most important group of water-soluble plant pigments visible to the human eye. With a few exceptions, e.g., betalains, they are universal plant colorants and largely responsible for the cyanic colors of flower petals and fruits. They may also occur in roots, stems, leaves, and bracts, accumulating in the vacuoles of epidermal or subepidermal cells.

The main positions of hydroxylation are 3, 5, and 7 in the A ring and 3′ and 5′ in the B ring (see Figure 1). Methoxyl groups can be attached to 3′ and 5′. In some cases, the 3-hydroxyl group is removed, and a few structures are known that have a hydroxyl group attached to C-6 of the A ring. The anthocyanidins that are commonly found in fruits are pelargonidin, cyanidin, delphinidin, peonidin, petunidin, and malvidin. These are all hydroxylated at the positions 3, 5, and 7. Normally, anthocyanins occur as 3-monosides, 3-biosides, and 3-triosides as well as 3,5-diglycosides and, in some cases, 3,7-diglycosides. The carbohydrates that are attached to the positions 3, 5, and 7 comprise glucose, galactose, rhamnose, arabinose, and xylose.

An example of a glycoside is cyanidin 3-rutinosid (6-*O*-α-L-rhamnosyl-D-glucose), which is very common in fruits, most commonly associated with cyanidin 3-glucoside. Other glycosides are cyanidin 3-sambubioside (2-*O*-β-D-xylosyl-D-glucose), which is present in elderberry, redcurrant, and black raspberry, and cyanidin 3-sophoroside (3-*O*-β-D-glucosyl-D-glucose), the main pigment in raspberries, loganberries, boysenberries, and mangosteen. The latter also occurs in redcurrants and sour cherries, but as a minor component (see Table 1).

The color-active form of the anthocyanins shows an absorption maximum at about 520 nm. This is due to the flavylium cation structure, which occurs only in an acidic environment. An increase in pH above 4 leads to a substantial fading of color. Other color changes occur during oxidation of the anthocyanins, leading to the browning of foods.

Table 1 Anthocyanidin content of selected vegetables and fruits (mg per 100 g fresh weight)

Food	*Total anthocyanidin content*
Fruits	
Blueberry	25–500
Elderberry	300–500
Strawberry	30–50
Cherry, sweet	350–450
Grapes, red	30–750
Vegetables	
Cabbage, red	20–40
Onion, red	10–20

Flavan-3-ols

Flavan-3-ols are components in the structure of proanthocyanidins (condensed tannins) as their monomers. Flavan-3-ols have been obtained from several tree species (*Quercus*, *Castandea*, *Acacia*, *Eucalyptus*, etc.). Four main flavan-3-ols are found in fruits. Two are orthodiphenols hydroxylated in the 3′ and 4′ positions in the B-ring ([+]-catechin and [−]-epicatechin), and two are trihydroxylated in the 3′-, 4′-, and 5′-positions ([+]-gallocatechin and [−]-epigallocatechin). C-2 and C-3 represent two centers of asymmetry in the molecule in such a way that the four mentioned flavan-3-ols in fruits are grouped in two pairs of diastereomers whose absolute configurations are as follows: 2R in all cases and either 3S for (+)-catechin and (+)-gallocatechin or 3R for (−)-epicatechin and (−)-epigallocatechin (see Figure 2).

Unlike in other classes of flavonoids, monomeric flavan-3-ols are generally found in free rather than glycosylated or esterified form in fruits (see Table 2). One exception is the case of the (−)-epicatechin-3-*O*-gallate identified in grapes. This ester has been found in several red grape cultivars.

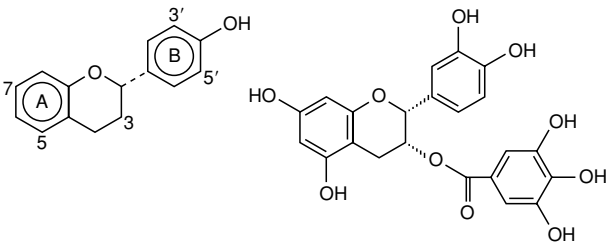

Figure 2 Structure and possible positions of hydroxylation and methoxylation of flavans; ((−)-epicatechin 3-gallate).

Isoflavones

The isoflavones are a distinctive but large subgroup of flavonoids. These compounds possess a 3-phenylchroman skeleton that is biogenetically derived by rearrangement of the flavonoid 2-phenylchroman system (see Figure 3).

Despite the restricted distribution of the isoflavonoids in the plant kingdom, the structural variation is surprisingly large. This arises not only from the number and complexity of substituents on the basic 3-phenylchroman system but also from the different oxidation levels in this skeleton and the presence of extra heterocyclic rings. Within the flavonoids, the isoflavones are the largest group of naturally occurring structures.

The enzyme that is responsible for the transformation of the flavones to the isoflavones is named isoflavone synthase. This enzyme catalyzes the isomerization of the two flavones (2S)-naringenin or (2S)-liquiritigenin to the isoflavones genistein and daidzein, respectively.

Soy foods have received considerable attention for their role in disease prevention, especially in relation to heart disease, osteoporosis, and cancer. The research interest in soy focuses on establishing the physiological effects of isoflavones. The occurrence of the isoflavonoids is restricted to only a few plants within the family of the leguminosae and some nonlegume dicotyledons. Soybeans and soyfoods are practically the only nutritionally relevant dietary sources of isoflavones. Isoflavones are weak estrogens in that they bind to estrogen receptors, but they also have important nonhormonal properties as well. Initial speculation that soyfoods, and in particular isoflavones, might promote bone health was based on the estrogenic properties of isoflavones. In ovariectomized rodents, isoflavones retard bone loss almost as effectively as estrogen. Most soyfoods are rich in isoflavones and favorably affect bone turnover and spinal bone mineral density in perimenopausal and postmenopausal women (see Table 3).

Table 3 Content of isoflavones in soy products (mg per 100 g (ml) fresh weight)

Food	*Total isoflavone content*
Soya bean	60–400
Tofu	8–70
Soy flour	80–180
Soya milk	3–180
Soy sauce	1–8

Flavones and Flavonols

Flavones are flavonoids characterized by a nonsaturated 3-C chain and have a double bond between C-2 and C-3, like flavonols, with which they differ by the absence of hydroxyl in the 3-position. It appears that this simple difference in structure between flavones and flavonols has very important consequences in the biogenesis, physiological, and pharmacological roles, and the phylogenetic and chemotaxonomic signification of these compounds. Flavones are widely distributed among the higher plants in the form of aglycones or glycosides (see Figure 4).

The edible portion of some foodstuffs has an unusually high concentration of quercetin. The concentrations of quercetin analyzed in hydrolyzed samples from fruits and vegetables are 284–486 mg kg^{-1} in onions, 110 mg kg^{-1} in kale, 32–45 mg kg^{-1} in French beans, 30 mg kg^{-1} in broccoli, 14 mg kg^{-1} in lettuce, and 8 mg kg^{-1} in tomatoes. The average concentration of quercetin in fruits is 15 mg kg^{-1}, with apples having the highest concentration (21–72 mg kg^{-1}) (see Table 4). Parsley and thyme are also major food sources of flavones.

Hydroxybenzoic Acids

Hydroxybenzoic acids have a general structure of the C6–C1 type derived directly from benzoic acid. Variations in structure lie in the hydroxylations and methoxylations of the aromatic cycle. Four acids dominate the family of these compounds: *p*-hydroxybenzoic acid, vanillic, syringic, and protocatechuic acids. The first three are constituents of lignin, from which they are released by alkaline hydrolysis. Gentisic acid has a particular pattern of hydroxylation, which can be related to that of salicylic acid, but it is much less common. Gallic acid is another well-known plant acid which participates in the formation of hydrolyzable gallotannins. Its dimeric condensation product (hexahydrodiphenic acid) and the related dilactone, ellagic acid, are also common plant constituents.

Hydroxybenzoic acids are commonly present in bound form (see Figure 5). They are the component of a complex structure like lignins and hydrolyzable tannins. The content of hydroxybenzoic acids in foods of plant origin is generally low (see Table 5), but in some berries and vegetables such as onions and horse-radish, the content of hydroxybenzoic acids may be very high.

Hydroxycinnamic Acids

Among the fruit phenolics, hydroxycinnamic acid derivatives play an important role because of both their abundance and diversity. They all derive from cinnamic acid and are essentially present as combined forms of the four basic molecules *p*-coumaric, caffeic, ferulic (see Figure 6), and sinapic acids. The free forms of these acids are very rare in fruits. Two main types of soluble derivatives have been identified: first, those involving an ester bond between the carboxylic function of phenolic acid and one of the alcoholic groups of an organic compound, for example chlorogenic acid, which has been identified in numerous fruits; second, those involving a glycosidic bond with one of the phenolic groups of the molecule (e.g., *p*-coumaric acid *O*-glucoside). The diversity of the hydroxycinnamic acids encountered in plants and particularly in fruits thus results from the nature of the bonds and that of the molecules involved.

Hydroxycinnamic acids occur most commonly in foods of plant origin. Of these, caffeic acid is the predominant hydroxycinnamic acid in many fruits, constituting over 75% of total hydroxycinnamic acids found in plums, apples, apricots, blueberries, and tomatoes. However, *p*-coumaric acid is the dominant hydroxycinnamic acid of citrus fruits and pineapple. Hydroxycinnamic acids are widely present in the bound form and are rarely found in free form. Processing of fruits and vegetables (freezing, sterilization, and fermentation) contributes to the formation of free hydroxycinnamic acids in such products (see Table 6). Chlorogenic acid is found in many foods, including apples, apricots, berries, peaches, pears, plums, avocados, and carrots. Chlorogenic acid is the key substrate for enzymatic browning, particularly in apples and pears. Its content is reduced by 70% during browning of the pear skins.

Analysis of polyphenols

Sample Preparation

Prior to extraction, solid food samples have to be homogenized or crushed using a mortar and pestle. Soluble phenolic compounds are generally extracted by means of alcohol–water mixtures. Extraction is performed using a mixture of ethanol (80%) and

Table 6 Content of hydroxycinnamic acid derivatives in selected fruits (mg per 100 g (ml) fresh weight)

Food	*Chlorogenic acid isomers*
Apple juice	6–20

Gooseberries	2–7
Raspberries	2–3
Redcurrants	1–2

water (20%) of the freeze-dried powder of the food to be analyzed. Methanol can be used instead of ethanol, and extraction with methanol gives good results, especially in the extraction of soluble phenolic compounds from fruits. Oxidation is avoided by working at low temperatures and, if necessary, by the addition of antioxidants such as ascorbic acid or butylated hydroxytoluene. To avoid enzymatic oxidation from polyphenol oxidases, samples may need to be heated to a temperature of more than 90 °C for a few minutes. These enzymes catalyze the oxidation of phenols to quinones with subsequent nonenzymatic rapid polymerization. These oxidases can also be inhibited by lowering the pH to below 4.0. Extraction of anthocyanins is normally carried out under cold conditions with methanol containing 1% of hydrochloric acid to obtain the flavylium cation, which is stable under acidic conditions.

For analysis of liquid samples like fruit juices, only dilution, filtration, and, in some cases, clarification are necessary. Carotenoids that can disturb the analysis should be extracted using nonpolar solvents. To remove the sugar moieties from the polyphenols, the glycosides have to be hydrolyzed. The cleaving off be carried out in acidic, basic, or enzymatic conditions. The hydrolysis of anthocyanins to anthocyanidins is often necessary owing to the difficulties of obtaining anthocyanin standards. This can be done by refluxing the dry anthocyanins in methanol acidified with 2 M HCl. Alkaline hydrolysis cleaves the acylated portions of anthocyanins using 2 M NaOH. During hydrolysis, care has to be taken that no polyphenols are destructed or rearrangement takes place so that artifacts are analyzed.

The water–alcohol extract obtained is a raw extract containing numerous nonphenolic substances (carbohydrates, organic acids, proteins, pigments, etc.). Before these crude extracts can be analyzed by high-performance liquid chromatography (HPLC), they should be purified using solid-phase extraction methods. Chlorophylls and carotenoids can be removed by applying conventional depigmentation techniques with petroleum ether.

HPLC Analysis

The columns used for HPLC analysis in the literature are almost exclusively reversed phase. Elution systems are usually binary, with an aqueous acidified polar solvent such as aqueous acetic acid, phosphoric acid, or formic acid and a less polar organic solvent such as methanol or acetonitril. Isocratic elution is mainly used for routine analysis if only a few polyphenols are to be determined.

For detection and quantification after separation, the absorption of ultraviolet or visible light is normally used. For flavonoids, two absorption bands are characteristic: the first in the range of 240–285 nm, which is believed to arise from the A-ring, and the second with a maximum in the range of 300–550 nm, which arises from the absorption of the B-ring (see Table 7). Since the absorption spectrum depends on the chemical substitution and the conjugated system, the different groups of flavonoids (flavanons/isoflavanons, catechins, flavons/flavonols, etc.) have distinct absorption bands. The anthocyanins show absorption above 500 nm, whereas the catechins have only a small maximum at 280 and no absorption at higher wavelengths.

The combination of liquid chromatography with mass spectroscopy for the detection of polyphenols has been increasing in recent years. Mass-selective detection is especially useful in identifying new structures and verifying known substances. With a quadrupole mainly the unfragmented molecule can be detected. Using tandem mass spectrometry, the molecules can be fragmented in a selective way. Thus, information on the chemical structure of the polyphenols can be obtained.

Intake and Bioavailability of Polyphenols

In the Western diet, the phenolic acids, catechins, proanthocyanidins, and anthocyanins dominate uptake. Especially for epidemiologic studies, it is necessary to estimate accurately the amount of

Table 7 Detections wavelengths of flavonoids

Structure	*Wavelength used for analysis (nm)*
Flavons, flavonols, flavonol glycosides	270
Anthocyanins	500–525
Isoflavones	236, 260, 280
Flavanones and glycosides	280, 290
Catechins	210, 280

polyphenols consumed. In general, fruits are richer in polyphenols compared to vegetables. Beverages contribute significantly to the uptake of polyphenols. Red wine, coffee, and black tea contain high amounts of polyphenols. Green tea, which also contains large amounts of these substances, is consumed in East Asia in high amounts. The uptake of polyphenols is estimated to be 50–200 mg per meal. The phenolic acids are constituents of coffee, fruits, vegetables, and cereals. Flavanols, which occur predominantly in onions, apples, and other fruits and vegetables, contribute about 20 mg per day. Catechins are provided by tea and various fruits and proanthocyanidines by various fruits, legume seeds, chocolate, and red wine. Flavanones are found in citrus fruits. The total uptake of flavonoids in the Western diet is estimated to be about 1000 mg per day. Examples of the distribution and quantity of flavonoids consumed daily include: 44 mg from cereals; 79 mg from potatoes, bulbs, and roots; 45 mg from peanuts and nuts; and 162 mg from vegetables and herbs. The largest portion of flavonoid intake comes from cocoa, cola, coffee, tea, beer and wine (420 mg per day), with an additional 290 mg per day from fruits and juices.

The uptake of 100 mg of polyphenols results in a concentration of about 300 μM in the gut. Normally, the plasma levels will not exceed 1 μM. Urinary excretion varies from less than 1% to about 25% depending on their gut absorption, enterohepatic cycling, and metabolism. In particular, the type of polyphenol and the glycosylation influence bioavailability. The uptake of proanthocyanidines is limited to monomers and dimers. A higher degree of polymerization results in a sharp decrease in bioavailability. The metabolism of polyphenols in the small intestine is mainly via glucuronidation, sulfatation, and methylation. The colon microflora contributes to the metabolism of the polyphenols. This has been investigated in detail for several types of polyphenols, and especially for quercetin. Most flavonoids enter the diet as glycosides, with quercetin and rutin being the most common flavonoid glycosides consumed. The hydrophilic nature and their relatively high molecular weight preclude absorption in the small intestine. Furthermore, flavonoid β-glycosides resist intestinal hydrolases, and consequently, flavonoid glycosides can pass unaltered into the large intestine. The resident microflora of the bowel produces glycosidases capable of releasing the aglycone from its sugar. In addition, the resident microflora can cleave the pyrone ring (ring C), producing phenyl acetic and phenyl propionic acids and other derivatives. But since glycosidase activity proceeds at a faster rate than ring cleavage, the intact flavonoid aglycone can persist in the large intestine with a clear potential for absorption.

Polyphenols as Antioxidants

It is well accepted that free-radical-mediated processes can lead to chronic degenerating diseases. The oxidative damage can be found on molecular level as oxidized lipids, proteins, or DNA. These can be detected, especially in patients with atherosclerosis, certain cancers, neurodegenerative diseases, and lung disorders. Many types of reactive oxygen species (ROS) and reactive nitrogen species (RNS) have been shown to induce a certain type of damage that is associated with disease development. These include the superoxide radical, hydrogen peroxide, hydroxyl radical, lipid alkoxyl and peroxyl radicals. Protection against damage induced by ROS/RNS can be achieved in several different ways:

- suppression of free-radical formation by antioxidants;
- scavenging of radicals by antioxidants to inhibit initiation of chain reactions and slow down chain propagation;
- repair mechanisms;
- transition metal chelation.

The polyphenols have structural features that characterize their antioxidative potential. This is the presence of hydrogen-donating substituents and the ability to delocalize the resulting free electron. Owing to the delocalization of the electron, the resulting radical does not have sufficient energy for further radical reactions. The antioxidative properties of flavonoids and other phenolics from natural sources are assessed by determining their activity as scavengers of radicals that arise from lipid oxidation or other biological processes. For evaluation of the antioxidant properties of flavonoids, the chemical structure can be related to the activity. Three structural groups are important determinants for radical scavenging: (1) the catechol structure (3′, 4′-dihydroxy) in the B ring, which is the obvious radical target site; (2) the 2, 3 double bond in conjugation to the 4-keto function, which is responsible for electron delocalization; and (3) the presence of both hydroxyl groups (the 3-OH and the 5-OH) for maximal radical-scavenging potentials. If all of these structural features are present, a maximum radical-scavenging potential would be expected.

Depending on the method of measuring the antioxidative potential, relative reactivities of structurally related polyphenols change. This can be seen especially in low-density-lipoprotein (LDL) oxidation experiments, in which quercetin and luteolin are strong antioxidants, that protect LDL with high efficiency, whereas kaempferol does not. In particular, if chelation of metal ions is the protecting mechanism, quercetin is a very strong antioxidant.

A simple chemical assay broadly applicable in determining the hierarchy of antioxidant activities of polyphenols measures their ability to reduce the ABTS-radical cation (2,2′-azinobis (3-ethylbenzothiazoline-6-sulfonate)). With this method, the relative ability of antioxidant or radical-scavenging substances to scavenge the ABTS cation radical in the aqueous phase is compared to a standard amount of the synthetic antioxidant Trolox, the vitamin E analog. Incubation of $ABTS^{o+}$ with peroxidase (metmyoglobin) and hydrogen peroxide results in the production of the radical cation ($ABTS^{o+}$). This species is blue–green in color and can be detected at 734 nm. Antioxidants or radical scavengers in the added sample suppress this color production to a degree that is proportional to their concentration. In this method, the activity of tested substances is expressed as an equivalent of the millimolar concentration of a Trolox solution. Table 8 shows the antioxidant activities of a range of flavonoids in comparison with the reduction potentials of the flavonoid radicals. It can be seen that the measured reducing properties of the phenolics, in terms of their antioxidant activities in this particular assay system, are consistent with the reduction potentials of their radicals.

The range of reduction potentials of selected flavonoid radicals, relative to those of ascorbic acid and α-tocopherol, is shown in Table 8, from the more oxidizable quercetin to kaempferol. These values reflect the ability of hydrogen-donating antioxidants to scavenge the $ABTS^{o+}$ radical cation, absorbing in the near-infrared region (650–820 nm) compared with that of ascorbic acid (E_7) and Trolox equivalent antioxidant activity (TEAC). Antioxidants reduce the absorbance to an extent dependent on the antioxidant activity. Spectral studies have revealed that the radical site is on the B ring and that the A ring has no influence on the properties of the radicals from the B ring in flavonoids with a saturated C ring, such as catechin. In flavone radicals in which the B ring with a 3′,4′-dihydroxycatechol structure is conjugated through the C ring 2, 3-double bond, evidence suggests that the radical is on the catechol B ring and that spectra resemble those of 3,4-dihydroxycinnamate radicals. The antioxidant activity of flavonoids depends critically on the part of the molecule with more efficient electron-donating properties. In most flavonoids, this is the B ring. Thus, the antioxidant activity of flavonoids as electron or hydrogen donors relates to the reduction potentials and reactivities of the substituent hydroxyl groups. A number of chemical studies on the reactivity of flavonoids with a range of radicals and the stability of the resultant antioxidant radicals have also emphasized specifically the role of the catechol structure in the B ring and unsaturation in the C ring.

Table 8 Reduction potentials (E_7) of flavonoid radicals and the TEAC

	E_7	TEAC
Quercetin	0.33	4.7
Epigallocatechin gallate	0.43	4.8
Epigallocatechin	0.42	3.8
Taxifolin	0.5	1.9
Catechin	0.57	2.4
Rutin	0.6	2.4
Kaempferol	0.75	1.3

Conclusion

Substantial epidemiological evidence links high antioxidant status in human populations with a low risk of degenerative disease. The consumption of large amounts of fruit and vegetables has been shown unequivocally in a considerable number of studies to be associated with a lowered risk of several kinds of cancer in a number of different body sites. It remains to be proven with certainty whether this effect is due to the content in the fruits and vegetables of antioxidant substances, which are the protective agents, but substantial circumstantial evidence points to the likelihood that antioxidant nutrient and nonnutrient substances in fruit and vegetables are the most important anticarcinogenic factors in these foods. Besides the classical antioxidants vitamin C, vitamin E, and β-carotene, many phenolic substances are also present in foods, including the flavonoids, which may also contribute to the total antioxidant potential of the diet and thus may lower the risk of cancer. Similar considerations apply to arteriosclerosis, with its cardiovascular and cerebrovascular risk connotations; it has been clearly shown that antioxidant nutrients can lower the oxidation of low-density lipoproteins in the vascular wall, which is thought to be a major early factor in the development of arteriosclerosis. It is also possible that antioxidants can play an important role in delaying the thrombotic events associated with the onset of heart attack or stroke, and there is thus a possibility that antioxidants have a dual effect in lowering the risk of vascular accidents. If it is proven that antioxidants can lower the risk of these degenerative diseases, it is vital that any enhancement of the diet with antioxidants is safe and free from the risk of any undesirable side-effects.

PHOSPHOLIPIDS

Contents

Properties and Occurrence

B F Szuhaj, Central Soya Company Inc., Fort Wayne, IN, USA

Introduction

Phospholipids have been scientifically studied since the 1700s and became commercially available as lecithin in the 1930s. Their primary commercial source today is the soya bean, but phospholipids can be found in all living cells as part of the cellular membranes. This article covers the properties and occurrence of phospholipids as commercial lecithins, their chemistry, manufacture, composition, specifications, and their potential use in food systems.

Occurrence

The International Lecithin and Phospholipid Society defines lecithin as 'a complex mixture of glycerophospholipids obtained from animal, vegetable or microbial sources, containing varying amounts of substances such as triglycerides, fatty acids, glycolipids, sterols, and sphingophospholipids.' Lecithins are natural surfactants primarily derived from soya beans and eggs. They are found most abundantly in seeds and nuts, eggs, brains, and cell walls, in a concentration range of 0.5–2%. (*See* **Eggs**: Structure and Composition; **Fatty Acids**: Properties; **Soy (Soya) Beans**: Properties and Analysis; **Triglycerides**: Structures and Properties.)

Properties of Phospholipids (Lecithins)

There are three types of properties necessary to define phospholipids and lecithins: (1) chemical, (2) physical, and (3) functional.

Chemical Properties

The chemical composition of deoiled and liquid soya bean lecithin is shown in **Table 1**. There are approximately 17 different compounds in commercial lecithin, including carbohydrates, phytosterols, and minor phytoglycolipids. The three major phospholipids are phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol.

Table 1 Chemical composition of soya bean lecithin

	Granular lecithin	*Typical liquid lecithin*
Phosphatides (acetone-insolubles) (%)	95 (minimum)	60 (minimum)
Soya bean oil (%)	2–3	39
Moisture (%)	1	0.7
Fat (g per 100 g product)	90	93
Monounsaturated (oleic acid) (%)	9.2	17.9
Polyunsaturated (linoleic, linolenic acids) (%)	65.9	60.7
Saturated (palmitic, stearic acids) (%)	24.9	20.3
Carbohydrates (g per 100 g of product)	8	5
Approximate composition (100-g sample)		
Fatty acid content (g)	50	66
Fatty acid content (relative composition) (%)		
Linoleic	58.9	54.0
Linolenic	7.0	6.7
Oleic	9.2	17.9
Palmitic	20.3	15.6
Stearic	4.6	4.7
Other fatty acids	0.0	1.1
Total	100.0	100.0

Structure of the Major Phospholipids

The chemical backbone of the major phospholipids is a diacylglycerol molecule with the third carbon attached to a phosphate molecule. Choline, ethanolamine, serine, and inositol can be attached to the phosphate group to change the physical and functional properties, leading to the formation of phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and phosphatidylinositol, respectively. The groups attached to positions 1 and 2 (α or β) are C_{14}–C_{18} fatty acids with double bonds associated with the lecithin source. The second carbon of the glycerol molecule, the β-position, usually contains linoleic acid.

Physical Properties

There are two major physical classes of lecithins: (1) fluid, and (2) waxy solids.

The fluid lecithins can have viscosities from 5000 to 100 000 cP, depending on processing conditions and diluents. The low-viscosity products are made through the addition of fatty acids and vegetable oil, depending on the function and stability required. Divalent metal ions like calcium can be added during drying to decrease viscosity. The moisture content can also make a difference. Water levels above 1% will increase the viscosity, eventually to a plastic state.

Deoiled lecithins are waxy solids that can be ground to various particle sizes. They are stable, free-flowing granules or powders.

Functional Properties

Lecithins are multifunctional agents. They can be used for many purposes in a food system, as shown in Table 2. The most popular functionalities are discussed below.

Antidusting agents Lecithins reduce static electricity by wetting dusty particles. They can be used alone or in conjunction with vegetable oils. Oils can be selected for the degree of shelf-life required.

Crystal formation modifier Lecithins retard nucleation in fats and even monoglycerides, reducing graininess in texture.

Emulsifiers Lecithins are most often used as amphoteric emulsifiers. They promote stable formation of oil-in-water and water-in-oil emulsions by reducing

the interfacial surface tension between immiscible liquids. (*See* **Emulsifiers:** Organic Emulsifiers.)

Mixing and blending aids Lecithins decrease time and increase efficiency of mixing of unlike ingredients such as sugar and shortening by providing lubricity as well as viscosity reduction at the contact surfaces of the incompatible solids.

Release agents Lecithins provide easy release from metallic surfaces by attaching to the metal surface during hot or cold cooking. They assist in the cleaning of hot surfaces where proteins or batters are applied. They also reduce sticking between frozen food products.

Separating agents Lecithins prevent the adhesion of products that normally stick when in contact, like cheese slices and caramel confectionery.

Viscosity modifiers Lecithins reduce viscosity by coating particles to reduce particle–matrix friction such as in chocolates.

Wetting agents Lecithins provide complete wetting of fatty or hydrophilic powders in aqueous systems. The fatty acids are attracted to the fatty portion and the hydrophilic portions of the molecules actively imbibe water and control the hydration of the powder.

Manufacture

The majority of phospholipids are solvent-extracted from their source. Usually, nonpolar hydrocarbons, like hexane, are used. Soya beans, for example, are cleaned, cracked, and dehulled before flaking and extraction. The hexane is removed from the solvent micelle and the crude soya bean oil is cooled for further refining. Figure 1 shows a flow diagram for the degumming of crude soya bean oil and the production of lecithin. Approximately 2–3% water is added to the crude oil and agitated for at least 30 min. The phosphatides hydrate, swell, and are separated by centrifugation. The wet gums with 50% moisture are dried through a thin-film drier. The important points here are careful drying temperatures and cooling of the product below 20 °C. Lightening the color of the product can be achieved with hydrogen peroxide in the gum stage. The hydrogen peroxide is removed through drying.

Modification

The chemistry and functionality can be altered by simple chemical additions with acids and bases as well as hydrogen peroxide and acetic anhydride. These modifications increase the dispersion and hydration properties of the lecithin. Enzyme modification is also possible with lipases and phospholipases. These changes markedly affect the functionality in emulsification.

Composition of Lecithins

The composition of lecithins and their phospholipids will vary depending on their source: vegetable, animal, or bacterial. There are minor differences within a class but major differences between the sources. Vegetable lecithins are high in phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidic acid, but very low in phosphatidylserine and contain no sphingomyelin. Animal lecithins are high in phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine and

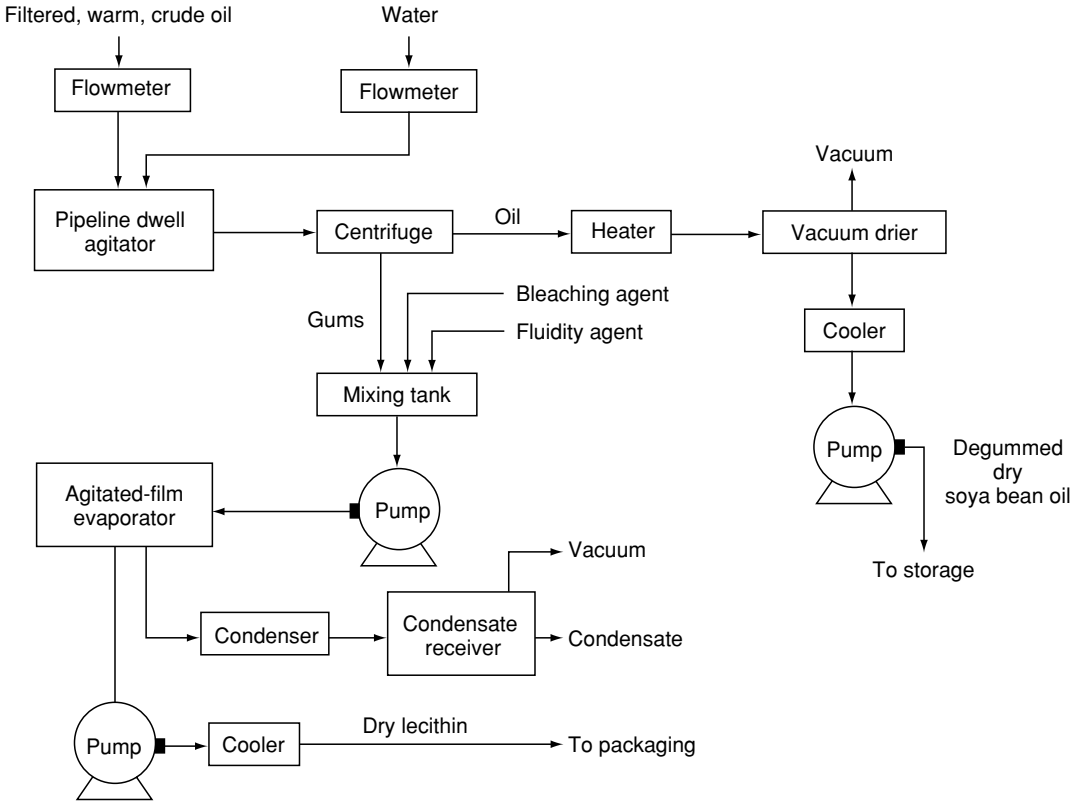

Figure 1 Flowsheet for degumming and crude lecithin production. Reproduced from List GR (1989) In Szuhaj BF (ed.) *Lecithins: Sources, Manufacture and Uses*, p. 149. Champaign: American Oil Chemists' Society, with permission.

sphingomyelin but contain no phosphatidylinositol. Microbes have phospholipids similar to the plant kingdom with high levels of phosphatidylethanolamine and phosphatidylcholine and phosphatidylserine or sphingomyelin.

Specifications of Lecithins

Lecithins may be qualified in several ways, chemically, physically, and functionally, but there are also specifications used to assess quality and purity (Table 3). These include acetone-insolubles (AI), acid value (AV), hexane-insoluble matter (HI), peroxide value (PV), moisture, color, free fatty acids (FFA), divalent metals (DVM), iodine value (IV), and phosphorus. Most of these analytical methods are found in the American Oil Chemists' Society (AOCS) *Official Methods and Recommended Practices*, Section J.

Acetone-Insolubles

Phospholipids are nearly insoluble in cold acetone. This quantitative method should measure the active ingredients in lecithin. Depending on the type of lecithin, the range is 35–98%.

Acid Value

The phosphorus group in lecithins have a titratable acidity that is measured with this volumetric method. FFAs are also measured in this test and should not be confused with phospholipid acidity. The AV range is 20–36 mg of potassium hydroxide per gram.

Hexane-Insolubles

In the processing of soya bean lecithin, particulate matter finds its way through some processes and gives the product a hazy appearance. The HI can be determined by dissolving the product in hexane, centrifuging and gravimetrically measuring the insolubles. The HI range for soya bean lecithins is 0.05–0.3%.

Peroxide Value

The PV is a measure of oxidation in fats and oils. In lecithin, however, the PV usually measures the residual hydrogen peroxide from processing. The range in unbleached products is 0–10 mmol kg^{-1} and in bleached products is 10–75 mmol kg^{-1}.

Table 3 Specifications range for commercial lecithins

Analysis	*Typical range*		
Acetone-insolubles (%)	35–98		
Acid value (mg KOH g^{-1})	20–36		
Hexane-insolubles (%)	0.05–0.3		
Peroxide value (mmol kg^{-1})			
Unbleached	0–10		
Bleached	10–75		
Moisture (%)	0.1–1.0		
Viscosity (Brookfield, 25 °C) (cP)	150–20 000		
Free fatty acids (mg KOH (g^{-1})	1–5		
Iodine value (cg I g^{-1})			
Natural	95–110		
Oil-free	80–90		
	Fatty acid composition (%)		
	Soya bean oil	*Natural*	*Oil-free*
$C_{16:0}$	10.3	15.6	20.3
$C_{18:0}$	4.4	4.7	4.6
Total saturates	14.7	20.3	24.9
$C_{18:1}$	24.5	17.9	9.2
$C_{18:2}$	53.8	54.0	58.9
$C_{18:3}$	7.0	6.7	7.0
Total unsaturates	85.3	78.6	75.1
Unsaturated: saturated ratio	5.8:1	3.9:1	3.0:1

Reproduced from Central Soya, Chemurgy Division (1990), with permission.

Moisture

The water content of lecithins is quite low, at 0.1–1.0%. It can be measured by oven drying but is more accurately determined by the Karl–Fischer method. This water content is so low that there is no measurable water activity for microbial growth. Moisture contents above 1% will change the viscosity from a fluid to a plastic state. (*See* **Water Activity**: Principles and Measurement.)

Viscosity

The Brookfield viscosity at 25 °C will have a range of 150–20 000 cP. Diluents and divalent metals can alter the viscosity to usable levels.

Free Fatty Acids

This method measures the true fatty acid levels in lecithins which range from 1 to 5 mg of potassium hydroxide per gram. Fatty acids are added as additives to adjust the viscosity. (*See* **Fatty Acids**: Analysis.)

Iodine Value

The IV is a traditional method for qualifying lecithin sources. The more unsaturated fatty acids are found in soya bean lecithins, which have a range of 95–110 in natural fluid lecithins, to 80–90 in deoiled lecithin.

Phosphorus

This wet chemical method is an indirect way of measuring the phospholipid content. The typical level of phosphorus is 2.0% in fluid lecithin and 3.0% in deoiled products. The AOCS method Ca 12–55 has an approximation for converting percent phosphorus to the phosphatides in soya bean oil. The equivalent phosphatides content is equal to percent phosphorus $\times$ 30.

Uses of Lecithin

There are many uses of phospholipids in the food industry. As seen from the functional properties, there are multiple functions for lecithins. The following is a listing of the major areas of use:

- margarines – emulsifier, stabilizer, and antispatter;
- confectionery and snack foods – crystallization control, viscosity control, antisticking;
- instant foods – wetting and dispersing agent, emulsifier;
- commercial bakery products – crystallization control, emulsifier, wetting agent, release agent;
- cheese products – emulsifier, release agent;
- meat and poultry processing – browning agent, phosphate dispersant;
- dairy and imitation products – emulsifier, wetting and dispersing agent, antispattering and release agent;
- packaging aid – release agent, sealant;
- processing equipment – internal or external release agent, lubricant.

Refer to individual foods

Applications of lecithins in foods are clearly supported by the Food Chemicals Codex, the European E322 regulations, and they are considered as generally regarded as safe substances by the US Food and Drugs Administration.

Storage and Handling

Lecithins are very stable products. They are shipped in drums or in bulk containers. They can be stored at ambient temperatures for up to 2 years without loss of activity or becoming rancid or spoiling. The water activity is so low that no microbial growth can occur. The products may be heated to 25 °C for easier application. (*See* **Water Activity**: Effect on Food Stability.)

Determination

B F Szuhaj, Central Soya Company Inc., Fort Wayne, IN, USA

Introduction

Phospholipids are a well-known class of lipids that have been thoroughly analyzed over the past three centuries. Their complete analysis was facilitated by the great advances in separation science and qualitative procedures that have occurred in the last 50 years. This article will cover the analysis of phospholipids from their structure and composition, extraction techniques, qualitative and quantitative assays, and industrial methodology. (*See* **Fats**: Classification.)

Structure of Phospholipids

There are at least a dozen compounds that fall into the class of phospholipids. They have a basic structure of a diacylglycerol backbone with a phosphate ester on the α or third carbon of the glycerol molecule. Usually another compound is attached that characterizes the phospholipid. **Figure 1** shows examples of the structures of the major phospholipids. These phospholipids (and their common abbreviations) are:

- phosphatidylcholine (PC, PtdCho)
- phosphatidylethanolamine (PE, PtdEth)
- phosphatidylserine (PS, PtdSer)
- *N*-acylphosphatidylethanolamine (NAPE, *N*-acyl-Ptd-Eth)
- phosphatidylinositol (PI, PtdIns)
- phosphatidic acid (PA, PtdA)
- phosphatidylglycerol (PG, PtdGro)
- plasmologen (PM)
- diphosphatidylglycerol (DPG, diPtdGro)
- lysophosphatidylcholine (LPC, lysoPtdCho)
- lysophosphatidylethanolamine (LPE, lysoPtdEth)

The proper nomenclature for phospholipids has been defined by the 1976 revised recommendations of the International Union of Pure and Applied Chemistry (IUPAC) and the International Union of Biochemistry (IUB) Committee on Biochemical Nomenclature. For example, the term 'lecithin' is permitted for phosphati-dylcholine but the systematic name is 1,2-diacyl-*sn* -glycero-3-phosphorylcholine. The generic name of 3-*sn*-phosphatidylcholine could be used. The abbreviation PtdCho is also allowed. This article will use the common names listed above since the literature has thousands of references with this terminology.

Composition of Phospholipids

The composition of phospholipids depends on the source of the phospholipids. Those from animal, plant, and microbial sources will have different compositions, depending on the nature of the tissue from which the lipids are extracted – for example, brain, liver, or blood. In plants, it will vary on whether they are from soya beans, corn, cotton, rapeseed, or sunflower. In microbial sources it depends upon the organism.

The phospholipid classes are similar within a species, but differ primarily in fatty acid acyl composition around the 1 and 2 positions on the glycerol backbone.

Fatty Acids

The fatty acid chain length is commonly from C_4 to C_{26}, with different degrees of unsaturation from one to six double bonds, which may be at different locations on the acyl group. However, there is a pattern that is relevant to the present discussion. (*See* **Fatty Acids**: Properties.)

In animals the primary fatty acids range from $C_{12:0}$ (lauric acid) to $C_{24:0}$ (tetracosanoic acid). Again, depending on the species and tissue extracted, the fatty acids can be variable.

In the plant kingdom, the primary diacyl groups on the phospholipids will range from $C_{12:0}$ to $C_{18:3}$, i.e., lauric to linolenic acid. There are usually no C_{20} fatty acids and higher, as in the animal kingdom. The degree of unsaturation depends on the origin of the crop, i.e., from temperate or tropical regions. Also, the climate within the zone can make a seasonal difference.

Figure 1 Structures of the major phospholipids. Reproduced from Scholfield CR (1985) In: Szuhaj BF and List GR (eds) *Lecithins*, p.3. Champaign: American Oil Chemists' Society, with permission.

Microbial phospholipid acyl groups are more similar to those found in the plant kingdom than they are to those from the animal kingdom. The predominant acyl fatty acids range from $C_{16:0}$ to $C_{18:3}$. There are more odd-numbered carbon fatty acids in microorganisms than elsewhere.

A further factor that makes phospholipid composition more complex is the ability to have different fatty acids on the 1 and 2 positions of the molecule. Most research has shown that polyunsaturated fatty acids are usually in the 2 position.

Extraction Techniques

One of the most important factors in phospholipid analysis is the initial extraction procedure. If the analysis is on a finished commercial lecithin there is no problem, but if the analysis is from tissue samples or food samples the extraction technique will be critical in obtaining meaningful results.

Tissue Samples

For many years the Folch extraction of tissue homogenates with chloroform/methanol 2:1 (v/v) has been the method of choice by most researchers. Some found that the use of chloroform/methanol 1:1 (v/v) was preferable and some have used a biphasic system of butanol/methanol with dilute hydrochloric acid. Some have used hexane/2-propanol 3:2 (v/v). Which solvent system used depends largely on the required accuracy, but in most cases chloroform/methanol 2:1 (v/v) is the best solvent to try initially.

Food Samples

Since food samples may have lecithin or phospholipid added rather than being incorporated into the tissues of the food matrix, the dried sample can be ground and extracted with petroleum ether. If the lipids are bound in the product through processing, chloroform/methanol 2:1 (v/v) can be used. Because of environmental considerations di- or trichloroethane should be used in place of chloroform.

Drying of high-moisture products is required, but not by oven drying or air drying, as oxidation of the fatty acids can occur. Freeze drying of the product is preferred.

Qualitative Analysis

There are several ways to detect the presence of phospholipids. Traditional instrumental methods using ultraviolet and infrared are not used as often since thin-layer chromatography (TLC) can give a qualitative and semiquantitative result in one assay. Also, the use of conformational chemical sprays on the TLC plates can further identify the products.

Thin-Layer Chromatography

There are several types of silica gel plates available for TLC. Silica gel G and H are the most useful. Phospholipids may be separated on a 20×20 cm plate in one or two directions. A polar solvent and a nonpolar solvent system are used. The polar system is chloroform/methanol/water (65:25:4, v/v/v) and the nonpolar solvent is petroleum ether/diethyl ether/acetic acid (90:10:1, v/v/v). See the American Oil Chemists' Society (AOCS) recommended practice Ja 7-86 for alternative methodology. (*See* **Chromatography**: Thin-layer Chromatography.)

These TLC plates are air- or oven-dried after separation of 20–50 μg of sample and are sprayed with 10% sulfuric acid and heated to char the phospholipids. Alternatively, they may be sprayed with a phosphorus spray containing molybdenum blue. Phospholipids stain a deep blue on heating the TLC plate. An example is shown in Figure 2.

Nondestructive visualization techniques can be used if the phospholipids are to be determined or the fatty acid composition is to be run. Ultraviolet light and 2′,7′-dichlorofluorescein easily detects lipids on TLC. On prep plates, the bands are scraped off and extracted with chloroform/methanol (1:1, v/v) and the fatty acids converted to methyl esters using boron trifluoride and then determined using gas–liquid chromatography (GLC).

Yaste, Central Soya, Food Research, Fort Wayne, Indiana, USA.

Quantitative Analysis of Phospholipids

Column Chromatography

Column chromatography precedes TLC in the separation of phospholipids. The techniques are slow and require good skill with column preparation, flow rates, and solvent removal. Commercial lecithins can be separated by dissolving the crude mixture in petroleum ether and passing it through a deactivated silica gel column with petroleum ether. The phospholipids are adsorbed and do not pass through the column, whilst triglycerides and sterol esters are eluted. The phospholipids are subsequently quantified by TLC and wet phosphorus analysis.

High-Performance Liquid Chromatography (HPLC)

Newer technologies have found that HPLC can separate and quantify phospholipids more quickly and accurately. Separation is carried out on several types of columns, including silica gel and an amino group bonded to the silica surface (μBondapak-NH_2). The columns are eluted with chloroform/methanol gradients, acetonitrile/methanol/85% phosphoric acid, or acetonitrile/methanol/ water. The eluent is measured at 205 nm or detected with flame ionization. Figure 3

shows an HPLC separation of commercial lecithin, using ultraviolet detection. The mass detector, an evaporative analyzer, has also been successfully used for the HPLC determination of phospholipids. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Densitometry

Densitometric scanning has been used as an indirect method for determining phospholipid content on TLC plates. While the method has some promise, a problem is the quanitative charring of the phospholipid spots. Each phospholipid has a different charring density and this depends on fatty acid composition. Only with proper standards can this method be useful.

Thincography

Thin-rod TLC combines TLC with quantification by flame ionization detection. Rods are used rather than plates but controversy still exists over the suitability of the technique for routine lipid analyses.

Phosphorus Analysis on Phospholipids

Phosphorus analysis is an indirect method for the quantification of phospholipids because the qualitative composition of the sample must be known, if accurate values are to be obtained. With pure phosphatides this will work well, but most separation techniques give mixed phospholipids. The preferred method for phosphorus in lecithins is the AOCS method Ja 5-55. This determines the total phosphorus content of the sample. For commercial lecithins a multiple factor of 30 is used to convert total phosphorus values to acetone-insoluble value.

There are various methods to determine phosphorus through molybdenum blue and molybdovanadophosphate yellow. To improve reproducibility many factors need to be evaluated. This includes the digestion method, chromogenesis, and sensitivity. The AOCS method is the most straightforward and should be used especially in the food area.

Industrial Methods of Analysis

Phospholipids are characterized by a different set of assays than the determination of compounds used for academic or biochemical use. Most commercially available phospholipids come from soya beans and from eggs, and the methods outlined below can be used to qualify or categorize the products.

Acetone-Insolubles (AI)

This method determines the content of phospholipids in commercial lecithins. The method employs AOCS method Ja 4-46. The AI is an approximation of the active ingredients in formulations. Cold lecithin-saturated acetone must be used in this test.

Acid Value (AV)

This method determines the phosphatide and fatty acid content of commercial phospholipids. The method utilized is AOCS method Ja 6-55. Phosphatide acidity is often confused with fatty acid addition to commercial lecithin. It is a combination of organic acids and phosphoric acid.

Peroxide Value (PV)

This is a measurement of oxidative state of commercial phospholipids. It measures the milliequivalents of peroxide per kilogram of sample which oxidize potassium iodide. It also measures the residual peroxide used in process stabilization and bleaching. AOCS method Ja 8-87 is used.

Free Fatty Acids (FFA)

This method utilizes AOCS method Ca 5a-40. When run on the acetone-soluble portion of the AI method, it gives the added fatty acids.

Phosphorus Content

The determination of total phosphorus is an indirect method for quantifying phospholipids. This method (AOCS method Ja 5-55) quantifies phospholipids through a molybdate reaction to a chromophore quantitated by phenolphthalein titration.

Gas Chromatography (GC)

This method is commonly used to measure the fatty acid composition and does not quantify the phospholipids themselves (AOCS method Ce 1-62).

High-performance Liquid Chromatography

This is gradually replacing the older techniques for qualifying and quantifying particular phospholipids in commercial mixtures. A uniform technique is being addressed by the AOCS.

Phospholipid analyses have come a long way since their study by Theuticum, *c*. 1800. Each analyst must choose the best method depending on constraints of accuracy and time.

Introduction

Phospholipids are ubiquitous molecules that, due to their chemical properties, have important structural as well as metabolic roles in the cell. The first phospholipid to be discovered was phosphatidylcholine. It was originally named lecithin after the Greek *lekithos*, which means egg yolk. The concept of phospholipids as mere structural and metabolic inert molecules associated with methological difficulties delayed the interest in these compounds until the 1950s, when elucidation on the biosynthetic pathway of phospholipids began to be published. Today, the metabolic and physiological roles of phospholipids are an active and exciting area of research. In this article we discuss the physical and biochemical properties of phospholipids in cellular and subcellular membranes, the biosynthetic and hydrolytic pathways, and the role of phospholipids in signal transduction.

Functional Role of Membrane Phospholipids

Phospholipids are a major component of cellular membrane and play a pivotal role in the communication between extra- and intracellular space. Phospholipids represent a large class of compounds that have fatty acyl chains esterified to glycerol and a charged or zwitterionic head group (**Figure 1**). The fatty acyl chains usually have an even number of carbon atoms from 12 to 26, with 80% being 16–20 carbon atoms long. They may have up to six double bonds, commonly present as a *cis* isomer in one of the fatty acids that creates a kink in the chain. Differences in the length and saturation of the fatty acid tails are important for their influence in the ability of phospholipid molecules to pack against one another, and for this reason they affect the fluidity of the membrane.

In animal cells phosphatidylcholine (PtdCho) is the major phospholipid, whereas in bacteria phosphatidylethanolamine (PtdEtn) is the predominant species. Sphingomyelin is found in most animal cell membranes and belongs to a different group of phospholipids that fits into the overall pattern of phospholipid structure (**Figure 1**). In many mammalian cells, four major phospholipids predominate in the plasma membrane: PtdCho, phosphatidylserine (PtdSer), PtdEtn, and sphingomyelin. Only PtdSer carries a net negative charge, while the other three are electrically neutral at physiological pH with one positive and one negative charge. Sphingomyelin and PtdCho carry a molecule of choline in their head group (**Figure 1**). The phospholipid bilayer of biological membranes confers the amphipathic feature with hydrophobic and hydrophilic domains. The polar head groups of phospholipids face the aqueous exterior of the membrane while hydrophobic regions of the

lipids are sequestered away from the water to the interior of the bilayer in the most thermodynamically favorable arrangement. Because of such chemical characteristics, membrane phospholipid molecules spontanously form bilayers in aqueous environments and form sealed compartments.

Cellular membranes are organized in mosaic-like structures which are dynamic and mobile. The terms 'fluidity' and 'motility' are used to describe properties of membrane and membrane components, respectively. Fluidy reflects the viscosity within the membrane that depends on both the composition and temperature within the membrane. The change in viscosity or in phase transition (from liquid to gel or crystalline state) is determined by the chain length and saturation of the hydrocarbon chains. A shorter chain length reduces the tendency of the hydrocarbon tails to interact with one another and *cis* double bonds produce kinks in the hydrocarbon chains that make them more difficult to pack together, making membranes more fluid at lower temperatures. Phospholipid mobility is determined by intramolecular and intermolecular motion. Intramolecular motion includes three main types: (1) rotation or vibration about each C–C bond within the fatty acyl chain (segmental motion); (2) rotation of the entire molecule about the long axis perpendicular to the plane of the bilayer; (3) a pendulum-like motion of the fatty acyl chains. Intermolecular motion refers to lateral diffusion of complete phospholipid molecules and occurs by interchange of one lipid molecule for another. These time motions have a different time scale, i.e., segmental motion is very fast, whereas lateral diffusion is slower. Flip-flop or migration of phospholipid molecules from one monolayer to another is a comparatively less common type of intermolecular motion. These movements are possible because of the presence of a special class of endoplasmic reticulum (ER) membrane-bound enzyme, called phospholipid exchange proteins or phospholipid translocators, which catalyze the rapid flip-flop of specific phospholipids from the inner to the outer monolayer of plasma membrane or from one organelle membrane to another, e.g., from microsomal vesicles to mitochondria. The phospholipid movements in biological membranes are presented schematically in Figure 2.

Phospholipid fraction of cellular membranes varies considerably in total amount and in the composition of the fatty acids. This diversity occurs across species, among tissues, and even among organelles in the same cell (Table 1).

The functional role of differences in fatty acid composition of cell membranes and the fatty acid asymmetry between phospholipids from the outer and the inner membrane have an important functional significance. In human red blood cell membranes, most of the PtdSer, which is negatively charged, is located in the inner monolayer. This position is important for the activity of the enzyme protein kinase C which requires the negative charge of phosphatidylserine (Figure 2). Similarly, specific inositol phospholipids are concentrated in the cytoplasmatic half of the plasma membrane where it can be reached by specific enzymes and the product of the phosphatidylinositol molecules serves as intracellular signals.

Biosynthesis of Phospholipids

A more direct approach about the biosynthetic pathways of phospholipids, known as the Kennedy pathway, became possible with the utilization of radioactive and stable isotopes, which permitted advances in the understanding of phospholipid active synthesis and breakdown in the cells and their role as a metabolic pool for cellular signals. These techniques are now combined with genetic manipulation for the study of the pathways involved in phospholipid metabolism.

The ER of eukaryotic cells is the predominant site of phospholipid and sphingolipid assembly, but there are phospholipid biosynthetic enzymes localized in the mitochondria and microsomes. The yeast *Saccharomyces cerevisiae* has become the model of choice for the study of the regulation of phospholipid biosynthesis, owing to the possibility of a biochemical, molecular, and genetic approach. The model system of *S. cerevisiae* has allowed advances in the study of intracellular transport and assembly of lipids into membranes, analysis of the genes, and gene products required for lipid metabolism and definition of the role of lipids in signal transduction. Many of the enzymes were isolated and purified and metabolic pathways were targeted by genetic manipulation of specific genes which were impossible in other eukaryotic organisms. In addition, the pathways of phospholipid metabolism in *S. cerevisiae* are, with few exceptions, similar to those found in higher eukaryotes. They also display the intracellular compartmentalization and subcellular membranes typical of eukaryotes which are important for the study of localization of the phospholipid biosynthesis enzymes.

Figure 3 shows the biosynthetic pathways in *S. cerevisiae*. The important steps are outlined, together with the enzymes responsible for specific reactions. The whole biosynthetic process is highly interconnected to the sorting and delivery of plasma and subcellular membrane. Synthesis of long-chain fatty acids is achieved by the coordinated action of acetyl-coenzyme A (acetyl-CoA) carboxylase, fatty acid synthase and acyl-CoA synthetases (FAAs),

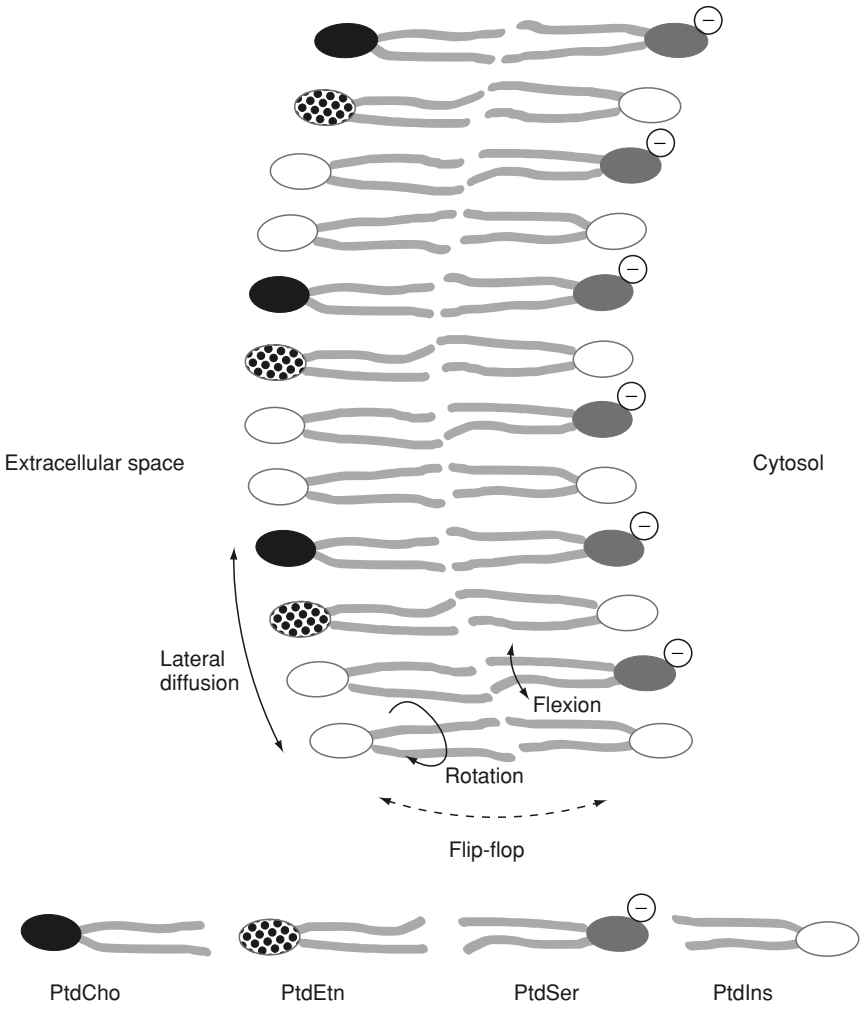

Figure 2 Schematic representation of a biological membrane section, showing the possible phospholipid movements within each phospholipid molecule, between molecules and between the inner and outer phospholipid monolayer. The asymmetry of phospholipid species is also presented, with the predominance of phosphatidylcholine (PtdCho) and phosphatidylethanolamine (PtdEtn) facing the outer half and phosphatidylserine (PtdSer) with a negative charge and phosphatidylinositol (PtdIns) facing the inner half of the membrane.

-elongase(s) and -desaturase(s). The fatty acids are esterified to sn-1 and sn-2 to glycerol-3-phosphate by the enzyme glycerol-3-phosphate acyltransferase (GAT) (Figure 3). Cytidine diphosphate-diacylglycerol (CDP-DAG) synthase (CDS) converts phosphatidic acid to CDP-diacylglycerol (CDP-DAG), the major intermediate in phospholipid synthesis. The availability of CDP-DAG at specific cellular sites will direct the synthesis of different phospholipids, such as cardiolipin (CL), which occurs exclusively in mitochondria and phosphatidylinositol (PtdIns) and PtdSer to distinct subfractions of the ER or the Golgi apparatus. There is extensive transfer of intermediates and cross-compartment integration for the synthesis of phospholipids. For example, the enzyme phosphatidylserine synthase (CHO1) is localized in the ER, while the steps of conversion of PtdSer to PtdEtn take place in the inner mitochondrial membrane. The PtdEtn synthesized in the mitochondria must again migrate to the ER to insure synthesis of PtdCho, the most abundant phospholipid of *S. cerevisiae*.

In the absence of exogenous choline, PtdCho is synthesized by the *de novo* pathway by a three-step methylation of PtdEtn, which is catalyzed by the ER methytransferases. In the case of mutants with defects in phosphatidylserine decarboxylase (PSD) and methyltransferases, choline and ethanolamine must be provided in the medium to enter phospholipid biosynthesis via the salvage pathway (Figure 3). This route also insures recycling of PtdEtn and

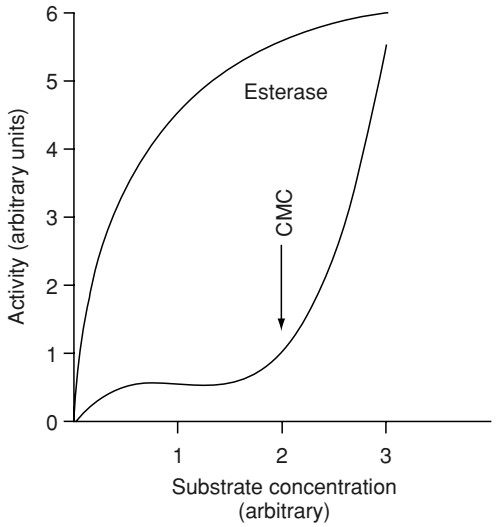

Figure 4 Esterase exhibits Michaelis–Menden kinetics, whereas phospholipase needs critical micellar concentration (CMC) of the substrate for full activity.

PtdCho degradation products and control of local levels of the potent second messenger diacylglycerol.

Degradation of Phospholipids

Undoubtedly, the most important function of phospholipids in the cell membrane relates to their breakdown by the action of phospholipases. The phospholipases are enzymes that hydrolyze phospholipids on water–lipid interfaces and are distinguished from other esterases by their relatively low activity in soluble monomeric phospholipids below their critical micellar concentrations (CMC), but become fully active in aggregated phospholipid structures above their CMC, such as in micelle, bilayers, or hexagonal structures.

As shown in Figure 4, whereas esterases show classical Michaelis–Menten kinetics, the phospholipases may reach more than 1000-fold increase in activity as the substrate phospholipid concentration reaches the CMC. Important factors responsible for this increased rate of hydrolysis include high local substrate concentration, amphipatic substrate orientation at the interface, enhanced diffusion of products from the enzyme to lipid or aqueous moieties, and conformational change of enzyme upon binding to the interface.

Phospholipases play a central role in the activation of various events related to phospholipid degradation. In general: (1) many phospholipases are digestive enzymes found in high concentrations in venoms, bacterial secretions, and digestive fluids of higher animals; (2) many phospholipases have a regulatory function with their products being cellular mediators such as diacylglycerols, inositol trisphosphate, platelet-activating factor, and the eicosanoids. The actions of lipid mediators, known collectively as second messengers, are highly sensitive and under rigid control by a variety of anabolic and catabolic enzymes. Many pathological states, as in inflammation, allergic reactions, and hypertensive states, are related to activation of the cascade of events involving phospholipid degradation and the intracellular second messenger pathway.

Phospholipases are classified as type A_1, A_2, B, C, or D, according to where they act on the substrate phospholipid (Figure 5).

The phospholipases A are acyl hydrolases, which means they remove one acyl group, yielding one fatty acid and lysophosphatide. Phospholipase A_1 and phospholipase A_2 remove fatty acids at positions sn-1 and sn-2, respectively. Phospholipase A_1 is widely distributed in nature and in mammals the major sources are found in the pancreas and the brain. Intracellularly, phospholipase A_1 is dominant in the ER. The best known examples of phospholipase A_2 are snake venom and the pancreatic enzyme that acts mostly on PtdCho and PtdEdn. It is the major phospholipase of mitochondria. Phospholipase B hydrolyzes both acyl groups (sn-1 and sn-2) and also has high lysophospholipase activity. Phospholipase C acts on the glycerophosphate bond while phospholipase D catalyzes the removal of the polar head group. In mammalian cells, phospholipase C is an important initiator of the PtdIns cycle. Phospholipase D is the major phospholipase in many plant tissues and acts specifically on intact phospholipids to give phosphatidic acid and an alcohol. In plants, it seems to be involved in cell turnover and energy utilization. Phospholipase D is also found in bacterial and mammalian sources, where it is involved in replacement of the polar head groups of membrane phospholipids.

Phospholipids as Precursors of Cellular Signal Transduction

In the cell membrane, phospholipids store important precursors of second messengers. Transduction of signals from hormones, across a membrane, involves the coordinated actions of receptor, membrane proteins, and phospholipids that either stimulate or inhibit the synthesis of a second messenger. A number of processes inside the cell are controlled by the level of second messengers.

Among the best described second messenger systems is the G-protein and phosphatidylinositide

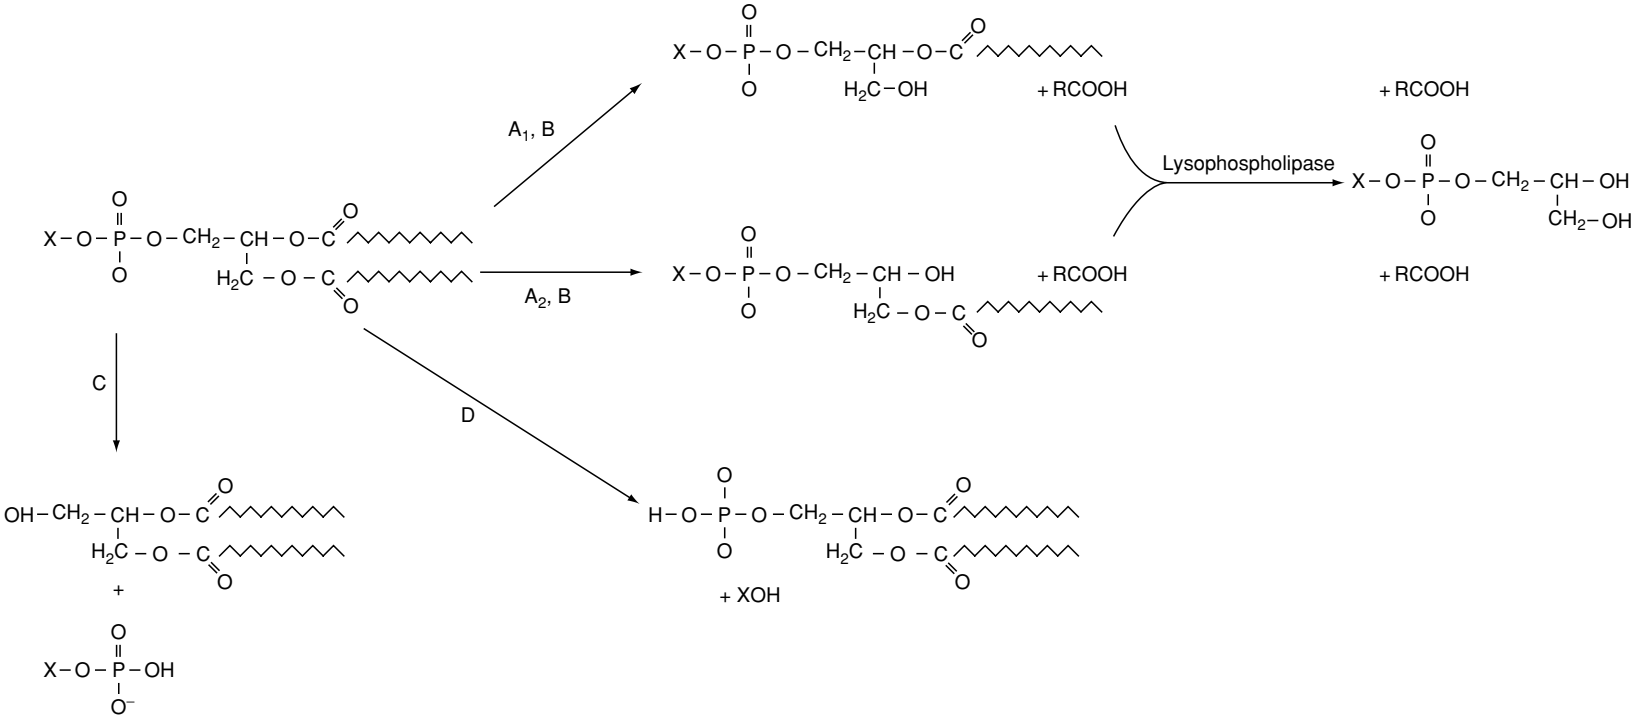

Figure 5 The action of phospholipases A_1, A_2, B, C, and D and lysophospholipase in the hydrolysis of phospholipids. X represents choline, serine, ethanolamine, etc.

system. This system is distinctive in that one stimulus activates membrane reactions that generate two second messengers. The first experimental observations noted that administration of neurotransmitter acetylcholine in pigeon pancreas led to a rapid turnover of PtdIns fraction of membrane phospholipids and release of the digestive enzyme amylase. Similar observations were made in other systems by hormones, neurotransmitters, or growth factors. Despite intensive efforts, the understanding of these mechanisms had not progressed until the early 1980s. It is now recognized that the initial events of inositol phospholipid metabolism occur within 20–30 s of binding of the agonist to the receptor.

Today, the role of specific inositol phospholipids in the phosphoinositide family, namely, phosphatidylinositol 4,5-bisphosphate ($PI(P_2)$), as a membrane-associated storage form of two second messengers, is quite clearly understood.

Figure 6 shows a simplified scheme of the events involved. When an agonist binds to a receptor, membrane G-protein is stimulated to bind guanosine triphosphate. The activated G-protein then acts on the membrane-bound enzyme, phospholipase C, which in turn cleaves $PI(P_2)$ to yield two products, sn-1,2-diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). Both of these products are second messengers. The function of IP_3 is to stimulate the release of calcium ion from intracellular stores, largely from the ER. The increased calcium concentration originates a cascade of events in the intracellular metabolism, including the activation of the membrane-bound protein kinase C (C from calcium). This enzyme requires calcium and PtdSer for its activity. The specific role of the second messenger DAG is to increase the affinity of the protein kinase C for calcium ions. Activated protein kinases will then phosphorylate target proteins inside the cell, which will then be activated and proceed within the cascade. Since many metabolic events are controlled by calcium fluxes and by phosphorylation of specific proteins, the phosphoinositol system shows great ingenuity as a control mechanism. Some of the known target proteins are the insulin receptor, β-adrenergic receptor, and glucose transporter. It is now quite clear that PtdIns is not the only source of DAG which can activate protein kinase C. PtdCho and PtdEtn also seem to serve this role. PtdCho is also a major source of arachidonic acid for the biosynthesis of eicosanoids.

Another well-described example of a regulatory function involving phospholipids in membrane is the generation of another second messenger, known as arachidonate cascade. As described earlier, when an

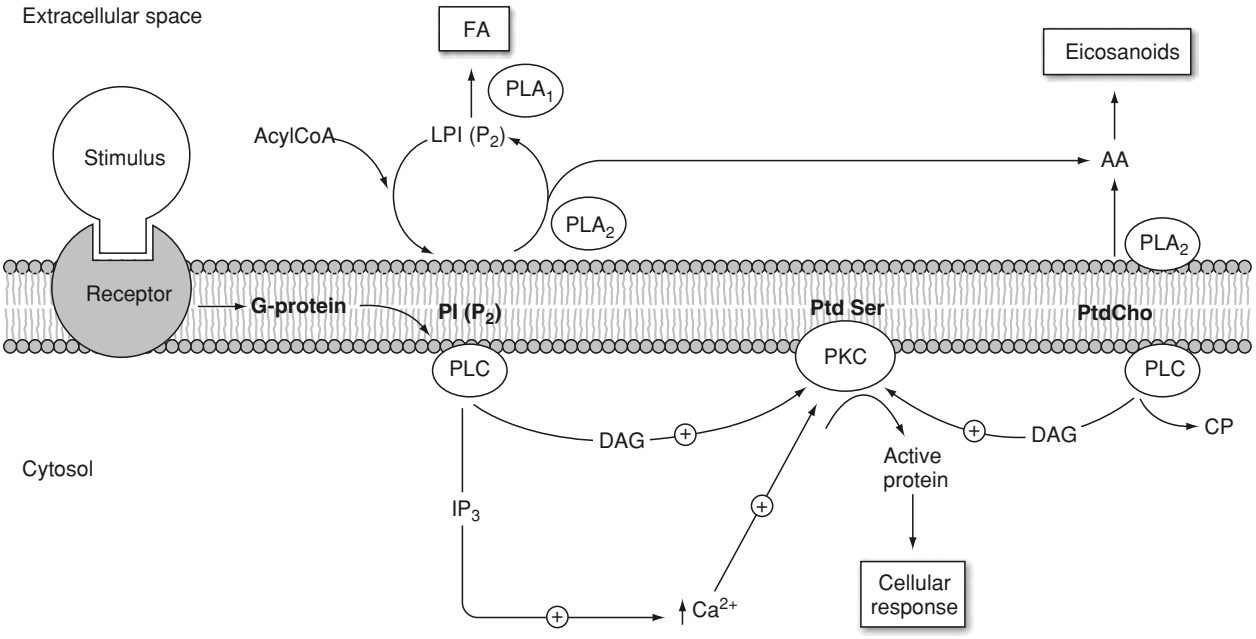

Figure 6 The role of phospholipids in signal transduction. PLA_1, PLA_2, PLC, phospholipases A_1, A_2, C; $PI(P_2)$, phosphatidylinositol 4,5 bisphosphate; IP_3, inositol 1,4,5-trisphosphate; AcylCoA, acyl coenzyme A; DAG, diacylglycerol; FA, fatty acids; AA, archidonic acid; CP, choline phosphate; PKC, protein kinase C; Ptd Ser, phosphatidylserine; PtdCho, phosphatidylcholine; LPI, lysophosphatidylinositol.

agonist stimulates a membrane receptor, a series of events occurs which may lead to the release of 20 carbon polyunsaturated fatty acids from membrane phospholipids, most commonly arachidonic acid (Figure 6). These are tissue-specific stimulants by hormones such as bradykinin or epinephrine, or proteases such as thrombins, to name but a few. Pathological release can occur if membranes are perturbed; for example, the bee sting may stimulate the release of arachidonate from local cell membrane and cause inflammation. This release involves the action of a specific phospholipase A_2 on PtdCho or PtdEdn, yielding arachidonate, and the action of a phospholipase C on PtdIns, yielding a diacylgycerol, which in turn undergoes cleavage to give free arachidonate, which is then converted into a specific eicosanoid in the cell. Eicosanoids, such as prostaglandins, leukotrienes, and thromboxanes are compounds with potent physiological properties which are formed from 20-carbon unsaturated fatty acids into one of a series of eicosanoids according to the enzyme present in the cell and the unsaturated fatty acid released from the membrane. Long-chain polyunsaturated fatty acids of the *n*-3 series, especially from marine origin, when present in the diet will be incorporated into the cell membrane and may replace arachidonic acid in the signal pathway. All eicosanoids are metabolized very rapidly. We still know relatively little about the subsequent effects of eicosanoids at a molecular level, though recent evidence points to their function in the communication pathway with nuclear receptors.

Figure 6 presents events as a coordinated response involving membrane phospholipids and their degradation products. This figure exemplifies the events associated with arachidonic acid release (top) and the mobilization of calcium ions and protein kinase C (bottom). The action of lipid mediators is highly sensitive and under rigid control and when this regulation is not maintained, a number of pathological states, such as those mentioned above, may result.

Current knowledge on the mechanisms involved in intracellular signaling is rapidly advancing and it underscores the importance of the physiological, pathological, as well as the pharmacological properties of this diverse and ubiquitous group of compounds, known as phospholipids. The nutritional significance of phospholipid physiology may be summarized by the fact that foods are the main sources of essential elements of this system.

Properties and Determination

A N Garg, Indian Institute of Technology, Roorkee, U.A., India

Introduction

The extensive and varied chemistry of phosphorus transcends the traditional boundaries of inorganic chemistry because of its vital role in the biochemistry of all living organisms as a constituent of adenosine triphosphate (ATP) and phosphoproteins. It was first isolated from urine by Hennig Brandt in 1669 as a white waxy substance. The spontaneous chemiluminescent reaction of white phosphorus with moist air was the first observed property and was also the origin of its name (Greek: '*phos*,' 'light'; '*pherein*,' 'bearing'). It was also the ancient name for the planet *Venus*, when it appeared before sunrise.

Chemical Properties

Phosphorus is a typical nonmetal placed in group VA of the periodic table. The element phosphorus (P) has an atomic number of 15 and atomic weight of 30.97 with electrons distributed as $1s^2 2s^2 2p^6 3s^2 3p_x^1 3p_y^1 3p_z^1$ and atomic energy levels as shown in Figure 1. Thus, three unpaired electrons, together with the availability of low-lying vacant 3d orbitals, account for the predominant oxidation states III and V in phosphorus chemistry. The most important biological form is the pentavalent oxygen compound phosphate PO_4^{3-}. Phosphorus exists in three main allotropic forms; white, red, and black, each of these being polymorphic. There are at least 11 known modifications, some amorphous, others of some indefinite identity, and all but three of unknown structure. Of these, white phosphorus is soft, waxy, most reactive, and thermodynamically least stable. It has a melting point of 44.1 °C, a boiling point of 80 °C and a specific gravity of 1.82 g cm^{-3}. Red and black forms are heavier with specific gravities of 2.2 and 2.69 g cm^{-3}, respectively. White phosphorus reacts with moist air and gives out light. It ignites spontaneously in air at about 35 °C and is therefore stored in water to prevent combustion. It is soluble in organic solvents such as CS_2 and benzene. If white phosphorus is heated to about 250 °C, or a lower temperature in the presence of sunlight, then red phosphorus is formed. It is a polymeric solid with a melting point of 280.5 °C and sublimes at 430 °C. It is much less reactive than white phosphorus and does not phosphoresce in air. Unlike white phosphorus, red phosphorus need not be stored under water. Its structure is extremely complex, involving a crisscross packing of infinite tubular chains of P atoms. When white phosphorus is heated under high pressure, a highly polymerized form called black phosphorus is obtained. It is also obtained by heating at 220–370 °C for 8 days in the presence of mercury as a catalyst and with a seed of black P. This is thermodynamically the most stable allotrope. It is inert and has a double layer structure with P atoms being bound to three neighbors, as shown in Figure 2. The entire structure consists of a stacking of these double layers with the closest P–P distances within each layer being 2.17–2.20 Å and the shortest P–P distance between layers at 3.87 Å. Therefore, the crystals are flaky like graphite. All forms of phosphorus melt to give the same liquid, which consists of symmetric P_4 molecules with phosphorus atoms occupying corners of a regular tetrahedron. Each atom is directly bonded to the other three atoms P–P = 2.21 ± 0.02 Å. The same molecular form exists in the gas phase at >800 °C and low pressure. The bonding orbitals in P_4 have only 2% of 3s and 3d character. It is most likely that pure

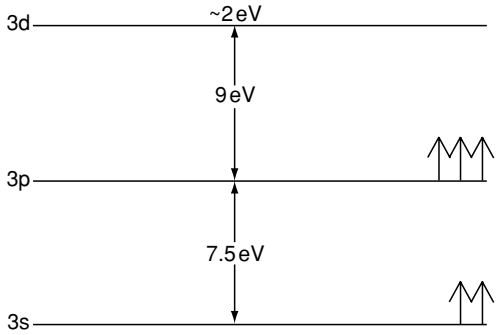

Figure 1 Atomic energy levels in phosphorus.

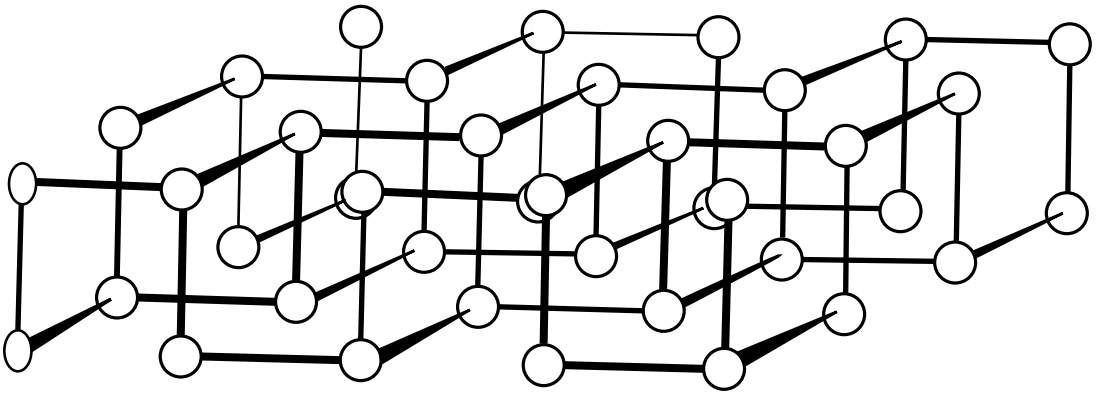

Figure 2 Arrangement of P atoms in the double layers in crystalline black phosphorus.

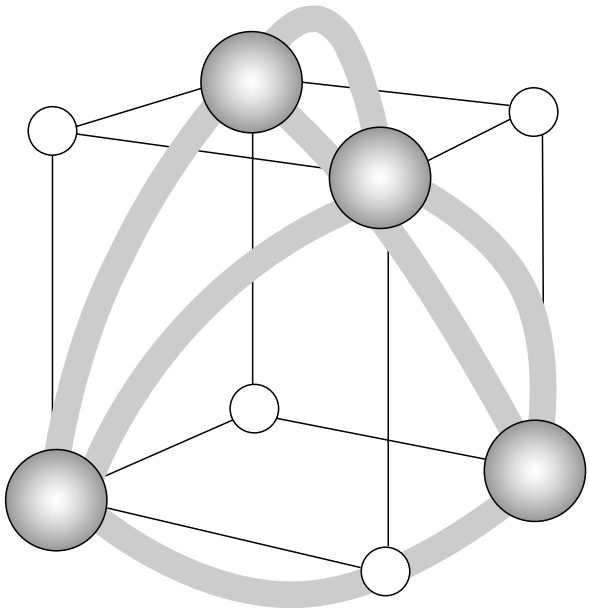

Figure 3 Three-dimensional distribution of valence shell electron density in the P_4 molecule. From Hart RR, Robin MB and Kuebler NA (1965) *Journal of Chemical Physics* 42: 3631–3638, with permission.

3p orbitals are involved, even though the bonds in P_4 are bent with $\angle P\text{–}P\text{–}P = 60^\circ$ and a strain energy of $96\,kJ\,mol^{-1}$, which accounts for its high reactivity. Electronic spectral studies suggest a resonance structure with strong π bonds. The regions of high electron density in the P_4 molecule are shown in Figure 3. The moment of inertia about any of its three major axes is $2.5 \times 10^{-40}\,g\,cm^2$. Thus, the P_4 molecule might be expected to have donor ability.

The only naturally occurring isotope, ^{31}P, has a nuclear spin $I = \frac{1}{2}h/2\pi$ and a large magnetic moment (1.13 NM) but no quadrupole moment. It is suitable for nuclear magnetic resonance (NMR) spectroscopy. In a 10-kG field ^{31}P resonates at 17.24 MHz. Phosphorus forms compounds with all elements except tin, bismuth, and the inert gases. It also reacts readily with heated aqueous solutions to give a variety of products. The bonding and stereochemistry of the phosphorus atom are varied, essentially due to empty d orbitals. It is known in at least 14 coordination geometries with coordination numbers up to 9, though the most frequently met coordination numbers are 3, 4, 5, and 6. Some typical geometries along with orbitals used in the formation of bonds are given in Table 1. Phosphorus has a significant tendency to catenation, forming a series of cyclic compounds $(RP)_n$ where $n = 3$–6, as well as some $R_2\,PPR_2$ type of compounds. (*See* **Spectroscopy**: Nuclear Magnetic Resonance.)

Forms in Foods

Plants need phosphate for healthy growth, especially for the development of roots, flowers, fruits, and seeds, though the requirement is less compared with that for nitrogen and potassium. All foods contain phosphorus in the form of the phosphate anion (PO_4^{3-}), and is consumed by living organisms as such. Very few natural compounds contain phosphorus in any other form. A summary of the types of biologically important phosphorus compounds is presented in Table 2. It is picked up from the soil, where it is present as organic and inorganic phosphates (soluble as well as insoluble) in nucleoproteins, nucleic acids, and the coenzymes nicotinamide adenine dinucleotide (NAD) 2-phosphate, ATP, and other high-energy phosphates. Organic phosphates include sugar phosphates such as glucose 6-phosphate (Figure 4), phospholipids, and pigments. Phosphate in the form of nucleotides serves as a source of a high-energy bond and performs an important function in conserving and providing bursts of metabolic energy.

Table 1 Types of phosphorus compounds and their molecular structure

Numbers of bonds	*Hybridization*	*Geometry*	*Shape*	*Examples*
3	sp^3 (with one lone pair)		Pyramidal	PH_3
4	sp^3		Tetrahedral	PH_4^+, $POCl_3$, $PO(OH)_3$ (d_π–p_π bonding in compounds with PO)
5	sp^3d		Trigonal bipyramid	PCl_5, PF_5, Ph_5P
6	sp^3d^2		Octahedral	PF_6^-

Table 2 Type of biologically important phosphorus compounds and their functions

Type	*Example*	*Function*
Nucleic acids	DNA	Storage of genetic information
	RNA	Transcription of DNA and protein synthesis
Phospholipid	Phosphatidyl choline	Structural components of membranes
Bone salt	Hydroxyapatite	Bone structure and function
Phosphoproteins	Casein	Nutrient storage
	Glutaminase	NH_3 production; acid–base regulation
	Stathmin	Cell proliferation and differentiation
Sugar phosphate	Glucose-6-P	Glycolysis
Nucleotides	ATP	Energy transformation, molecular activation
	cAMP	Second messenger
	Uridine di-P glucose	Glycogen synthesis

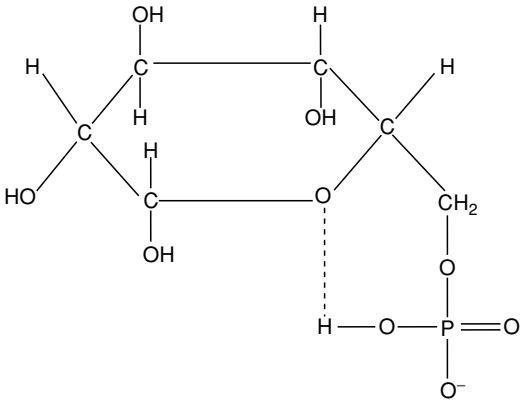

Figure 4

Most of the phosphorus in foods is in the form of organic phosphates that are digested in the intestines to form inorganic phosphates of sodium, calcium, and potassium. A special regulatory mechanism, the parathyroid hormone (PTH)–vitamin D–thyro calcitonin axis is involved in the control of both calcium and phosphorus balance. This hormonal axis controls the absorption rate in the gut, the excretion rate in the kidney, and the storage capacity of bones. Therefore, phosphorus is involved in a multitude of process in the entire life cycle, serving both a structural and catalytic function.

In egg yolk and fish, it occurs in the form of phospholipids, phosphatidylcholine, and phosphatidylethanolamine. In certain foods such as cereal grains and proteins from vegetable sources, 50–80% of the phosphorus occurs in the form of phytin, which is usually the calcium/magnesium salt of phytic acid (the hexaphosphate ester of inositol). Natural starch, particularly of potato, contains phosphoric acid as an ester (Figure 5). (*See* **Phospholipids**: Properties and Occurrence; **Phytic Acid**: Properties and Determination; **Starch**: Structure, Properties, and Determination.)

The phosphate cycle in water is controlled by the biocycle. The inorganic part of the cycle consists of HPO_4^{2-} in solution equilibrium with $H_2PO_4^-$, (PO_4^{3-}), and H_3PO_4. Planktonic algae can absorb inorganic phosphates. Some algae also have a method of

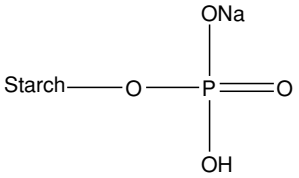

Figure 5

breaking down polyphosphates and even utilizing phospholipids.

Occurrence

Phosphorus is the 11th element in order of abundance in the earth's crust and occurs to the extent of 1120 p.p.m. Elemental phosphorus is not found free in nature but is combined with other elements in the form of inorganic minerals or as components of organic compounds. It occurs in various orthophosphate minerals, notably fluoroapatite [$3Ca_3(PO_4)_2{\cdot}CaF_2$] and also as hydroxyapatite [$Ca_3(PO_4)_2{\cdot}Ca(OH)_2$], chloroapatite [$Ca_3(PO_4)_2{\cdot}CaCl_2$]. About 90% of phosphate rock is used directly to make fertilizers, and the remainder is used to make phosphorus and phosphorus acids. World production of phosphorus is about 1.2 million tonnes per year but is declining. It is obtained by the reduction of calcium phosphate with C in an electric furnace at 1400–1500 °C. Sand is added to remove the slag (calcium silicate) and to drive off the P_4O_{10}, which is then reduced to P by C:

$$2Ca_3(PO_4)_2 + 6SiO_2 \rightarrow 6CaSiO_3 + P_4O_{10}$$
$$P_4O_{10} + 10C \rightarrow P_4 + 10CO.$$

However, in the human body, it is the sixth most abundant element, after O, H, C, N, and Ca. It is an essential constituent of every known tissue and cell in the body and accounts for about 1% of the body weight. Eighty-five percent of it remains in hard tissue and the rest in muscles and blood, as illustrated in Figure 6. Ordinarily, about 70% of phosphorus ingested in foods is absorbed by the body. As phosphate is a major constituent of all plant and animal cells, it is present in all natural foods, mostly in the organic form. Heavy concentrations of phosphorus are found in the meristematic regions of actively growing plants, where it is involved in the synthesis of nucleoproteins. Phospholipids, along with proteins, are significant constituents of cell membranes. Generally, phosphorus is more concentrated in seeds. In plant tissues and juices, it exists as phosphoric acid and the phosphate anion. In some citrus fruits, it occurs up to 2.7% as dihydrogen phosphate anion ($H_2PO_4^-$).

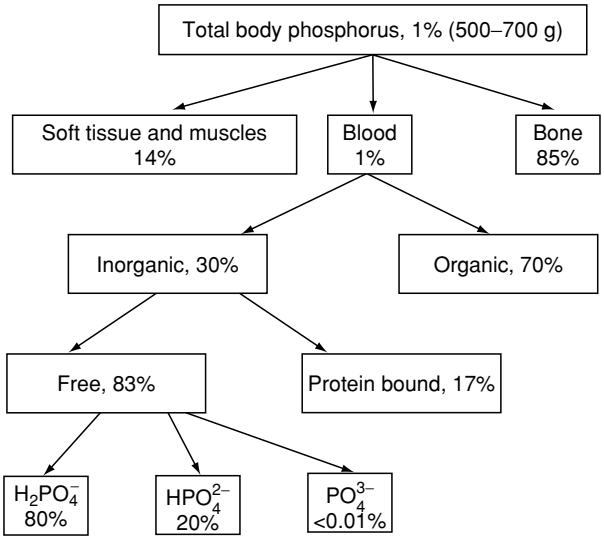

Figure 6 Distribution of phosphorus in the human body.

Table 3 Phosphorus contents in various foods

Food group	*Content (mg per 100 g)*
Cereal grains	100–500
Pulses	300–600
Leafy vegetables	20–500
Fruits	10–500
Nuts and oilseeds	10–1000
Condiments and spices	10–500
Fish and seafood	200–2000
Meat and poultry	150–800
Milk and dairy products	100–1000
Fats and edible oils	10–200
Sugars	10–400
Beverages	10–100

Diets rich in protein and calories also contain P in adequate amounts, regardless of the source of protein, carbohydrates, and fat. Milk and dairy products are the richest source of P in the diet, but P is widely available in other foods. The phosphorus contents in various foods are listed in Table 3. Semirefined brown sugar contains a high level of phosphorus, but refined sugar is completely stripped of the element. In the refinement of cereals, 50–60% of phosphorus is lost. The dietary intake of P can vary substantially with the types of foods consumed. Not all the P in our diet is of natural origin. Polyphosphates are popular additives in many meat products. These enhance the water-binding properties of meat proteins. Total food supplies in the UK and USA provide 0.8–1.5 g of phosphorus per person per day, of which about 10% is added artificially. During pregnancy and the lactation period, however, the requirement for phosphorus is increased. In muscle tissues, phosphorus is present as phosphocreatine (PCr), which synthesizes ATP. Its

deficiency in adults may occur with excessive use of alcohol, prolonged vomiting, liver disease, or hyperparathyroidism. The dietary content of P has been shown to regulate physiologically the serum concentration of PTH and thus indirectly the phosphate homeostasis. Refer to individual food.

Plants lacking phosphorus may develop necrotic areas on the leaves, petioles, or fruits; they may have a general overall stunted appearance, and the leaves may have a characteristic dark to blue–green coloration.

Properties of Phosphates

All phosphates are salts of oxyacids that contain a P = 0 group and at least one P–OH group that ionizes. Some species also have P–H group where the hydrogen atom is not ionizable. Phosphates of metal ions and other cations, mixed metal phosphates, and condensed phosphates are well known because of their commercial and technical importance. Many phosphates, especially long-chain polyphosphates, are known for their toxicity as they adversely affect the osmotic pressure of body fluids and prevent absorption of mineral nutrients. Phosphates are capable of interacting with many of the constituents of food systems, and inactivate metal ions, and are thus important in food processing.

Monosodium phosphate (NaH_2PO_4) is water-soluble and is used as a phosphatizing agent on steel surfaces. Its acidic property is used in effervescent laxative tablets and as a leavening agent in baking powder. Monopotassium phosphate (KH_2PO_4) crystals show a piezoelectric effect and are used in submarine sonar systems. Disodium and dipotassium phosphates are used as buffering agents to maintain pH. This property is used for stabilizing meat. These salts are also used as sequestering agents in the food industry. Sodium orthophosphate (Na_3PO_4) is highly alkaline and finds use in industrial hard surface cleaners. Its aqueous solution is a valuable constituent of scouring products, paint strippers, and grease saponifiers. Its complex with sodium hypochlorite [$(Na_3PO_4{\cdot}11H_2O)_4{\cdot}NaOCl$] releases active chlorine when wetted; this combination of scouring, bleaching and bacterial actions makes the adduct valuable in automatic dish washing powder formulations. Potassium orthophosphate (K_3PO_4) is used to regulate the rate of polymerization of styrene–butadiene rubber. Mono- and diammonium phosphates are used as fertilizers and nutrients. An important property of ammonium phosphate is a flame-retarding agent for cellulose materials. The action depends on its dissociation to ammonia and orthophosphoric acid when heated. Acid so generated catalyzes the decomposition of cellulose to char and smother the flame. Urea phosphate is generally used to flameproof cotton fabrics. A dilute solution of diammonium phosphate, with an initial pH of 7.85, upon boiling evolves ammonia, and the pH drops to 5.78 in 2 h. This property is used for the precipitation of colloidal dyes on wool fabrics. Dicalcium phosphates are used in pharmaceutical tablets as supplements. Natural phosphate minerals are all orthophosphates, the major ones being fluoroapatite; partly carbonated hydroxyapatite makes up the mineral part of teeth. These are important constituents of bones. Calcium orthophosphates are particularly important in fertilizer technology. (*See* **Leavening Agents; Stabilizers**: Types and Function.)

Many phosphate complexes of transition metal ions are known. Ce^{4+}, Th^{4+}, Zr^{4+}, U, and Pu form insoluble phosphates from fairly strong acid solution (3–6 M nitric acid). Condensed phosphates contain more than one phosphorus atom and P–O–P bonds with three main building units – the end unit (Figure 7), middle unit (Figure 8), and branching unit (Figure 9).These units can be readily distinguished by reactivity with water and ^{31}P NMR. These can also be incorporated into linear or cyclic polyphosphates. Linear polyphosphates are salts with the general formula $[P_n O_{3n+1}]^{(n+2)-}$ ($n = 2$–10) such as $M^1_4P_2O_7$

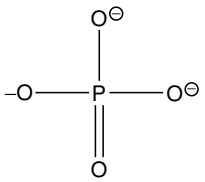

Figure 7

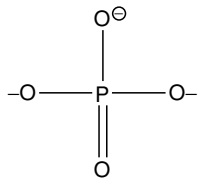

Figure 8

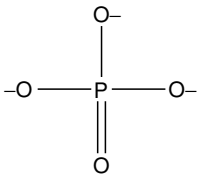

Figure 9

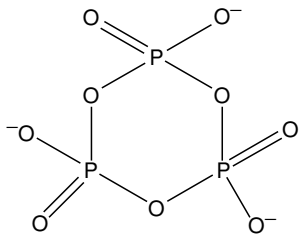

Figure 10

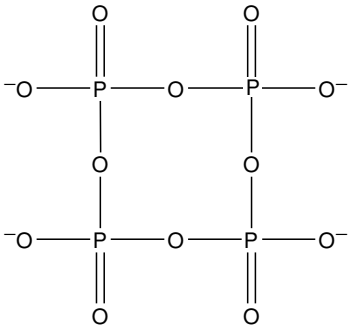

Figure 11

and $M_5^1P_3O_{10}$. Many polyphosphates with different chain lengths have been known. Disodium dihydrogen pyrophosphate, $Na_2^1H_2P_2O_7$ is mixed with $NaHCO_3$ and used in bread making to leaven the bread, that is to make it rise. They react and evolve CO_2 when heated together. Sodium pyrophosphate, $Na_4P_2O_7$, is mixed with starch and a flavoring agent to make instant pudding mixture. At one time, it was also added to soap powders and solutions as a water softener. $Ca_2P_2O_7$ is used as the abrasive/polishing agent in fluoride paste. Cyclic polyphosphates or metaphosphates are the salts with the general formula $[P_nO_{3n}]^{n-}$ with $n = 3$–7 such as $M_3P_3O_9$ (Figure 10) and $M_4P_4O_{12}$. The eight-membered ring of the $P_4O_{12}^{4-}$ (Figure 11) is puckered with equal bond lengths. Condensed phosphates form soluble complexes with many metals. These are usually prepared by dehydration of orthophosphates under various conditions of temperature (300–1200 °C) and also by appropriate hydration of dehydrated species. Chain phosphates are used as water softeners in industry. Polyphosphates aid in controlling the microbiological population on the surface of poultry meat. Some metaphosphates having an infinite chain length are also known, e.g., KPO_3.

Organic phosphates contain phosphate groups linked through OH groups of organic compounds (–C–O–P linkage) such as sugars. Large numbers of phosphate esters, $RO–PO(OH)_2$ are known. These occur in the form of mono-, di-, and triphosphoesters Each form has specific chemical properties leading to different biological functions. These are constituents of numerous highly active intracellular compounds. Release of free energy by hydrolysis of ATP provides the main source of energy for various metabolic processes and for muscle contraction. Intracellular phosphate is a regulator of enzymes in the glycolytic pathways. Some of the alkyl phosphorus compounds are of industrial importance, particularly for solvent extraction of metal ions from aqueous solutions. They extract metal ions by cation exchange and/or by solvation. Among these, di(2-ethylhexyl) phosphoric acid (DEHPA), tri-*n*-butyl phosphate (TBP), and tri-*n*-octylphosphine oxide (TOPO) have been used most extensively. Organic derivatives of fluorophosphoric acid $[FP=O(OH)_2]$ have promising properties as insecticides.

ANALYSIS

Phosphorus is generally detected on the basis of the reaction between orthophosphoric acid and the molybdate ion (MoO_4^{2-}), which gives a yellow-colored precipitate in a strongly acid solution.

Total Phosphorus

Any solution containing phosphorus is fumed with aqua regia almost to dryness, followed by heating with 1 M nitric acid, whence lower oxidation states are oxidized to the orthophosphate (PO_4^{3-}) form. The resultant solution can be used for the estimation of the total phosphorus by gravimetric, titrimetric, or spectrophotometric methods. Some of these have been recommended by the Association of Official Analytical Chemists for the analysis of total phosphorus in vegetables, fruits, cereals, and other foods. These are dried in a silica/platinum crucible and heated over a low Bunsen flame to volatilize organic matter. A 10% sodium bicarbonate solution is added and the contents evaporated to dryness. Oil may be burnt off at a lower temperature without smoking, and finally, ashing is carried out in a muffle furnace at 500 °C. The contents are dissolved in concentrated nitric acid and heated to dryness, and then dilute hydrochloric acid is added.

Gravimetric methods include the formation and weighing of phosphorus as ammonium phosphomolybdate, ammonium magnesium phosphate or pyrophosphate, and quinoline molybdophosphate. On addition of ammonium molybdate solution (12.5 g dissolved in 75 ml of water are slowly added to another solution containing 125 g of ammonium nitrate in 125 ml of water and 175 ml of nitric acid diluted to 500 ml) a yellow-colored precipitate is

obtained, which is filtered, dried at 105 °C, and weighed as $(NH_4)_3PO_4{\cdot}12\ MoO_3{\cdot}H_2O$. On further heating at 450 °C, a dark greenish blue complex, $P_2O_5{\cdot}24MoO_3$, is obtained, which may be weighed. In another method, the ammonium molybdate is replaced by a reagent containing sodium molybdate and quinoline so that quinoline molybdophosphate, $(C_9H_7N)_3[PO_4{\cdot}12MoO_3]$, is precipitated. Alternatively, magnesia reagent (magnesium chloride and ammonium chloride in ammoniacal solution) may be used as the precipitating reagent. The precipitate may be weighed as $Mg(NH_4)PO_4{\cdot}6H_2O$, or after heating in a muffle furnace at 1000 °C as $Mg_2P_2O_7$.

The most common titrimetric method consists of precipitation as $Mg(NH_4)PO_4.6H_2O$, filtration, washing, and dissolution of the precipitate in excess of dilute hydrochloric acid. An excess of standard ethylene diamine tetraacetic acid (EDTA) solution is added, and its pH is adjusted to 10. Excess EDTA is titrated with a standard solution of magnesium chloride or magnesium sulfate using Eriochrome black T as the indicator. Alternatively, the precipitate of ammonium molybdophosphate may be titrated with standard sodium hydroxide solution using phenolphthalein indicator.

Several spectrophotometric methods such as the molybdenum blue method and those using ammonium vanadate and 1-amino-2-naphthol-4-sulfonic acid have been used. A solution containing orthophosphate and molybdate ions condenses in acid solution to give phosphomolybdic acid, which upon reduction with hydrazinium sulfate produces a blue color due to molybdenum blue of uncertain composition. It exhibits a maximum at 620–630 nm. When phosphate, ammonium vanadate, and ammonium molybdate react, a bright yellow-colored complex of phosphovanadomolybdate is formed with a λ_{max} of 460–480 nm. In yet another method, molybdate reagent and 1-amino-2-naphthol-4-sulfonic acid solution (0.5 g with 30 g of sodium bisulfite and 6 g of sodium sulfite made up to 250 ml) are added. After standing for 10 min, the absorbance is measured at 650 nm. Determination of P concentration in plasma and other body fluids is the most common way to evaluate physiological status. The urinary concentration determines mainly how the kidneys handle phosphate. In such cases, the phosphate concentration is measured by the Fiske–Subbarrow colorimetric method. Commonly, the results are reported in units of mass per volume (mg per liter). In all these methods, a blank is always taken, and a standard calibration curve is constructed, from which the concentration of phosphorus is calculated. (*See* **Spectroscopy**: Overview.)

Phosphate is also determined nephelometrically. On adding molybdate strychnine reagent (in two parts: solution A of molybdenum trioxide in 5 M sulfuric acid, solution B of 1.6 g of strychnine sulfate in 500 ml of water; both solutions are mixed before use), a white-colored turbidity is obtained. The phosphorus content is determined from the calibration graph.

In recent years, several instrumental methods, *viz.* inductively coupled plasma (ICP) and/or direct current plasma (DCP) atomic emission spectrometry(AES), spark source mass spectrometry (SSMS), high-performance liquid chromatography (HPLC), flow injection analysis with continuous microwave oven digestion, an enzyme sensor system and X-ray fluorescence (XRF) have been used. Since the advent of body-imaging systems based on nuclear magnetic resonance measurement, it is now possible to detect phosphate in different tissues *in vivo* and determine changes with time under different physiological conditions. Thus, ^{31}P NMR can be used to detect levels of ADP, ATP, PCr, etc., and the metabolic activity of the cells can be determined. This method is used to study mainly the functioning of human liver and heart. Being most sensitive, it opens the most fascinating horizons for understanding the role of phosphorus in different metabolic pathways. With the availability of nuclear reactors, more sensitive methods employing radioactivity measurement have been employed. On thermal neutron irradiation, ^{32}P (β emitter, 1.71 MeV, half-life, 14.3 days) is formed by the (n, γ) reaction. A gas flow proportional counter is used with an aluminum absorber (thickness 27 mg cm^{-2}). Only a small sample size ($\sim$50 mg) is required. A derivative activation analysis method, and those employing Cerenkov and Bremsstrahlung counting have also been employed. Some radiotracer methods employing ^{32}P have been used for investigating the uptake of phosphate ions by plants through roots. (*See* **Chromatography**: High-performance Liquid Chromatography; **Mass Spectrometry**: Principles and Instrumentation.)

Organic Phosphorus

Phosphorus-containing organic compounds are first extracted into benzene or any other suitable solvent. An aliquot is transferred to a beaker, and the solvent is evaporated slowly on a water bath. The residue is heated with concentrated nitric acid and then with a small amount of potassium chlorate to dryness. After cooling, concentrated hydrochloric acid is added repeatedly until a clear solution is obtained. A 2.5% ammonium molybdate and potassium iodide/sodium carbonate solution is added. The flask is immersed in a steam bath for 15–20 min. After cooling, 0.5% sodium sulfite solution is added dropwise until the

iodine color disappears. Finally, the absorbance is measured at 650 nm.

Organophosphorus compounds can also be combusted in a Schoninger oxygen flask to give orthophosphate, which can be absorbed by either sulfuric or nitric acid. Phosphorus can then be determined spectrophotometrically. Recently, malonyl dihydrazide has been proposed for spectrophotometric extraction of organophosphorus compounds in vegetables. Chromatographic separations employing aluminum oxide and thin-layer chromatography (TLC) have also been used. Gas chromatography–mass spectrometry (GC–MS) has been suggested for the confirmation of organophosphorus pesticide residues in foods. A TLC enzymatic method has been suggested for the determination of organophosphorus compounds down to a detection limit of 10^{-10} g. (*See* **Chromatography**: Thin-layer Chromatography; High-Performance Liquid Chromatograpy.)

Other Forms

Phosphorus may also be found as phosphite PO_3^{3-}, which may be determined as mercurous chloride or ammonium magnesium phosphate. In the first case, an acid solution of phosphite reduces mercury(II) chloride solution (eqn 1), and mercury (I) chloride is weighed, the latter being directly proportional to the phosphite concentration.

$$2HgCl_2 + H_3PO_3 + H_2O \rightarrow Hg_2Cl_2 + H_3\ PO_4 + 2HCl \quad (1)$$

In the other case, phosphite is oxidized by nitric acid to phosphate, which is determined as $Mg(NH_4)PO_4{\cdot}6H_2O$ or as $Mg_2P_2O_7$.

Yet another form of phosphorus is hypophosphite (PO_2^{3-}). It is oxidized quantitatively by excess of ceric (IV) sulfate in sulfuric acid solution in 30 min at 60 °C; the excess Ce^{4+} is titrated with ferrous ammonium sulfate to a permanent red end point using ferroin indicator (eqn 2).

$$4Ce^{4+} + H_3PO_2 + 2H_2O \rightarrow 4Ce^{3+} + H_3PO_4 + 4H^+ \quad (2)$$

It is possible to determine both hypophosphite and phosphite by affecting complete oxidation to phosphate. These different forms may also be differentiated by ion chromatography.

Physiology

J J B Anderson, University of North Carolina, Chapel Hill, NC, USA

Introduction

Phosphorus, an essential nutrient, is required for many different functions in body tissues, both intracellularly and extracellularly. This element, which exists in biological systems as phosphates, is used by cells to make structural molecules and outside of cells to make the crystals of bones and teeth; it serves as a component of intracellular regulatory molecules; it serves as a buffering component in both intra- and extracellular fluids, and it is an important factor in cellular energetics, especially in the mitochondria, where it is used to make most of the high-energy

bonds needed for cellular activities. Lastly, the metabolism of inorganic phosphate is closely linked to that of calcium, and this review will, therefore, also deal to some extent with calcium and its homeostatic control. Adequate phosphorus and calcium intakes are critical not only for skeletal growth, but also for growth and development of soft tissues, especially in neonates. (*See* **Bone**; **Calcium**: Physiology; **Cells**; **Energy**: Measurement of Food Energy.)

Phosphorus, in both the inorganic phosphate (Pi) and organic phosphate forms (Po), is abundant in nearly all foods traditionally consumed. This element is especially rich in animal products, such as meats, fish, poultry, eggs, milk, and other dairy products, but it also exists in cereal grains and most vegetables in good quantities. Because Pi ions are so readily absorbed across the small intestine, with an efficiency of roughly 65–75% in adults and with a somewhat higher efficiency in children, the prompt rise in blood Pi after a meal or snack influences calcium homeostasis, when Pi ions enter the blood from the gut, essentially unaccompanied by the more slowly absorbed calcium ions. An elevation in the plasma concentration of Pi tends to depress the serum calcium concentration, mainly Ca^{2+}, through the formation of a complex of the two ions, and this decline in Ca^{2+} stimulates parathyroid hormone (PTH) release. Although the specific mechanism through which Pi exerts this effect on plasma Ca^{2+} has not been fully established, many experimental data support the existence of this phenomenon.

Dietary phosphorus deficiency, although highly unlikely because of the abundance of this element in foods, contributes to low serum Pi concentration and thereby limits bone mineralization via osteoblasts and the total amount of bone mineral mass deposited in the skeleton. Furthermore, Pi deficiency increases bone turnover, which, during infancy, can lead to rickets.

Dietary Sources of Phosphorus

Although both organic and inorganic forms of phosphorus are widely distributed in foods, 75% or so of the phosphorus in foods is converted to Pi following the various digestive steps in the stomach and upper small intestine. The organic phosphorus usually remains associated with the fat-soluble dietary molecules that are absorbed without digestion of the phosphate groups from these molecules, as is the case with phosphatidylcholine (lecithin).

Phosphate additives in processed foods and in beverages can also make an important contribution to total phosphorus intakes. Concern has been raised about the quantity of phosphate added to cola-type soft drinks, which usually contain approximately 60 mg of phosphate per 12-oz. (336-g) container in the United States, but in reality, much greater amounts of phosphates are added to other processed foods commonly consumed in developed nations. Phosphate additives are used most by the food industry in baked goods, meats, cheeses, and milk products in the United States.

Mean phosphorus intakes of American women, according to recent surveys, range between 900 and 1200 mg per day, depending on age and caloric intake; older women consume less phosphorus than younger women, and active women consume more than sedentary individuals. Men usually consume closer to an average of 1500 mg per day, and their intakes also decline with age and with declining activity and caloric intake. The US Recommended Dietary Allowance (RDA) for each sex over 19 years of age was reduced in 1997 to 700 mg (Institute of Medicine) from 800 mg (NRC), whereas recommended calcium intakes were increased for adults until the end of life. Adequate intakes of phosphorus are readily achieved from foods in the USA, but those of calcium are not. The ratio of Ca:P in typical diets of American adult females is approximately 0.5:1, which raises concern among nutritionists because of the potential adverse effects of nutritional secondary hyperparathyroidism (see below). (*See* **Dietary Requirements of Adults**.)

Table 1 gives representative values of these same foods; the Ca:P ratio of these foods is also given as reference for later discussion of this ratio under Nutritional Secondary Hyperparathyroidism.

Intestinal Absorption of Phosphates

The net absorption of Pi is highly efficient; and the Pi efficiency is more than twice that of calcium absorption, which is usually stated as being between 25 and 30% in adults. The efficiency of Pi absorption by infants has been reported to be as high as 80–90%. Typical meals that contain representative items from all food groups, including dairy, have ratios of Ca:Pi approaching 0.7:1.0. If the actual amount of calcium in the meal is 350 mg, and the amount of phosphorus is 500 mg, then 75% of the phosphorus, or 375 mg, will be absorbed, most of it within the first postprandial hour, but only 30% or 105 mg of calcium will be maximally absorbed, and this process usually takes several hours to be completed. The net effect is that the rise in blood Pi concentration tends to depress the serum Ca^{2+}, perhaps through a reciprocal adjustment in the serum ion concentration product, i.e., $[Ca^{2+}] \times [Pi] = \text{constant}$, a mechanism proposed in the 1940s. Parathyroid hormone (PTH) secretion from the parathyroid glands responds to the depressed serum Ca^{2+} concentration as long as absorbed Pi continues

Table 1 Phosphorus and calcium composition of representative foods in a serving and the Ca:P ratio of these foods

Food item	*Weight (g)*	*Calcium (mg)*	*Phosphorus (mg)*	*Ca:P ratio*
Dairy

to lower the Ca^{2+} concentration. (*See* **Hormones:** Thyroid Hormones.)

Pi absorption occurs by two major routes, transcellular and paracellular, throughout the small intestine and probably also the large intestine. The transcellular route is considered the more significant route, but not much is known about the paracellular pathway in terms of location in the small intestine or the quantitative contribution of this component. The transcellular route involves at least two distinct mechanisms

of entry at the brush-border membrane (mucosa) and probably as many as part of the exit step at the basolateral membrane (serosa). Much of the Pi absorption is considered passive because of cotransport with Na^+ or other cations. Because of the cotransport mechanism with Na^+ following a meal, Pi ions may be much more rapidly absorbed than if a separate and independent mechanism for Pi absorption *per se* were required. Understandings of the mechanisms of Pi absorption remain limited. The hormonal form of vitamin D, 1,25-dihydroxyvitamin D, increases Pi absorption via the intracellular route, but much less is known of this pathway than the vitamin D-mediated Ca^{2+} absorption. (*See* **Cholecalciferol**: Physiology.)

Some secretions of Pi ions into the gastrointestinal tract occur at every level, i.e., salivary glands, stomach, intestine, pancreas, liver, and large intestine. Thus, net Pi absorption represents the difference between total Pi absorption and endogenous Pi secretion. Pi ions not absorbed by the gut pass into the stools.

Blood Concentrations of Phosphates

The distribution in human blood serum is compared with the distribution of calcium in Table 2. Po in the lipid fraction of blood plasma generally represents a fairly stable value in individuals on diets with considerable amounts of phosphorus, i.e., typical Western diets, but it will decline if the diet becomes deficient or much lower in phosphorus. The reason for this change is not clear, but it may result from a homeostatic adaptation to the low-phosphorus intake through which membrane-bound Po groups are cleaved and released to the blood in order to keep the plasma Pi concentration at or near its 'set' level. The set level, which is determined genetically in a species, is regulated by various homeostatic mechanisms; in the case of serum Pi, several hormones, especially PTH, are involved in maintaining serum Pi at or near its set level.

The hormonal form of vitamin D – 1,25-dihydroxyvitamin D – is thought to enhance the intestinal absorption of Pi, as it does for Ca, but relatively little is known about the cellular mechanism of this action. For example, Pi-carrier proteins have been identified at the brush border membrane, but no intracellular Pi-binding proteins have been found after vitamin D treatment in animal models.

Table 2 Serum fractions of phosphates and calcium

Phosphate form	*Percentage of total*	*Calcium*	*Percentage of total*
Free HPO_4^{2-}	44	Free Ca^{2+}	48
Free $H_2PO_4^-$	10	Protein-bound	46
Protein-bound	12	Complexed	3
Cation-bound	34	Other	3

Adapted from Bringhurst FR (1989) Calcium and phosphate distribution, turnover, and metabolic actions. In: DeGroot LJ (ed.) *Endocrinology*, 2nd edn, vol. 2. Philadelphia, PA: WB Saunders.

Pi ions in the blood or extracellular fluids are distributed to all tissues in the body to meet cellular needs and to be taken up by the bone fluid compartment for incorporation in hydroxyapatite crystals. During tooth development, Pi ions are taken up by cells (odontoblasts, ameloblasts) and transferred into the extracellular compartment of the developing hydroxyapatite crystals.

Phosphate Homeostatic Mechanisms

The serum Pi concentration is not as rigorously regulated at any time during the life cycle as that of calcium. Several hormones are involved in Pi homeostasis. PTH, calcitonin, and the hormonal form of vitamin D are considered the major regulators, but many other hormones also affect Pi homeostasis, including insulin, glucagon, growth hormone, estrogens, adrenaline, and adrenal corticosteroids. (*See* **Hormones**: Steroid Hormones.)

An elevation of PTH acts to stimulate renal Ca^{2+} reabsorption while acting to block renal Pi reabsorption during this postprandial period, and at the same time, PTH is thought to be relatively inactive on bone cells because of the dominance of calcitonin. The net effect of PTH actions on different tissues is to try to conserve Ca^{2+} in the face of an elevated plasma Pi. However, if PTH remains elevated after the blocking effect of calcitonin decays, then an increased transfer of Ca^{2+} from the bone fluid compartment to blood and PTH-stimulated osteoclastic resorption together can slowly deplete bone when the dietary phosphorus intake greatly exceeds calcium on a long-term basis. This potential mechanism, then, is considered a highly likely way in which low-calcium diets contribute to osteopenia and subsequent fractures that characterize osteoporosis. The name given to this condition is nutritional 'secondary hyperparathyroidism' (see below). (*See* **Osteoporosis**.)

Regulation of the plasma Pi concentration is not well understood, but PTH and other hormones are involved through their renal, intestinal, and skeletal activities. High Pi intakes are handled readily and promptly by healthy individuals, primarily through increased renal excretion. The problem of a high-Pi intake coupled with low-calcium consumption in a typical dietary pattern, however, is handled at the expense of bone mineral through a chronic elevation of PTH and 1,25-dihydroxyvitamin D. Whether

1,25-dihydroxyvitamin D actually exerts a major enhancing effect on intestinal Pi absorption is not clear, but it does increase cellular transfer of Ca^{2+} from the gut lumen to the blood.

Other hormones that also have an influence on Pi homeostasis are important metabolic regulators, such as insulin following carbohydrate ingestion. Insulin stimulates glucose uptake in many extrahepatic tissues, and Pi moves into the cells along with glucose, probably in a 1:1 molar ratio. However, in situations when glucagon is elevated, glucagon enhances renal excretion of Pi, probably through a mechanism that blocks renal tubular Pi reabsorption. Calcitonin is also phosphaturic. Growth hormone and other anabolic hormones and local tissue factors generally stimulate Pi incorporation into organic structures, much like insulin, to meet the needs of growth, cell division, or structural requirements for tissue maintenance. (*See* **Carbohydrates**: Requirements and Dietary Importance.)

Another aspect of Pi homeostasis involves membrane-bound organic (Po) molecules, such as the phospholipids. Animal models fed low-phosphorus intakes have increased degradation of these Po membrane components, which release Pi to the blood and help to maintain the blood Pi concentration at its set level. These findings strongly suggest that membrane phospholipids have a role in Pi homeostasis.

Estrogen may also enhance Pi transfer into cells because plasma Pi becomes somewhat elevated in postmenopausal women and in women who have had an oophorectomy. This rise may also reflect bone turnover and Pi release to blood from the skeleton. Estrogen-replacement therapy in postmenopausal women causes a slight decline in serum Pi.

Excess Pi in cells can be stored in various organelles, such as mitochondria and endoplasmic reticulum, along with Ca^{2+} as calcium phosphates, which can be solubilized in times of need to be retrieved for cellular requirements.

Functional Roles of Phosphates

Phosphorus as Pi and/or Po exists in all tissues, both intracellularly and extracellularly. In extracellular sites, phosphorus exists in the hydroxyapatite crystals of bones and teeth and in phosphorylated proteins in diverse extracellular matrices. The phosphorylation of Type I collagen in bone may trigger the mineralization process. Phosphates also serve as a buffer system in blood and other extracellular fluids.

Intracellularly, phosphates also serve as important buffers, and Po is a component of numerous classes of molecules, including membranes, high-energy molecules, regulatory proteins, regulatory phospholipids, and nucleoproteins. In the phospholipids of nervous tissue, Po is a critical component of many diverse molecules. Phosphorylation of inositol to phosphatidylinositol and cleavage of inositol triphosphate represent an important regulatory mechanism in cells. In addition, phosphorylation of certain enzymes by a variety of protein kinases and the dephosphorylation of these same enzymes (proteins) by phosphatases is central to activation and inactivation of key regulatory enzymes controlling specific metabolic pathways in cells. Pi uptake by cells for the synthesis of regulatory peptides and regulatory phospholipids is also important in metabolically active cells. Thus, phosphorus is much more widely distributed within cells than is calcium, and it serves many diverse roles.

Pi uptake by cells is enhanced by insulin, but other hormones also increase the uptake of this anion, including estrogens, adrenalin, calcitonin, and many growth factors, such as insulin-like growth factor (IGF-1). Once in the cytosol, Pi ions are used for phosphorylating glucose and related intermediate molecules derived from glucose in a meal. In addition, Pi ions are shuttled across intracellular organelle membranes for use or storage. For example, in mitochondria, Pi ions are essential if oxidative phosphorylation is to be adequately coupled. Mitochondria also store roughly 20% of the cells' Pi as calcium salts. Similarly, the endoplasmic reticulum (ER) uses and stores Pi for phosphorylation of various proteins. Also, the ER contains approximately 30% of total cellular Pi for storage and use in phosphorylation of proteins and other molecules. The nucleus, Golgi complex, and lysosomes contain the remainder of the total Pi.

Phosphate in Health and Disease

The balance of phosphorus is determined by the difference between input and output, and it is kept remarkably constant in healthy individuals until late in the life cycle when lean tissue loss accelerates. The balance is clearly negative prior to death in ill patients because of the death of numerous cells without renewal. Pi absorption declines slightly late in life, i.e., sometime after the fifties, because of a reduced efficiency of absorption and because food energy intake also declines in the elderly. Thus, the overall input of Pi is lowered. Pi excretion also declines slightly in healthy older individuals, but it declines more so if renal function is seriously compromised. Normally, urinary excretion of Pi approximates 67% of Pi consumed in the diet, and this percentage holds throughout life in healthy individuals. Unabsorbed phosphorus makes up nearly all of the remainder of fecal Pi elimination, although sweat and skin losses

do contribute a small percentage to the total excretion of Pi.

Several issues of Pi homeostasis need further explanation because of their potential impact on health and disease in populations of developed nations.

Aging and Renal Function

Serum Pi concentration changes little in women with a healthy renal function, but it does increase when the renal function becomes compromised, though the percent reduction in GFR needed for this increase in serum Pi has not been established. Less is known of changes of the serum Pi concentration in men with increasing age, but the same relationship to renal function probably holds in men as in women. Because intestinal Pi absorption efficiency remains fairly constant in aging women, whereas calcium absorption efficiency declines within a decade or so following the menopause, it is possible that PTH secretion is increased in these women 10 or more years beyond the menopause without any other perturbation. Under these conditions, serum PTH concentrations rise, but they typically remain within the upper limit of normality. Severe reductions in renal function clearly elevate serum Pi concentration. Refer to Renal Secondary Hyperparathyroidism.

Nutritional Secondary Hyperparathyroidism

The major concern of nutritionally induced hyperparathyroidism, even if the PTH level remains within the upper range of normal, is the reduction of both bone mass and bone mineral density. A low Ca:P ratio from a diet that provides too little calcium and plentiful amounts of phosphorus may increase PTH in a fairly persistent manner, which in turn increases bone turnover. If bone formation cannot keep up with PTH-governed bone resorption, bone loss will follow (Figure 1). Although not fully established by research evidence, this scenario of a persistently elevated PTH in response to a low Ca:P ratio ($\ll 0.5{:}1$) is suspected of contributing first to osteopenia and then to osteoporotic bone that is more fragile and at increased risk of fracture (see Table 1 for examples of foods with low Ca:P ratios). Recent reports, for example, have shown that the adverse effects of a low Ca:P diet can be improved and largely overcome by simple calcium supplementation. Because the diets of so many adolescents and adults in the USA and probably adults in other technologically advanced nations with significant use of phosphate additives and inadequate calcium intakes have low Ca:P ratios, it is expected that rates of osteoporotic fractures, especially of hip fractures, will increase in the next several decades.

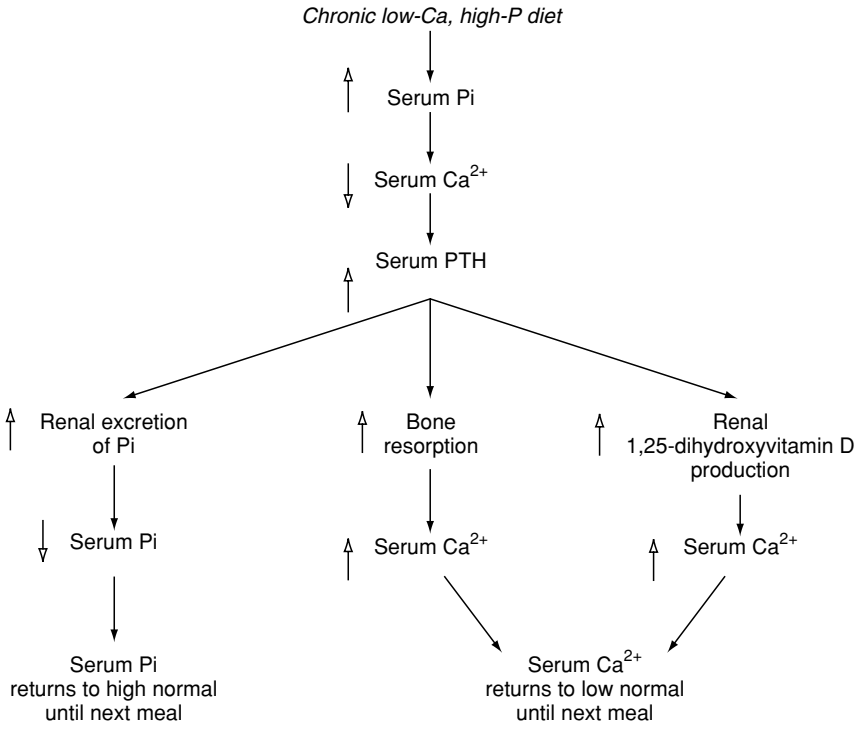

Figure 1 Illustration of steps in development of long-term nutritional secondary hyperparathyroidism: chronic low-calcium, high-phosphorus diet. Reproduced from Phosphorus, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Renal Secondary Hyperparathyroidism

When renal function becomes compromised to such an extent that creatinine, other nitrogenous metabolic products, and Pi are retained abnormally and excessively by the body, then several pathophysiological adaptations occur that have serious effects on health. One of the important adverse effects of the retention of Pi is the rapid and progressive loss of mineral mass. The chronic elevation of serum Pi causes a decline in serum Ca^{2+}, which triggers PTH secretion. The net effect is a constantly elevated PTH concentration that continues to act on bone tissue, i.e., resorption, to try to raise $[Ca^{2+}]$ to its homeostatic set level. Since Pi is also released from bone along with Ca^{2+} during resorption, the serum Pi concentration also increases. Because the kidneys cannot eliminate Pi adequately, $[Ca^{2+}]$ can never be raised to its set level, and bone tissue continues to be degraded as part of an unending vicious cycle.

Various dietary manipulations have been tried to control the loss of bone mass, but no one regimen has been very successful. Reductions of both dietary protein, especially animal protein, and phosphorus have been moderately successful in slowing the progress of chronic renal disease, but the diets are not very palatable or satisfying.

Conclusions

Pi metabolism is much more complex than that of calcium because of the many intracellular pathways that utilize Pi ions at one stage or another. The cytosolic utilization of Pi is closely linked with that of glucose for the formation of glucose 6-phosphate and for triglyceride synthesis through glycerol 3-phosphate formation, as well as with other molecules, during the postprandial period. Pi is utilized by cells for many diverse molecules, including regulatory peptides and phospholipids. Extracellular regulation of Pi is closely associated with that of calcium through PTH and other calcium-regulating hormones. Under typical dietary conditions of excessive phosphorus intake compared with calcium, i.e., low Ca:P ratio, nutritional secondary hyperparathyroidism and the long-term development of osteopenia are likely to result. Food fortification with calcium and calcium supplementation are common ways in which the low Ca:P ratio can be minimized, but individual behaviors aimed at selecting a diet higher in calcium will be needed to overcome the adverse ratio ($\ll 0.5$), despite calcium fortification and/or supplementation. Renal secondary hyperparathyroidism, a serious consequence of renal functional impairment, produces severe bone loss because of altered homeostatic regulation of Pi.

Introduction

The proper chemical designation for phytic acid is *myo*-inositol(1,2,3,4,5,6)hexakisphosphoric acid. Salts of this acid, designated as phytates, are found in plants, animals and soil. Phytate has been considered as an antinutrient due to its inhibitory effect on the bioavailability of essential dietary minerals. During food processing and digestion, phytate can be dephosphorylated to produce degradation products, such as *myo*-inositol pentakis-, tetrakis-, tris-, bis-, and monophosphates. Besides the adverse effects of phytate and other highly phosphorylated *myo*-inositol phosphates on mineral bioavailability, some novel metabolic effects of phytate and some of its degradation products have been recognized. Certain *myo*-inositol phosphates have been suggested to have positive effects on heart disease by controlling hypercholesterolemia and atherosclerosis and to prevent renal stone formation. The most extensively studied positive aspect of *myo*-inositol phosphates is their potential for reducing the risk of colon cancer. Furthermore, much attention has been focused on *myo*-inositol with fewer than six phosphate residues, since some of these compounds have been shown to play an important part as intracellular second messengers and some have shown important pharmacological effects, such as the prevention of diabetes complications and antiinflammatory effects. The position of the phosphate groups on the *myo*-inositol ring is therefore of great significance for their physiological function. Thus, it is important to have reliable techniques available to determine qualitatively and quantitatively *myo*-inositol phosphates not only by the number of phosphate groups, but also by the position of the phosphate groups on the *myo*-inositol ring. (*See* **Plant Antinutritional Factors:** Characteristics.)

Structure, Occurrence, and Biological Significance

Phytate is a *meso* compound and consequently possesses a plane of symmetry with either five equatorial and one axial phosphate groups (5-eq/1-ax) or five axial and one equatorial phosphate groups (5-ax/1-eq: Figure 1). The carbon bearing the single axial or equatorial phosphate group is numbered C2 and the other ring carbons can be numbered C1–C6 from a C1 atom either side of C2, proceeding around the ring in a clockwise or counterclockwise fashion. Some less phosphorylated *myo*-inositol derivatives are optically active (Table 1). Their absolute configuration must be clearly defined. According to convention, a counterclockwise numbering gives rise to *myo*-inositol phosphates with a D-prefix and a clockwise numbering to *myo*-inositol phosphates with an L-prefix. The choice of prefix is normally determined by giving preference to that which results in the lowest numbering of substituents (Figure 2). The predominant conformation of the *myo*-inositol phosphates depends on the specific *myo*-inositol phosphate, pH value, type of cations present, and ionic strength. At pH values above 9.5, phytate exists exclusively in the 5-ax/1-eq conformation, whereas with *myo*-inositol pentakisphosphates a small amount of the 5-eq/1-ax conformer is found in equilibrium with the predominant 5-ax/1-eq conformer. In *myo*-inositol phosphates with fewer than five phosphate residues, the *myo*-inositol ring appears to have a conformation in which only the phosphate group at C2 is axially oriented. Below pH 9.5 the 5-eq/1-ax conformer is predominant with all *myo*-inositol phosphates. The binding of some cations such as Cu^{2+} and Ca^{2+} is proposed to occur mainly via phosphate groups at the equatorial position of phytate; other cations such as

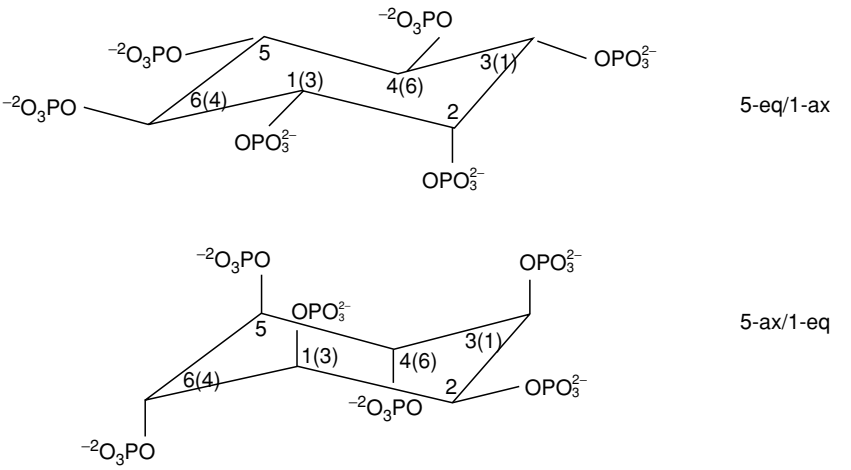

Figure 1 Possible chair conformations of phytate.

Myo-inositol phosphate isomers found in nature are indicated in italics.

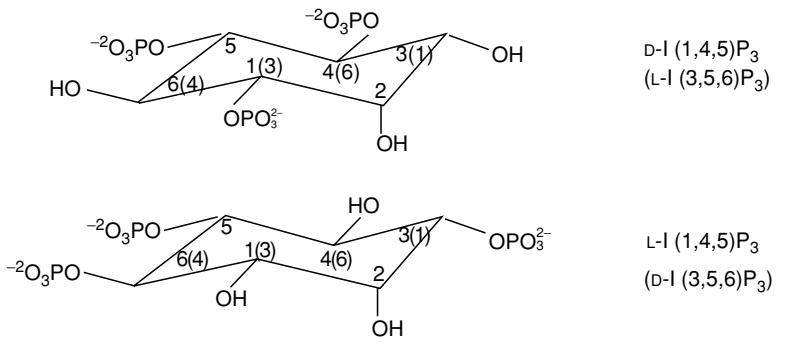

Figure 2 Absolute configuration of D- and L-*myo*-inositol(1,4,5)trisphosphate.

Zn^{2+}, Mn^{2+}, and the alkali metal ions seem to have preference for phosphate groups at the axial position. A single-crystal X-ray analysis of the sodium salt showed the 5-ax/1-eq conformer. In solution, the inositol ring also occurs over a wide pH range in a chair conformation in which five phosphate residues are arranged axially and only the phosphate at C2 is equatorially-oriented. Raman data indicate that alkali metal ions preferentially bind to, and thus stabilize, the 5-ax/1-eq phytate conformer in the order $Li^+ \sim Na^+ > Cs^+$. In contrast, the Raman spectrum of solid Ca_6-phytate is characterized by the 1-ax/5-eq conformer.

Plants

Phytate is ubiquitous among plant seeds and/or grains, comprising 0.5–5% (w/w). It is primarily present as a salt of the mono- and divalent cations K^+, Mg^{2+}, and Ca^{2+} and accumulates in the seeds during the ripening period. In dormant seeds phytate represents 60–90% of the total phosphate. Only a very small part of the *myo*-inositol phosphates exists as *myo*-inositol penta- and tetrakisphosphate of unknown isomeric state. The function of these high phytate concentrations in plant seeds is unclear. It has been suggested that phytate may serve as a store of phosphate, of cations, of the cell wall glucuronate precursor, of high-energy phosphoryl groups and, by chelating free iron, as a potent natural antioxidant. In amoeba, two diphospho-*myo*-inositol pentakisphosphate isomers and one bis(diphospho)-*myo*-inositol tetrakisphosphate isomer are present in concentrations exceeding that of phytate and thus may in fact represent a compact store of high-energy phosphate.

Until now only little is known of the pathway of phytate synthesis in either the plant or animal kingdom. A study in the slime mould *Dictyostelium discoideum* established that phytate synthesis from *myo*-inositol proceeds via Ins(3)P, Ins(3,6)P_2, Ins(3,4,6)P_3, Ins(1,3,4,6)P_4, and Ins(1,3,4,5,6)P_5. Early studies of phytate synthesis in plants led to the proposal that phytate synthesis from Ins(3)P was mediated by phosphoinositol kinase(s) via a series of undefined *myo*-inositol phosphates. Recently the first description of the synthetic sequence to phytate in the plant kingdom was given. From the identities of *myo*-inositol phosphates found in duckweed (*Spirodela polyrhiza* L.), at a development stage associated with massive accumulation of phytate, it was concluded, that synthesis of phytate from *myo*-inositol proceeds according to the sequence D-I(3)P, D-I(3,4)P_2, D-I(3,4,6)P_3, D-I(3,4,5,6)P_4, I(1,3,4,5,6)P_5. An unanswered question that relates to the pathway of phytate synthesis in plants concerns the source of D-I(3)P. Two enzyme activities that are capable of synthesizing D-I(3)P have been identified. These are *myo*-inositol phosphate synthase (EC 5.5.1.4), which converts glucose-6-phosphate, the ultimate source of *myo*-inositol in plants, to D-I(3)P, and *myo*-inositol kinase (EC 2.7.1.64), which converts *myo*-inositol to D-I(3)P. The spatial and temporal distribution and the relative contribution of these two enzymes to phytate synthesis via D-I(3)P are unclear.

During germination, phytate is rapidly hydrolyzed in a stepwise manner by phytate-specific phosphohydrolases (phytases, EC 3.1.3.8, EC 3.1.3.26) or a concerted action of phytases and other phosphatases to supply the nutritional needs of the plant without an accumulation of less phosphorylated *myo*-inositol intermediates. Neither the isomer structure of these intermediates nor the final product of phytate degradation is known to date. From *in vitro* investigations on the stereospecificity of phytate hydrolysis by purified phytases from cereals it was established that these enzymes dephosphorylate phytate in a stereospecific way by sequential removal of phosphate groups via D-I(1,2,3,5,6)P_5, D-I(1,2,5,6)P_4, D-I(1,2,6)P_3, and D-I(2,6)P_2 to finally I(2)P. Moreover, the phytases from bacteria and fungi investigated for phytate degradation release five of the six phosphate groups, and the end product was identified as I(2)P. Thus, the

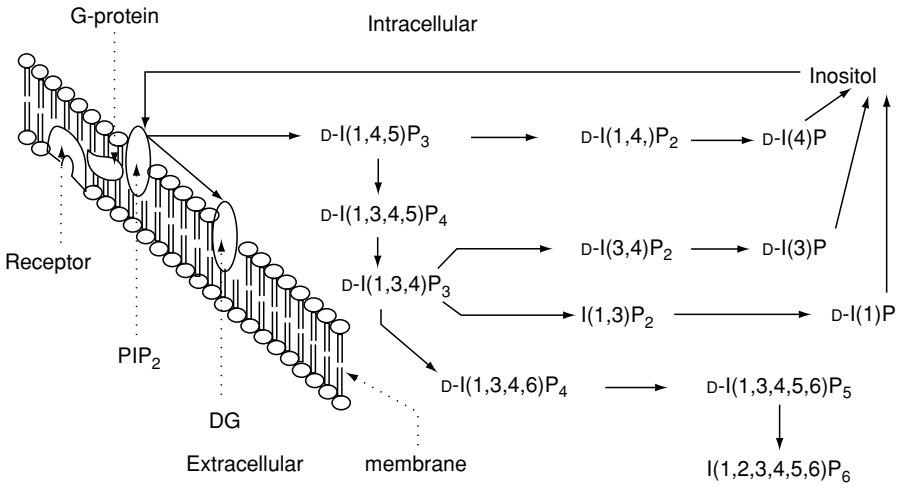

Figure 3 The phosphatidylinositol pathway. PIP_2, phosphatidylinositol 4,5-bisphosphate.

phosphate at C2 seems to be particularly resistant to enzymatic cleavage. (*See* **Enzymes**: Functions and Characteristics.)

Soil

In the soil, phytate as well as less phosphorylated *myo*-inositols are found. Their biological sources are unknown.

Animals

In animal tissue, a considerable number of *myo*-inositol phosphates containing one to six phosphate residues have been found. In most tissues stimulation of the phosphatidylinositol pathway (Figure 3) causes release of D-*myo*-inositol(1,4,5)trisphosphate, which is subsequently metabolized to a wide range of *myo*-inositol phosphate isomers. For D-I(1,3,4)P_3, metabolism is complex, involving both dephosphorylation via D-I(1,4)P_2 to D-I(4)P and phosphorylation to D-I(1,3,4,5)P_4, this latter compound being eventually degraded to D-I(1)P or D-I(3)P. The full significance of this complex metabolism is not clear, but there is now evidence that certain products of the phosphoinositide metabolism play second messenger roles in most cells. D-I(1,4,5)P_3 and D-I(1,3,4,5)P_4 bind to specific receptors and regulate Ca^{2+} release from or movement between intracellular Ca^{2+} stores. D-I(1,3,4,5)P_4 is also the starting point for metabolic pathways generating other *myo*-inositol tetrakisphosphate isomers as well as higher phosphorylated *myo*-inositols. There are no known functions for these higher phosphorylated *myo*-inositols; these metabolites comprise the bulk of *myo*-inositol phosphate content in mammalian cells, but evidence for their association with cell signaling was recently suggested.

D-*myo*-inositol(1,3,4,5,6)pentakisphosphate was also found in the erythrocytes of birds, turtles, and frogs. The functional importance of this compound as a key regulator of oxygen affinity becomes evident with the discovery that erythrocytes of adult birds contain virtually no 2,3-bisphosphoglycerate, the potent allosteric regulator of hemoglobin in mammalian erythrocytes.

Chemical Properties

Numerous studies have been made on the protonation constants of phytate, but the results are often conflicting. This could be due to the fact that the protonation constants of phytate to a large extent are dependent on the ionic strength of the medium. Phytic acid contains six strong acid groups which are completely dissociated in solution (pK_a 1.1–3.2), three weak acid protons (pK_a 5.2–8.0), and three very weak acid protons (pK_a 9.2–12). There unusually high pK_a values for the second protonization step seem to be due to intramolecular hydrogen bonding between the *syn*-axial phosphate residues at C1 and C3 as well as C4 and C6. These pK_a values imply that phytic acid will be strongly negatively charged over a wide pH range and have immense potential for binding positively charged species, such as cations or proteins. Free phytic acid is an unstable compound and decomposes to yield lower *myo*-inositol phosphates and orthophosphate. It is generally isolated as a sodium or calcium salt. In its free form, phytic acid is a light-yellow to light-brown syrupy liquid, soluble in polar solvents (water, methanol, ethanol, 2-propanol, acetone tetrahydrofuran, dimethyl sulfoxide, dimethyl formamide), but insoluble in nonpolar solvents (benzene, toluene, hexane, chloroform). In

contrast to free phytic acid, their salts are very stable compounds. The phosphate groups can be removed hydrolytically by enzymes or acid/heat to yield a large number of homologs and positional isomers ranging from *myo*-inositol mono- to pentakisphosphates (Table 1). In spite of the considerable number of isomers identified *in vivo*, they still represent only a small percentage of the number possible in theory. Above pH 5, there is almost no decomposition of phytate at 100 °C within 10 h. The rate of acid hydrolysis is low – as in other orthophosphoric esters it reaches a maximum at pH 4, e.g., 27% of phytate is cleaved after 6 h at 100 °C, and even the use of strong acids leads to an only moderate increase in the rate of hydrolysis. In 5 mol l^{-1} HCl 47% of phytate is cleaved after 6 h at 100 °C. Final products of acid hydrolysis are *myo*-inositol and *myo*-inositol(2)monophosphate. As with enzymatic cleavage, the axial phosphate at C2 seems to be particularly resistant to hydrolysis. Complete decomposition of phytate was achieved with 3 mol l^{-1} H_2SO_4 at 165 °C for 4 h. Under acidic conditions and higher temperatures in particular, monophosphorylated *cis*-diol groups of the inositols, in competition with hydrolysis, exhibit the phenomenon of phosphate migration. Thus, for example, D-*myo*-inositol(1)phosphate can yield a mixture of D-*myo*-inositol(1)phosphate, *myo*-inositol(2)-phosphate and L-*myo*-inositol(1)phosphate. For this migration, an intermediate formation of cyclic phosphodiesters is essential which is only sterically favored in *cis*-diol groups.

Phytate–Cation Interaction

Phytate forms complexes with numerous divalent and trivalent cations. The stability and solubility of the cation–phytate complexes depend on the specific cation, pH value, phytate-to-cation molar ratio, and the presence of other compounds in the solution. Phytate has six reactive phosphates and meets the criterion of a chelating agent. In fact, a cation can complex not only within one phosphate group or between two or more phosphate groups of one phytate, but also between two or more phytate molecules (Figure 4).

Studying the solubility and relative stability of various phytate–metal complexes by potentiometric titration, the following order of stability at pH 7.4 was found: $Cu^{2+} > Zn^{2+} > Ni^{2+} > Co^{2+} > Mn^{2+} > Fe^{3+} > Ca^{2+}$. Most phytates tend to be more soluble at lower than at higher pH values. The pH value below which the solubilities increase is about 5.5–6.0 for calcium, 7.2–8.0 for magnesium, and 4.3–4.5 for zinc phytate. In contrast, ferric phytate is insoluble at pH values in the 1–3.5 range at equimolar Fe^{3+}-to-phytate molar ratios. Solubility increases above pH 4, reaching 50% at pH 10. When Fe^{3+}-to-phytate molar ratio is increased to 3.5:1, there is increased solubility below pH 2, reaching a maximum of 90% at pH 1.5 and lower solubility at pH values above pH 4. By forming a complex with Fe^{3+} that lacks iron-coordinated water and thus is unable to catalyze the formation of hydroxyl radicals in the Fenton reaction, phytate is a good antioxidant.

Another important fact is the synergistic effect of secondary cations, among which Ca^{2+} has been most prominently mentioned. Two cations may, when present simultaneously, act together to increase the quantity of phytate precipitation. For example, Ca^{2+} enhanced the incorporation or adsorption of Zn^{2+} into phytate by formation of a Ca-Zn phytate. The effect of Ca^{2+} on the amount of Zn^{2+} coprecipitated with phytate is dependent on Zn^{2+}-to-phytate molar ratios. For high Zn^{2+}-to-phytate molar ratios, Ca^{2+} displaces Zn^{2+} from phytate-binding sites and increases its solubility. The amount of free Zn^{2+} is directly proportional to the Ca^{2+} concentration. For low Zn^{2+}-to-phytate molar ratios, Ca^{2+} potentiates the precipitation of Zn^{2+} as phytate. The higher the Ca^{2+} level, the more extensive the precipitation of the

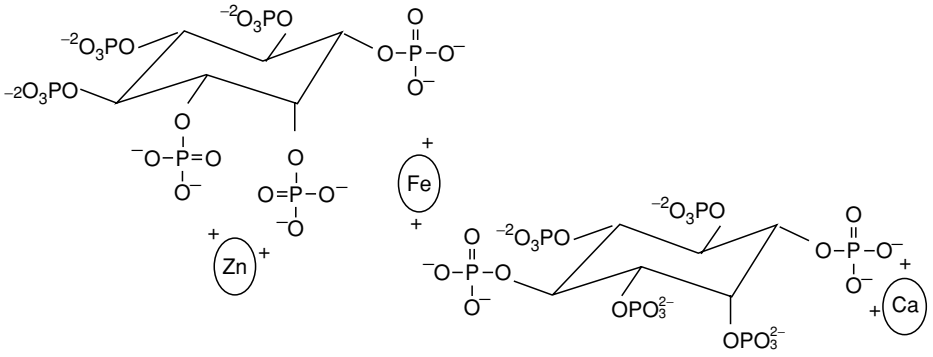

Figure 4 Phytate–cation interaction. DG, diacylglycerol.

ions. Mg^{2+} also has been shown *in vitro* to potentiate the precipitation of Zn^{2+} in the presence of phytate; however, Mg^{2+} has been found to exert a less pronounced effect on Zn^{2+} solubility than Ca^{2+}.

The knowledge about the interaction of the lower *myo*-inositol phosphates with different cations is limited. Recent studies have shown that *myo*-inositol pentakis-, tetrakis-, and trisphosphates have a lower capacity to bind cations (Ca^{2+}, Cu^{2+}, Zn^{2+}, Fe^{2+}, Fe^{3+}) at pH values in the 5–7 range. The capacity to bind cation was found to be a function of the number of phosphate groups on the molecule. The cation-*myo*-inositol phosphate complexes seem to become more soluble as the number of phosphate groups decreases. There is also some evidence for weaker complexes when phosphate groups are removed from phytate. Furthermore, the binding affinity of cations to *myo*-inositol phosphates has been shown to be affected by the orientation of the phosphate groups.

Phytate–Protein Interaction

Phytate interactions with proteins are pH-dependent. Phytate is known to form complexes with proteins at both acidic and alkaline pH (Figure 5). At pH values below the isoelectric point of the protein, the anionic phosphate groups of phytate bind strongly to the cationic groups of the protein to form insoluble complexes that dissolve only below pH 3.5. The α-NH_2 terminal group, the ε-NH_2 of lysine, the imidazole group of histidine, and guanidyl group of arginine have been implicated as protein-binding sites for phytate at low pH values. These low-pH protein–phytate complexes are disrupted by the competitive action of multivalent cations.

Above the isoelectric point of the protein, both protein and phytate have a negative charge, but in the presence of multivalent cations soluble protein–cation–phytate complexes occur. The major protein-binding site for the ternary complex appears to be the unprotonated imidazole group of histidine. The ionized carboxyl group of the protein are also suggested sites. These complexes may be disrupted by high ionic strength, high pH (> 10), and high concentrations of the chelating agents.

Protein–phytate complexation may effect changes in protein structure that can decrease enzymatic activity, solubility, and vulnerability to attack by proteolytic enzymes. Phytate has been shown to reduce the activity of lipase, α-amylase, pepsin, trypsin, and chymotrypsin *in vitro*. The inhibitory effect increases with the number of phosphate groups per *myo*-inositol molecule and the *myo*-inositol phosphate concentration. (*See* **Protein:** Interactions and Reactions Involved in Food Processing.)

Application

Phytate has found industrial application, including uses in the food industry (Table 2). The focus of research on phytates includes occurrence and functions in plant seeds, nutritional significance, preservative applications in food technology, and potential medical and industrial uses. (*See* **Preservatives:** Food Uses.)

Determination

The measurement of *myo*-inositol phosphates in any material requires an initial extraction. The reagents most commonly used to extract *myo*-inositol phosphates from foodstuff and biological samples include 3% trichloroacetic acid and 2.4% hydrochloric acid. Since *myo*-inositol phosphates do not have a

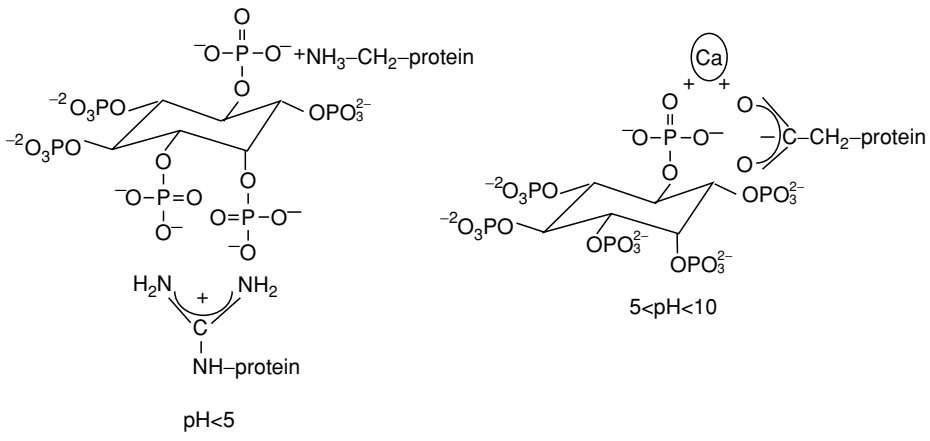

Figure 5 Phytate–protein interaction.

Table 2 Application of phytate

Action	*Application*
Metal chelation	Prevention of color and quality changes in processed agricultural (chestnut, bean sprouts, pickles, asparagus, etc.) and fishery (tuna, clams, shrimps, crabs, etc.) products
	Removing metal ions from wine
	Rust-proofing and dissolving-out prevention inside cans
	Prevention of oxidation in oil/water emulsion-type food such as cream, dressings, butter, chesses, soups
	Additive for etching solution for offset printing
	Anticorrosion agent for paints, antifreezes, and metal surfaces (steel, tin, aluminum, iron)
	Stabilizer for perfumes and cosmetics
	Antioxidant for industrial oils and greases
pH control	Prevention of quality changes by controlling pH value
Fermentation promoter	Improvement of product yield and quality by promoting the growth of microorganisms such as lactic acid bacteria and yeasts (fermented food, antibiotics, methanol, etc.)

characteristic absorption spectrum, nor can they be identified using specific colorimetric reagents, the determination of these compounds has remained a persistent problem.

Qualitative Separation Methods

Qualitative separation and detection of *myo*-inositol phosphates have been developed in the 1950s and 1960s. Paper chromatography has been shown to be useful for separating *myo*-inositol phosphates by the number of phosphate groups. *Myo*-inositol mono- to hexakisphosphate could also be resolved relatively rapidly by electrophoresis. Thin-layer chromatography, even if successfully applicable, has not been widely adopted for the separation of *myo*-inositol phosphates.

Quantitative Separation Methods

Precipitative methods Quantitative methods for determining phytate often employ the addition of a controlled amount of Fe^{3+} to an acidic sample extract to precipitate the phytate. Phytate is subsequently estimated either by determining the phosphate, inositol, or iron content of the precipitate (direct method), or by measuring the excess iron in the supernatant (indirect method). The indirect methods are generally more convenient and reproducible, because the stoichiometric ratio of phosphate to iron in Fe^{3+}-*myo*-inositol phosphate precipitates is affected by several variables, including the way in which the precipitate is washed. These methods are not specific for phytate due to coprecipitation of less phosphorylated *myo*-inositols and should therefore be limited to the analysis of material which contains negligible amounts of these *myo*-inositol phosphates.

Nonprecipitative methods Nonprecipitative methods for *myo*-inositol phosphate determination include ^{31}P-Fourier transform nuclear magnetic resonance (^{31}P-FT NMR) spectroscopy, near-infrared reflectance spectroscopy, low-pressure anion-exchange chromatography, several high-performance liquid chromatographic (HPLC) separation systems, and capillary electrophoresis. The main limitation of ^{31}P-FT NMR and near-infrared spectroscopy is that these methods are specific for phytate only when the sample contains negligible amounts of less phosphorylated *myo*-inositols. Additionally, sophisticated instruments which are not available in most laboratories are required.

Low-pressure anion-exchange chromatography
Low-pressure anion-exchange chromatography is widely used in the determination of *myo*-inositol phosphates. The method currently accepted by the Association of Official Analytical Chemists (AOAC) for measuring phytate in foods and feeds is based on a step gradient (0.7 mol l^{-1} NaCl) anion-exchange method (Dowex AG1-X8). Unfortunately, the anion-exchange resin also retains less phosphorylated *myo*-inositols. The method should therefore be limited to the analysis of material with negligible amounts of these *myo*-inositol phosphates. *Myo*-inositol mono-to hexakisphosphate and even some positional isomers could be resolved using anion-exchange chromatography with a linear eluting gradient of hydrochloric acid or a stepwise elution with either hydrochloric acid or ammonium formate/formic acid solutions of increasing concentrations. Unfortunately, these methods require long elution times (up to 24 h) and a large number of eluate fractions must be hydrolyzed for quantitation as phosphate or inositol, since these systems preclude the use of refractive index and conductivity detection methods. Methods designed by those studying calcium metabolism are dependent on the use of radiolabeled *myo*-inositol phosphates to facilitate detection and quantitation, but it is not feasible to label existing *myo*-inositol phosphates in dietary constituents.

High-performance liquid chromatoraphy More recently, HPLC techniques have been introduced into *myo*-inositol phosphate determination. Purification of crude acid extracts of biological samples is usually required prior to injection on to the analytical HPLC system. The techniques used for detection and quantitation of the *myo*-inositol phosphates is heavily dependent on the system employed for their separation. The *myo*-inositol phosphates may be separated using anion-exchange, reverse-phase, micellar and ion chromatography, and detected/quantified by a variety of techniques, including refractive index, conductivity, indirect photometry, online postcolumn spectrophotometric detection, and offline phosphate or inositol assay. Among these, ion-pair reverse-phase and anion-exchange chromatography are largely used. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Ion-pair reverse-phase chromatography Ion-pair reverse-phase chromatography with refractive index detection has been successfully applied to analysis of *myo*-inositol phosphates. The retention of *myo*-inositol phosphates on reverse-phase packings is markedly increased through the use of ion-pair reagents, allowing the simultaneous separation of *myo*-inositol tris- to hexakisphosphates, but neither *myo*-inositol mono- or bisphosphates nor the individual positional isomers are resolved (Figure 6). However, sample extracts must be passed through anion-exchange resin to remove orthophosphate and concentrate the *myo*-inositol phosphates. Acidic column eluent is then evaporated to dryness to remove hydrochloric acid and reconstituted in water prior to injection on to a silica-based C18 reverse-phase HPLC column. The mobile phase consisted of formic acid/methanol and tetrabutylammonium hydroxide. The affinity of *myo*-inositol phosphates for the stationary phase increases with the increasing number of phosphate groups on the inositol ring and with increasing pH. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Anion-exchange chromatography To date, published procedures involving anion-exchange HPLC fall into two categories: isocratic and gradient ion-chromatographic techniques. The capability of resolving the different *myo*-inositol phosphates depends on the stationary phase used and the chromatography conditions. *Myo*-inositol mono- to hexakisphosphates have been successfully resolved by isocratic elution from low-capacity weak anion-exchange columns. These single eluent systems are compatible with refractive index, indirect photometric, thermospray mass spectrometric, and conductivity detection.

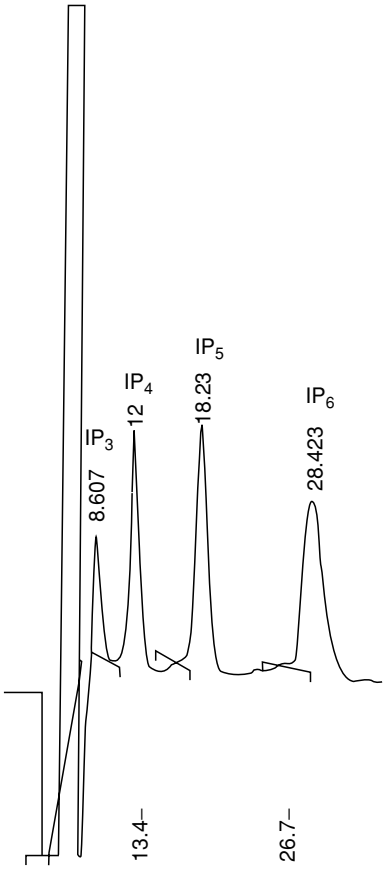

Figure 6 Chromatographic profile of a *myo*-inositol phosphate standard by high-performance liquid chromatography (HPLC) ion-pair chromatography on Ultrasep ES 100 RP18 (2 × 250 mm). The column was run at 45 °C and 0.2 ml min^{-1} of an eluent consisting of formic acid:methanol:water: tetrabutylammonium hydroxide (TBAH: 44:56:5:1.5 v/v), pH 4.25. *Myo*-inositol phosphates were detected by refractive index a standard. Peaks (8.607) IP_3; (12) IP_4; (18.23) IP_5; (28.423) IP_6.

However, in the case of conductivity detection, sensitivity is low unless counterions in the eluent are continously removed using a suppressor column or membrane suppressor system.

In the last few years a number of isomer-specific ion-exchange chromatography methods with gradient elution for separation and quantitation of *myo*-inositol phosphates in the picomolar range have been developed. Eluents with high ionic strength, such as formate, acetate, citrate, phosphate, nitrate, sulfate, sodium chloride, or hydrochloric acid, have been used. The most commonly used detection method with gradient elution is online postcolumn derivatization or complexation reactions followed by spectrophotometric detection. Three approaches have been employed in the postcolumn detection and quantitation of *myo*-inositol phosphates. The first is based on the direct reaction of *myo*-inositol phosphates with a

reagent to form a fluorescent complex or one which has an absorbance in the ultraviolet or visible part of the spectrum. For example, the eluate from the column was mixed, online, with 0.1% $Fe(NO_3)_3$ in 2% $HClO_4$ to form ultraviolet-absorbing phytate–Fe^{3+}–ClO_4 complexes. The use of postcolumn derivatization through ligand-exchange reaction between the iron(III)-sulfosalicylate complex and eluted *myo*-inositol phosphates has been described as an alternative. Furthermore, a complexometric technique based on competition between *myo*-inositol phosphates and the cation-specific reporter dye 4-[2-pyridylazo]resorcinol for the transition metal yttrium has been described. The second approach is based on the online enzymatic hydrolysis of *myo*-inositol phosphates which is then mixed with a molybdate solution in the reaction coil. The colored phosphomolybdate complex may be quantified spectrophotometrically. Finally, *myo*-inositol phosphates may be quantified by online thermospray mass spectrometric techniques.

A remaining problem, however, is to separate isomers from the whole spectrum of *myo*-inositol phosphates in the same run. Separation is generally performed on HPLC columns with gradient elution in two combined systems. *Myo*-inositol mono- to trisphosphates have been acidic gradient-eluted, post-column-derivatized, and ultraviolet-detected and *myo*-inositol bis- to hexakisphosphates have been alkali gradient-eluted and detected using chemically suppressed conductivity detection. The sensitivity of the analysis of *myo*-inositol mono- and bisphosphates was improved 10–100 times by using sodium acetate gradient elution in a sodium hydroxide environment and pulsed amperometric detection.

Capillary electrophoresis Recently capillary electrophoresis has been applied to the determination of *myo*-inositol phosphates. Capillary electrophoresis is attractive, since only a few nanoliters of sample are used in each analysis, there is the potential for concurrent separation of mono- to hexakisphosphate species in the same analysis, and run times are usually short due to the intrinsically high efficiency of the technique. Indirect ultraviolet detection was used to allow the detection of the nonchromophoric *myo*-inositol phosphates. Thus, no derivatization of the compounds is needed. Separations of all six *myo*-inositol phosphate groups in deionized water has been achieved in about 13 min. The position isomers *myo*-inositol(1)phosphate and *myo*-inositol(2)phosphate are easily separated in a phthalate electrolyte system, demonstrating the potential for separating *myo*-inositol phosphate isomers. However, further work is required on the development of capillary electrophoretic methods for the separation and quantiation of the different *myo*-inositol phosphate isomers.

All in all, efficient analytical systems for separation and quantitation of *myo*-inositol phosphate isomers are available. One problem in developing methods to determine *myo*-inositol phosphate isomers is their availability as reference compounds. They may be produced by chemical or enzymatic hydrolysis of phytate. Then identification of these isomers is needed. This requires sophisticated methods. The earliest developed technique is chemical analysis by oxidation with periodate, reduction, dephosphorylation, and subsequent identification of the polyols found. Further information can be obtained from the above-mentioned *cis* phosphate migration. In the past few years, high-resolution nuclear magnetic resonance (NMR) spectroscopy has evolved as a much simpler technique in the identification of the isomeric nature of *myo*-inositol phosphates. Thirty-nine of the 63 theoretically possible *myo*-inositol phosphate isomers can be identified by NMR. Only for the 24 enantiomeric pairs among these isomers (Table 1) absolute configurations are indistinguishable from NMR, but these enantiomers are also not separated on the achiral columns in use. Separation techniques using chiral columns have to be developed to resolve the enantiomers. The absolute configuration of such enantiomers may be determined using high-affinity binding proteins or enzymatic assays.

Introduction

Mixed salts of phytic acid [*myo*-inositol(1,2,3,4,5,6)-hexakisphosphoric acid) are common constituents of foods and feed, since phytate is a naturally occurring compound formed during the maturation of seeds and cereal grains. Depending on the amount of plant foods in the diet and the grade of food processing, the daily intake of phytate can be as high as 4500 mg. On average, the daily intake of phytate was estimated to be 2000–2600 mg for vegetarian diets as well as diets of inhabitants of rural areas of developing countries and 300–1300 mg for mixed diets (**Table 1**).

Phytate behaves in a broad pH region as a highly negatively charged ion and therefore has a tremendous affinity for food components with positive charge(s) (*See* **Phytic Acid**: Properties and Determination). There is a large body of evidence that minerals are less available from foods of plant origin as compared to animal-based foods. Minerals of concern in this regard include zinc, iron, calcium, magnesium, manganese, and copper. The formation of insoluble cation–phytate complexes at physiological pH values is regarded as the major reason for the poor mineral bioavailability, since these complexes are essentially nonabsorbable from the gastrointestinal tract. Furthermore, phytate phosphorus may not be nutritionally available, since phytate is not hydrolyzable quantitatively in the human gut. Consumption of phytate, however, seems not to have only negative aspects on human health. In the last few years, results of epidemiological and animal studies also suggest beneficial effects, such as decreasing the risk of heart disease and colon cancer, but data from human studies are still lacking.

Table 1 Phytate content of foods of plant origin

Food	*Phytate (mg g^{-1} dry matter)*
Cereal-based	
French bread	0.3–0.4
Mixed-flour bread (70% wheat, 30% rye)	0.2–0.7
Mixed-flour bread (70% rye, 30% wheat)	0–0.3
Sourdough rye bread	0–0.3
Wholewheat bread	4.3–6.8
Whole rye bread	2.5–4.8
Unleavened wheat bread	9.2–19.5
Corn bread	5.2–7.1
Unleavened corn bread	11.4–16.3
Oat bran	12.4–29.6
Oat flakes	8.2–10.3
Oat porridge	7.7–10.6
Pasta	2.2–8.6
Maize	11.5–14.2
Cornflakes	0.8–1.3
Rice (polished, cooked)	1.4–2.9
Wild rice (cooked)	16.4–20.1
Sorghum	5.6–9.8
Legume-based	
Chickpea (cooked)	4.9–6.1

Phytate as an Antinutrient

The main concern about the presence of phytate in the diet is its negative effect on mineral uptake. Most studies have shown an inverse relationship between phytate content and mineral availability, although there are great differences in the behavior of individual minerals (Table 2).

Difficulties in Experimental Approaches

The effect of phytate on mineral absorption is highly controversial, since many investigations have shown a negative effect, but some studies have also shown no effect or even enhancement of mineral uptake. This controversial result gives an idea of the complexity of mineral absorption in the intestine (Figure 1). The differing types of experimental design may explain much of this controversy. *In vitro* studies can only incompletely simulate the physiological factors and physicochemical conditions affecting mineral availability. Also, *in vivo* approaches, widely used in mineral bioavailability studies, are not easily comparable due to the existence of many factors that cannot be reproduced in the different experiments. In addition, part of the variability may arise from differences in the method of phytate analysis and experimental techniques for measuring mineral bioavailability. (*See* **Minerals – Dietary Importance**.)

The solubility of phytate complexes is a critical and perhaps overriding issue, because complexes that are insoluble in the upper small intestine, where maximum mineral absorption normally occurs, are highly unlikely to provide absorbable essential elements. Thus, chemical interactions of phytate in the upper gastrointestinal tract are of particular concern. The form in which many minerals occur in foodstuffs is largely unknown, as is also the form in which they occur in the gut. Thus, predicting the specific interactions of phytate in the gastrointestinal tract and the nutritional implications of these interactions is very difficult. As foods are ingested and the digesta travels through the gastrointestinal tract, phytate may continue to maintain associations developed during ripening or food processing or phytate complexes may dissociate and other chelates form, since binding of phytate with minerals or proteins depends upon the pH value, which changes from low pH in the stomach to about neutral in the upper intestine.

The total composition of experimental diets has a great importance on mineral bioavailability, since the reduced availability of essential minerals depends on several dietary factors, such as the total concentration and composition of minerals or the phytate concentration. Phytate *per se* seems not to have a direct adverse affect on mineral absorption, since the physiological concentration of a single mineral is generally not sufficient for the formation of insoluble phytate complexes in the small intestine. Since calcium concentration in the diet is high enough for complete precipitation of phytate, leading to a coprecipitation of other minerals, the calcium content of the diets is of vital importance to the negative impact of phytate on mineral bioavailability. Calcium clearly augments the adverse effects of phytate on mineral absorption, and numerous other dietary components have lesser effects, both beneficial and adverse. For example, the intake of organic acids such as ascorbic acid and/or meat effectively counteracted the inhibitory effect of phytate, whereas dietary fiber and polyphenols intensified it. Both phytate and fiber have a high potential binding capacity for minerals and, because they are generally presented together in many foods, it is very difficult to separate completely the effects of these two in studies with typical human diets.

Phytate degradation during digestion in the gastrointestinal tract may have a positive effect on mineral absorption, since results of animal and human studies indicated that besides phytate, only the first degradation product of phytate, *myo*-inositol pentakisphosphate, showed negative effects on zinc, iron, and calcium absorption in its isolated form, while *myo*-inositol tetrakis- and trisphosphates had no effect in the concentrations under investigation. Furthermore, phytate phosphorus becomes available for utilization after release from the *myo*-inositol ring. The hydrolysis of phytate in the gastrointestinal tract of monogastric animals, including humans, may be carried out by the action of phytate-degrading enzymes from three sources: dietary phytases, phytases from the bacterial flora in the gut, and intestinal mucosal phytases. The level of dietary calcium is thereby of particular interest. A low calcium concentration may favor increased phytate hydrolysis in the gut, whereas elevated dietary calcium decreases its hydrolysis. It was recently reported that mucosal phytase, if present in the human small intestine, does not seem to play a significant role in phytate digestion, whereas the dietary phytases are an important factor, since these enzymes are active in the stomach for a certain time. Phytate degradation by phytases from the bacterial flora in the colon does not contribute to mineral and phytate phosphorus absorption, since, with the exception of calcium, absorption is negligible there.

Furthermore, the history of food processing appears to be of great interest insofar as it can affect the availability of phytate phosphorus and phytate-associated cations. Depending on the manufacturing process, reduction in phytate content of the foods,

Table 2 Effect of phytate on mineral and phosphorus availability

Zinc	*Iron*	*Calcium*	*Copper, manganese, magnesium*	*Phosphorus*
Zinc was reported to be the essential mineral most adversely affected by phytate. Zinc deficiency in humans was first reported in 1963 in Egyptian boys whose diet consisted in the main of bread and beans. These patients, who were characterized by dwarfism and hypogonadism, showed a response to zinc supplementation of their diet. It became accepted that the presence of phytate in plant products was an important factor in the reduction of zinc absorption from foodstuff. Zinc absorption was shown to be inversely correlated with phytate content of the meal. There is, however, some lack of agreement among studies, particularly with respect to specific foods and their components. In addition, it was shown that phytate not only depresses the bioavailability of dietary zinc, but also substantially reduces the reabsorption of endogenous intestinal zinc	A great deal of controversy exists regarding the effect of phytate on the availability of dietary iron. Much of this controversy may be due to the low absorption of iron in general, the presence of different iron phytates with different solubility, and the existence of two types of food iron, heme and nonheme iron. Heme iron is better absorbed and is little influenced by dietary factors; nonheme iron is less easily absorbed, and its absorption is affected by other dietary factors. Since many human studies indicated that phytate had a very strong inhibitory effect on iron absorption, it is well accepted today that phytate appeared to be the major contributor to the reduction in iron availability in humans, but some other factor(s) also contribute	Human studies indicated that phytate inhibited calcium absorption, but the effect of phytate on calcium availability seems not to be as extreme as on that of iron and particularly zinc. This may be due to the relatively high calcium content of plant-based foods, the ability of phytate degradation by microbial phytases of the gut flora, and the absorption of calcium in the large intestine	Relatively few studies have dealt with the effects of phytate on dietary copper, manganese, and magnesium utilization. Phytate has been shown to decrease their bioavailability in *in vivo* studies. It appears that the effect of phytate on copper, manganese, and magnesium bioavailability is less marked than those for some other essential elements	The fact that phytate phosphorus is poorly available to monogastric animals, including humans, was demonstrated several years ago. Phosphorus is absorbed as the orthophosphate. No conclusive evidence for absorption of phytate or other *myo*-inositol phosphates is available at present. Thus, the utilization of phytate phosphorus by monogastric animals will largely depend on their ability to hydrolyze phytate

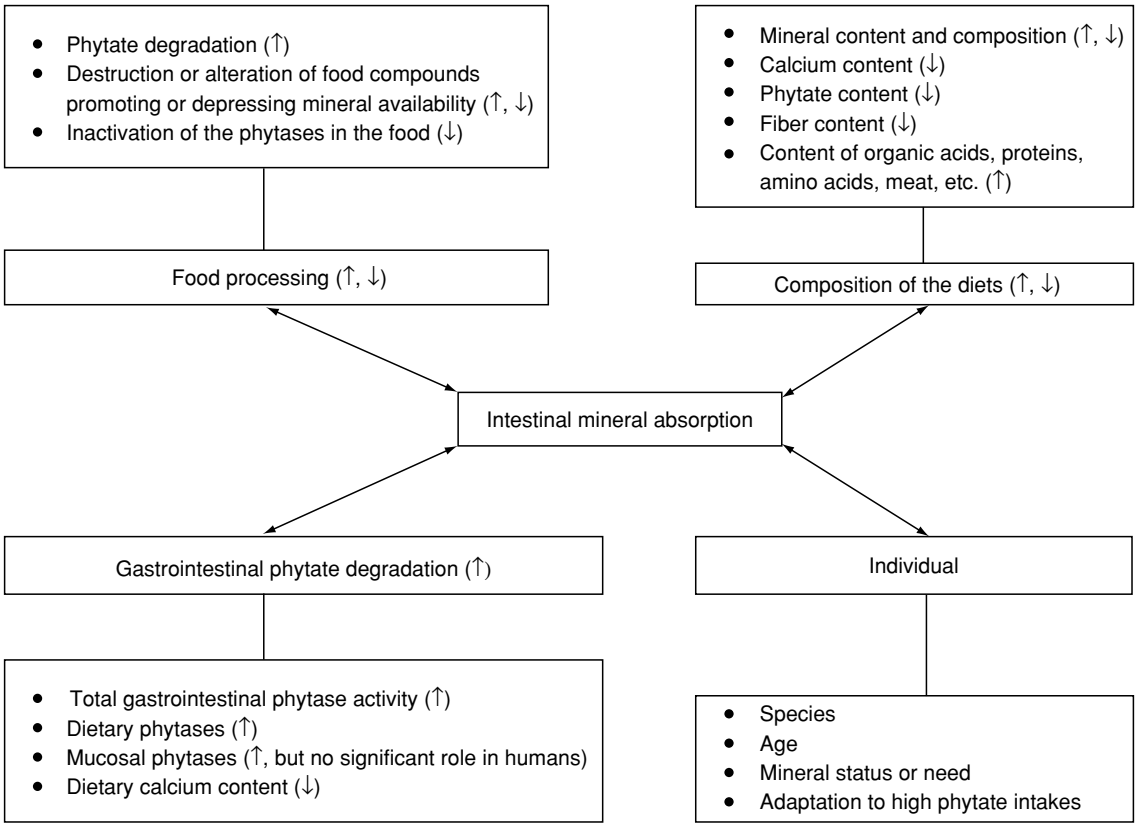

Figure 1 Factors interacting with intestinal mineral absorption. ↑ promoting mineral uptake; ↓ depressing mineral uptake.

destruction or alteration of food compounds promoting or depressing mineral availability, and inactivation of phytate-degrading enzymes may occur. Inactivating the endogenous dietary phytase leads to a limited degradation of phytate in the stomach and therefore to a lower bioavailability of minerals and phytate phosphorus. During food processing and food digestion, phytate can be partially dephosphorylated to yield a large number of positional isomers of *myo*-inositol pentakis-, tetrakis-, tris-, bis-, and monophosphates (*See* **Phytic Acid**: Properties and Determination). Especially with respect to the isomers, their chelating potential has not been carefully studied. This is of great importance, since processed foods and digesta may contain lower *myo*-inositol phosphates in great amounts and human studies have shown that *myo*-inositol tetrakis- and tris-phosphates contribute in high concentrations to the negative effect on mineral absorption. On the other hand, recent evidence has suggested that, besides the adverse effects of phytate and other highly phosphorylated *myo*-inositol phosphates on mineral absorption, lower phosphorylated *myo*-inositol phosphates may improve mineral absorption. Therefore, a reliable and accurate determination of the individual *myo*-inositol phosphates in diets must be utilized before any useful evaluation can be made of their physiological effect on mineral availability (*See* **Phytic Acid**: Properties and Determination).

The source of phytate and minerals also influences the results of experimental studies. Endogenous phytate and added phytate are not necessarily equal. Usually sodium phytate is added to experimental diets; this is capable of chelating the multivalent cations therein, whereas endogenous phytate is already bound to those cations in the seeds and grains. Furthermore, the availability of minerals has mostly been examined after addition of ionic salts to the experimental diets. Results obtained under such conditions may not represent the level of absorption of minerals present in natural sources.

The effect of phytate on mineral absorption also seems to be dependent on the experimental species used. Phytate degradation in the stomach and small intestine varies with the species. For example, it was suggested that rats may not be a good model for assessing mineral absorption from phytate-containing foods due to the existence of rat intestinal phytase activity. In addition, the age of the individuals is of importance, since it seems that phytate digestion decreases with age. The ability of endogenous carriers in the intestinal mucosa to absorb essential minerals

bound to phytate or other dietary substances as well as the mineral status and need of the individual also have to be considered. A possible adaptation to a high-phytate intake is controversially discussed. A long-term study did not show any human adaptation to a high phytate diet with respect to iron absorption, whereas the normal bone and teeth calcification throughout the world in several populations who depend almost exclusively on cereal diets suggests human adaptability towards high phytate consumption with respect to calcium absorption.

Protein

Phytate also interacts with proteins, which may affect protein digestibility negatively. Strong evidence exists that phytate–protein interactions negatively affect protein digestibility *in vitro*. The extent of this effect depends on the protein source. The inhibition of digestive enzymes such as alpha-amylase, lipase, or proteinase by phytate may also be of significance, as shown in *in vitro* studies. This may be due to the nonspecific nature of phytate–protein interactions, the chelation of calcium ions which are essential for the activity of trypsin and alpha-amylase, or the interaction with the substrates of these enzymes. The inhibition of proteases may be partly responsible for the reduced protein digestibility. *In vivo*, phytate has also been considered to inhibit alpha-amylase, as indicated by a negative relationship between phytate intake and blood glucose response. A negative effect of phytate on the nutritive value of protein, however, was not clearly confirmed *in vivo*. While some have suggested that phytate does not affect protein digestibility, others have found improvement in protein utilization with decreasing levels of phytate. This difference may be at least partly due to the use of different protein sources. Thus, the significance of protein–phytate complexes in nutrition is still under scrutiny. (*See* **Protein**: Digestion and Absorption of Protein and Nitrogen Balance.)

Beneficial Effects of Phytate

In view of the above results, the evidence seems overwhelming that high intakes of phytate can have adverse effects on mineral uptake in humans. In the last few years, however, some novel metabolic effects of phytate or some of its degradation products have been recognized. Results of epidemiological and animal studies suggest possible protective effects of certain *myo*-inositol phosphates on heart disease, renal stone formation, and colon cancer in humans. Moreover, the potential beneficial effects of phytate in the prevention of severe poisoning should also be considered. Calcium phytate 1–2% in the diet has been found to protect against dietary lead in experimental animals and in human volunteers. Furthermore, calcium phytate was capable of lowering blood lead levels. Thus, phytate seems to be a helpful means of counteracting acute oral lead toxicity. The effect of calcium phytate on acute cadmium toxicity is still controversially discussed.

Phytate and Diabetes Mellitus

Diabetes mellitus is one of the commonest nutrition-dependent diseases in western society. It may be caused by hypercaloric diets with a high percentage of quickly available carbohydrates. Foods that result in low blood glucose response have been shown to have great nutritional significance in the prevention and management of diabetes mellitus. In this regard phytate-rich foods are of interest, since a negative relationship between phytate intake and blood glucose response was reported. For example, phytate-enriched unleavened bread based on white flour reduced *in vitro* starch digestibility as well as flattening the glycemic response in five healthy volunteers compared to bread without the addition of phytate. The *in vitro* reduction of starch digestion was positively correlated with the *myo*-inositol phosphate concentration and negatively with the number of phosphate groups on the *myo*-inositol ring. It has to be noted that there are also studies which have not found an inhibition of alpha-amylase and starch digestion by phytate. (*See* **Diabetes Mellitus**: Etiology.)

Phytate and Coronary Heart Disease

Heart disease is a leading cause of death in western countries, yet it is low in Japan and developing countries. Elevated plasma cholesterol or, more specifically, elevated low-density lipoprotein (LDL)-cholesterol concentrations have been shown to be one of the risk factors. It has been proposed that dietary fiber or, more specifically, phytate as a component of fiber may influence the etiology of heart disease. Animal studies have demonstrated that dietary phytate supplementation resulted in significantly lowered serum cholesterol and triglyceride levels. This effect was accompanied by a decrease in serum zinc level and in the ratio of zinc to copper. Thus, the hypothesis was put forward that coronary heart disease is predominantly a disease of imbalance in regard to zinc and copper metabolism. The hypothesis is also based on the production of hypercholesterolemia, which is a major factor in the etiology of coronary heart disease, in rats fed a diet with a high ratio of zinc and copper. It was thought that excess zinc in the diet resulted in decreased copper uptake from the small intestine,

since both minerals compete for common mucosal carrier systems. As phytate preferentially binds zinc rather than copper it is presumed that phytate exerts its effect probably by decreasing zinc without affecting copper absorption. It should be pointed out that the support for the preventive role of phytate in heart disease is only based on a few animal and *in vitro* studies. Results from human studies are still lacking. (*See* **Coronary Heart Disease**: Etiology and Risk Factor.)

Phytate and Renal Calculi

The increase of renal stone incidence in northern Europe, North America, and Japan has been reported to be coincident with the industrial development of these countries, making dietary intake suspect. Epidemiological investigations found that there were substantial differences in renal stone incidences between white and black residents of South Africa. Whereas renal stone occurred in the white population with no less frequency than in other Western communities, it was seldom seen in the black South Africans. The major dietary difference is that, compared to the white population, blacks consumed large amounts of foods containing high levels of fiber and phytate. Furthermore, a high-phytate diet has been used effectively to treat hypercalciuria and renal stones in humans. Thus, there is evidence to support the role of phytate in the prevention of renal stone formation.

Experimental evidence indicates that *myo*-inositol bis- and trisphosphates are effective in preventing the formation of hydroxyapatite crystals *in vivo*, which can function as nuclei for stone formation. Thus, the hypothesis was put forward that a high dietary phytate intake results in an increased urinary content of lower *myo*-inosital phosphates, which may act as very effective inhibitors of stone formation. (*See* **Renal Function and Disorders**: Kidney: Structure and Function.)

Phytate and Caries

The higher incidence of caries in industrialized compared to developing countries was suggested to be nutrition-dependent. Phytate lowers the solubility of calcium, fluoride, and phosphate, the major components of enamel. Thus, teeth are more protected against the leading cause of caries, the attack of acids and bacteria. Furthermore, the very high affinity of phytate for hydroxyapatite may prevent the formation of plaque and tartar. (*See* **Dental Disease**: Etiology of Dental Caries.)

Phytate and Cancer

The frequency of colonic cancer varies widely among human populations. It is a major cause of morbidity and mortality in western society. The incidence of cancer, especially large intestinal cancer, has been associated principally with dietary fat intake and is inversely related to the intake of dietary fiber. It was further suggested that the apparent relationship between fiber intake and rate of colonic cancer might arise from the fact that many fiber-rich foods contain large amounts of phytate and that this latter might be the critical protective element, since an inverse correlation between colon cancer and the intake of phytate-rich fiber foods, but not phytate-poor fiber foods, has been shown. A high phytate intake may also be an important factor in reducing the breast and prostatatic cancer mortality in humans. (*See* **Cancer**: Epidemiology.)

Both *in vivo* and *in vitro* experiments have shown striking anticancer potential for phytate. It was demonstrated that a treatment regimen of 1–2% sodium phytate in the drinking water of growing rats significantly decreased the number of colon tumors and tumor volume when treatment was commenced prior to carcinogenic induction or when administered up to 8 months postinitiation. The inhibitory effect of phytate was dose-dependent and a mixture of 1% *myo*-inositol and 1% phytate was more effective in suppressing cell proliferation. Unfortunately, these investigations failed to study and/or report the mineral status of the animals.

A recent study demonstrated that phytate also has antineoplastic effects on another tumor model, the murine fibrosarcoma. Further rat studies indicated that phytate may also reduce the risk of breast cancer.

Not only pure phytate dissolved in the drinking water, but also phytate in experimental diets such as wheat bran has a protective effect against colon cancer, as shown in animal studies. It was concluded that, while having a role, endogenous phytate is not the sole active component in wheat bran. This result clearly emphasizes the fact that dietary components should not be studied individually for their antineoplastic effect. Though phytate at the 2% level significantly reduced the weight gain of the animals, it does not seem to be of major consequence.

How phytate exerts its antineoplastic and antiproliferative action is not understood. It was proposed that the mechanism by which dietary phytate reduced colon cancer was via chelation of iron and suppression of iron-related initiation and promotion of carcinogenesis, since *in vitro* experiments demonstrated that phytate is a powerful inhibitor of the Haber–Weiss reaction, in which iron catalyzes hydroxyl radical formation (**Figure 2**). These radicals are mediators of several tissue damages related to tumor initiation and promotion. Phytate not only suppresses

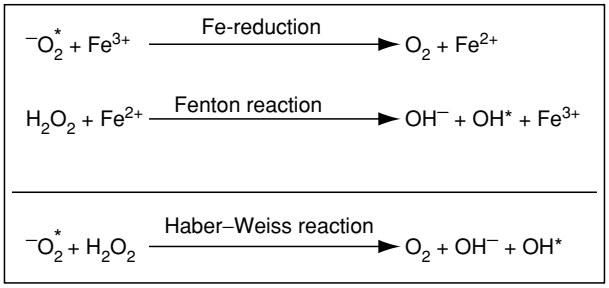

Figure 2 Iron-catalyzed radical formation.

iron-catalyzed hydroxyl radical generation, but also acts to inhibit almost totally iron-catalyzed lipid peroxidation. *Myo*-inositol tris-, tetrakis-, and pentakisphosphate are also shown to be effective. The effects of phytate on cancers distant from the intestine, such as breast cancer, might be simply explained by limitation of iron absorption.

According to a further hypothesis, suppression of tumor incidence in experimental animals may be mediated in part by natural killer cells, since phytate treatment enhanced the activity of natural killer cells involved in the destruction and growth inhibition of tumor cells. It was also suggested that phytate acts by influencing cell regulation. Decreased tumor cell growth may be due to the complexation of zinc and magnesium, which play an important role in cell regulation and gene expression, or due to an influence of extracellular phytate on the intracellular phosphatidylinositol phosphate system, which is important in regulating a variety of physiological and biochemical processes, including cell growth via the second messengers D-Ins(1,4,5)P_3 and D-Ins(1,3,4,5)P_4 (*See* **Phytic Acid**: Properties and Determination). Theoretically, dietary phytate could serve as a precursor for second messengers *in situ* or as a negative-feedback inhibitor for their formation. As a prerequisite, phytate or its hydrolysis products have to be taken up by tumor cells. It was shown that, after exposure of human-transformed cells to [^{3}H]-phytate, a rapid uptake of radioactivity occurred, whereas nontransformed cells showed only a limited uptake. The uptake of radioactivity seems to correspond with tumor cell growth rate. Furthermore, intragastric-administered [^{3}H]-phytate is rapidly absorbed through the upper gastrointestinal tract and distributed to various organs in the rat. Analysis demonstrated that in both studies most of the radioactivity was due to *myo*-inositol and *myo*-inositol monophosphate. The authors suggested that phytate could be absorbed as such or after a variable degree of dephosphorylation, but it cannot be ruled out that phytate was taken up after complete dephosphorylation to *myo*-inositol. From the extracellular area, phytate or its degradation products may be internalized by endocytosis involving fluid-phase pinocytosis, phagocytosis, or receptor-mediated endocytosis, as well as by partitioning into and/or through the plasma membrane. The possibility of receptor-mediated endocytosis was supported by identification of a receptor protein for phytate in rat brain.

Conclusion

Numerous reports suggest that a high phytate intake may suppress absorption of minerals such as zinc, iron, and calcium and that removal of dietary phytate significantly improves the bioavailability of those minerals in humans and animals. Thus, maintaining a diet exceptionally high in phytate may not be entirely without risk. However, there is no uniform agreement on this score, and several studies indicate that phytate may have minimal or no adverse effects on mineral bioavailability in humans. Furthermore, it has been suggested that phytate may exhibit some beneficial health effects, such as reducing the risk of heart disease, renal stone formation, and certain types of cancer.

The most severe effects attributable to phytate in humans have occurred in populations with unrefined cereals and/or pulses as a major dietary component. In particular, zinc and iron deficiency, but not calcium, magnesium, manganese, or copper deficiency, were observed as a consequence of high phytate intake. Therefore, the anticalcifying and rachitogenic effect of phytate has been questioned; it appears that marginal vitamin D status is more important in the etiology of rickets and osteomalacia. Furthermore, marked mineral deficiency syndromes attributed to phytate have not been identified in highly developed countries. Thus, phytate intake does not necessarily result in mineral deficiency. The absorption of minerals depends on the total composition of the meal and in a balanced diet containing animal protein, a high phytate intake does not imply a risk of inadequate mineral supply. Therefore, the recommendation for increasing dietary fiber in western diets would not be expected to have any adverse effect on mineral absorption. The higher phytate intake with whole-grain products will undoubtedly lead to a percentage decrease in mineral absorption, but the absolute amount of absorbed minerals may remain unchanged, because of the large amounts of minerals in these products. In addition, the impact of phytate on phosphorus availability can be considered to be of little consequence in humans, since the phosphorus intakes are usually high, and phytate phosphorus represents only a small portion of the total phosphorus in the diets.

In population groups where phytate-containing foods contribute to poor or marginal mineral status, fortification of some such foods with the corresponding minerals and/or the reduction in phytate content are possibilities to reduce the risk of mineral deficiencies. Since phytate and certain phytate degradation products have been proposed to exhibit health benefits in humans, complete degradation or removal of phytate during food processing should not be followed up, but a controlled degradation to lower *myo*-inositol phosphates. This seems to be a way of avoiding the adverse effects of phytate on intestinal mineral absorption and of utilizing their potential beneficial properties. Controlled degradation is most easily feasible by using phytases. The addition of exogenous or activation of endogenous phytases during food processing has already been shown to result in extensive phytate degradation without affecting other food components.

Phytases are also of interest in areas of intensive animal agriculture. There has been widespread concern in recent years about possible phosphorus pollution from animal manures. The accumulation of phosphorus over time from excessive excretion in manure increases the potential for contaminating water sources from runoff and erosion. The effect of increased content of phosphorus in water is eutrophication, which decreases the available oxygen within the water, thus posing a hazard to fresh-water animal life. Effluent control is therefore a high priority in areas of intensive animal production and, in this context, phytase can become an important waste management tool, since phytase is active in the stomach for a certain time and thus increases phytate hydrolysis during digestion. Phytase not only has the potential to reduce environmental pollution by minimizing the excretion of phosphorus and nitrogen in manure, but also reduces the need for mineral supplementation by increasing the availability of cations bound to phytate.

Because suggestions for the beneficial aspects of *myo*-inositol phosphates are only derived from *in vitro*, animal, or epidemiological investigations, carefully controlled human and animal studies should be carried out to evaluate simultaneously the potential benefits and adverse effects of dietary *myo*-inositol phosphates. If certain phytate degradation products induce physiological effects (the position of the phosphate groups on the *myo*-inositol ring is of great significance for the physiological function), phytase may also find application in food processing to produce foods with improved nutritional value, health benefits, and maintained sensory properties (functional foods). By adding the phytase to the raw material, the antinutritional factor phytate will be degraded to physiologically active *myo*-inositol phosphates during food processing. Thus, foods with a reduced content of phytate and a regulated content and composition of lower *myo*-inositol phosphate with beneficial health effects could be designed.

PICKLING

D M Barrett, University of California Davis, CA, USA

Introduction

Pickling is one of the oldest, and most successful, methods of food preservation known to humans. This article reviews the origins of pickling, the various methods of pickling employed commercially, and the nature of preservative action. The optimization of pickle quality depends on maintenance of proper acidity, salt concentration, temperature, and sanitary conditions.

History and Tradition

It is difficult to suggest a date for production of the first pickled foods, but it is known that both vinegar and spices were being used during biblical times. Fermentation of plant and animal foods was known to the early Egyptians, and fish were preserved by brining in prehistoric times. By the third century BC, Chinese laborers were recorded to be consuming acid-fermented mixed vegetables while working on the Great Wall. In about 2030 BC, northern Indians brought the seed of the cucumber to the Tigris Valley. The Koreans created kimchi from acid-fermented Chinese cabbage, radish, and other ingredients many centuries ago. Corn, cassava, and sorghum were fermented and became staples of the African diet. In the west, acid fermentation of cabbage and cucumbers produced sauerkraut and pickles, products that are still popular today. Early explorers carried kegs of sauerkraut and pickles that prevented scurvy on their voyages.

Peterson in 1977 defined pickling, in a broad sense, as 'the use of brine, vinegar or a spicy solution to preserve and give a unique flavour to a food.' In a 1936 document, the US Department of Agriculture described cucumber pickles as:

> immature cucumbers properly prepared, without taking up any metallic compounds other than salt, and preserved in any kind of vinegar, with or without spices. Pickled onions, pickled beets, pickled beans and other pickled vegetables are vegetables, prepared as described above, and conform in name to the vegetables used.

Literature references concerning the technology of acid fermentation began to appear in the western press in the early 1900s. In 1919, Orla-Jensen isolated strains of *Betacoccus arabinosaceus* from sour potatoes, sour cabbage, and sour dough. Pederson, in a number of classic studies in the 1930s, enumerated and identified the sequence of microorganisms involved in sauerkraut fermentation. *Leuconostoc mesenteroides* was identified as being one of the most important microorganisms for initiation of vegetable fermentation. Numerous investigators have carried out studies on acid-fermented vegetables over the past century. (*See* **Fermented Foods: Beverages from Sorghum and Millet.**)

Advent of New Pickling Methods

Brining vegetables in salt, and the resultant lactic acid fermentation, is an ancient form of preservation. Two new methods of pickling cucumbers, which represent the largest volume of a single vegetable preserved by pickling, have been developed during the 1900s. Both methods use lower salt concentrations and result in a milder product. The first new method, pasteurization and direct acidification, was developed and began commercial production in the 1940s. The second,

refrigeration and direct addition of acid and preservative, was introduced in the 1960s. Relative quantities of cucumbers preserved by the three pickling methods in 1984 were: brine fermentation, 43%; pasteurization, 43%; and refrigeration, 14%.

Pickling remains a major form of preservation in many countries because it: (1) yields desirable organoleptic qualities; (2) provides a means for extending the processing season of fruits and vegetables; and (3) requires relatively little mechanical energy input.

Outline of the Process

Pickled products may be produced by one of three methods, i.e. fermentation, acidification followed by pasteurization, or refrigeration. Because they are relatively straightforward, the methods for producing pasteurized and refrigerated pickled products will be described first.

Pasteurized Pickles

Vegetables which are fresh or only partially fermented may be preserved by the addition of vinegar or acetic acid and subsequent pasteurization. Vinegar alone is not sufficient to insure product safety, and so requires an additional form of preservation such as heat or refrigeration. The steps involved in producing pasteurized or 'fresh-pack' pickles are the following:

- slice, cube, or dice product;
- place in clean container;
- mix water, salt, vinegar, sugar, spices and bring to boil;
- add hot brine to container;
- seal and pasteurize.

Two possible pasteurization methods include: (1) heating such that the center of the jar or can reaches 75 °C, and holding for 15 min, followed by a prompt cooling to 35 °C or below, or (2) heating at 70 °C for 10 min, followed by prompt cooling. (*See* **Vinegar.**)

The pasteurization process essentially destroys spoilage microorganisms and prohibits fermentation from occurring. Both acid-forming bacteria, which are active in brine fermentation, and yeasts, which cause gas production, are destroyed by pasteurization. The pasteurization process inhibits polygalacturonase, the enzyme responsible for pickle softening. Enzyme activity may also be controlled through use of appropriate salt concentrations. Calcium chloride is often added to brine to aid in firming cucumber pickles. Pasteurized pickled products have steadily gained in popularity, and have a very different flavor and texture to that of fermented pickled products. (*See* **Pasteurization**: Principles.)

Refrigerated Pickles

Refrigerated pickle products, which represent the latest development in pickling technology, are produced by direct acidification and addition of sodium benzoate or another preservative. In these nonfermented pickles, the preservative takes the place of pasteurization in preventing spoilage of the product. This process is essentially the same as that used for pasteurized pickles, but instead of pasteurizing, the sealed containers are refrigerated. It is essential that this type of pickle is kept refrigerated throughout the production process and during subsequent consumption.

Fermented Pickles

Cucumbers are by far the most common vegetable fermented; therefore, most of the following processes will be described using cucumbers as an example. There are three general methods which may be used for cucumber fermentation; (1) salt stock; (2) genuine dill; and (3) overnight dill.

Salt stock The first method, salt stock, involves fermentation in 5–8% sodium chloride until all fermentable sugars have been converted to acids and other end products. The cucumbers are then stored in open tanks containing 10–16% salt to maintain stability for up to 1 year. Figure 1 outlines the general process for salt stock pickles. Desalting to an acceptable organoleptic level (2–2.5% salt) is carried out by

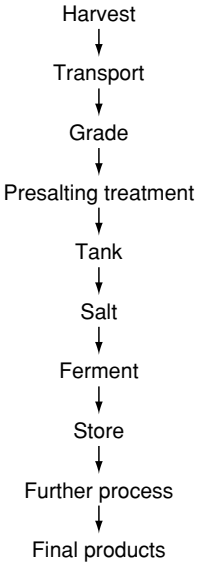

Figure 1 General flowchart for preservation of vegetables by brining. Reproduced from Fleming HP and McFeeters RF (1981) Use of microbial cultures: vegetable products. *Food Technology* 1: 84–88, with permission.

leaching in water. Salt stock pickles make up the largest percentage of fermented pickle products.

The controlled fermentation of pickles has been a goal of the industry for years. In 1973, such a procedure was introduced in the USA. Although the industry has yet to adopt the entire process, addition of some of the modifications outlined has improved pickle quality in general. In particular, most processors now acidify and purge tanks after brine is added. Acidification inhibits the growth of acid-sensitive Gram-positive and Gram-negative bacteria and, therefore, favors the growth of lactic acid bacteria. Purging decreases the incidence of bloating, which results from carbon dioxide production by both the fermenting microorganisms and the cucumber itself.

Genuine dill These pickles are fermented in 4–5% sodium chloride, to which dill weed, garlic, and other spices have been added. It takes approximately 3–6 weeks for fermentation to reach completion, where the lactic acid content is 1.0–1.5% and the salt content is 3–3.5%. This type of pickle does not require desalting, but may be sold as such with the filtered fermentation liquor. Genuine dill pickles are somewhat susceptible to scum yeast development and should be consumed within 12 months of manufacture.

Overnight dill Overnight dill pickles are fermented in 2–4% sodium chloride, containing dill weed and garlic, until the desired level of acidity (0.75–1% titratable acidity as lactic acid) is reached, which should take approximately 1 week. The product must then be refrigerated, and should not be kept longer than 6 months due to its extreme perishability.

Nature of Preservative Action

Two components of the pickling process, acid and salt, are key participants in the preservation of perishable products. Acid, which may be added directly or produced through microbial conversion of indigenous sugars to acids, will lower the pH of the product and inhibit spoilage microorganisms. Only undissociated acid molecules are active in inhibiting microorganisms; therefore, it is important that the acidity of pickles be pH 3.5 or below, when most of the acid present will be in the undissociated form. Salt also acts to inhibit the growth of undesirable bacteria and to delay enzymatic softening. (*See* **Acids**: Natural Acids and Acidulants; **pH – Principles and Measurement**.)

In fermented pickles, microorganisms ferment sugars to lactic acid and also produce enzymes which modify pickle texture. The absence of fermentable carbohydrates is a deterrent to undesirable secondary fermentations which can be initiated by yeasts at pH values below 3.8. Residual sugars can also cause gas production and brine turbidity in finished products if yeast and bacteria growth continues.

Lactic acid bacteria are the primary microorganisms involved in preservation of fermented pickled products. Although these microorganisms represent only a smaller proportion of the total microbial flora present on the surface of plant materials, they predominate under acidic conditions. In cucumbers, *L. mesenteroides* typically grows until the pH begins to drop, then *Pediococcus pentosaceus* predominates, followed by *Lactobacillus brevis* and finally *L. plantarum*. (*See* **Lactic Acid Bacteria**.)

Acidity, salt concentration, temperature, and sanitary conditions are the primary environmental factors which control fermentation. Most vegetables range in pH from 6.5 to 4.6, while fruits range from 4.5 to 3.0. In fruits and fruit juices, yeasts and molds predominate in the more acidic environments. Salt inhibits the growth of undesirable microorganisms and, in addition, it withdraws water and nutrients from plant tissues and allows these to become substrates for lactic acid bacteria.

Low temperatures inhibit the growth of lactic acid bacteria and thus slow fermentation. At 7.5 °C, *Leuconostoc mesenteroides* will grow, but the growth of *Lactobacillus* and *Pediococcus* species is very low. At temperatures in the range 18–23 °C, *L. brevis* and *L. plantarum* exhibit active growth while, at 32 °C, *L. plantarum* and *P. pentosaceus* predominate. Pasteurization is often the final step in pickle processing. The US Department of Agriculture recommends that all pickled products should be pasteurized for safety.

Sensory and Nutritional Attributes

Pickling imparts unique characteristics to fruits and vegetables. Desirable changes in flavor, texture, and color take place in fermented, pasteurized, and refrigerated pickles, and are carefully monitored. However, some of the same bacteria involved in normal fermentation, such as the lactic-acid-formers, may cause spoilage if not destroyed. Selected pickling problems which may affect sensory quality are listed in Table 1.

Pickled cucumbers are composed primarily of water (Table 2). They are not a good source of protein or fat, but are a fairly rich source of vitamin A, vitamin C, and phosphorus. Salt and sugar additions to the brine will affect the sodium and carbohydrate contents. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.) Refer to individual nutrients.

Table 1 Selected pickling problems

Problems	*Cause*
Soft, slippery slimy pickles (discard pickles, spoilage is occurring)	Hard water Acid level too low Cooked too long or at too high a temperature Water bath too short, bacteria not destroyed Jars not airtight Jars in too warm a resting place
Shriveled, tough pickles	Pickles overcooked Syrup too heavy Too strong a brine or vinegar solution Pickles not fresh enough at outset Fruit cooked too harshly in vinegar/sugar mixture
Dark, discolored pickles	Iron utensils used Copper, brass, iron, or zinc cookware used Hard water Metal lid corrosion Too great a quantity of powdered and dried spices used Iodized salt used

Reproduced from McNair JK (ed.) (1975) *All About Pickling*. San Francisco: Ortho Books, with permission.

Specific Examples

Pickled cucumbers are by far the most abundant pickled product available in the western world today. Other common pickled products include sauerkraut, pickled pears, peaches and plums, pickled nuts, relishes, cured meats, fish and poultry, and specialty items such as pickled mushrooms and cherries.

Salt stock is used to prepare sour cucumber pickles, which typically have a final acidity not lower than 2.5%. Sweet pickles are prepared in a similar fashion, except that a sweet, spiced vinegar solution is added to the salt stock.

Sauerkraut is produced through salt-controlled bacterial fermentation. Cabbage selected for sauerkraut should have at least 3.5% sugar to insure an adequate carbohydrate source for bacteria. Shredded cabbage is mixed with salt (2.25% by weight) and the final product contains an average of 1.5–2.0% lactic acid.

Table 2 Nutritive analysis of pickles: the composition of 100 g of edible portion (approx. 1 large dill pickle or 1/2 cup of fresh cucumber pickle slices)

PINEAPPLES

L G Smith, Maroochy Research Station, Nambour, Queensland, Australia

Introduction

The pineapple (*Ananas comosus* (L.) Merr.), botanically a member of the ornamental Bromeliaceae family, originated in tropical South America but is now widely grown in all tropical and subtropical areas of the world. In Spanish-speaking countries the fruit is known as pina; in Portuguese-speaking countries as abacaxi; as ananas in Dutch- and French-speaking former colonies, and as nanas in southern Asia. More than 4.5×10^6 t, both fresh and canned, is marketed worldwide each year from at least nine major countries (Tables 1 and 2), with the major cultivar by far being the large juicy-fruited smooth-leafed cultivar Smooth Cayenne. Wild pineapple varieties still grow in the tropical savanna of South America but most have small, seedy, fibrous fruits. (*See* **Fruits of Tropical Climates:** Commercial and Dietary Importance.)

The Plant, its Appearance, and Physiology

The pineapple is a perennial, monocotyledonous, xerophytic plant, up to 1.5 m high, of herbaceous, lily-like habit, but with tough, spiny-tipped leaves that are waxy on the upper surface and possess a fragile dusty bloom on the underside. The leaves in all but a few cultivars, such as the important Smooth Cayenne, also have numerous formidable barbs along the edges, which make cultivation hazardous. In all varieties the concave leaves channel any precipitation into the plant center for absorption by spongy leaf tissue and roots. Other features which enhance the shallow-rooted plant's adaption to low rainfall include leaves that do not wilt, and its crassulacean acid metabolism (CAM), in which the stomata open at night to take up carbon dioxide rather than in the day, greatly reducing water loss. Malic acid is accumulated during the night and is decarboxylated during the day.

The fruit of the pineapple, botanically a sorosis or a syncarp, comprises spirals of fused fleshy fruitlets radiating from a fibrous but succulent core and topped with a leafy crown or top, an extension of the peduncle or central plant stem of the plant (Figure 1). The crown is planted for reproduction, when available. The commercial fruit, grown as a monoculture of genetically identical plants, is normally seedless due to a genetic self-incompatibility. If cross-pollinated, by wind, natural vectors, or deliberately by humans, as in breeding trials, viable small hard-coated seeds 1–2 mm across will form, capable of producing a new plant and fruit within 2–3 years. The commercial plant produces one fruit 14–24 months after planting, but two or more vegetative shoots (suckers) subsequently produce additional rattoon crops. Fruits become smaller with successive rattoons and usually a maximum of two rattoon crops are commercially viable.

Because pineapple plants cannot tolerate frost or prolonged cold, production is restricted to coastal or near-coastal areas of low or moderate elevation. They tend to thrive on tropical and subtropical islands, where the surrounding water mass maintains a more ideal constant temperature and moderate humidity.

Varieties

The classification of existing pineapple varieties is currently under complete review. The Cayenne variety was previously seen as but one of five recognized groups of *A. comosus*, the other four being Spanish, Queen, Pernambuco, and Mordilona. The five groups are compared in Table 3. Most likely these will soon be reclassified to be just varieties of the one species *A. comosus*, better to reflect the true genetic

differences between the five groups, now known to be smaller than originally believed. The Cayenne variety is the most productive and the most widely grown variety around the world. All other varieties have inferior commercial characteristics, from inadequate yield, fruit morphology, or susceptibility to a range of diseases and disorders. Subselections or 'clones' of Smooth Cayenne have been made in different production areas of the world, and more recently many new cross-bred varieties have been produced, particularly for the fresh-fruit market. Breeding and refining new pineapple varieties are very difficult due to the extremely heterozygous nature of the genotype. Plant breeders normally back-cross new varieties to eliminate the more minor unwanted characteristics, but in the pineapple this procedure results in the reintroduction of

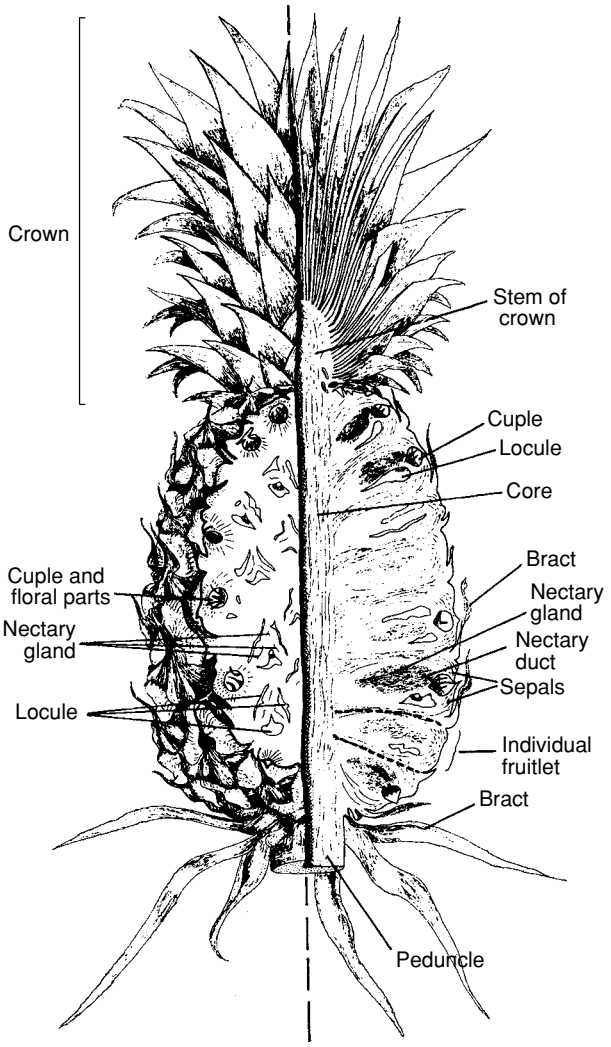

Figure 1 Mature pineapple: on the right, median longitudinal section; on the left, tangential longitudinal section. Adapted from Py C, Lacoeuilhe JJ and Teisson C (1987) *The Pineapple: Cultivation and Uses*. Paris: GP Maisonneuve et Larose, with permission. Reproduced from Pineapples, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

many unwanted genotypes. Genetic engineering is being investigated as a way around the problem of extreme heterozygosity, but to date no new genetically modified variety has been commercially released.

Composition and Nutritional Value

The pineapple fruit is typically a supplementary food rather than a staple. The pineapple's very sweet and sour taste, its mild aromatic flavor, and firm succulent flesh in a large and attractive form make it somewhat unique among foods. While very palatable by itself, it is equally used as a flavoring component, both cold and hot, making many other less attractive but nutritionally sound foods more edible. The dietary composition of Smooth Cayenne, both fresh and canned, is shown in Table 4. The nutrient profile of the pineapple is, in general, similar to many other fruits, containing high levels of carbohydrate and low levels of fat and protein. Dietary fiber constitutes about 14% of the dry matter and, as with most fruits, can be incorporated into a cholesterol-lowering diet. Its vitamin C content is about one-tenth that in citrus, and the level of retinol equivalents (3 per 100 g) is low compared to those of pawpaw (papaya) (153) and mango (356). Refer to individual nutrients.

The total sugar content is the major quality determinant of the fruit for both fresh and canned markets and in commercial practice sugar content is often regularly monitored, using a refractometer calibrated in degrees Brix which, in pineapples, is virtually identical to percentage total sugar. Fresh Smooth Cayenne fruit above 15 ° Brix would be considered of excellent eating quality by most tasters and fruit of 9–12 ° Brix of marginal quality; however, taste preferences towards Smooth Cayenne of a particular Brix level vary considerably between individuals and also between ethnic groups. In canned pineapple the sugar content of the fresh fruit makes less difference to consumer quality.

Variability of Organoleptic Parameters

Wide variations occur in the total sugar content and titratable acidity in fresh pineapples. Not only is the bottom of the fruit always about 3 ° Brix higher than the top but, more importantly, there is wide variation between samples. For example, the 8% total sugars from Queensland fruit in Table 4 is very low compared to fruit from Hawaii or Ivory Coast and is either from immature summer fruit (average mature fruit is 15–18 ° Brix) or is from winter-grown fruit (6–11 ° Brix). Fruit grown under cooler conditions is lower in sugar and higher in acid, although the sour taste of winter-grown pineapples is caused by the low sugar content rather than the high acidity.

Postharvest Changes

The postharvest changes in various parameters in fruit held near 20 °C during 15 days after harvest are illustrated in Figure 2. Total sugar concentration and eating quality remain relatively constant after harvest; acidity and carotene content increase moderately, while the shell color (degree of yellowness of the skin) and ester concentration increase substantially.

Skin Color and Ripeness

Although the fruit normally changes from green to yellow as the fruit ripens on the plant, skin color is a

poor indication of palatability in Smooth Cayenne pineapples grown under commercial practices. Green-skinned fruits can taste quite acceptable. Such 'green-ripe' pineapples can either be physiologically 'unripe' (meaning physiologically not fully developed) but have sufficient sugar to taste acceptable, or their flesh may be prematurely ripened before the skin as a result of specific climactic (i.e., climate, nothing to do with the nonclimacteric fruit physiology) conditions during growth. This latter type of 'green-ripe' fruit tend to taste insipid and the condition is now regarded as a physiological disorder. On the other hand, attractive yellow-skinned fruit can taste sour. (*See* **Ripening of Fruit**.)

One way of selecting intact Smooth Cayenne fruit of uniform ripeness is on the basis of fruit specific gravity. Fruits that float in water are less ripe than those that sink. Fruits that sink in a 3% common salt solution are very ripe. This method works well for Queensland and Hawaiian fruit but reportedly not South African. The difference has not been explained.

Fresh Fruit Selection

Probably as a result of the variability of eating quality, there is a degree of folklore applied in the determination of when a harvested pineapple is 'ripe,' with potential purchasers plucking crown leaves, or squeezing, smelling, and tapping the fruit. Leaf plucking is completely useless, but fruits that feel heavy for their size will be riper than lighter fruit of the same size. However, the postharvest nonripening character of pineapple means that once the fruit is picked the eating quality is fixed. There is no advantage for consumers in waiting for the harvested fruit to yellow, as delay only results in the fruit losing volatile flavors and going 'stale.'

Factors Affecting Pineapple Eating Quality

At its best, Smooth Cayenne is a most delightful fresh fruit to eat, but the eating quality of fruits produced from different seasons and growing areas is extremely variable, much more so than other pineapple varieties. The eating quality of Smooth Cayenne is probably the most variable of any commercial fruit. It is difficult, if not impossible, even for an expert, to predict the eating quality, even when the fruit is cut. The eating quality or flavor of pineapple is almost totally dependent on the percentage of sugar in the flesh rather than the degree of visual ripeness. The sugar content is strongly affected by the temperature and light intensity during the last 3–4 weeks of growth, and, as a consequence, the sugar content in the fresh fruit is greatly affected by the season, climate, the degree of maturity at harvest and, to a lesser extent, the farm production methods.

Smooth Cayenne grown in equatorial regions generally have consistent and excellent eating quality. In the subtropical regions, where significant quantities of the Smooth Cayenne of fresh commerce are grown, the eating quality is most often very variable as a result of the daily and seasonal variations of temperature. Many subtropical production areas have developed because they are closer to areas of major urban populations and consumption, but in these areas the seasonal inconsistency of flavor is an important problem, particularly in fresh-market pineapples.

Fruit Physiology

A unique feature of the pineapple is that flowering (with subsequent fruit set) is controllable by growth hormones over an extremely wide range of plant maturity. Modern commercial production practices can regulate date of harvest to fall virtually any day of the year; thus fruit production can be precisely programmed.

Pineapples are nonclimacteric fruits and do not get better to eat (i.e., do not ripen) after harvest, in spite of any subsequent color change (Figure 2). Other members of this same group of fruits include oranges, strawberries, grapes, and cherries. The absence of starch in the fruit is often cited as the cause of the nonripening postharvest behavior, but many climacteric fruits also contain no starch. The physiology involved needs to be better clarified.

Handling, Storage, Refrigeration, and Chilling Injury

Handling

In spite of its tough appearance, Smooth Cayenne is very susceptible to injury and needs to be handled with care. The fruits will readily bruise if they fall more than 20 cm and, once bruised or injured, a ubiquitous fungal disease caused by *Ceratocystis paradoxa* (*Thielaviopsis paradoxa*), which generally spreads quickly throughout the fruit, can readily develop. Commercially, fruit are commonly treated with fungicides such as thiabendazole, benomyl, or triadimefon. In contrast to Smooth Cayenne, Queen fruits develop fewer postharvest rots and in many ways are ideal fresh-market fruits. They keep well without refrigeration and, if free from developing blackheart, have a much longer shelf-life than Smooth Cayenne. (*See* **Fungicides**.)

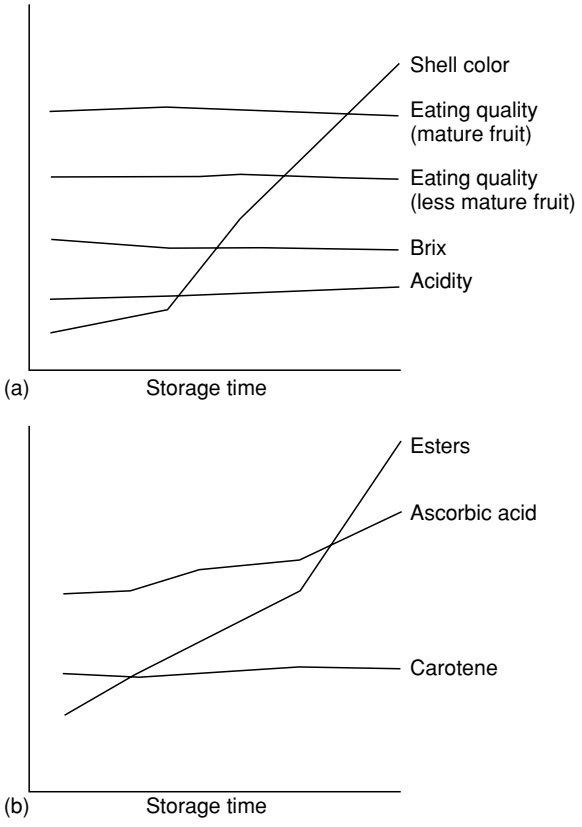

Figure 2 Postharvest changes in chemical and sensory parameters over 15 days. Eating quality data from the author (unpublished). Other data from Singleton (1959), as quoted by Dull GG (1970). The pineapple: general. In: Hulme AC (ed.) The Biochemistry of Fruits and their Products, vol. 2, pp. 303–324. London: Academic Press. Reproduced from Pineapples, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Figure 3 Blackheart or internal browning in pineapple, a serious disorder in fresh-market pineapples which can develop following refrigeration, but which also naturally occurs in subtropical production areas. It is a physiological disorder (i.e., not a pathogenic disease), known as chilling injury and caused by prolonged exposure to temperatures below 21 °C. Reproduced from Pineapples, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Storage and Refrigeration

Although pineapples can keep reasonably well without refrigeration, particularly if the humidity is kept high to prevent desiccation, refrigeration is necessary to maintain a glossy, fresh-looking skin and to reduce the incidence of rots. However, pineapples do not outturn well if kept refrigerated for longer than 2 weeks. They can suffer from 'chilling injury,' a physiological injury caused by cool temperatures, resulting in disruption of the cellular enzymic processes. It is a disorder characteristic of many tropical fruits which will often develop within 2–3 days after removal from refrigeration. In pineapples, chilling injury is manifest most commonly by the fruit developing brown spots adjacent to the core; these are sometimes called endogenous brown spots. With increasing severity, the spots darken further, and in severe cases the complete center of the fruit can become black, giving rise to the other name for the disorder, blackheart (Figure 3).

Chilling injury is a constant threat when pineapples are shipped under refrigeration, and intermittent heavy losses occur. Storage for 3–12 days at temperatures as high as 21 °C have been shown to induce blackheart, but injury incidence is unpredictable, possibly dependent on the intensity of available sunlight during the 3–4 weeks prior to harvest. Temperatures of 15–18 °C induce the greatest injury but, as the fruits are usually shipped at 8 °C for 7–10 days from tropical production areas, they are usually consumed before any injury develops.

Fruits from the Queen group are very susceptible to chilling injury but a Hawaiian variety, known as 53/116, appears to be entirely resistant. This hybrid variety has several quality deficiencies (often

developing a cannonball shape, or lacking a crown), but because of its good blackheart resistance and lo\w acidity, it is slowly developing wider acceptance in Australia. Dipping the fruit in a carnauba-based wax, or applying a lipid-carboxymethyl cellulose coating, can control blackheart. These skin coatings function by reducing the oxygen concentration in the flesh, necessary for the melanin pigment to develop, but the anaerobic flesh can develop an alcoholic flavor. Heating the fruit to 40 °C for 24 h either immediately before or after cool storage also reduces blackheart and improves pineapple eating quality, but is not commercially used because of logistical limitation.

Pineapples that are cool-stored for prolonged periods can also develop other symptoms of chilling injury such as flaccid watery flesh, skin necrosis, crown wilting, and crown necrosis, but fruit with such injuries are often already damaged by internal chilling. Overcoming chilling injury in fresh-market pineapples is currently under investigation.

Controlled-Atmosphere Storage

Controlled-atmosphere storage does not prolong the life of the cool stored pineapples and is not used for international shipping. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

Field Blackheart

Pineapples from cooler production areas are particularly susceptible to blackheart, where it can develop in the field following periods of cool overcast weather. Because the disorder shows no external symptoms, affected fruit cannot be identified. In Queensland and Hawaii pineapple canneries close or restrict intake during such periods and thus avoid excessive losses.

Pineapple Products

Canned pineapple is a commodity of major international trade; figures showing exports and imports are shown in Table 1. Pineapples are also processed into a number of other products other than canned fruit. Pineapples are often used as a component of commercially marketed fresh fruit salad, either fresh or frozen. Less ripe fruits freeze best as they have firmer flesh. Soft ripe fruits can develop off-flavors when frozen, as well as turning out very flaccid. Fried pineapple pieces are commonly used in Asian cuisine. Dried pineapple pieces are easily prepared and are being sold in increasing quantities as they retain a more attractive appearance than other fruits that strongly darken when dried. Sliced thin and dried, pineapple 'chips' are also sold as a snack food. Glacé pieces are readily prepared from either the fresh product or, more easily, from canned rings. Pineapple juice is a major item of commerce, as fresh or frozen, full strength, or as a concentrate. Reasonably high in carbohydrates, fermented juice is used to make vinegar. It does not make a good-quality wine but, fermented and distilled, it makes a potent, if somewhat disreputable, alcoholic spirit, available in several Pacific island countries. Cannery waste (crushed skins, etc.) makes a good cattle feed supplement, while old plantation fields are often let out to cattle. Pineapple leaves are used to make cloth or rope in both Taiwan and the Philippines, while use of the whole plant as a source of energy is under current investigation. (*See* **Canning**: Quality Changes During Canning; **Freezing**: Structural and Flavor (Flavour) Changes.)

Bromelain

Pineapple fruits contain a proteolytic enzyme, bromelain, which can constitute nearly half the measured protein in the fruit. Much higher concentrations of the basic isoenzyme (the fruit form is acidic) exist in the stem. Stem bromelin is commercially extracted and sold, as a buff-colored powder, slightly soluble in water and practically insoluble in alcohol, chloroform, and ether. Bromelin is used in the pharmaceutical industry for digestive and antiinflammatory products, in the manufacture of cattle feed and to 'chill-proof' beer (to prevent formation of a haze of proteinaceous material which can form when brewed products are refrigerated). Some recent pharmacological reports indicate that bromelin may have value in modulating tumor growth and blood coagulation, as well as debridement of third-degree burns.

Commercial Farm Production

Modern commercial culture of pineapples is generally capital-intensive, requiring substantial land preparation, machinery for planting, boom (fertilizer) spray and harvesting, plus bulk equipment for cannery fruit and/or harvester-packers for fresh market fruit.

By using a combination of plant hormones and appropriate planting practices, the harvest date and the fruit size and quality can be preset and regulated as required. This makes modern pineapple production function with almost clockwork precision. On modern fresh-fruit farms a year-round cycle is maintained of weekly, if not daily, planting and harvesting. Combined with modern planting machinery, modern herbicides, and large mobile harvesting equipment, production of 1000–2000 t of fruit per staff year is common.

Being parthenocarpic (seedless, but otherwise normal), pineapple propagation is vegetative and can be problematical as only limited planting material is available from any one plant. The best planting material, that producing the most uniform plants and fruits, is the fruit crown, but if the fruit is sold as fresh fruit (as opposed to canning), tops are not available, so that suckers and other vegetative material must be collected and used. Up to 80 000 pieces of planting material (tops, suckers or slips) are required per hectare, planted in double rows. The time of planting and the size and type of planting material affect the date of harvest and fruit size, and are predetermined. Weeds can be readily controlled as the plant is resistant to several effective herbicides (e.g., diuron, fluazifopbutyl, ametryne) which are applied over the rows of growing plants with a boom spray. Ten to fourteen months after planting, a flower-inducing hormone (commonly the ethylene-releasing compound Ethrel, 2-chloroethyl-phosphonic acid) is applied, and the treated plants uniformly produce a single, blue-petalled inflorescence about 8 weeks later. Fruit development occurs without further interruption, but as sunburn can be a serious injury, fruit may be individually covered (bagged) or sprayed with a reflective bentonite clay suspension.

Harvesting pineapples at the correct stage of internal ripeness is important as it is the major factor that determines the fruit quality at consumption. As skin color is an inconsistent guide to eating quality, pickers have to use past experience and market demands.

Sodium naphthaleneacetic acid (NAA) is sometimes applied as a spray on the fruit to increase fruit size by delaying degreening (becoming yellow). Adverse effects on fruit quality from using NAA are reportedly minor but are under current debate. Ethrel is also sometimes sprayed on both fresh and cannery crops to increase flesh yellowness and to 'accelerate ripening.' While very effective and cost-saving on cannery fruit, its use on fresh-market fruit has been shown to be of questionable value as the variability of the eating quality is greatly increased.

PINE KERNELS

B T Styles†, University of Oxford, Oxford, UK

Background

Pine nuts, also known as Indian nuts, piñons, or pignolias, have been an important food crop in some areas of the world since prehistoric times. The 'nut' is, in fact, the seed of different species of pine (*Pinus*), nearly all of which belong to a group known as 'soft' or 'white' pines or their relatives. These species are evergreen, coniferous trees whose cones are softly woody and have few scales and two large seeds per scale that lack a wing (see **Figure 1**). The kernel consists of the endosperm tissue of the seed containing the stored food material and the developing embryo (germ). The 'shell' surrounding it is the testa. This must be removed before the kernel can be eaten.

†Deceased.

Sources

Pine nut kernels are almost all obtained from wild forest trees. Piñons from the drier areas of southwest USA and Mexico form the largest wild source, but the Italian pignolia tree has been cultivated and protected in the Mediterranean region for centuries. Almost all the other species grow in upland mountainous areas, but information about them is scanty (**Table 1**). The harvest of pine nuts is only a fraction of the production of cultivated nuts such as pecan, macadamia, walnut, or filbert, and the crop is generally irregular, with bumper harvests occurring approximately every

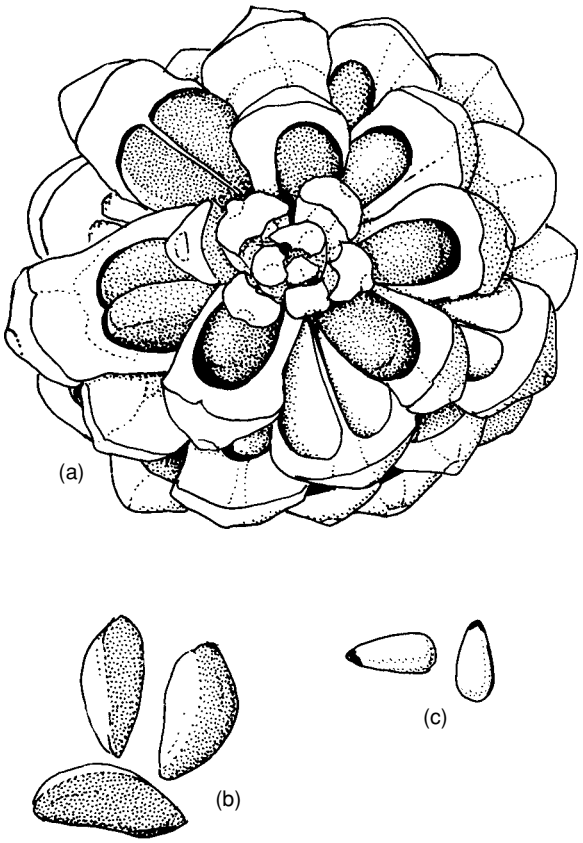

Figure 1 Pignolia (*Pinus pinea*): (a) cone; (b) seeds; (c) polished kernels (all natural size). Reproduced from Pine Kernels, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

5 years. Harvesting is chiefly by an itinerant labor force that moves into the pine forests during the autumn. Green cones are cut from the trees, dried in the sun and opened to release the seeds, or the seeds are collected from beneath the trees. The collection and later preparation can at best be considered as a cottage industry. The kernels of only two or three of the piñon pines and the pignolia pine are important in commercial trading on a large scale. They may be bought in health food shops or delicatessens but are considered expensive, £12.50 per kilogram in the UK.

Kernels of most of the other pines may be found on sale in local markets near the site of collection. There are no reliable statistics on yields of these wild crops, but it has been estimated that about a million kilograms of Colorado pine nuts were collected annually in southwest USA. This quantity has probably not changed a great deal since then.

Storage and Preparation

After harvesting, nuts should be kept unshelled, in a dry, cool, well-ventilated place in cloth or paper bags. Tannins in the shell and in the seed coat of the kernel may function as antioxidants in preserving the fat and oil in the nuts. Fresh kernels stored in closed containers soon go moldy or rancid, but after drying, they can be safely preserved and have excellent keeping qualities for up to 3 years. They freeze well when fresh. Shelling of the nuts can be done domestically by lightly crushing the nuts on a cloth with a rolling pin. Those of the thin-shelled, single-leaf pine can be easily removed with the fingers. The thicker Colorado piñon, stone pine, and pignolia nuts must be cracked mechanically to release the kernels. (*See* **Antioxidants**: Natural Antioxidants; **Oxidation of Food Components**.)

Although the kernels can be eaten raw, roasting is necessary to bring out their full flavor. They may be roasted with or without the shell, the amount of time required depending on shell thickness and moisture content.

Composition and Nutritional Value

The richness and flavor of pine kernels are well known, and they rank highly among all other nuts in food value. There are, however, considerable differences in the properties of the kernels of different species. A comparison of the nutritional value of pine kernels and some commercial nuts is provided in Table 2.

Refuse and Wastage

When compared with other nuts, piñons have low percentages of shell waste or refuse. Shell thickness

varies considerably: 30–35% of seed weight of the very-thin-shelled single-leaf piñon is made up of shell, whereas the thicker-shelled Colorado pine has a waste factor of 42%. Mediterranean pignolia has a particularly thick shell that must always be removed before it is sold. Thus, pine kernels of piñons constitute some 58–70% of the edible portion. The average is lower than that found in all other commercial nut crops except peanuts.

Protein

The average protein content is about 15% for piñon nut kernels and about 34% for pignolias. It is higher than for pecan nuts and about the same as that for English walnut and Brazil nut. It is only greatly exceeded by peanuts. A study in the former Yugoslavia has shown that kernels of pignolias are richer in proteins than pork and goose meat. Kernel protein has a digestibility value almost as good as that of beef and is distinctly better than almost all other nuts. It is near the proportion required for a balanced diet. Colorado and single-leaf kernels are especially rich in tryptophan and cystine. (*See* **Protein**: Requirements.)

Fat (Lipid) and Oil

Piñon pine kernels average about 60% of fatty materials. This is lower than pecan, English walnut, and Brazil nut, which approximate to 70%. Pignolia kernels in the former Yugoslavia are reported to contain 48% of lipid, which is again higher than for fat pork (37%) and goose meat (44%). As Table 2 indicates, the Siberian stone pine is also very rich in fats and oil. This is processed commercially for the production of cooking oil, but no published details of production methods or quantities are available. The fats of piñons, particularly Colorado and single-leaved pine, contain monounsaturated oleic, and polyunsaturated linolenic and linoleic acids. It has been reported that pignolia kernels from the Mediterranean region contain up to 50% of linoleic acid. Commercially produced pine kernels studied contained 46.40 g of fat by weight, of which 6.12 g is saturated (fatty acid not named). (*See* **Fats**: Requirements.)

Table 2 Comparison of the nutritional value of pine kernels and some commercial nuts

Type of nut	*Food content*

Brazil nut, *Bertholletia excelsa*	16	69	8

Typical energy value per 100 g = 556 kcal.
Data from Lanner RM (1981) *The Pion Pine*. Reno, Nevada: University of Nevada Press and Botkin CW and Shires LB (1948) The Composition and Value of Pion Nuts. Bulletin 344, New Mexico Experiment Station.

Carbohydrate

The average oily piñon kernel of Colorado pine contains 19% carbohydrate, but this can increase to as high as 54% in the more starchy kernels of the single-leaf pine. In the Parry pine, it is 44%, but the former is much preferred. (*See* **Carbohydrates**: Requirements and Dietary Importance.)

Other Substances

Pine kernels are extremely rich in phosphorus (6040 mg kg^{-1}) which is about the same as for soya bean, and iron (53 mg kg^{-1}). They also contain significant amounts of vitamin A, thiamin, riboflavin, and niacin. Refer to individual nutrients.

Uses

In the past, pine kernels were a staple component in the diet as well as a subsistence food, but because of their enormous versatility, they now hold a high profile in modern cuisine among people of the developed nations, particularly in the USA, Europe, Asia, and North Africa. As roasted nuts, they are very widely used in the preparation of soups, sauces, and dressings, and may be served as a garnish for fish meals, in mixtures with cooked meat and as part of side-dishes with rice. They form suitable ingredients in cakes, puddings, and biscuits, and as a garnish for icecream. They are also highly appreciated in fruit desserts and vegetable salads. The kernels are so nutritious that a number of recipes have recently appeared under the label of 'Backpackers' Friends.' These products bear such names as Piñon Pemmican and Granola, and may be carried as bars in the rucksack as emergency rations or snacks. Pine kernels will probably become even more popular as the rise in vegetarianism continues.

PLANT ANTINUTRITIONAL FACTORS

Contents

Characteristics

G D Hill, Lincoln University, Canterbury, New Zealand

Background

The growing of plants as a major food source for humans only started about 10 000 years ago with the birth of agriculture. At that stage, human intervention disrupted the chain seed – plant – seed. Because the seeds, tubers, and fruits of a number of plant species are rich in carbohydrates, protein, and fats, plant materials now provide a substantial proportion of the food energy that is consumed by humans and their domestic animals. When that process happened, a number of chemical compounds occurring naturally in plants, and often with a role in protecting the plant from attack by animals – be they insect, ruminant herbivore, or monogastric – became antinutritional factors (ANFs).

Other articles will deal in detail with most of these ANFs, which are sometimes called secondary metabolites. This chapter will consider the plant species involved and their interaction with animals and humans when they are eaten. The chapter will also consider briefly how the effects of ANFs can be overcome. It will not cover their exact chemical structure, their determination, or their biosynthesis.

Plant Antinutritional Factors

Antigens

A number of legume species, but particularly soybean (*Glycine max*) and peanut (*Arachis hypogaea*), produce severe antigenic reactions in both people and animals. Affected persons can go into anaphylactic shock, and unless treatment is quickly applied, death can follow. In a recent case in the USA, a person who was allergic to peanuts died after licking his fingers having touched a chicken leg coated with peanut sauce. Similarly, some airlines now have peanut-free flights. Other plant foodstuffs that are reported to induce allergenic reactions include rice (*Oryza sativa*), hazelnuts (*Corylus avellana*), apples (*Malus sylvestris*), and celery (*Apium graveolens*).

Compounds responsible The proteins that are thought to be responsible for the development of allergenic reactions are generally water-soluble glycoproteins that are resistant to breakdown by heat, acid, and digestive enzymes. In soybean and peanuts, the glycoproteins are thought to be the storage proteins, glycinin and β-conglycincin. These proteins resist digestion and are absorbed into the intestinal mucosa. The body responds by producing immunoglobulins or antibodies in the Peyer's patches of the gut and their associated lymphoid tissue. These antibodies are then released into the gut and react with the antigens to prevent their absorption. Antigens that escape absorption cause inflammation of the intestinal mucosa.

Three mechanisms are involved. An immediate mechanism that involves IgE antibodies and mast cells (type I hypersensitivity), semidelayed, which is brought about by antigen–antibody complexes (type III), and delayed caused by specific activated T-lymphocytes (type IV). The last is so called because there can be a delay of several days between the antigen challenge and the onset of observable symptoms. (*See* **Food Intolerance**: Food Allergies.)

Symptoms Affected animals show poor growth and diarrhea, and may die. In the gut, there are changes in the structure of the mucosa, increased gut motility, and reduced absorption of electrolytes (Na^+, K^+, and Cl^-). Once animals are sensitized, they can remain so for a considerable period. In laboratory animals, chronic stimulation by antigens has given reduced disacchiridase activity, reduced surface area of the brush borders of the microvilli, reduced microvilli height, crypt hyperplasia, cell degranulation, and increased numbers of mast cells.

Minimization of problems In humans, the development of food allergies seems to be related to age. Among young children, up to 8% can suffer from food allergies. In adults, the rate of occurrence is considered to be $< 1\%$. Thus, as people get older, they seem to be less prone to the development of food allergies. Where products such as soybean are used as milk substitutes, it is possible to treat the material by procedures such as steam heating to reduce the level of antigenicity.

α-Galactosides

It is probably not strictly correct to refer to the α-galactosides as ANFs, as they are not toxic. However, their presence in plant foods can cause severe digestive upsets in monagastrics that are embarrassing in humans and can lead to severely reduced growth rates in animals such as pigs.

Compounds responsible The α-galactosides or oligosaccharides comprise the sugars raffinose, stachyose, verbascose, and ajugose. They are simple sugars comprising a sucrose molecule to which are attached α-D-galactopyranosyl units in α-1,6-galactosidic linkages. They are a common carbohydrate present in the seed of grain legumes. It is thought that on seed germination, they provide energy for the emerging plant embryo.

Symptoms When members of the raffinose group of sugars are consumed by monogastrics, the animals do not have the necessary gut enzymes to digest these sugars in the intestinal tract. Consequently, they pass undigested to the large intestine where they are anaerobically fermented by gut bacteria. The products of this fermentation are, among other things, the gases carbon dioxide, methane, and hydrogen. Thus, consumption of legumes rich in these sugars leads to a considerable increase in flatus production. Some legumes can produce up to 137 ml h^{-1} of flatus, causing severe abdominal discomfort, bloating, belching, flatulence, constipation, and diarrhea. In pigs, in particular, high levels of oligosaccharides in their rations can cause severe digestive upsets and reduced growth.

Minimization of problems There is considerable interspecific variation in the level of oligosaccharides in legume seed. Soybean, chickpea (*Cicer arietinum*), and *Phaseolus* spp. tend to contain high levels, whereas lentil (*Lens culinaris*) and mung bean (*Vigna radiata*) contain lower levels. There is also some evidence of intraspecific variation among cultivars within species.

Traditional methods of processing grain legumes prior to their consumption significantly reduced the level of oligosaccharides. In the production of bean sprouts, the oligosaccharide level falls as germination continues. *Tofu*, which is a traditional protein precipitate produced from soybean, has low levels of oligosaccharide. In the production of *tempe*, which is a traditional Indonesian soy-based food, cooked beans are fermented with *Rhizopus oligosporus*. During fermentation, the oligosaccharides are utilized by fungus as an energy source, and the resulting *tempe* contains low levels of oligosaccharides.

Traditional legume-processing methods cannot be used for bulk quantities, however, because of the cost of processing. In the stock food industry, the problem is approached by the plant breeders trying to reduce the level of these sugars in the seed using selection within the species.

Alkaloids

A number of plant species contain significant amounts of alkaloids. Of the alkaloids, the most universally

known is probably nicotine, which is a component of tobacco (*Nicotiana tabacum*) and is ingested on a daily basis by millions of people. Edible members of the plant family Solanaceae, such as potato (*Solanum tuberosum*), tomato (*Lycopersicon esculentum*), and and eggplant (*Solanum melongena*), may contain high levels of glycoalkaloids. (*See* **Alkaloids**: Toxicology.)

Among legumes that are eaten by humans, or used in stock rations, plants of the Genus *Lupinus* contain high levels of alkaloid in both their foliage and their seed. In most lupin species, the alkaloids present are quiniolizidine alkaloids. However, *Lupinus luteus*, which is from the Iberian Peninsula, contains the indol alkaloid gramine.

Compounds responsible The alkaloids present in food plants of the family Solanaceae are glycoalkaloids. They have a stereoalkaloid nucleus, which is attached to a sugar side-chain. Their role is to protect the plant from insect attack. They are also implicated in both fungal and nematode resistance. The alkaloids tend to be concentrated near the epidermis and in the leaves. In green tomatoes, the fruits are protected while ripening by the alkaloid tomatine. As the fruit matures, the tomatine level falls.

In potato, the major alkaloids present are α-solanine and α-chaconine. They are present throughout the plant. Apart from a case in Scandinavia, where plant breeders increased the alkaloid levels in a new cultivar to the level where they produced toxic symptoms in humans, potato alkaloids are not a problem, provided that the tubers have been properly grown and stored. If potato tubers form too close to the soil surface, or are exposed to light after harvest, there is a rapid increase in alkaloid level. Harvested potatoes should be stored in the dark. In modern shopping systems, potatoes are often exposed to light in supermarkets when they are packed in clear plastic bags.

Among lupin species that are grown for their seed, there are a large number of quinolizidine alkaloids (Table 1). However, only eight of these occur in amounts of more than 4% of total alkaloids. The main alkaloids are sparteine, lupanine, 13-hydroxylupanine, albine, multiflorine, angustifioline, tetrahydrorhombifoline, and lupinine. The distribution of the alkaloids tends to vary with plant species. Most of the alkaloid in *Lupinus albus, L. angustifolius*, and *L. mutabilis* is lupanine. In *L. luteus*, the major alkaloid present is lupinine. The gramine in *L. luteus* (an indol alkaloid) can comprise up to 0.12% of total seed dry matter.

Symptoms Both potato and lupin alkaloids affect the nervous system. An excess of potato alkaloids can produce symptoms similar to a bad hangover. There have been deaths reported from the ingestion of excess potato alkaloids. Ingestion of lupin alkaloid leachate by a human has been known to produce blurred vision, an irregular heart beat rate, and urine retention. In animal feeding, the response to foods high in alkaloids is a loss of appetite, because of their bitter taste. This induces a reduction in feed intake and reduces growth rate.

Minimization of problems Fortunately, the alkaloids in both potatoes and lupins are water-soluble. Further, in potatoes, they are concentrated under the skin. Peeling the potato removes most of the alkaloid in the tuber. Soaking and boiling in water further reduce alkaloid levels. In both the altiplano of South America and southern Europe, *L. mutabilis* and *L. albus* are processed to reduce alkaloid levels. The seed is soaked and boiled and then soaked in running water for up to three days, by which time the alkaloid levels are significantly reduced. As noted above, with potatoes, correct storage in the dark, after harvest and prior to use, is also important.

Table 1 Distribution of total alkaloids present in smooth seeded lupin species used in human diets and animal feeding

	Lupin species			
Alkaloid	L. albus	L. angustifolius	L. luteus	L. mutabilis
Sparteine	Trace	Trace	30–50%	5–20%
Lupanine	50–80%	50–80%	Trace	50–70%
17-Oxylupanineo	Trace	Trace	[a]	
4-Hydroxylupanine				7%
13-Hydroxylupanine	5–15%	10–20%		10–20%
Albine	5–15%			
Multiflorine	3–10%			Trace
Angustifoline	Trace	5–20%		Trace
Tetrahydrorhombifoline	Trace	Trace	Trace	4%
Lupinine			40–70%	Trace
Esteralkaloids	1–5%	1–3%	Trace	1–5%

[a]Not detected.

In lupin, since the early 1920s, an alternative approach has been to select for low-alkaloid genotypes. Since then, because of work by plant breeders in Germany, Australia, and South America there are now low-alkaloid genotypes of *Lupinus albus, L. angustifolius, L. luteus*, and *L. mutabilis*. In Australia, low-alkaloid genotypes of rough-seeded Mediterranean lupins have now been bred. Thus, lupin seed is a safe food, and alkaloids are not likely to be a problem, provided the seed is processed before consumption or only low-alkaloid types are used.

Cyanogenic Glycosides

A number of plant species produce hydrogen cyanide (HCN) from cyanogenic glycosides when they are consumed. These cyanogens are glycosides of a sugar, often glucose, which is combined with a cyanide containing aglycone.

Plant species of major importance in human and animal feeding are cassava (*Manihot esculenta*), linseed (*Linum usitatissmium*), various sorghums (*Sorghum* spp), white clover (*Trifolium repens*), and some species of *Lotus*. Lesser quantities are found in the kernels of such plants as almonds (*Amygdalus communis*), apricots (*Prunus armeniaca*), peaches (*Prunus persica*), and apples (*Malus sylvestris*).

When plant material containing the glycoside is consumed, it is broken down by a β-glucosidase to produce a sugar and an aglycone. The aglycone is then acted upon by a hydroxynitrile lyase to produce cyanide and an aldehyde or a ketone.

Compounds responsible The compounds responsible vary with plant species. However, the major cyanogens are amygdalin and prunasin, which are found in fruit kernels. The latter also occurs in bracken fern (*Pteridium aquilinum*), dhurrin, found in members of the genus *Sorghum* and linamarin, found in clovers, linseed, cassava, and lima beans (*Phaseolus lunatus*). Cassava root contains relatively low levels at 53 mg of CN per 100 g of plant tissue. Sorghum forage contains 250 mg of CN per 100 g of plant tissue and lima beans up to 300 mg of CN per 100 g of plant tissue.

Symptoms As cyanide is extremely toxic, one of the most obvious symptoms is death. In the body, cyanide acts by inhibiting cytochrome oxidase, the final step in electron transport, and thus blocks ATP synthesis. Prior to death, symptoms include faster and deeper respiration, a faster irregular and weaker pulse, salivation and frothing at the mouth, muscular spasms, dilation of the pupils, and bright red mucous membranes.

In Africa, where many people consume cassava on a regular basis, many members of the human population are regularly exposed to low levels of cyanide in their diet. This is associated with a condition called tropical ataxic neuropathy. Symptoms include neurological disturbances, which affect vision, hearing, and the peripheral nervous system. There are also raised levels of blood thiocyanate and goiter. Cassava consumption, combined with protein deficiency, which is often common in societies that consume large amounts of starchy tubers, can lead to reduced glucose tolerance and diabetes. There is some evidence that the symptoms can be partially alleviated by the administration of vitamin B_{12} and methionine.

Minimization of problems As with many other problems of plant ANFs, one method of reducing the problem is via plant breeding. Older varieties of white clover used to produce high levels of cyanide. Newer cultivars have much lower concentrations. Similarly, breeding work has been carried out with lima beans to reduce their potential toxicity.

To produce cyanide, plant enzyme systems need to be active, and so heating plant material, and denaturing the enzymes, will generally render it safe. Thus, in the production of linseed meal, which is the residue left over after oil extraction, the material is generally heated sufficiently, while passing through an oil press, to render the enzyme system inactive. The use of entire linseed seeds in bakery products usually leads to their being exposed to high temperatures before they are eaten. In home consumption of cassava, cooking is used to inactivate the enzymes. Roots are also washed, grated, and soaked in water, and further washed to eliminate the cyanide. As with clover and lima beans, plant breeders are also trying to reduce the level of the cyanogen in cassava roots.

Glucosinolates

Glucosinolates are a common component in plants of the family Brassicacea. They have become of more interest in recent years following the considerable increase in the production of rape oil (Canola) from the seed of spring and winter forms of *Brassica campestris* and *B. napus*. Following oil extraction in these, and other *Brassica* spp., a high-protein meal is left, which contains high levels of sulfur amino acids. However, the presence of glucosinolates in the resulting meal has limited the use of the meal in animal feeding because of its tendency to produce goiter and other symptoms associated with low iodine availability. (*See* **Glucosinolates**.)

Compounds responsible Glucosinolates are glycosides of β-D-thioglucose. They contain an aglycone, which, on hydrolysis, can yield an isothiocyanate, a

nitrile, or a thiocyanate. Glucosinolates are responsible for the sharp flavor of such plants as horseradish (*Armoracia rusticana*) various mustards (*Brassica* spp), watercress (*Nasturtium officinale*), and radish (*Raphanus sativus*).

In plant tissues, the glucosinolates are present at the same time as the enzyme myrosinase, which is a thioglucosidase. In intact plants, the enzyme and the substrate occur in different parts of the plant. However, when plant tissues are disrupted, as may occur in chewing, or in pressing and grinding for oil extraction, the two components come together. As a result, the myrosinase breaks the thioglucoside bond on the glucosinolate. The result is the production of glucose and an aglucone intermediate product. The latter breaks down to produce a number of possible toxic components. The most common are isothiocyanates and nitriles. However, this depends on the conditions at the time of breakdown, and other products, such as goitrin, may be produced.

Symptoms The major effect of the breakdown products of the glucosinolates is interference with thyroid function. Goiter can occur in both humans and animals, but it mainly appears in animals when they are fed on rations in which rapeseed meal provides a considerable amount of the protein in the ration. Besides obvious morphological effects on the thyroid gland of animals, differences can be shown in biochemical parameters such as decreased serum thyroxin levels. In pigs, when sows are fed on high-glucosinolate rations, it can lead to abortion of piglets and increased death of piglets after birth.

Minimization of problems As with many other ANFs, moist heating the meal prior to feeding it to the animals or heat extrusion can reduce problems associated with the feeding of glucosinolates in *Brassica* meals. Bacterial fermentation and enzymes have also been used. However, the most significant recent achievement in reducing the problem was wrought by Canadian plant breeders who produced new cultivars of both major oils seed rape species, which contain considerably reduced levels of glucosinolates. These were originally known as '00' rapes but have since been renamed Canola. This major plant breeding advance has meant that considerably greater amounts of *Brassica* meal can now be incorporated into monogastric rations without any deleterious effects on thyroid function and iodine metabolism.

Lectins

Lectins, or phytohemagglutinins, are present in the seed of a number of legume species that are consumed by humans. The most important legume species, which is high in lectin, is *Phaseolus vulgaris*, because of its major role in the diet of central and northern South American populations. *Phaseolus vulgaris* lectin is highly toxic, as is the lectin from scarlet runner bean (*Phaseolus coccineus*) and tepary bean (*P. acutifolius*). At the other extreme, legume species with low to zero lectin activity include chick pea (*Cicer arietinum*), cow peas (*Vigna unguiculata*), faba bean (*Vicia faba*), lentil (*Lens culinaris*), mung bean (*Vigna radiata*), peas (*Pisum sativum*), pigeon pea (*Cajanas cajan*), and soybean (*Glycine max*). (*See* **Hemagglutinins (Haemagglutinins)**.)

In the plant, it appears that lectins are involved in the chemical recognition of the legume root by *Rhizobium* bacteria. Thus, although plant breeding may be used to reduce their absolute concentration in seed, it is unlikely that they could be entirely eliminated from legume seeds because of their importance in biological nitrogen fixation.

Compounds responsible Lectins are either carbohydrate-binding proteins or glycoproteins. They are capable of recognizing and binding carbohydrates in complex glycoconjugates. More than 70 lectins have now been isolated from legumes. They usually contain two or four subunits, each with a single carbohydrate-binding site.

Symptoms The main effect of lectins, when they are included in the diet, is through their interference with digestion in the small intestine. Lectins are resistant to breakdown in the digestive tract and bind to surface receptors. These bound lectins then cause changes in the metabolism of the epithelial cells. These changes include cell hypertrophy and hyperplasia. Indeed, animals fed high levels of toxic lectin can suffer rapid body weight loss, while the weight of the small intestine is significantly increased. Other changes that may occur are changed gut endocrine systems and hormone production, changed gut immune systems and disturbances in gut bacterial ecology, which, combined, can cause a greater sensitivity to bacterial infection. At the gross level, these effects are mediated via reduced growth, diarrhea, reduced nutrient absorption, and increased incidence of bacterial infections. In highly toxic species such as the red kidney bean (*Phaseolus vulgaris*), these symptoms, when combined, cause death.

Minimization of problems As indicated above, it is unlikely that it will be possible to breed the lectins out of legume seed entirely because of their role in the establishment of biological nitrogen fixation. However, it may be possible to select for reduced levels and/or to select for less toxic lectins. Fortunately,

most lectins are heat-labile. Dry *Phaseolus* beans require long soaking and cooking times before they are soft enough to eat, and therefore, for human consumption, most seed is rendered safe before it is consumed. However, there are reports that if beans are heated at 80 °C, lectin levels may be increased, and thus the beans are more, not less, toxic.

For animal feeding, however, lectin-containing seed needs to be processed to reduce lectin levels before the seed can be fed to monogastric animals. Generally, seed can be rendered safe by heat treatment prior to consumption. Other techniques that have been employed include chemical treatment, production of protein isolates, germination, and moist extrusion.

Saponins

Saponins are a diverse group of chemicals, which derive their name from their ability to form soap-like foams in aqueous solutions. They occur in a considerable number of plant species ranging from asparagus (*Asparagus officinalis*) to cucumber (*Cucumis sativus*). They are also present in a number of commonly used herbs and spices such as fenugreek (*Trigonella foenumgraecum*), ginseng (*Panax* spp.), liquorice (*Glycyrrhiza glabra*), and nutmeg (*Myristica fragrans*). (*See* **Saponins**.)

Saponins fall in a gray area between being ANFs or beneficial plant constituents. When monogastric animals such as pigs and poultry are fed rations containing such products as alfalfa (*Medicago sativa*) meal, there is a reduction in growth. However, experiments with a number of animal species have failed to show any significant effect of saponins on a number of growth parameters. As saponins are very bitter, one hypothesis is that their effects are mediated through reduced food intake.

On the positive side, it has been shown that saponins can form complexes with cholesterol in the gastrointestinal tract. This leads to increased excretion of cholesterol and a reduction in blood cholesterol level. With the high level of coronary artery disease in most developed countries, this is seen to have potential medical benefits. The most common form of ingestion by humans is through alfalfa sprouts. Recent publicity would suggest that the sprouts are more dangerous because of bacterial contamination, leading to gastroenteritis, than because of their saponin content.

Compounds responsible All saponins contain an aglycone, which is either sapogenol or sapogenein. The aglycone is linked to one or more sugars or oligosaccharides. However, the saponins fall into two groups, depending on whether the aglycone is triterpenoid or steroidal. Most cultivated plants have a triterpenoid aglycone, whereas in many herbs, it is steroidal. Saponin's structure is complex and depends on the variation in the aglycone structure and the position and nature of attachment of the glycosides to the molecule. Aglycones can be linked to D-glactose, L-arabinose, L-rhamnose, D-glucose, D-xylose, D-mannose, and D-glucuronic acid. The chain lengths are generally linear and comprise two to five saccharide units. This diversity in structure leads to a diversity of biological activity.

Symptoms The major physiological effect of saponins is on cell membrane permeability. It has been proposed that the saponins combine with membrane cholesterol to form permeable micelles in the plane of the membrane. However, as indicated above, the major effect of saponins in reducing intake appears to be the result of their bitter flavor-reducing feed intake, as experiments on a range of animal species have not shown any pathogenic effects of saponin intake.

Minimization of problems Saponins that are present in herbs and spices are likely to be present in such small quantities in the diet that they are unlikely to have any deleterious effect. Alfalfa has been selected by plant breeders to contain low levels of saponins. Similarly, quinoa (*Chenopodium quinoa*) seed, which is a minor Andean food crop, has reported saponin levels ranging from 0.14 to 2.3%. This has allowed for the selection of low saponin genotypes. In the Andes, in households, saponins are removed by soaking, washing, and rubbing to reduce the saponin levels in quinoa grain. Industrially, the seed is milled, or washed and milled.

Tannins

Many plant species contain tannins. However, the seed of a number of legume species and some sorghum lines contain appreciable quantities of tannins. These have dietary impacts on animals that consume them. Tannin is a generic name for polyphenolic compounds derived from plants. They have molecular weights of between 500 and 3000 and are divided into two classes, hydrolyzable and condensed. The former can be broken down by acid, alkali, and some hydrolytic enzymes. The latter are resistant to being broken down.

Faba bean (*Vicia faba*) tannins are involved with the human disease favism. The inclusion of high levels of tannin in rations for a range of monogastric animals reduces weight gain and feed-conversion efficiency. When fed to hens, tannins reduce egg production. However, the consumption of forage with high tannin levels can be advantageous in ruminant animal production. Tannins prevent the formation of the stabilized foams that produce bloat. Further, tannins

form complexes with free protein in the rumen and prevent protein degradation in the rumen. (*See* **Tannins and Polyphenols**.)

Compounds responsible Hydrolyzable tannins have a polyhdric alcohol at their core, the hydroxyl groups of which are partially, or fully, esterified with either gallic or hexahydroxydiphenic acid. They may have long chains of gallic acid coming from the central glucose core. On hydrolysis with acid or enzymes, the hydrolyzable tannins break down into their constituent phenolic acids and carbohydrates.

Condensed tannins are dimers, the simplest of which is procyanidin, or higher oligomers of substituted flavan-3-ols. Monomeric tannins are usually linked by carbon–carbon bonds between carbon-4 and carbon-8 of two flavan-3-ols. The bonds that are formed are highly stable and require heating with strong acids to break them down.

Symptoms In humans, favism produces acute hemolytic anemia. After susceptible subjects eat the beans, symptoms can occur in 5–24 h. The symptoms include headache, vomiting, nausea, yawning, stomach pains, and a raised temperature. The symptoms may subside naturally or, in severe cases, lead to hemolytic anemia, followed by hemoglobinuria. Previously, deaths in children could reach 8%. The disease is due to the lack of an enzyme in red blood cells, glucose-6-phosphate dehydrogenase. It is thought that over 100 million people, of mainly eastern Mediterranean origin, are susceptible to the disease. There has been some suggestion that the high levels of tannins in the diet of people who use sorghum as their main staple may be associated with an increased incidence of esophageal cancer.

The condensed tannins provide an important plant defense against herbivory. In particular, bird damage can be reduced by high tannin levels in crops such as sorghum and insect damage in seed of species like faba beans. The adverse nutritional effects of tannins are due to their reaction with proteins to form indigestible complexes. They can also form complexes with digestive enzymes and reduce the overall digestibility of food. They can irritate the gut lining and stimulate the secretion of mucus. This increases endogenous protein secretion and therefore increases protein demand. They also form complexes with divalent metals and reduce mineral absorption. A common feature of diets high in tannin is weight loss.

Minimization of problems In most legume species, there is a strong relationship between the level of condensed tannin in the seed and their flower color. Plants that have white flowers have low tannin levels in their seed. Thus, in a number of the legume species that have high tannin levels, the development of white-flowered genotypes gives pale-colored seed with low tannin levels.

In both legume seed and sorghum seed, the tannins are located mainly in the seed coat. Thus, dehulling the seed and discarding the hulls reduce the tannin level. Heat treatments do not destroy tannins in sorghum. However, sorghum tannins are unstable under alkaline conditions. Soaking in an alkaline solution followed by washing reduces the level of condensed tannins. The tannins in sorghum can also be neutralized by treatment with anhydrous ammonia. In contrast, in faba beans, the principal thermolabile antinutritional factor is the condensed tannins.

Toxic Amino Acids

In the legume family, there are two toxic amino acids that have a major negative effect on animals or humans that consume them. The tropical tree species *Leucaena leucocephala* contains the amino acid mimosine, which is an amitotic agent. Seed of the hardy annual legume species *Lathyrus sativus* contains a neurotoxic amino acid, generally referred to as ODAP or BOAA. The latter can cause paralysis of the lower limbs when eaten in excess.

Compounds responsible The full chemical name of mimosine is β-[1-(3-hydroxy-4-pyridone)]-α-amino propionic acid. The amino acid ODAP is β-*N*-oxalyl-L-α-β-diamino-propionic acid.

Symptoms Mimosine is an amitotic agent, and one of its major effects is to stop hair growth. It has been tested for a possible role in the chemical shearing of sheep. *Leucaena* seed, which is high in mimosine, is usually only used to a limited extent in human diets as a curry sambal in Indonesia.

The effects of *Lathyrus sativus* seed consumption are somewhat more problematic. Consumption of large amounts of *Lathyrus* seed in the diet often occurs in countries such as India and Bangladesh at times of food shortages as a result of drought. The condition produced is neurolathyrism, which is paralysis of the lower limbs caused by damage to nerve cells in the spinal cord. There is some evidence that the response to *Lathyrus* consumption may be sex-linked, as it seems to have a major effect on young males.

Minimization of problems With regard to mimosine, there have been some attempts to breed genotypes of *Leucaena leucocephala* that are low in mimosine. As it is such a minor component in human diets, it is unlikes to be a major problem. During

World War II in Hawaii, *Leucaena* leaf meal was used in both pig and poultry rations as a substitute for alfalfa meal. Provided that the levels that were fed were less than 10% there were no ill effects. Finally, ruminants can modify the spectrum of their rumen microflora to convert mimosine to 3,4-dihydroxypyrididine, which appears to have no biological activity.

With regard to *Lathyrus sativus* consumption, three approaches have been taken to reduce the problems associated with its consumption. In India, the crop has been banned. However, it apparently has a pleasant flavor and is a common adulterant of red gram (pigeon pea dhal). There is some suggestion that since the ban, the total area sown to the crop has increased. Therefore, the two following methods of dealing with the problem would appear to have a greater potential.

As with many other legume species that contain ANFs, they can be removed by traditional processing methods such as soaking, boiling, and fermentation. The major problem is that often in times of famine, it is not only food that is in short supply. Reduced amounts of wood for cooking often mean that food is cooked for less time, and the ANFs are therefore not destroyed to the same extent. At the same time, because of the drought resistance of the mother plant, it may become the only grain legume that is available, so the total amount consumed, and thus the dose of ODAP, is increased.

In Bangladesh, *Lathyrus sativus* is the most important single pulse crop and is grown on about 82 000 ha. To this end, plant breeders in Bangladesh, in association with workers from Belgium and Canada, have selected lines of *Lathyrus* with low levels of ODAP. The aim is to produce cultivars that are safe to eat with no, or a reduced, requirement for processing.

Trypsin Inhibitors

Trypsin inhibitors that inhibit the activity of the enzymes trypsin and chymotrypsin in the gut, thus preventing protein digestion, are found in many plant species. These species include a range of grain legumes such as common bean (*Phaseolus vulgaris*), cowpea (*Vigna unguiculata*), Lima bean (*Phaseolus lunatus*), peanut (*Arachis hypogaea*), peas (*Pisum sativum*), soybean (*Glycine max*) and winged bean (*Psophocarpus tetragonolobus*). However, they are also found in cereals such as wheat (*Triticum aestivum*) and barley (*Hordeum vulgare*), potatoes (*Solanum tuberosum*), and a number of species in the genus *Cucurbita*. Because of the extensive use of soybean meal in monogastric feeding, the trypsin inhibitors associated with this plant species have been studied most extensively. (*See* **Trypsin Inhibitors**.)

When monogastric animals are fed rations, which contain large amounts of raw soybean meal, there is poor growth, poor hair and feather production, and digestive disturbances. However, there is recent evidence to suggest that consumption of food containing trypsin inhibitors may have a role in combating breast cancer in humans.

Compounds responsible There are many plant-derived trypsin inhibitors. Most of these inhibitors differ in their specificity. Many can inhibit one or two enzymes. Different forms of inhibitor may be present in the same seed, and most of the inhibitors can inhibit trypsin, but they may also inhibit chymotrypsin. However, in legume seed, the two most important inhibitor families are the Kunitz trypsin inhibitor family and the Bowman–Birk trypsin inhibitor family.

The Kunitz inhibitor family was the first family to be isolated. It is a peptide comprising 181 amino acids containing two disulfide bridges with a molecular weight of about 21 000 Da. As this inhibitor inhibits trypsin stoichiometrically to form a stable complex, it is known as a single-headed inhibitor. It primarily inhibits trypsin, but it can weakly inhibit chymotrypsin. It is inactivated by heat and by gastric juices.

The Bowman–Birk inhibitor family is widely distributed in legume seed. It is a smaller peptide molecule and contains 71 amino acids. It contains a high level of cystine and has seven disulfide bridges. The molecular weight is about 8 000 Da. It is a double-headed molecule and inhibits both trypsin and chymotrypsin at two different binding sites. Bowman–Birk inhibitors are resistant to gastric juices and to proteolytic enzymes. There is also a suggestion that they may be resistant to breakdown by heat.

Symptoms Animal response to trypsin inhibitors in the diet varies with animal species. In chicks, rats, and mice, the inhibitors cause pancreatic hypertrophy and increased pancreatic secretion. However, they do not have these effects on pigs, dogs, or preruminant calves. Most monogastrics have reduced growth when fed on rations with high levels of raw soybean meal. Protein digestibility may be reduced, and dietary protein is excreted in the feces. There is also reduced nitrogen and sulfur absorption. One of the effects of the inactivation of digestive enzymes in the intestine is the stimulation of trypsin and chymotrypsin secretion from the pancreas, which can create an increased demand for the sulfur amino acids methionine and cystine. In turn, this leads to increased endogenous loss of both nitrogen and sulfur. Finally, the inhibitors can stimulate the release of

cholecystokinin into the blood stream, which further increases pancreatic secretion.

A number of factors can modify the effect of trypsin inhibitors in the diet. These include the animal species, the age of the animal, other ANFs present in the diet, and the type and level of protein in the diet. It appears that human trypsins are not inactivated by either family of the soybean trypsins.

Minimization of problems As with many other ANFs, the level of trypsin inhibitors can be reduced by moist heat treatments. Loss of activity is associated with temperature, duration of heat treatment, moisture conditions, and particle size. Up to 95% of activity can be destroyed by heating at 100 °C for 15 min. Autoclaving for 15–30 min has also been shown to destroy most trypsin inhibitor activity in a range of grain legume species. However, the results are not universally applicable. In the industrial production of soybean oil and meal, the heating caused during the process substantially reduces the level of trypsin inhibitor activity.

Plant breeders have been able to show that there is considerable variation in the level of inhibitor activity among genotypes of the same legume species. Recently, in peas, breeders have produced isogenic lines that differed only in their level of seed trypsin inhibitor. Similarly, there are also inhibitor-free lines of soybean. Thus, the breeding of plants with reduced levels of trypsin inhibitors in their seed is possible. However, as with a number of other ANFs, it is not clear what role the inhibitors serve in the possible protection of the plant. Until this is resolved, given that they are mainly rendered inactive by the processing of the seed, it may be better to leave the inhibitors in the seed.

Conclusions

It appears that our ancestors, and people in many societies in the developing world today, have been well aware of the ANFs that are present in the plant material eaten. They have long established methods of reducing the risks involved by one or more of the processes of soaking, testa removal, heating, fermenting, germinating, or protein extraction to produce isolates. However, these systems do not always work, and in many developing countries, the problems of already-poor nutrition are exacerbated by the presence of ANFs in the diet.

In the developed countries, in recent years, there has been a swing away from meat-based diets towards the consumption of more legume seed. A result has been an increased number of cases reported where people have become ill after eating legume seed that had not been fully processed. It has been suggested that this is because the need to remove the ANFs is no longer common knowledge.

In the processing of some plant materials to produce products like Canola or soybean oil, the heat that is produced during crushing and milling may be sufficient to render the resulting press cake safe to feed to nonruminants, including humans. Industrial producers prefer to use products that require as little extra processing as possible. To try to meet this demand, plant breeders have been actively trying to reduce the levels of ANFs in plant products. However, the downside is that this often renders plants more susceptible to attack by birds, insects, and fungi while they are growing, and to increased depredations of stored products by insects, particularly weevils.

It is possible that, if the controversy over the use of GM-modified plants for human food can be resolved, plant breeders could remove the ANFs from food plants. The partial protection that the ANFs currently provide could be obtained by the insertion of one or a few specific genes.

Detoxification

I E Liener, University of Minnesota, St. Paul, MN, USA

Introduction

Proteins of plant origin, particularly oil seeds and legumes, provide a valuable source of protein for humans and animals, despite the fact that they contain substances that can adversely affect the nutritional quality of the protein (**Table 1**). Fortunately, in many cases, these substances are heat-labile and can be readily eliminated or inactivated by the heat treatment involved in domestic cooking and commercial processing, or by treatment with chemicals. In other cases, potential toxicants remain innocuous until they are acted upon by enzymes of endogenous origin. Paradoxically, advantage can sometimes be taken of the action of these enzymes to detoxify certain plants employing such traditional modes of food preparation as germination or fermentation.

Protease Inhibitors

Proteins capable of inhibiting mammalian digestive enzymes, such as trypsin and chymotrypsin, are widely distributed in nature and have been shown to retard the growth of animals by virtue of their ability to interfere with the digestion of dietary protein. The animal tends to adapt to this situation by stimulating the secretory activity of the pancreas as well as its size. In extreme cases, such as the long-term ingestion of these inhibitors, the pancreas may exhibit precancerous lesions.

Because of its economic importance, the soya bean, which is very rich in protease inhibitors, has received the most attention with respect to the means whereby these inhibitors can be inactivated. Because they are proteins, they can be denatured by heat treatment, and this is accompanied by a loss in inhibitory activity. In general, destruction by heat treatment is a function of the temperature, duration of heating, particle size, and moisture content, conditions that are carefully controlled in order to minimize thermal damage to the nutritive value of the protein, which may occur if excessive heat is applied. An example of the relationship between the destruction of the trypsin inhibitor and the concomitant improvement in the nutritional value of the protein in shown in **Figure 1**. It is reassuring to note that most commercially available soybean products intended for human consumption such as tofu, soy protein isolates and concentrates, and textured meat analogs have received sufficient heat treatment to reduce the trypsin inhibitor activity to nontoxic levels.

Although the treatment of soya beans and other legumes by boiling in water or exposure to live steam (sometimes referred to as 'toasting') are the most commonly employed methods for inactivating the trypsin inhibitor, other modes of heat treatment or processing have proved to be equally effective. These

Table 1 Examples of naturally occurring toxicants of plant origin, their distribution and physiological effects

Toxicant	*Distribution*	*Physiological effect*
Protease inhibitors	Most legumes	Impaired growth, enlarged pancreas
Lectins	Most legumes	Impaired growth
Goitrogens	Cabbage family	Hyperthyroidism
Cyanogens	Lima beans, cassava	Respiratory failure
Phytate	Most plants	Interference with mineral availability
Tannins	Most legumes	Interference with protein digestion
Oligosaccharides	Most legumes	Flatulence
Mimosine	*Leucaena*	Goiter
β-*N*-oxalyl-α,β-diamino-propionic acid	*Lathyrus sativus*	Lathyrism

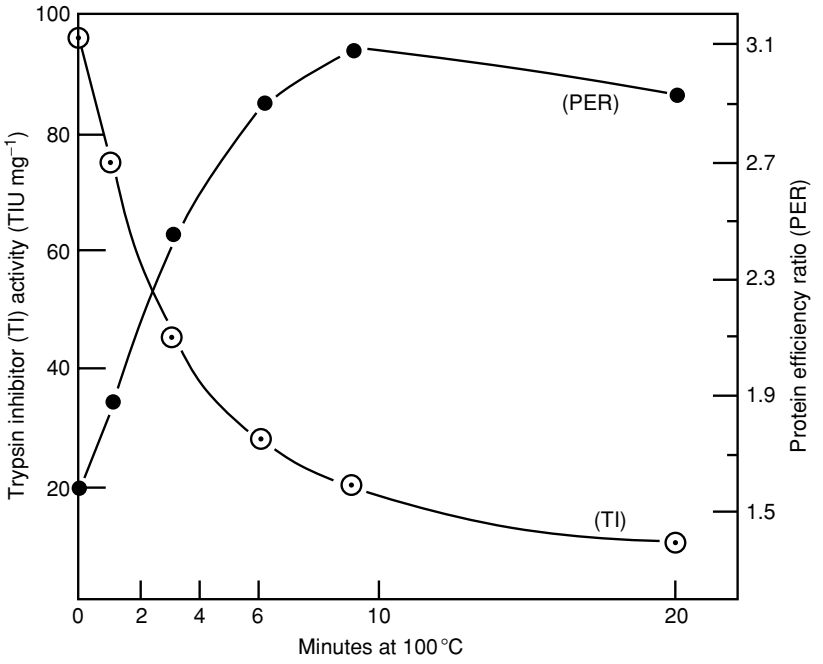

Figure 1 Effect of heat treatment on the trypsin inhibitor (TI) activity and protein efficiency (PER) of soya beans. PER=gain in weight (g)/protein intake (g). Courtesy of Academic Press, New York.

include dry roasting, microwave cooking, γ irradiation and infrared radiation.

Traditional methods of preparing various foods derived from beans generally result in products that are quite low in protease inhibitor activity. For example, tofu comprises mainly protein that has been precipitated from a hot-water extract of soya beans with calcium–magnesium salts, and soya milk is simply a hot-water extract of soya beans that may have been clarified by filtration. In both cases, the boiling or steaming of the soya beans prior to extraction with water serves to inactivate the inhibitors. The same holds true for fermented preparations of soya beans and other legumes such as tempeh, miso, and natto in which the beans have been subjected to boiling prior to the fermentation step.

The trypsin inhibitors are protein molecules whose activity is retained only if the disulfide bonds of the cystine residues remain intact. Thus, cleavage of these disulfide bridges by treatment of soya beans with reducing agents (cysteine, *N*-acetylcysteine, mercaptoethanol, or reduced glutathione) or with sodium metasulfite causes inactivation of the inhibitors.

A search for varieties of soybeans that might be devoid of trypsin inhibitors has led to the indentification of a cultivar that has only about half of the inhibitory activity of most commercial varieties of soya beans. This is due to the absence of the Kunitz trypsin inhibitor, the Bowman–Birk inhibitor, presumably accounting for the remainder of the activity. This particular variety of soya bean has the economic advantage of requiring less heat than conventional soya beans in order to produce a product of comparable nutritional value for animal feeding. (*See* **Plant Antinutritional Factors:** Characteristics.)

Lectins

Paralleling the distribution of protease inhibitors present in oil seeds and legumes is a class of proteins referred to as 'lectins'. These are proteins that exhibit the unique property of being able to bind to specific sugars that are part of the structure of so-called glycoproteins. Their antinutritional effect lies in the fact that, by binding to the glycoproteins located on the surface of the cells lining the small intestines, they interfere with the absorption of nutrients; the result is a failure in growth and eventual death.

The toxic effects of the lectins can be effectively eliminated by heat treatment, essentially under the same conditions as those that inactivate the protease inhibitors. However, there are documented cases where beans that have been eaten raw or only partially cooked have led to serious outbreaks of

gastrointestinal illness. For example, bean-containing stews and casseroles, when cooked in a slow cooker where a relatively low temperature is maintained for a long period of time, retain sufficiently high levels of lectin to cause illness.

With the availability of the soya bean variant devoid of the Kunitz trypsin inhibitor (see above) as well as one that was found to be free of the lectin, it became possible to compare the relative contribution of these two antinutritional factors to the poor nutritive value of raw soya beans. In comparison with conventional raw soya beans, a greater improvement in the growth performance of chicks was noted for the Kunitz inhibitor-free soya beans than that obtained with the lectin-free soya beans. These results may be taken to indicate that the Kunitz trypsin inhibitor is a more important antinutritional factor than the lectins. It is important to note, however, that heat treatment is necessary for the inactivation of both of these factors in order to achieve a maximum nutritive value.

Goitrogens

Goiter-causing agents in the form of glycosides (also referred to as 'glucosinolates') are found in members of the cabbage family, which includes not only cabbage but also broccoli, Brussels sprouts, cauliflower, turnips, rapeseed, and mustard seed. These compounds are biologically inactive as long as they remain bound to glucose ((**1**) Figure 2), but an enzyme, myrosinase, present in the same plant, serves to release the active goitrogenic principle, goitrin ((**2**) Figure 2). The glucosinolates found in the cabbage family appear to pose little risk to human health since the enzyme responsible for the release of goitrin is inactivated by household cooking. The glucosinolates may also be removed to a great extent by leaching out into the cooking water. The common usage of rapeseed meal in the feeding of livestock may prove to be toxic unless it has been treated with moist heat. Alternative methods of detoxification of rapeseed may involve prior extraction of the glucosinolates with water or acetone or by decomposition with iron salts or soda ash. These procedures, however, do not preclude the possibility that some goitrin produced enzymatically prior to processing may still remain in the meal. A more effective means of detoxification is one in which an aqueous slurry of the meal is deliberately allowed to undergo autolysis, which serves to liberate virtually all of the goitrin; the latter is then removed by extraction with water or acetone. Lactic acid fermentation or treatment with a specific fungus (*Geotrichum candidum*) has also been reported to be an effective means for the biological destruction of the glucosinolates in rapeseed meal. The immobilization of myrosinase on a solid matrix offers a promising approach for the hydrolysis of the glucosinolates, provided the goitrogenic end products are subsequently removed by extraction, as described above. (*See* **Plant Antinutritional Factors**: Characteristics.)

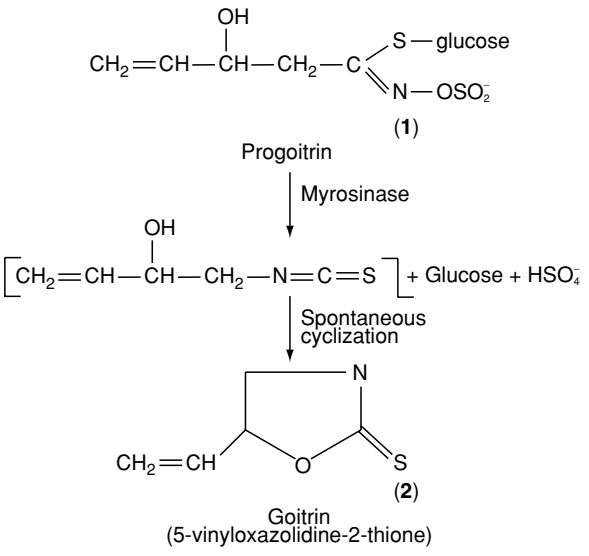

Figure 2 Structure of one of the goitrogenic compounds present in the cabbage family. Progoitrin (1) is biologically inactive, but, upon hydrolysis by the enzyme myrosinase, the active principle goitrin (2) is released.

Cyanogens

Many plants are potentially toxic because they contain glycosides, principally linamarin ((**3**) Figure 3), from which hydrogen cyanide may be released by the action of an endogenous enzyme, linamarinase, when the plant tissue is macerated. Among the cyanogenic

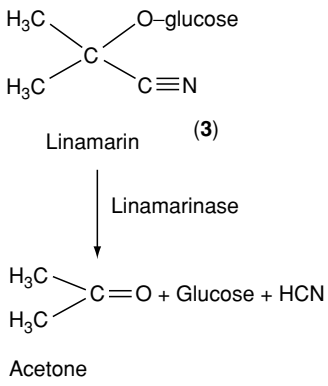

Figure 3 Structure of the major cyanogen present in lima beans. Enzymatic hydrolysis of linamarin (3) releases acetone, glucose and hydrogen cyanide.

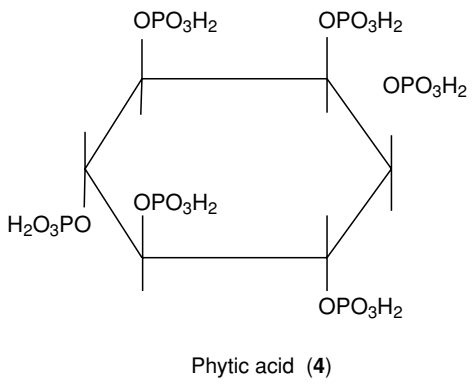
plants most likely to be consumed by humans are the lima bean and cassava. Although some tropical varieities of the lima bean may contain toxic levels of cyanide, those varieties consumed in the USA and Europe generally have levels of cyanide below the dosage known to be toxic to humans. Cassava is a staple food item in the tropics and often contains toxic levels of cyanide unless properly processed. The traditional method of preparing cassava involves the removal of the peel, which is particularly rich in linamarin, followed by a thorough washing of the pulp with running water. A further reduction in toxicity is achieved by the application of heat (boiling, roasting, or sun drying), which serves to inactivate linamarinase and to volatilize any hydrogen cyanide that may have been produced. The cyanide content of casava can also be reduced by a lactic acid fermentation to produce a native Nigerian dish called gari. The hydrogen cyanide released by the enzymes elaborated by the fermenting agent is then eliminated by frying. The use of an exogenous source of linamarinase derived from one of several species of fungi and bacteria has also been proposed for enhancing the detoxification of gari. An appreciable degree of detoxification of cassava pulp for use in the feeding of livestock can be achieved by ensilage.

Phytate

Phytic acid ((**4**) Figure 4) or its salt, phytate, is inositol combined with six phosphate groups and is a common constituent of most plants. Its antinutritional effect lies in the fact that it forms a chelate with metal ions such as calcium, magnesium, zinc, and iron to form poorly soluble compounds that are not readily absorbed from the intestine, thus interfering with the bioavailability of these essential minerals. The ability of phytate to bind metal ions is lost when the phosphate groups are removed by hydrolysis through the action of phytase. Heat alone is relatively ineffective in reducing the phytate content of plant materials, but the phytate content can be reduced by taking advantage of the endogenous phytase that accompanies the phytate in separate compartments of the plant tissue. For example, by the simple expedient of allowing ground soya beans to undergo autolysis under conditions that are optimal for phytase activity, one can obtain a significant reduction in phytate content. An exogenous source of phytase is commercially available as a feed additive to livestock and poultry diets. This not only serves to eliminate the mineral binding ability of the phytate that may be present from other plant ingredients of the diet, but also makes more phosphate available to the animal.



Phytic acid (**4**)

Figure 4 Structure of phytic acid (4). Enzymatic removal of the phosphate groups by phytase serves to eliminate its metal-binding property.

Traditional fermented dishes derived from such plants as soya beans, cassava, rice, maize, cowpeas, or yams have reduced levels of phytate, presumably due to the action of phytase produced by various molds, bacteria or yeasts involved in the fermentation. Even the use of yeast in breadmaking serves to reduce the phytate content of wheat flour. The germination of mature seeds of various legumes results in a great increase in phytase activity with a concomitant reduction in phytate. Other techniques for removing phytate such as ultrafiltration and ion exchange chromatography have been proposed, but these are unlikely to replace the simpler methods already described. (*See* **Phytic Acid**: Properties and Determination; Nutritional Impact.)

Tannins

Oilseeds and legumes contain appreciable levels of polyphenol compounds, broadly referred to as 'tannins' ((**5**) Figure 5). The negative nutritional effects of tannins are diverse and incompletely understood, but the major effect is to interfere with the digestibility of dietary protein. This may be due to the binding of the tannins to the protein to form substrates that are resistant to digestive enzymes or to a direct binding to these enzymes themselves.

Since tannins are located primarily in the seed coat of dry seeds, the physical removal of the seed coat by dehulling or milling markedly reduces the tannin content with a resultant improvement in the nutritional quality of the protein. Soaking in water or salt solution prior to household cooking also causes a significant reduction in tannin, provided the cooking broth is discarded. Treatment with a variety of chemicals such as ammonia, hydrogen peroxide, formaldehyde, polyethylene glycol, or polyvinylpyrrolidone has also proved to be an effective means for reducing the

tannin content of plant sources of protein. Germination leads to more than a 50% loss in tannins in legumes such as the chick pea, green gram, mung bean, and black gram, presumably due to the action of polyphenol oxidase of endogenous origin. (*See* **Tannins and Polyphenols**.)

Flatulence-producing Factors

One of the important factors limiting the use of legumes in the human diet is the production of intestinal gas (flatulence), which is generally attributed to the inability of the gut enzymes to hydrolyze the α-1,6-galactosidic linkages of such oligosaccharides as raffinose, stachyose and verbascose ((**6**), (**7**) and (**8**) respectively Figure 6). In their unhydrolyzed forms, these oligosaccharides become metabolized by the microflora of the large intestine into carbon dioxide, hydrogen, and methane, gases that are responsible for the characteristic features of flatulence, namely nausea, cramps, diarrhea, and the social discomfort associated with the release of rectal gases. Advantage may be taken of the endogenous galactosidases present in the plant tissue by allowing a slurry of the raw ground beans to undergo autolysis under suitable conditions or by treatment with an exogenous source of these enzymes derived from molds or bacteria. Such traditional dishes as tofu and tempeh, which have undergone fermentation by microorganisms, likewise have little flatus activity. Protein isolates from which these oligosaccharides have been eliminated during the course of their isolation are essentially devoid of the offending oligosaccharides. Preparations of galactosidases from microbial sources that have been immobilized as continuous flow reactors or in the form of a hollow-fiber dialyzer have also been employed for removing flatulence-producing factors.

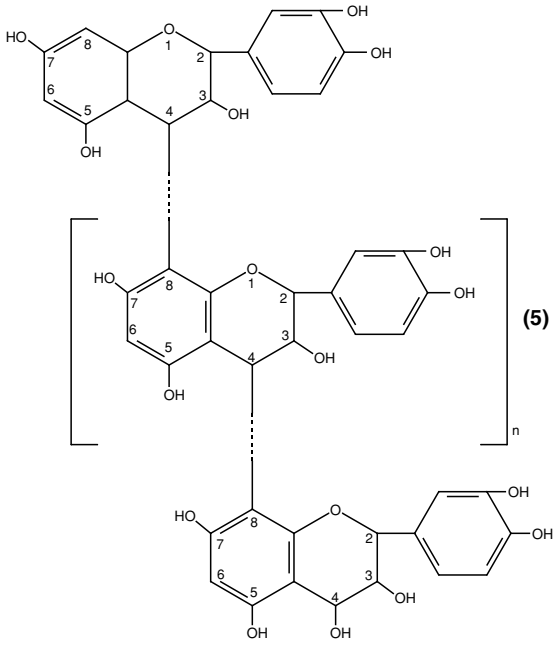


Figure 5 Structure of condensed tannin (5), which, by forming a complex with dietary protein, interferes with the digestion of protein.

Saponins

Saponins comprise a large family of structurally related compounds containing a steroid or triterpenoid aglycone (sapogenin) linked to one or more oligosaccharide moieties. Despite the fact that saponins are widely distributed in the plant kingdom, only a small number of such plants are actually toxic to mammals. It has long been recognized, however, that saponins, such as the glycoside of medicagenic acid ((**9**) Figure 7), which is found in alfalfa, is considered to have an adverse effect on the productive performance of nonruminant animals such as swine and poultry.

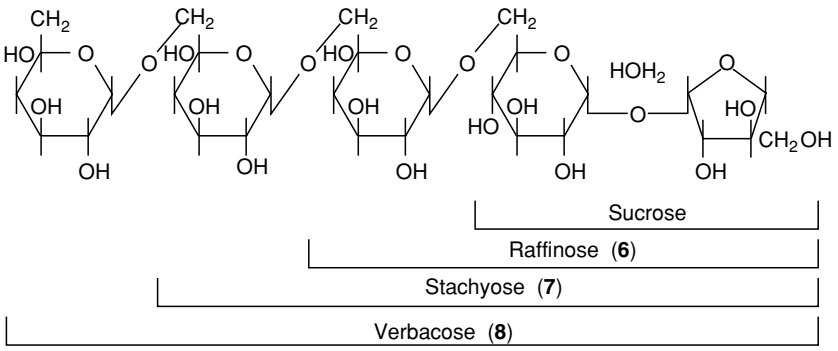

Figure 6 Structure of the oligosaccharides (6, 7, and 8) responsible for flatulence. In the absence of enzymes in the small intestine of humans that are capable of hydrolyzing α-1,6-galactosidic likages, these compounds are metabolized by the microflora of the gut into gaseous end products.

The negative effect of the saponins can be reversed, however, by the inclusion of dietary cholesterol, which interferes with the absorption of saponins by forming an insoluble complex with saponins. By the same token, dietary saponins may exert a positive effect by reducing cholesterol levels in the tissue and serum of experimental animals. (*See* **Saponins.**)

Mimosine

Leucaena leucephela is a tropical legume used primarily as a forage crop for feeding livestock, but its use is limited by the fact that it contains an unusual amino acid, mimosine ((**10**) Figure 8). This compound has an adverse effect on the growth of ruminants because bacteria can convert mimosine to 3,4-dihydroxypyridine ((**11**) Figure 8) which acts as a goitrogenic agent. In Hawaii, ruminants can convert greater amounts of the *Leucaena* before it becomes toxic than ruminants in Australia because of the presence of bacteria in the rumen capable of detoxifying mimosine. In fact, when Australian ruminants were inoculated with these organisms, they became more resistant to the toxic effects of mimosine.

Lathyrism

Human consumption of the legume chickling vetch (*Lathyrus sativus*) causes a neurological condition known as 'lathyrism,' a disease that is common in India and Bangladesh. The causative factor of this disease has been identified as β-*N*-oxalyl-α,β-diaminopropionic acid ((**12**) Figure 9), but over 90% of this toxin can be eliminated by the simple expedient of soaking the seeds overnight in an excess of water followed by steaming, roasting, or sun drying.

PLANT DESIGN

Contents

Basic Principles

H L M Lelieveld and G J Curiel, Unilever Research and Development Vlaardingen, Vlaardingen, The Netherlands

Background

If a plant is not of a proper hygienic design, it will be difficult to clean, and if not clean, the inactivation of microorganisms can be extremely difficult. After inadequate cleaning, harmful microorganisms may grow and affect product quality and safety. This chapter summarizes the basic principles of hygienic plant design to control the microbiological quality and safety of the final product.

Raw materials usually contain microorganisms. When given time and the right environment, they can grow out and increase to very high numbers. In food-processing equipment, the temperature and availability of nutrients are often ideal for the growth of many types of microorganisms. Consequently, when given enough time, such as in areas where the product is stagnant or residing for a long time for any other reason, microorganisms will cause problems. Product that is free from (viable) microorganisms may become recontaminated by microorganisms in the environment (air, people, insects, and other pests), by the processing and packaging equipment and by the packaging materials. Equipment must be hygienically

designed and fabricated, installed in a sufficiently hygienic environment, and be operated by staff who consistently observe the critical hygiene rules that apply.

Requirements for Hygienic Food Plants

Location and Buildings Exterior

Preferably, food plants should not be located near areas where levels of microorganisms, insects, or rodents can be exceptionally high. Therefore, a food plant should not be near a sewage treatment plant or in the middle of an animal farm area. Also, although decorative, there should be no trees, bushes, and plants near the factory. Such flora attracts insects and birds, which are sources of all kinds of pathogenic microorganisms. Also, there should be no breeding places for insects, so there should be no decorative ponds and generally no stagnant water at all in the vicinity. To avoid attracting insects, external lighting should never be mounted to, or near to, the wall of the plant. If positioned at a suitable distance, illumination will be adequate while insects move away from the plant. The outer walls of factories should not provide landing or breeding places for birds or other animals. The lower part of the walls must be rodent-resistant. Also, walls should be deep enough to prevent rodents from digging tunnels underneath to gain access to the plant. Measures must be taken to prevent animals gaining access to any area between the ceiling and roof. Roofs should not retain water (breeding of insects and bacteria) and thus slope such that draining is adequate. Doors must be self-closing; windows and doors that are opened infrequently, including emergency exits, should be such that there is little space between door and frame.

Layout

As the requirements for raw materials differ from those applying to intermediate or final products, the design of food plants should start with defining the hygiene requirements for the product in the subsequent stages of the production process. Based on that inventory, the layout of the plant should be decided, taking into account the various flows: of product, packing material, people, and air. Air, unless freed from microorganisms, should always move away from the exposed final product. Primary packing materials should be clean (complying with the microbiological requirements for the product to be packed). Neither people nor any material should move from the raw materials area to the finished exposed product area unless measures have been taken to prevent the carryover of microbial contamination. To protect microbiologically sensitive products, high-care areas may be needed. The entrance to such an area should have facilities for (compulsory) change of footwear and coats. All areas should have well-designed and well-maintained handwash facilities.

It is essential too, that, if the layout is correct, staff do not nullify the effect of correct measures by not knowing or not following the rules. For example, one is easily tempted to open doors and windows on a hot summer day, thereby completely destroying the airflows needed to prevent product contamination. Also, if possible and unobserved, people are likely to take 'shortcuts' to move from one place to another and thereby entering high-care areas from raw material areas. It is part of correct plant design to ensure that the rules are correct and sensible and that everybody is aware of their importance – and perhaps of the sanctions in case of breach: the health of consumers and the reputation of the factory are at stake.

Construction

Floors Floors are one of the great challenges: on the one hand, for obvious reasons, they should not be slippery. On the other hand, because they must be cleaned, floors must be smooth. In the case of dry floors, the problem is relatively easy to control, but any spilled liquid (water or product) may present an occupational hazard. The hazard selfevidently is related to both floor and footwear, and their interaction must be taken into account. Clearly, a 'dry-floor policy' will help to reduce both hygiene and occupational problems. Smooth concrete floors are acceptable for reception and many raw material storage areas. In areas where product is not protected, ceramic tiles or seamless mortar resin floors are preferred. In high-care areas, often, seamless resin floors are the best choice. Floors must have rounded corners where the floor meets the wall and should slope approximately 2% towards drains or gutters.

Walls Walls should be smooth and cleanable and should be covered by ceramic tiles or a good-quality coating or paint. If sandwich panels are used, all sides should comply with the chemical resistance required. It is important that all seams are reliably sealed. In some cases, seams can be sealed by welding with the parent material. In other cases, and where walls meet the floor, sealants should be used. Also, anything mounted to the wall should be sealed all around to prevent access to insects and dirt. The surface of choice should be strong enough to meet factory conditions, and repairs to any damage should be carried out within a short time. Where walls separate various hygiene areas, care must be taken that any holes for service lines are properly sealed.

Ceilings Panels similar to those used for walls (see above) may be used, and the same requirements apply. Lighting should be preferably built into the ceiling, with the underside flush with the ceiling. All suspended items, including lights at lower levels and exposed beams must be such that the upper side is sloped sufficiently to avoid the accumulation of dust and dirt. Ceilings and anything suspended from them must be easy to clean. Where acoustic ceilings are needed, it should be noted that sound-absorbing panels often cannot be cleaned and that panels that are easily cleanable usually are excellent sound reflectors. Consequently, a compromise will have to be found. Whenever possible, try to avoid noisy equipment in the plant, and when unavoidable, try to contain the noise near its location, where it may be easier to inspect for cleanliness.

Service lines and air ducts Service lines (hot and cold water, drains, electricity, compressed air) may harbor insects and other pests. Preferably, they should be combined in suitable, thus externally, smooth ducts, with all ends effectively sealed against vermin. Where mounted to a flat surface, sealant may be needed to close recesses.

Air ducts as well as cold-water pipes and drains, owing to their lower temperature, often may collect moisture, resulting in drops falling down on to product and food contact surfaces, and these may also support microbial growth. Hence, in areas where this will happen, cold surfaces must be insulated. The insulation should be sealed, sealing requirements being the same as for the ducts mentioned above. If the conditioned air is too humid, water may collect within the air ducts, allowing microbial growth, and so, the air becomes a significant source of contamination. This should be taken into account when designing the air system in the plant.

Equipment

Cleaning Cleanability is very important. Equipment that is not cleanable cannot be decontaminated other than with great difficulty or not at all.

Inactivation of microorganisms It must be possible to treat all product contact surfaces with whatever means has been chosen to inactivate the relevant microorganisms. Where the equipment is intended for pasteurized products, the equipment should preferably be 'pasteurizable.' In other words, it must be ascertained that all surfaces come in contact with water of the correct temperature for the required time. Entrapped air, e.g., in the top of tanks, will hamper pasteurization. Equipment for sterilized products must be made sterile. Steam sterilization is preferable, but again, there are pitfalls: in this case, lower parts of equipment may collect condense and thereby not be treated with steam. The considerably lower degree of heat transfer of water may reduce the temperature too much at such a spot. Where equipment is not sufficiently heat-resistant, chemical means may be used. Also, here, air entrapment must be prevented to ensure treatment of all surfaces.

Migration of microorganisms – aseptic processing and packaging A hygienic plant should protect the product from contamination. The ingress of microorganisms should be limited and, in the case of aseptic processing, fully prevented. For so-called closed plants, microorganisms may migrate to the product through crevices, leaking connections and moving parts of machinery, such as valves and pumps. Prevention is achieved by correct mounting and sealing of parts and by the application of barriers where movable parts are unavoidable. When choosing equipment, it should be realized that reciprocating shafts facilitate the ingress of microorganisms: the shaft transports small amounts of product to the outside, providing nutrients to any microbes present there, and every other stroke, microorganisms are transported to the inside. Rotary shafts display a similar effect, but to a greatly reduced extent. Where ingress must be prevented completely, such as for aseptic processing and packaging, diaphragms should be used to separate the product from the environment. Where this is not possible, such as with rotating shafts, double seals should be used, with an antimicrobial liquid circulating between them.

Growth Where, for functional reasons, such as blending (nonsterile), food products reside in equipment for a long time, measures must be taken to prevent excessive growth. This can be done by keeping the product below or above temperatures suitable for growth of the relevant microorganisms. Where this is done, it must be taken into account that there will be warm spots, e.g., where a shaft enters the equipment (centrifugal pump, rotary stirrer). Where the residence time is too long, because of the presence of avoidable dead areas in equipment, the equipment must be considered unhygienic. Such equipment should not be used for food processing, unless it can be cleaned easily and is used for production runs that are too short to cause microbial problems.

Principle hygienic design requirements for equipment Although hygiene is essential, the measures taken to ensure hygiene should not generate other health problems. Therefore, the principle requirements for the design of hygienic equipment also must take other aspects into account.

The basic principles are as follows:

- To cope with the aforementioned issues, food-processing equipment should meet the following requirements to be acceptable: all product contact surfaces must be noncorrosive, i.e., resistant to the product and chemicals under the operating and cleaning conditions. Furthermore, materials used (basic construction materials, but also auxiliary materials such as coatings, lubricants, sealants, adhesives, and fillers) should not have the potential of contaminating the food product such that the food becomes toxic or allergic.
- All product contact surfaces must be free from crevices and other irregularities that would be difficult to clean. Thus, no metal-to-metal connections (other than by welding or soldering) are allowed, and screw threads must be avoided or otherwise sealed.
- Product contact surfaces must be smooth enough for easy cleaning. Both the Hygienic Engineering and Design Group and 3-A prescribe a surface roughness for product contact surfaces of $R_a = 0.8\,\mu m$ or less.
- All product contact surfaces must be drainable to make it possible to remove all liquids from process equipment. Thus, surfaces and pipes should not be completely horizontal but slope towards drain points, and there should be no ridges, which may hamper draining. Where it is not possible to build equipment in such a way that proper draining is possible, procedures must be designed to ensure that residues of cleaning and disinfection liquids can be removed in another way. Even if no chemicals are used for cleaning, draining is important because many microorganisms can grow easily in residual water, needing only tiny amounts of nutrients.
- Dead legs and product stagnant areas must be avoided or, where unavoidable, should be designed to minimize the residence time. The presence of such areas should be taken into account when deciding on the frequency and procedure of cleaning. Dead legs of tees, if not too long, may be reasonably easy to clean if the direction of the flow of cleaning liquid is towards the dead leg. Special attention should be given to provisions for temporary connections, such as those used for filling transportable containers, road tankers, etc. If not used for some time and not cleaned, they present a large 'dead' area, very much alive with microorganisms.

Fabrication and installation The fabrication must be such that product contact surfaces are not damaged to adversely affect the cleanability. Welds should not be rough and, where necessary, should be polished to obtain a smooth finish. Welding should be done skillfully, as welds otherwise may soon corrode. This is particularly important for welds that cannot be seen anymore after assembly, such as with pipelines. Pipe-bending can be applied to preclude the need for too many welds and too many piping components. In general, the risk of contamination of food product is proportional to the number of microorganisms in the surrounding, and so the nonproduct side of equipment also must be accessible for cleaning. External features should not collect water, product, or dirt in areas that cannot be inspected and cleaned and thus provide places for harboring pests. That means that there must be either no space at all or an insufficiently large space between parts of machinery. The same applies to the space between machinery and the supporting structure, i.e., the floor, wall, ceiling, or any other support.

The installation of components should be such that the assembly is also hygienic. Hygienic components may be built together in such a way that the completed installation is not hygienic because the assembly cannot be drained or cleaned, and creates dead areas. Connections may result in crevices, components may cause obstructions for draining, and in a closed process line, a hygienic diaphragm pressure sensor on an easily cleanable tee may create a large dead area. The food-processing manager should not only decide on hygienic equipment but also keep a close eye on how the contractors intend to build the entire process line. In addition, care should be taken that overhead lines and components are not a source of contamination. Vertical piping is preferred, and horizontal pipework should slope to drains.

Sources of Further Information

There are a number of professional organizations that provide detailed information on the hygienic aspects of plant design. The EHEDG is an organization with about 25 subgroups specializing in the many different aspects of hygienic design and processing. The organization is supported financially by the European Commission to support the development of guidelines and to ensure their availability in many European languages. Currently, over 20 guidelines are available, covering subjects such as hygienic design criteria, the design of hygienic equipment for open and closed plants, designing hygienic pumps and valves, microbiologically safe pasteurization and sterilization of liquid products, hygienic as well as aseptic packaging of food products, and welding to meet hygienic requirements. In addition, the EHEDG has developed methods to determine whether equipment

meets the hygienic design criteria. Equipment complying with the EHEDG criteria may be certified. Much of EHEDG's guidelines can be found in the standards for machinery developed by the European Standardization Organization (CEN, Commission Européenne de Normalisation). Details can be found at www.ehedg.org. In the USA, the 3-A organization develops standards for food-processing equipment. Currently, 3-A provides a self-certification scheme for equipment complying with the 3-A standards, which may result in authorization to use the 3-A symbol on equipment. Information on 3-A can be found at www.3-A.org. Also, the USA-based NSF (National Sanitation Foundation) International produces standards for hygienic equipment, but traditionally focused on the catering area. NSF's website can be found at www.nsf.org. The three organizations have recognized the importance of harmonization between the various regions in the world and increasingly work together. NSF International has an office in Brussels, and one of EHEDG's regional sections is in Japan. EHEDG guidelines are produced with the assistance of 3-A and NSF, and 3-A standards are produced with assistance from EHEDG. Recently, NSF and 3-A have started to produce joint standards. The organizations also all work closely together with national, regional, and global authorities.

Concluding Remarks

It is important to ensure that the plant or process line will deliver safe products. Validation of the cleanability and the disinfectability and, where relevant, imperviousness to microorganisms are essential in the selection and commissioning steps. Not only must the food be safe just after commissioning the plant, but the plant or installations must continue to comply with the hygienic requirements. Therefore, an appropriate scheme for preventive maintenance should be devised.

Designing for Hygienic Operation

J P Clark, A. Epstein and Sons International Inc., Chicago, IL, USA

Background

As with facility design, discussed in the previous article, process and equipment design has many elements specific to the food being processed and others that represent common principles. This article discusses a number of those common principles, types of equipment, and common processes.

Overall Considerations

Equipment used in food-processing plants must be appropriate, effective, noncontaminating, easy to clean, and easy to inspect. It must also be safe for the workers using it. In the USA, equipment used in meat, poultry, and fish processing must be specifically approved in advance by the US Department of Agriculture (USDA). Equipment used in dairy processing should be listed in 3A standards (a voluntary industry standard-setting group), and equipment used in baking should satisfy Baking Industry Sanitation Standards Committee requirements. There are other standard-setting groups in other countries and for other industries.

In general, such standards address the aforementioned general requirements in light of the specific conditions. For example, the USDA emphasizes cleaning and inspection, because most meat processing equipment is cleaned daily. Dairy equipment is often cleaned in place, and so surface finish and absence of crevices are important. Baking equipment is less often cleaned with water, but is vulnerable to insect infestation. (*See* **Cleaning Procedures in the Factory**: Overall Approach; **Insect Pests**: Insects and Related Pests.)

As a result of nearly universal sanitation requirements, much food equipment is constructed of stainless steel, usually type 304, but often 316 and occasionally some other alloy. The alloys differ in their weldability and resistance to stress corrosion cracking, which is accelerated by chloride ions found in many foods and cleaning materials. Stainless steels are nonmagnetic, and so fragments that may occur as a result of wear or misuse are not removed by magnets. Metal detectors, which function by measuring changes in inductance, can detect stainless steels and are often used on final packages of foods. (*See* **Corrosion Chemistry**.)

Many polymers are acceptable for food use, especially Teflon, Neoprene, polyethylene, and polypropylene. Carbon steel is acceptable where conditions will not promote corrosion and contamination. Copper is used occasionally, for special purposes such as candy cooking.

Equipment designed for food processing can usually be disassembled with few tools and uses wide screw-threads or flanged connections to avoid creation of places where residues can be caught. Wherever possible, pipelines are welded, taking care to make inside surfaces of welds smooth and flush. Long runs of pipe or tubing must have inspection access and must be installed carefully so that drainage is complete. Dead spots are avoided in pipes so that systems can be cleaned thoroughly.

Clean-in-place

The concept of cleaning in place by flowing cleaning solutions and rinse water through a system in place of food liquids has significantly increased the productivity of food plants. Previous to its wide use, dairies and other food plants were disassembled and washed completely by hand. This consumed so much time and labor that it limited the practical size of plants.

The elements of a typical clean-in-place (CIP) system are chemical storage, solution supply and recovery tanks, supply and return pumps (usually centrifugal), spray devices in tanks, air-controlled automatic valves, manual connection stations (flowverters), additional piping to complete circuits, and automatic control devices such as programmable logic controllers. Empirical design rules have evolved from experience for flow velocities, spray intensities and solution strengths for effective cleaning of typical soils from food plants.

Most experience is with dairy and other liquid-product plants, such as soft drink, fruit juice, and syrup plants. Minimum velocities of $1.5\,m\,s^{-1}$ are generally required in pipelines to achieve sufficient turbulence. Tees and dead legs should not exceed three pipe diameters' length from the flowing stream so as to ensure cleaning. Tanks are sprayed at about 37 liters per minute per meter of circumference. Often, such flow rates surpass the normal process flow rates, and so special pumps may be needed just for CIP. Sometimes, it may be possible to use dual-speed process pumps, with a low speed for process flow and a higher speed for CIP. Such a technique saves investment cost and space.

It is common to design CIP systems so that cleaning solutions and final rinse water are recovered for reuse, to save costs and reduce discharges. Caustic soda solutions (1.5%) and nitric, phosphoric, and citric acids are common cleaning agents. Sometimes, detergents are used, alone or with acids or bases. In addition, sanitizing agents, such as iodophores, quaternary ammonium compounds, and chlorine-releasing agents, may be used, usually as a final rinse that is allowed to sit overnight. In the morning, the sanitizing agent is displaced with fresh water and then with product. (*See* **Cleaning Procedures in the Factory**: Types of Detergent; Types of Disinfectant; Modern Systems.)

With a properly designed CIP system, most of the plant waste water should be discharged during cleaning from the CIP unit. This permits monitoring and pretreatment, if necessary.

Some manual labor is involved in cleaning even highly automated systems. Positive-displacement pumps must be disassembled, bypassed, and cleaned by hand because their construction prevents complete cleaning by flushing. It is common practice to require manual connections at flowverters to prevent accidental contamination of food with cleaning solutions. Connections are commonly verified by electronic signals to the controller.

It is difficult to separate CIP design from process system design in many cases; they are best developed together. Physical arrangements, details of nozzles on tanks, valve placement, pump utilization, pipe runs, and other details are significantly affected by CIP.

Food Plant Layout

Overall process flow is dictated in part by location of shipping and receiving and also by constraints on equipment. For example, cookie and cracker baking ovens are as long as 100 m and must run in a straight line, because they use metal bands as baking surfaces, and partially baked pieces cannot be transferred easily. Hydrostatic sterilizers for cans and jars are usually located on outside walls for ease of access and maintenance. Cooling tunnels for chocolate enrobing are usually long and straight.

Dry equipment and processes should not be physically adjacent to wet ones; cold process areas should

be separated from hot ones; 'dirty' areas should be separated from clean ones, and so forth. Such separations are not merely physical, in the sense of walls and doors, but also include separate air-handling units, and perhaps limited access by people from other areas.

Vehicle traffic should be separate from people traffic. Often, it is desirable to keep visitors, who may be customers, off the production floor, in part for their own safety, but also to reduce exposure of food to humans. At the same time, if visitors are likely, it is desirable to offer a decent and controlled view of the process. One solution is an elevated, enclosed walkway with viewing windows. If the process side of the windows is refrigerated, as many food plants are, the windows need to be heated to prevent condensation.

Plant layout can encourage or inhibit communication among workers; with fewer people running modern food processes, good communication is essential. A serpentine layout may be helpful, compared to a long, straight arrangement. Clever use of closed-circuit television can overcome distance and obstructions.

Typical Unit Operations

Some unit operations are so common and important to food processing that they deserve individual discussion.

Mixing

Processes of mixing solids with solids, solids with liquids, and liquids with liquids are all quite common in food processing. For hygienic operation, mixers must be designed to empty completely, to be easily cleaned, and to be easily inspected. Access for addition of minor ingredients and for sampling may also be necessary. Doughs and pastes, such as bread dough, cookie batter, and confection fondants are prepared in specially designed machines with relatively high-powered motors.

Incorporation of gas, especially of air, may be desirable or undesirable for a given case; the mixer design changes accordingly. (High speed, giving high shear, leads to gas incorporation.)

Dispersion of powders into liquids, such as starch or gums into water or syrup, requires high-speed agitation to avoid the formation of partially wet agglomerates, called 'fish eyes.' One technique is to pour solids into a deliberately inefficient centrifugal pump, which is circulating liquid from and to a tank. The inefficiency means that energy is applied to dispersing the solids rather than pumping the liquid.

Dissimilar liquids, such as oil and water, do not form solutions but can be made to form stable suspensions or emulsions by formation of very small droplets of oil and by using surfactants. The small droplets are formed by high-shear agitation and by pumping under high pressure through small orifices or special valves in a homogenizer. Many foods contain natural surfactants, such as proteins and polysaccharides, which reduce surface tension at the interfaces between liquids and so help maintain an emulsion. Milk, icecream and salad dressings are examples of foods containing oils and aqueous solutions in stable suspension. (*See* **Colloids and Emulsions**.)

Heat Transfer

Heating and cooling of foods is critical to many preservation and processing techniques, including pasteurization, freezing, baking, and other types of cooking. One of the more common heat exchangers used in food processing is the plate type. This has dimpled or otherwise embossed plates separated by gaskets and held together by mechanical pressure on a sturdy frame. Hot and cool fluids pass on opposite sides of the plates, providing a large heat transfer surface in a rather compact space. The major advantage of the plate exchanger for food service is the ease with which it can be disassembled for inspection and maintenance. It can also be reconfigured easily by adding or removing plates on the same frame (up to the limit of the frame). (*See* **Heat Transfer Methods**.)

Shell and tube, concentric tube, and spiral tube heat exchangers are also found in food plants. Direct steam injection is also common.

Cooling and freezing are performed in several ways. Wiped-surface heat exchangers are common for freezing flowable fluids, such as icecreams, and for cooling fluids that have been heated for sterilization. Refrigerated plates are used for contact freezing of packages of food, such as vegetables or preplated dinners. Direct contact with very cold vapors or snow from liquid nitrogen or carbon dioxide is used in cryogenic freezing, usually on continuous belts passing through tunnels. Air cooled by refrigeration can also be used in similar tunnels. Cryogenic equipment is less expensive than mechanical refrigeration equipment but is more expensive to operate. The exact balance depends on local costs, but cryogenics are a good choice when minimizing capital is key; mechanical freezing is more common for established, ongoing processes, where operating costs are more critical. (*See* **Freezing**: Principles; Operations; Blast and Plate Freezing; Cryogenic Freezing.)

Steam heating of food in sealed containers, such as cans, jars, and pouches, is commonly performed in pressure vessels known as retorts. Batch retorts may be horizontal or vertical, and may have water in addition to steam or steam alone for heating. For

containers such as jars and pouches, which cannot tolerate internal pressure, air is added during the cooling phase, which uses water, to counter the internal pressure built up during cooking.

There are several approaches to continuous cooking of foods in containers. One of the more efficient is the hydrostatic retort, in which containers are transported in carriers on a chain through a 'U'-shaped tower in which the vertical leg of water serves as a seal to contain a high-pressure chamber. (In both batch and continuous retorts, pressures to reach 120 °C are used so as to shorten the time required to sterilize food without giving it overcooked taste and texture.) (*See* **Sterilization of Foods**.)

Another approach uses a helical track inside a horizontal cylindrical shell. The track rotates, transporting metal cans. Cans enter and leave through a star wheel valve. A similar shell and track is used to cool the cans under pressure.

Conveying

Many foods are solids or are made from solids, and so solids material handling is critical to food processing. Pneumatic conveying, by pressurized air or vacuum, is commonly used to move flour, sugar, and grains in food plants. Pressure conveying permits movement from one source to several delivery points, such as flour to several dough mixers. Vacuum conveying works well for several sources to one delivery point, as in dust collecting. It is also often used to unload bulk material delivery vehicles, such as rail cars or trucks. Dense-phase pneumatic conveying is a variation used for fragile materials, such as sugar, which might be damaged by the high velocities encountered in pressure or vacuum conveying. Typically, for dense-phase conveying, powders are blown from a holding vessel in slugs rather than being entrained in conveying gas.

Screw conveyors are used to move pasty or granular materials, often up inclines. They can be difficult to clean and are very dangerous, but for some purposes, they are uniquely appropriate.

Belt conveyors can be used to move loose food materials, but are best for packages and containers. They can also pose safety hazards, with numerous pinch points and motors, which start and stop under remote control.

Vibratory conveyors are well suited to many food applications, especially for fragile materials such as fried snacks, because they can be quite gentle and are easily cleaned.

No matter what solids conveying system is used, it can rarely be properly designed without specific measurement of the physical properties of the actual materials involved. Solids used in food plants vary widely in the properties that influence conveying and handling, and these properties are difficult to predict from theory or correlations. Examples of key properties include bulk density, particle size distribution, angle of repose, cohesiveness, abrasiveness and moisture content.

Pumping

Many foods are quite viscous and non-Newtonian, so proper design of pumps is challenging. Positive-displacement pumps, especially those using close-fitting lobes and screw-shaped rotors, are common. Such pumps are usually made of stainless steel and are designed for easy disassembly. Centrifugal pumps are more conventional but also likely to be stainless steel and built to be taken apart by hand with few tools.

A special case of pumping, which combines the functions of mixing and heating, is screw extrusion. Extruders may be single or double screw, with heating or cooling in jackets, and with a wide variety of die designs. When starchy materials, such as corn, are extruded under pressure through a die, an expanded foam is formed, which has a desirable texture and density. Pet foods, cereals, and snacks are made in large quantities in this way. (*See* **Extrusion Cooking: Principles and Practice**.)

Typical Food Processes

Many food processes have a number of steps in common, including mixing of ingredients, forming of pieces or shapes, filling of containers or packages, cooking and cooling, packaging for shipment, and unitizing. The specific details obviously depend on the product and circumstances. However, some issues are almost universal.

Formulation

In order to be mixed, a formula must be weighed or measured; this may involved feeding and scaling of particulate solids, metering of liquids and addition of small quantities of key ingredients. Most formulas for foods contain three categories of ingredients: major (percentages in the tens), minor (single-digit percentages), and micro (less than 1%). (Even these distinctions may vary from case to case.) It is common to prepare formulas in batches of several thousand kilograms, even if subsequent processing is continuous. Issues that arise include whether to use one scale, which must then be capable of weighing the entire batch, or multiple scales, sized for accuracy of each category. The cycle time of batching is longer if fewer scales are used, but the costs are lower. Liquid ingredients can be metered using any of several devices.

Sometimes, ingredients are simply added by units, such as entire bags or drums, but this is less precise than scaling, because usually, such units are slightly heavier than their label weight.

Critical issues in any automatic formulating system are reliable feeding and flow of highly variable solids; even such common commodities as flour and sugar can clump, cake, and bridge in hoppers and chutes, disrupting flow and upsetting operations.

Forming

Forming operations are highly specific, but can include such examples as flaking, extrusion, sheeting (rolling into thin layers), cutting, laminating, decorating, dicing, and many others. Usually, these operations are continuous and so need careful metering of a mix, which may have difficult flow properties (doughs or pastes, for instance). Forming operations usually work best when operated at a smooth and constant rate, so the surge capacity ahead of the operation and reliable removal of output are important.

Filling

Primary containers may be filled before or after such processing as cooking, baking, or sterilization. If the material is liquid or a suspension, it can be filled volumetrically; if it is free flowing solid, it may be filled volumetrically, or it may be scaled. Weighing of valuable particulate solids is often done with multicompartment digital scales, in which a computer scans compartments to select several whose summed weight most closely approaches the target. Such scales are very accurate and justify their considerable cost by reducing overweight packages.

It is common for food packages, such as cans of soup, to be filled in several successive steps, with the final 'mixing' occurring in the package. Chicken noodle soup, for instance, has noodles, chicken, and broth each added separately using specialized fillers.

Cooking

The meaning of cooking varies from food to food but almost always involves some heating, directly or indirectly, to cause desirable chemical reactions, remove excess moisture, develop color (usually browning), and reduce microbial populations. Heat may be applied by flames, steam, hot air, oil, microwaves, or hot water. After heating, cooling often occurs by exposure to ambient air but may be accelerated by refrigeration. Cooking almost always involves more than one reaction, some of which may be undesirable, so control is complex. In frying, for example, water is removed and largely replaced by fat, the volume increases, and browning occurs. (*See* **Browning**: Nonenzymatic; **Cooking**: Domestic Techniques.)

Packaging

In addition to a primary package, which may be filled before or after cooking, there are usually additional layers of package to provide additional protection during storage and shipping. These may include cartons and cases. Cartons are usually made of heavy paper and are part of the consumer package, so usually have multicolor printing of brand names, ingredients, use instructions, weight, and nutritional information. Shipping cases are usually removed in a store, are rarely seen by consumers, and so can be made of sturdy corrugated cardboard with minimum printing and graphics.

Plastics are increasingly important as components of food packaging, because they are lighter in weight than metal or glass, can be used in microwave ovens to reheat contents, and do not break as easily as glass. Plastic containers usually cost more than the metal or glass containers they replace but are perceived to add value to the consumer. Recycling of food containers is an increasingly important concern to consumers and complicates the selection of packaging material. Some of the most effective plastic containers are composed of several types of plastic, each providing particular properties, such as barriers to oxygen or strength. Such multicomponent materials are less easily recycled than single-component materials.

Unitizing

Shipping cases of food are usually assembled into larger units, often of about 450 kg on wooden pallets, for storage and shipment. These pallet loads may be wrapped in stretch plastic, wrapped with heat-shrinkable plastic, strapped, or stabilized by glueing boxes or bundles together. Alternatively, large cardboard sheets known as slip sheets may be used to hold a unit load. Special equipment is needed to pick up and move loads on slip sheets, in contrast to the common forklift truck for which wooden pallets are designed, but the slip sheets are less expensive than pallets and take less space in storage and shipping.

In automatic storage systems and racks, used to achieve higher volumetric density in warehouses, special captive or slave pallets may be used, which are not shipped with the product load. This may require an additional transfer operation.

Some short-shelf-life foods are unitized on special carts, baskets, and trays suited for storage on small delivery trucks for direct shipment to stores. Fluid milk, cultured dairy products, and baked goods are often handled this way.

Analysis of the best packaging and unitizing procedure and equipment is a specialized area of engineering and requires balancing investment costs, operating costs and delivery system costs to achieve the best overall arrangement.

Conclusion

Design of food plants for hygienic and effective operations requires consideration of the interaction of the building with the process, selection of the proper equipment, development of an efficient layout, and consideration of the roles of people, materials, and processes. The goals are safety, quality and cost efficiency. Many special pieces of equipment have been developed to aid in reaching these goals.

Process Control and Automation

J P Clark, A. Epstein and Sons International Inc., Chicago, IL, USA

Background

Food processes, like other industrial operations, are measured and controlled in order to obtain consistent, safe, and efficient results. Wherever possible, response to measurements is automated, to reduce human labor and the risk of error. Modern processes rely heavily on computers to monitor operations, record data, and generate reports. Increasingly, computing power is in the form of microprocessors, which are dedicated components of instruments, relieving control computers of functions, simplifying installation, and increasing versatility. This article discusses techniques for measuring typical parameters, especially those found most often in food processes, and the ways in which measurements are used to control processes. The food industry has adopted measurement and control techniques from other industrial processes, including computer-integrated manufacturing (CIM), which is discussed briefly at the end of the article.

Typical Parameters

Weight

Weight, usually of solids, but also of mixes, packages, and storage vessels, is one of the most important and common measurements made in a food plant. Mechanical lever arrangements with counterweights and indicating dials are still widely used, but more common is the use of electronic strain gauges or load cells. These have a quick response and give a signal that is converted to a digital signal that can be read directly by a computer. Load cells need to be calibrated and their limitations understood; they can be sensitive to temperature, moisture, and vibration, and they must be selected for the total weight range they will experience.

The combination of an electronic scale with a variable-speed screw or vibrating cone creates a feeder that can be programmed to deliver a given rate or a given total amount of material. Such a feeder may operate by tracking the loss in weight from a hopper or by weighing the receiving bin (gain in weight). Loss in weight is most common. Periodically, the feed bin must be refilled; during this time, the feeder continues to run at the last speed it had. To minimize the time in which this 'volumetric' feeding occurs, refilling is kept to 5–10% of the cycle time. This means that the refill flow rate is 10–20 times the controlled feed rate; for high flow rates, this can be quite substantial and represents a significant shock to the receiving bin. Refilling can also aerate solids and make them hard to control or force them out of the feeder. Thus, bin sizing, delivery system, and flow control are all integral to successful weighing and delivery of solids.

Checkweighers are special scales placed in line with a package conveyor to weigh individual packages. Usually, a checkweigher controls a kick-out device

to remove over- or underweight packages. Data are also accumulated to calculate averages, standard deviations, and other quality statistics, which are used for statistical process control. This involves identifying process capabilities by measuring performance, then using such data to detect abnormalities and gradually to improve performance. Occasionally, a checkweigher is used to control a filler or other process affecting package weight.

When storage or process tanks and bins are to be weighed, they must be carefully isolated from other supports so that the load cells bear the true weight. This requires flexible connections from delivery pipes and other gear, which may be attached to a typical tank. Sometimes, load cells are installed to permit calibration of other instruments, such as meters, which are regularly used to control formulations.

Flow of Fluids

The traditional method of measuring flow rates of liquids and gases is by measuring pressure drop across an orifice (a small hole in a plate inserted in a pipe). For food fluids, an orifice plate may pose an unacceptable obstruction to suspended solids and may also be hard to clean in place. For homogeneous, clean fluids, this approach is reliable and inexpensive, but it provides a limited turn-down ratio of about 3:1.

Better for measuring homogeneous fluids (liquids or gases) is the vortex meter, which detects small changes in capacitance created as vortices are shed from a bluff body inserted in the fluid path. The vortices, or swirls of fluid, are created and shed in direct proportion to the flow rate. The turn-down ratio can be 10:1 or greater, and the measurement is independent of temperature, density, and viscosity. Installation is simple, and obstruction of the flow path is slight.

An increasingly common technique, which has no flow obstruction and does not require long runs of straight pipe before measurement, is the mass flow meter. A tube is inserted into a pipe as part of the flow path. The tube is vibrated at a resonant frequency. As fluid flows through the vibrating tube, it changes the phase difference of vibration at two points on the tube (or it imparts a twist to a bent tube), which can be detected and converted to a signal proportional to the flow rate. Magnetic or optical detectors measure the location of the tube, and electronic devices convert the signals to flow rates.

Other flow-rate-measuring devices count turns of rotors, vanes, or some other signal of flow rate. For electrically conducting fluids, changes in a magnetic field due to flow can be measured without any obstruction to the flow path. Positive-displacement meters use the flow directly to generate a signal by driving a lobe or piston connected to a shaft; rotations are proportional to flow. If a measurement is used to control flow, it usually signals an air or electrically operated valve, but it could signal a variable-speed drive on a pump.

Temperature

Temperature is a critical measurement in many food processes because it controls sterilization and cooking operations; too high or too low a temperature may be harmful. Thermocouples are inexpensive and reliable. They generate a small but consistent voltage difference at the junction of dissimilar metals, which can be correlated with temperature.

Most common for accurate measurement over larger ranges are resistance temperature detectors, which use the change in resistance of platinum with temperature to measure temperature. A common standard is to set the resistance at 100 Ω for 0 °C.

Bimetallic thermometers are commonly used as temperature indicators – the familiar dial thermometer – but they do not provide an electronic signal. Various solid-state devices, such as thermistors, are used to measure temperature because they give a signal directly compatible with electronic equipment, are compact, and do not require special wiring, as do thermocouples; however, they are not very accurate.

When temperature must be controlled, the signal usually drives a steam, gas, or water valve. Control of temperature in multizone equipment, such as baking ovens, can become very complex, as there are many temperatures to measure and many valves to control, most of which interact with each other. Safety interlocks are also required, to detect temperature excursions, to trigger alarms, to activate fire-suppression equipment, to control exhaust blowers (preventing buildup of gas), and to indicate restoration of operating conditions.

Mercury-in-glass and alcohol-in-glass thermometers are still found in canning operations, as calibration standards for retorts, but are rarely used in other food plants, because of the risk of contamination. (*See* **Canning**: Principles; **Mercury**: Toxicology.)

Temperature can be measured at a distance by infrared instruments. These are useful for checking insulation on overhead lines, roofs, and tall tanks.

A difficult temperature measurement challenge is to follow the temperature history of a container in a continuous sterilizer, such as a hydrostatic retort. The solution is a solid-state measuring and recording device, which fits within or on a container and is plugged to a computer when it is recovered. The data are recorded in semiconductor memory, which is read by computer or special instruments. Similar devices are used to track the temperature history of refrigerated and frozen foods in the distribution chain.

Traditionally, sterilization and pasteurization processes were required to keep ink tracings of temperature history continuously, usually on familiar circular instruments charts. Such records are still seen, but electronic data collection is increasingly accepted. It is critical to ensure the integrity of such data, if it is to displace the ink recorder. (*See* **Pasteurization**: Principles; **Sterilization of Foods**.)

Pressure

Solid-state strain gauges, similar to those at the heart of electronic scales, can also be used to measure pressure, since both parameters involve force. Sanitary pressure gauges involve flush-mounted diaphragms whose deflection generates a signal. The same device can serve as a level indicator in a tank.

Traditional Bourdon tube pressure indicators are found in food plants, especially on utilities such as steam. If used in direct contact with food, they need to be designed to prevent contamination by the food or of the food by any filling material.

Level

The level of fluids is measured by weight or pressure at the bottom, but also can be detected by floats, position detectors, or conductivity switches. The level of solids is more difficult to measure because hydrostatic pressure is not directly proportional to solids height in a bin. A variety of devices, using plum bobs, ultrasonics, and light are used to measure the distance to the top surface of solids, but these suffer from the tendency of solids to remain in a pile with an uneven surface. Bin weight is the best way to control inventory of solids.

Probes can be used to measure capacitance change, as liquids or solids cover more or less of the length, thus giving level indication around the location of the probe. Vibrating reeds or 'tuning forks' generate a change in signal when they are covered, thus indicating the presence of solids or liquid at their location in a bin. Capacitance detectors can also be used as point indicators of level, as can devices that detect change in resistance to rotation of a small paddle.

Composition

The refractive index correlates with the solids content of many liquid food materials, such as syrups, milk, and juices. Thus, instruments to measure refractive index can report results in terms of composition and can be used to control blending operations. Other properties found to correlate with solids content include viscosity and density. On-line instruments exist to measure these properties also.

Direct measurement of composition is quite difficult except by versions of analytical instruments, such as gas chromatographs, mass spectrometers, and pH meters. Ion content can be detected and quantified by ion-specific electrodes, and salt content can be measured by conductivity. Relatively few of these techniques are found directly connected to processes; more often, they are used as off-line quality control devices. (*See* **Chromatography**: Gas Chromatography; **Mass Spectrometry**: Principles and Instrumentation; **pH – Principles and Measurement**.)

Moisture

Moisture is very important in foods and is usually measured by drying a sample. Instruments exist to give moisture determination in minutes, but this is still too slow for direct process control. Water activity can be detected by a humidity sensor over a sample in a closed container, but again it requires minutes. Changes in radio-frequency signals or of microwaves can be used for noncontact, on-line sensing of moisture in some foods.

Moisture, fat, and protein content can be measured quickly for meats and other foods using infrared spectrometery. This has been an off-line technique, but it can be done on the process floor, giving results in time to modify a batch, if necessary. Reflected near infrared is used on-line to measure some composition changes, including moisture and oil content. (*See* **Protein**: Determination and Characterization; **Spectroscopy**: Near-infrared; **Water Activity**: Principles and Measurement.)

Color can be detected and quantified on-line and has been used to control baking ovens, and also to help sort out burnt potato chips (crisps). (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; Properties and Determinants of Synthetic Pigments.)

Other Parameters

Counting, most often of packages and cases, can easily be done simply by breaking a light beam to a photo detector or by using proximity switches, which detect changes in capacitance or magnetic fields due to the presence of an object. Such switches are also used to detect position and control starting and stopping of machinery, such as accumulation conveyors.

Seal integrity, most often of heat-sealed polymer packages, such as snack foods, is difficult to detect quickly. Visual inspection is the most frequently used technique. Often, such packages have a small amount of inert gas, such as nitrogen, injected to displace oxygen; the 'pillowing' effect that this creates can be used to detect presence of leaks in seals by lightly compressing the package and measuring its resistance to deformation.

The integrity of cans and jars is measured by detecting the deflection of lids due to the internal vacuum. The vacuum is created when hot-filled contents cool or by steam-flushing of the head space. The deflection can be measured physically or by tapping to create a distinctive tone; 'duds' are rejected as likely to have leaked.

Vision systems are complex combinations of optical devices and computers to observe, quantify, and report on shapes. Such systems are becoming less expensive and more useful as the cost of computing power continues to decline. A vision system can check pizzas for the proper count and placement of garnish, such as pepperoni slices; it can look for and discard 'doubles' in a candy bar process; and it can detect the presence and proper placement of labels on containers. Special devices can read bar codes on cases and report data to an inventory management system.

Vision systems will become more complex and useful with time and will assume many duties now performed by humans, such as sorting, grading, trimming, and assembling.

Integration of Processes

Integration of processes means the linking of data from various sources to maintain smooth operation and the use of such data to improve operations. At a primitive level, such techniques as signaling downstream or upstream operations about stoppages can avoid waste and prevent damage to equipment. On a more sophisticated level would be recording data about stoppages for later analysis. A computer can be used to coordinate the signaling and to do the analysis. It can even write the report, recommending process improvements!

CIM encompasses both levels cited plus more. The basic idea is to avoid ever having to reenter data or information once it exists in a computer. For example, direct process data, such as case counts or batch weights, are available in a process control computer. It should not be necessary to obtain a report and reenter that data in another computer in order to calculate daily, weekly, or monthly production results. Nor should it be necessary to correlate data from two or more different sources to identify production problems and detect improvements. In a CIM environment, all data are available on a common data base shared among various computers linked electronically.

Computers included in such a network range from mainframes and minicomputers through desktop or microcomputers to factory-floor devices such as programmable logic controllers. The power found in each of these devices is increasing as the cost decreases, so the capabilities available to those running food plants are constantly improving. Current practice in modern food plants is to control nearly all equipment (pumps, conveyors, ovens, sterilizers, feeders, etc.) through operator-interface terminals, which have color graphic displays and keyboards, keypads, or touch screens.

The displays, of which there may be several dozen, usually show flow diagrams of the process and status of the equipment (on or off, temperature, etc.). Time histories of any measured parameter can be plotted on command, deviations from desired ranges flagged, and correlations tested among measured parameters.

Standard reports are generated, and data can be summarized for use at the next level of management. For example, on the operational level, the instantaneous rate of production is a concern (cans per minute, kilograms per hour, etc.); at the next level, the interest might be cases or pallets per day (calculated by summing all the actual cans, kilograms, cases, or pallets counted); at the plant and corporate levels, totals for weeks, months, quarters, and years are the only concern. If all the results, at whatever level, are calculated from the same basic data, with little human intervention, they will be consistent and available quickly, and people will be relieved of tedious and unnecessary time-consuming labor.

Barriers to this ideal situation have included incompatibilities among computers, languages, programs, and communications media. Additional barriers have been low computer literacy among workers involved and institutional resistance to sharing of information. Evolution and cooperation among vendors have led to the emergence of common protocols for exchanging information electronically, so that many of the previous technical barriers have fallen. Training and the use of computers in early school grades is reducing the literacy problem. The institutional resistance may be the most difficult, but as the significant benefits of computer integration are appreciated, this too will disappear.

Conclusion

The overwhelming importance of computers in process control and business systems, which are increasingly linked together, has a significant impact on food plant design. The need to have data compatible with computers influences the selection of instruments and measurement techniques. Instruments are being made 'smarter' by incorporating computing power in them with microprocessors, leaving only simple connections to control computers. Such smart instruments calibrate themselves, control drift, correct for changing conditions, and are inexpensive to install. The ability of fewer people to manage and control large processes reduces the labor requirements while raising the education and training requirements of the employees.

PLUMS AND RELATED FRUITS

C F Hansmann and J C Combrink, ARC Infruitec-Nietvoorbij, Stellenbosch, South Africa

Background

The European plum (*Prunus domestica*) probably originated in eastern Europe or western Asia around the Caucasus and the Caspian Sea. It has been known in Europe for more than 2000 years. Prunes are the most important subgroup. Others are the greengage, yellow egg, imperatrice, and lombard groups. The Japanese plum (*P. salicina*) originated in China and was domesticated in Japan. An American fruit breeder, Luther Burbank, developed many commercial cultivars from it after its introduction into the USA around 1870. Native plum species occur in some countries, such as North America (e.g., *P. americana, P. hortulana, P. subcordata*) and the UK (*P. spinosa*, blackthorn sloe; *P. institia*, damson or bullace), but these are not extensively grown commercially. Some are used in breeding programs with Japanese plums. Other plum types, used as rootstocks or in plum breeding programs, or occurring in home orchards, are *P. cerasifera* (myrobalan, cherry plum), *P. simoni* (apricot plum), and *P. institia*.

Plums are cultivated over a wide range of climatic conditions. In 2000, world production of plums was estimated at 8 830 000 tonnes (**Table 1**), representing about 8.5% of the world production of deciduous fruit. Fifteen countries produced more than 100 000 tonnes each, or more than 85% of the total production. The ratio of Japanese plum to European plum is approximately 99:1 for Japan, 60:40 for South Africa and Israel, 40:60 for Canada (Ontario) and Italy, and 0:100 for Yugoslavia (Montenegro, Serbia).

Anatomy and Morphology of the Fruit

The plum is a succulent fruit, called a drupe, and is formed by thickening of the ovary wall following fertilization. The floral remnants become senescent and drop off. The skin (epicarp) consists of a layer of elongated living cells (epidermis) covered by a thin film of cutin (cuticle). It protects the underlying tissue and permits exchange of metabolites or gases with the external environment through openings (lenticels). Wax deposited on the cuticle forms a light gray bloom that gives the skin a dull appearance and makes it impermeable to water. The thick, fleshy, edible portion (mesocarp) consists of parenchyma cells that have an active protoplast where all metabolic reactions occur. The protoplast is enclosed by a pectinaceous cell wall. Middle lamellae, which occur between adjacent cell walls, have a high calcium content and play a vital role in maintaining cohesion between cells, thus providing structural rigidity. The single seed is enclosed by a hard stone (endocarp) consisting of isodiametric cells with thick, lignified cell walls (sclerenchyma). The mesocarp usually clings to the endocarp, although some cultivars are freestone (i.e., the mesocarp is free from the endocarp).

Japanese plums are large and attractive, round or heart-shaped, with or without a prominent apex. The surface of some cultivars is covered by a heavy bloom. The flesh and skin color of ripe fruit may vary from

yellow to blood red. The skin of the red-colored cultivars changes during ripening from green to red, usually starting at the apex. Fruit texture varies from firm and nonmelting to soft and melting. European plums are usually oval, with bulging of the central side, and compressed bilaterally. Their skin color is blue or purple, and they have a thick, meaty, freestone flesh. Fruit texture is usually firm and semimelting.

Physiology of Plum Fruit

Cultivar, climatic, environmental, and cultural factors significantly affect physiology. Cell division, multiplication, and differentiation of tissue occur during the first few weeks after fertilization. Cell enlargement and maturation follow. Numerous biochemical changes occur in plum fruits during the last few weeks prior to harvest, whilst the fruits are still attached to the tree. Many of these physiological changes are consistent and predictable, and can be used as indices for determining harvesting maturity. Substances synthesized in the leaves through photosynthesis are translocated to the fruit and transformed into products, which eventually determine the quality and nutritional value of the fruit.

The sugar and total soluble solids content increase throughout the period of growth. Organic acids accumulate in the fruit during the early stages of growth and then gradually decrease. The phenolic content of the fruit is high during the early stages, decreases, and then remains contant until harvest. Volatiles, which determine the flavor or aroma, are produced. Wax develops on the skin of the fruit. The fruit attains its full size and optimum maturity, although it is still unripe. (*See* **Phenolic Compounds**; **Sensory Evaluation**: Aroma; Taste.)

During ripening, pectic substances in the cell walls change from an insoluble to a soluble form, resulting in softening of the fruit. The chlorophyl (green pigments) content of the skin decreases, and the carotenoid (yellow pigments) and anthocyanin (red pigments) content increases. Based on its respiration pattern, the plum is a climacteric fruit. The respiration rate is high during and immediately after cell division. As maturity approaches, it decreases to the preclimacteric minimum and then increases irreversibly to a maximum (climacterium) during ripening. At the climacterium, the fruit are soft and sweet, with a characteristic flavor, and are ideal for eating. Subsequently, senescence sets in, whereupon the respiration rate decreases, and the fruits become overripe and decayed. (*See* **Ripening of Fruit**; **Phenolic Compounds**.)

Chemical Composition and Nutritional Value

Food composition tables generally do not specify the cultivar analyzed, nor whether a sample was fresh or cold-stored before analysis. Nevertheless, they are useful guides to the composition and nutritional value of fruit. A typical composition table for plums and related fruits is given in Table 2. The anthocyanins present in plums are 3-glucosides and rutinosides of cyanidin and peonidin. Refer to individual nutrients.

Table 2 Nutrient and mineral content of fresh plums, damsons, and prunes

Nutrient	*Content (per 100 g edible portion)*		
	Plum[a]	*Damson*[b]	*Prune*[a]
Moisture (%)	85.2	69.7	32.4
Energy value (kJ)	230.0	146	1000.0

Taste is largely determined by a balance between the sugar and acid contents. Low acid and high sugar contents result in a bland taste, and high acid and low sugar contents in a sour taste. The contents of individual sugars and acids vary between cultivars, but citric acid as well as malic acid are present in the fruit. For example, in Australia, the cultivar Santa Rosa contains approximately twice as much malic acid as Mariposa, but has a lower soluble solids content. (*See* **Acids**: Natural Acids and Acidulants.)

Harvesting, Handling, and Storage

Plums are harvested in summer, from about December to February in the southern hemisphere and from about July to October in the northern hemisphere. It is important to harvest at the correct stage of maturity. If plums are harvested while still immature, the characteristic flavor will not develop, and fruit quality will be inferior. Plums harvested too ripe are very susceptible to injuries and fungal infection during harvest and postharvest handling, and their storage life will be short.

Dessert Plums

Dessert plums are harvested when they are physiologically mature but unripe. Ripening to a stage at which the fruit has a pleasant taste and aroma occurs during and, mostly, after storage. Plums that are to be sold soon after harvest must be picked at a riper stage than usual, or cold-stored for a few days to promote proper ripening. They require extra care during handling.

Total soluble solids content, estimated by means of a refractometer, and mesocarp firmness, measured by means of a probe (penetrometer) forced into the flesh, are good indicators of maturity. However, these tests are destructive, and pickers use skin color, in combination with these tests, as a maturity index. Fruit size is an additional criterion used to determine optimum maturity stage. Fruits are picked by hand into picking bags and carefully transferred to containers with a capacity of about 500 kg. Plums bruise easily and must be handled carefully during and after harvest. Filled containers are transported to a packhouse. Bruised, cut, or decayed fruit and culls are removed. The plums are sorted according to size and either hand- or mechanically packed into cardboard or wooden containers. These usually have a capacity ranging from about 5 to 20 kg. Trays or padding material immobilize the fruit in the container to prevent transit injuries. Packed containers are unitized (palletized) to facilitate handling and protect the fruit.

To extend the storage life of the fruit, its temperature must be lowered as soon after harvest as possible. Precooling, which removes field heat from the fruit, commences immediately after packing and palletizing. Cold air is distributed through the pallets in such a way that it comes into contact with all fruit. The ideal storage conditions for plums are a temperature of -0.6 to $0\,^{\circ}C$ and a relative humidity of 85–90%. The storage period depends on the cultivar. Most cultivars cannot be stored for longer than 3–4 weeks, but others can be stored for up to 3 months. The fruit of some cultivars are susceptible to chilling injury. To prevent chilling injury, the temperature is raised from $-0.6\,^{\circ}C$ to about $7\,^{\circ}C$ after 7–10 days, and this temperature is maintained for the rest of the storage period. This is called dual-temperature storage. Controlled- or modified-atmosphere storage increases the storage life of some cultivars. (*See* **Controlled-atmosphere Storage**: Effects on Fruit and Vegetables; **Storage Stability**: Mechanisms of Degradation.)

Prunes

Prunes are harvested when fully ripe and in an ideal condition for fresh consumption. Overmature fruit

discolor and break down during drying. The fruit of some cultivars drop from the trees naturally and must be gathered promptly to prevent losses. Soluble solids content and flesh firmness are important maturity indices. As in the case of fresh plums, these indices are related to skin color.

Most prunes are dried rather than sold fresh. Fresh prunes can be cold-stored, but their storage life is shorter than that of dessert plums. Sorted prunes are dipped into a hot caustic solution (generally 0.5% sodium hydroxide at boiling point) for sufficient time to remove the wax layer and cause minute cracks in the skin. This facilitates moisture loss and speeds up drying. The prunes are then packed on to trays and dried in the sun. Prunes can also be dried in mechanical dehydrators, usually tunnel dehydrators. The fruits are washed and placed on trays in the dehydrator without application of a lye treatment. Hot air circulates through the trays, and drying takes place within 24 h. Dehydrators used for drying prunes are frequently operated in the parallel-flow mode (concurrent movement of fruit and heated air through the drying section), with the fruit entering the dehydrator at air temperatures of up to 90 °C. Prunes are gathered when dry but still pliable, with a moisture content of about 20%. Considerable degradation of the red pigments present in the fresh fruit occurs during drying. (*See* **Drying**: Drying Using Natural Radiation; Theory of Air-drying.)

Market Disorders and Diseases of Plum Fruit

Disorders

Disorders are transit- or storage-related. Transit-related disorders include bruising as a result of rough handling, freezing injury owing to temperatures below the freezing point of plums, and shriveling owing to moisture loss caused by low relative humidities in the storage atmosphere. These disorders can be controlled by effective postharvest management.

Storage-related disorders are similar to transit-related disorders but include internal breakdown or internal browning. When a fruit is cut open, internal browning can be seen as a reddish brown discoloration, which is more intense around or near the endocarp. It is responsible for extensive losses during cold storage. It usually occurs at low temperatures and can be prevented by storing fruit at slightly elevated temperatures. Some cultivars are more susceptible than others. Dual-temperature storage is used where plums have to be shipped over long distances.

Diseases

Fungi cause market diseases. The most important postharvest diseases of plums and prunes are brown rot (*Monilinia laxa*, *M. fructicola*), blue mold rot (*Penicillium expansum*), gray rot (*Botrytis cinerea*), mucor rot (*Mucor piriformis*), and rhizopus rot (*Rhizopus* spp.). These fungi cause decay in a wide range of commodities, and their occurrence is not limited to plums. Fungal spores present in the orchard on plant debris or in the air are dispersed to fruit by wind or insects. The spores of *B. cinerea* and *Monilinia* spp. can infect uninjured fruit in the orchard, especially during the 1–2 weeks prior to harvest, when the susceptibility of fruit to infection increases. However, disease symptoms are only expressed during cold storage. The other fungi are wound pathogens that penetrate fruit through skin breaks caused by rough handling or insects. Decay symptoms are related to the fungus involved. Mucor and rhizopus rots develop rapidly, and affected plums become soft and watery, and are covered by black spore masses. Brown rot starts as a small, water-soaked spot, which enlarges rapidly and becomes brown or black. The skin becomes leathery but remains intact. Fruit infected by *B. cinerea* are firm, spongy, and only slightly moist. The skin covering lesions readily slips away when slight pressure is applied. Decay development is slower, and, in advanced stages of decay, gray spores cover the affected areas. Blue mold rot lesions are wet and soft and covered with blue–green mold growth. (*See* **Spoilage**: Molds in Spoilage.)

Control of postharvest decay involves the integration of preharvest factors (soil preparation, spray programs, orchard hygiene, etc.) with sound postharvest crop management. Fruit produced under optimal conditions possess a high natural resistance to infection. Proper sanitation in the orchard and packshed keeps the number of spores to a minimum and is an important precautionary measure. All fungi causing postharvest decay, except *Rhizopus* spp., can grow at 0 °C, and cold storage does not prevent decay development. Chemicals can be used to control decay, but only a few are registered for postharvest use. (*See* **Fungicides**.)

Industrial Uses

Plums have a wide variety of industrial uses. Japanese plums are mostly eaten fresh, although a small percentage are dried. European plums are mostly dried (prunes), cooked (greengages), canned (greengages, yellow egg, damsons, other European plums), or used in jams (plums, greengages, damsons) or jellies (American plums). Prune juice is used as a laxative and plum purée as a baby food. Some plums are used

as rootstocks (e.g., marianna, myrobalan) or in breeding programs (*P. simoni*) and are planted as ornamentals in home gardens. In some parts of Europe, plums are fermented and distilled into a 'brandy.' In Romania, Hungary, and Yugoslavia (Montenegro, Serbia) it is called slivovitz, and in other parts of Europe the name depends on the cultivar used (e.g. Quetsch or Mirabelle).

POLITICS AND NUTRITION

C Geissler, King's College London, London, UK

Introduction

Politics can be defined as both the art and science of government, as well as the play of competing economic and ideological interests. This article reviews some aspects of government nutrition policies and the effects of disparate interests on nutrition in developing and developed countries.

Nutrition Policies

Governments in both developed and developing countries have over the last two decades increasingly focused attention on nutrition through explicit national nutritional policies. (*See* **Nutrition Policies in WHO European Member States**.)

Hunger and malnutrition were put on the international agenda by the League of Nations in the 1930s and remained an important focus of the United Nations (UN) technical agencies, the Food and Agricultural Organization (FAO), World Health Organization (WHO), and United Nations Children's Emergency Fund (UNICEF), which were created immediately after World War II. The types of nutrition interventions and development policies supported were shaped by the World Food Surveys conducted every decade by the FAO (these estimated the extent and defined the causes of malnutrition) and by post-colonial theories of economic development. During the 1950s and 1960s, the prevailing policy encouraged industrialization and large-scale agriculture in order to increase economic wealth, from which improved nutrition would 'trickle down' rather than be achieved by improved distribution. Nutrition continued to be approached mainly through piecemeal interventions, including child-feeding programs and nutrition education, but also via some integrated village-level 'Applied Nutrition Programs', that addressed the economic, educational, and food resource constraints on good nutrition. (*See* **World Health Organization**.)

By the early 1970s, it had become clear that rapid economic growth had led to increased inequalities, as well as increased absolute poverty in some countries such as Pakistan, Nigeria, and Brazil, resulting in greater levels of undernutrition in the impoverished.

Dissatisfaction with the effectiveness of past approaches in improving malnutrition led to the concept of National Nutrition Planning, based on the coordination of sectoral policies to focus on nutrition. The aim was to remove the barrier to economic growth of malnutrition that results in increased morbidity and mortality, poor educational achievement, low work capacity, increased absenteeism, and low productivity. This integrated, systematic, intersectoral approach was endorsed and promoted by the FAO and the United States Agency for International Development (USAID), that assisted several countries to prepare explicit integrated nutrition policies. (*See* **Malnutrition**: The Problem of Malnutrition.)

In this international context, the need for integrated national food and nutrition policies was also expressed in the developed countries, where the malnutrition of poverty had been largely eliminated but where malnutrition of affluence, reflected in increased rates of coronary heart disease, diabetes, obesity, and cancer, is the current concern. Several countries developed national dietary goals in the 1960s and 1970s to encourage their populations to consume a more healthy diet, but Norway was the first to pass an intersectoral Food and Nutrition Policy in 1975. (*See* **Malnutrition**: Malnutrition in Developed Countries.)

During the 1980s, this extent of integration fell out of favor because of practical difficulties, and the international community concentrated on improving the nutritional impact of agricultural and other sectoral development programs. In the 1990s, the focus moved to micronutrient interventions to eradicate the most prevalent vitamin and mineral deficiencies. However, in 2000, the pendulum of opinion is swinging away from specific 'magic bullet' interventions and back to calls for more integrated approaches to national policy.

Types of Nutrition Interventions

The types of interventions that form part of national nutrition policies tend to be limited to palliative measures such as vitamin supplementation, nutrition education, and child-feeding programs, because the underlying political issues that lead to malnutrition, whether undernutrition or overnutrition, involve fundamental economic and political interests. These are much more difficult and contentious issues and rarely features overtly in nutrition policies. (*See* **Community Nutrition**.)

Famine

One extreme example of the political aspects of nutrition is famine, with mass starvation and death, often attributed to climatic causes such as drought or flooding. Such factors may precipitate famine, but it is only the most vulnerable members of society who starve in this type of famine. To quote Amartya Sen, 'starvation is the characteristic of some people not *having* enough food to eat. It is not the characteristic of there *being* not enough food to eat.' He argues that poverty and famines are related to 'entitlement' or the ability of individuals to obtain food through the legal means available in the society, including production possibilities, trade opportunities, state provisions, and other methods of acquiring food. When individuals can no longer obtain enough food in exchange for their products or services, they suffer from famine, as happens with food price rises owing to local shortages and hoarding. Several examples exist where aggregate food supplies were adequate but certain groups could not afford to buy them, such as the Irish famine of 1846, the Bengal famine of 1943, and more recent famines in the Sahelian countries.

War

War is an extreme example of political crisis and is an increasingly common contributor to the causes of famine through the blockade or diversion of food supplies, the destruction of cropland and the migration of farmers away from their lands in the war zones. War contributed to the famines in Bengal, The Netherlands and Warsaw (World War II) and more recently in Nigeria, Timor, Kampuchea, Laos, Vietnam, Afghanistan, Chad, Uganda, and the Sudan. War and its aftermath also have an strong impact on nutrition, short of famine. One example is the 1990–1991 Gulf War, which resulted in extensive destruction of Iraq's infrastructure and economy so that widespread malnutrition, particularly of children, has occurred.

Refugees

War and political crises also create refugees. The number of people in the world who have either fled their country as refugees, or have been displaced internally, mainly as a result of civil war increased greatly during the 1980s and 1990s and at the beginning of the new millenium stands at around 50 million. Refugees suffer from the same type of diseases as other vulnerable groups in developing countries, the main killers being measles and diarrhea, to which they are more susceptible because of malnutrition. They often receive food inadequate in quantity and quality. If prolonged, this deprivation leads to starvation, and debilitating outbreaks of scurvy, pellagra, beriberi, and other deficiency diseases are now common. This is attributable to the dependency of refugees on the food provided by governments and aid donors, which

has little diversity and is inadequately planned. (*See* **Refugees; Scurvy.**)

Poverty

Famine is only the tip of the iceberg of the larger problem of poverty and access to resources, which affects nutrition on a longer-term basis. Various economic models or political views exist on the causes of poverty and wealth creation, ranging from simplistic models of idleness and ignorance to systematic models such as the Marxist model, which views poverty as an inevitable and even necessary part of the capitalist economic system. These models form the framework of what policymakers believe can be done to break out of poverty and malnutrition, what the implications are for the rest of the economy, and therefore the type of interventions they support.

Poverty reduction

Poverty reduction became a specific target of the international community: an International Development Goal was set in 1990 to halve poverty and was expected to be met within 20 years in most areas of the world. However, the financial crisis later in the decade led to a rise in levels of poverty and inequalities, setting back progress and leading to renewed calls for debt relief.

Debt relief

Some countries are unable to tackle poverty adequately because past loans have led to a level of debt that is now too high for them to repay. For example, in Africa as a whole, governments spend four times as much paying back their debts to developed countries in repayments as they do on health and education. In 1996, the International Monetary Fund (IMF), the World Bank, Regional Development Banks and other external creditors launched the Heavily Indebted Poor Countries Initiative (HIPCI) to reduce the debts of the poorest countries who are deemed eligible by their economic track record over the previous 5–6 years. However, few countries qualified (Uganda and Bolivia), and in 1998, a fundamental review was agreed upon to speed up the process and increase the level of relief.

Equity

Poverty is a major, but not the only, determinant of undernutrition. At the same level of family or national income, some individuals or countries do better than others in terms of nutrition. Internationally, there is a clear relationship between gross national product (GNP) and several indicators of health and nutrition, including food available for consumption, infant mortality, etc. Countries that have done best in improving nutrition in recent decades are those where there is a greater equity or where policies have concentrated on insuring the satisfaction of basic needs, including adequate food. These include a wide spectrum of political ideologies from communist China to capitalist South Korea. China has been a classic example of a country that was still poor but conquered millennial problems of malnutrition and famine – except during the disastrous Great Leap Forward policy of rural industrialization at the end of the 1950s – through effective organization of food production and distribution. Other examples are Kerala state in India, Sri Lanka, Vietnam, Indonesia, Malaysia, and Thailand, which have had better nutrition conditions than other countries with similar GNPs. In contrast, some countries have extensive chronic malnutrition, e.g., Brazil and some other Latin American countries (Bolivia, Ecuador, Gwatemala), most countries in Sub-Saharan Africa, and Bangladesh despite massive aid.

Since the early 1980s, there has been a widespread rise in income inequalities with an acceleration in the 1990s in several countries, including all economies in transition such as China. This has challenged the poverty reduction targets set by the international community.

International Relations

Poverty and malnutrition are controlled not only by national policies and resource distribution but also by the power play of international economic relations. Again, opposing political views shed very different lights on their effects.

On one side are those who believe that the rich industrialized countries and the international agencies do much to assist poor developing countries through technical advice and monetary or food aid, while international corporations provide them with employment opportunities.

On the other side are those who believe that the odds are stacked against poor countries breaking out of poverty, as the countries that became industrialized first now hold economic power internationally, dominating trading and banking systems. In this view, national elites of many countries assist the world powers to dominate their economies through concessions to multinational companies, the acceptance of aid, and requests for finance from the international banking system.

During the 1980s, the latter view received wider acceptance and led to calls for a 'new economic order' by such groups as the Brandt Commission, which warned that the inequalities of opportunity between

the North (the rich industrialized countries) and the South (the poor developing countries) could lead to political and environmental instability, and it was therefore in the interests of both to allow the South greater control of its destiny.

The questions of international food trade, food aid, and the role of international agencies in relation to poverty reduction and nutrition are therefore highly contentious political issues that can be touched on only briefly here.

Food Trade

The economies of the developing countries are affected by the policies of the major producers of food and other essential commodities. For example, the 'world food crisis' in 1973, which was marked by soaring prices of grain and other food commodities on the world market, was the result of several factors. These included climate, the USA policy of deliberately reducing its grain stocks by taking land out of production to maintain producer prices, and Russia's sudden increase in its grain purchases from the world market to support its policy of livestock production. These, and the oil crisis, caused great economic hardship for many developing countries that depended on imports for their food supply, and led to a spate of policies to increase food self-sufficiency.

Similarly, the Common Agricultural Policy (CAP) of the European Union (EU) has had a controversial impact on the Third World through price fluctuations caused by periodic dumping of surplus food on the world market and through tariff barriers that restrict imports. Some trade concessions were made by the EU to the developing countries through the Lome Convention, but this provided little protection in practice. (*See* **European Union**: European Food Law Harmonization.)

These protectionist policies are the subject of international bargaining for free trade that is carried out in periodic rounds of talks in the council on the General Agreement on Trades and Tariffs (GATT). However, these mainly reflect the interests of the seven most economically powerful nations, the USA, Canada, Germany, France, Italy, the UK, and Japan (the G7) and only in the 1986–1992 round included food commodities, prompted by the food price policies that are detrimental to the food trade of the USA and other countries.

GATT was succeeded by the World Trade Organization (WTO) from 1995, which, by the end of the decade, had 134 members, accounting for 90% of world trade and 30 others, including China, negotiating for membership. The costs of participation are high for the poorest countries, which means that the agenda is still dominated by the large economies.

Food Aid

Food and other international aid has often been used as a political weapon, given to politically friendly countries, such as South-east Asia in the late 60s and to Egypt and Syria in 1974, and withdrawn from those that do not conform to the policies of the donor countries, such as Chile in 1971 and Mozambique in 1981.

Food aid has also received much criticism on the grounds that it has been used by the donor countries to dispose of surpluses and to penetrate food markets of developing countries in order to create a long-term trade demand, that it is unreliable, involves excessive opportunity costs, reinforces expensive subsidy programs, provides opportunities for corruption, and is used by governments to keep urban prices down, thereby acting as a disincentive to agriculture and maintaining rural poverty and malnutrition.

Food aid and capital intensive agricultural policies are also seen to contribute to the rapid rural urban migration seen in so many developing countries, where cities are unable to cope with the rate of influx to provide adequate housing, sanitation, water supply, and employment. As a result, the migrants can often only scrape a living through petty trading, begging, and low wage employment. This influx undermines minimum wage legislation or enforcement and keeps the cost of labor, and therefore incomes, low. The consequent inability of the urban poor to purchase adequate diets, and the insanitary living conditions, result in extensive urban malnutrition in many developing countries. Such effects are seen to negate the short-term benefits of food aid used in famine situations, and of child-feeding and food-for-work projects that act as welfare benefits or resource transfers to the poor.

The structure of food aid has altered since it became a permanent international transfer mechanism in the 1954 when the USA enacted the public law PL480, referring to sales to 'friendly nations,' to be paid initially with local money deposited as counterpart funds for use by the USA or with their approval (Title 1), and donations for famine relief and projects (Title II). The latter represents a small proportion contrary to the popular belief that all aid is a gift. Initially, the USA supplied nearly all aid, but now the EU, Japan, Canada, Australia, and other countries contribute about 50%. About 35% of food aid is channeled through the multilateral World Food Program for feeding projects; this reduces political bias. However, 40% is still bilateral, and several countries, such as Bangladesh, remain dependent on food aid and, therefore, politically dependent on the donor. There is widespread recognition of the need for reform of food aid and its international infrastructure

to better handle hunger and meet targets in poverty reduction, but consensus is difficult to reach.

Structural Adjustment

Over the last decades of the millennium, many developing countries experienced severe economic crises owing to rapid changes in oil prices, falling and unstable prices of export commodities, rapidly increasing rates of interest, and increasing dependence on foreign borrowing, resulting in reduced foreign exchange reserves, and inability to service debts.

To deal with the crisis, countries had to implement a variety of 'macroeconomic adjustment policies,' including reductions in government spending. These conditionalities have been rigidly imposed by the International Monetary Fund (IMF) and the World Bank (International Bank for Reconstruction and Development (IBRD)), to obtain new financial loans. These institutions are funded by quotas from members who have voting rights in proportion to their contribution, assessed according to economic status. The USA has the majority of the votes, followed by the European countries, and others very small percentages, so that decisions are effectively in the hands of the major industrialized countries, especially the USA. This banking structure means that the policies of borrowing countries are dictated by the industrialized nations.

The primary aim of macroeconomic adjustment policies is to improve the balance of payments. Therefore, short-term effects on the poor have often been ignored unless they threaten political stability, e.g. through urban riots. Adjustment has frequently included changes that are of particular concern to the poor, such as increased food prices and decreased expenditure on social programs. The effects of these policies on health care, food consumption, incomes, and prices have led to a serious deterioration in indicators of nutrition, health status, and school achievement in several countries. Efforts have been made by UNICEF and other bodies to buffer vulnerable groups from these effects.

Affluence

In most developed countries, the problems of poverty-related malnutrition have been largely overcome by higher incomes and a safety net of welfare benefits, and replaced by the problems associated with affluent diets. The politics of nutrition in this case are very different from those associated with poverty. Only a small proportion of the population is involved in primary food production (2–3% in the US and UK), and the majority of the population depends on the food industry, which is a major industry in economic terms in Europe and the USA: in the UK agriculture, food processing and distribution contribute more than 7% to the GDP. Therefore, the agricultural and food industry lobbies are potentially important in food and nutrition policy formulation. In food policy, nutrition generally has a very low priority. For example, the EU CAP has no explicit nutritional component, its main aims being to support farm incomes and food security for Europe in terms of adequate supplies and stable prices. The emphasis is therefore on quantity, not on nutritional quality. The concept of food quality has lagged behind current values and has generally referred to the purity, hygiene, and richness of nutrients. These are all extremely important, but now that nutritional deficiencies have been largely overcome, the concept of a healthy diet can no longer be related only to purity and abundance. Government policies have also lagged behind current needs such that food legislation and producer incentives continued to favor a high fat diet, including premium producer prices for high-fat milk and inappropriate grading systems for livestock.

Efforts during the 1980s to translate general nutritional advice on healthy eating into explicit policies were initially met with considerable concern and opposition from some sections of the food industry that were threatened with change. The debate included the following arguments: the evidence for the relationship between diet and disease is not adequately conclusive; the level of risk to the population as a whole for certain dietary components such as salt does not warrant blanket nutritional policies, only targeted interventions to those at risk; and in a democratic society, the individual must be free to make his or her own choice of food consumption without coercive pressures from a 'nanny state.'

This initial resistance of the food industry and of government was viewed in some quarters as a conspiracy of vested interests between food producers, government policymakers and advisory committees. However, others viewed it as a natural cautious attitude that is necessary because of the widespread industrial and economic changes entailed. Despite this resistance, the food industry has responded to pressures for change in various ways including research into leaner livestock, the formulation of a variety of low-fat and low-energy products, and voluntary nutritional labeling. Also, since 1993, UK health policy explicitly addresses nutrition and associated 'diseases of affluence,' including obesity and heart disease.

Much stronger political support exists for interventions based only on informed choice, and little for coercive measures to improve the diet such as price manipulation through consumer subsidies and taxation, even though these instruments are used for other purposes. There is therefore much effort put into legislation on food labeling.

The food industry has become progressively more vertically integrated, from production through processing to retailing, by the development of multinational agribusiness and large chain food stores, that increasingly order food directly from the producers. This means that the buyers for these food chains become exceedingly important arbiters of the national diet in deciding the choice available to the consumer.

Emerging Issues

The creation of the WTO and the increasing power of large food corporations have highlighted several issues of control over food, from consumer pressures to national and international governance.

New Technologies

Consumer and environmental lobby groups have put a brake on the use of genetically modified (GM) foods: they disrupted the WTO meeting in Seattle in early 2000 by protests against the trade in GM crops; they caused agribusiness to discontinue the development of terminator genes to prevent plant replication; and consumer pressure in developed countries such as the UK has curtailed the sale of GM products as well as the conduct of field trials.

Resistance to the use of the new technology in agriculture and food production is based on several fears: the safety for consumption; the control over world food supply of the large corporations that develop the technology; the potential detrimental effects on the environment from cross-pollination; and the lack of benefits to developed country consumers as opposed to the seed and pesticide manufacturers. These arguments currently outweigh the arguments for the potential benefits, within appropriate socio-economic structures, to farmers and consumers in other parts of the world by the development of crops that are resistant to adverse climatic conditions and pests and that have higher yields and content of specific nutrients, factors that could expand the areas of crop production, increase total food production, and hence price in line with the expected population growth, and improve nutritional value.

Governance

Such consumer pressures have also led to other issues of governance in relation to national and international political bodies that control economics, including food. For example, consumer and professional pressures following a series of food safety scares in the UK during the 1980s have led to the separation within government of the structures that regulate the food supply from those that regulate agriculture as there are potentially conflicting interests between consumer and producer. A Food Standards Agency was established in 2000 to regulate food 'from farm to fork.' The EU has subsequently proposed a similar structure at European level. This brings to the fore the tensions in governance between national and regional control over food and the extent to which these are dominated by WTO rules in the interests of free trade. Similar issues arise in global governance, underlining the need for new arrangements to make more effective the relationships between the UN, WTO, G7, IMF, and other bodies.

Conclusion

Food and nutrition involve highly political issues that determine both access to sufficient food and the commercial and consumer pressures on a balanced diet.

POLYCYCLIC AROMATIC HYDROCARBONS

E Menichini and B Bocca, Istituto Superiore di Sanità, Rome, Italy

Introduction

Polycyclic aromatic hydrocarbons (PAHs) are a large class of organic compounds containing two or more fused aromatic rings. In particular, the term PAHs refers to compounds containing only carbon and hydrogen atoms (i.e., unsubstituted parent PAHs and their alkyl-substituted derivatives), whereas the more general term 'polycyclic aromatic compounds' also includes the functional derivatives (e.g., nitro-PAHs) and the heterocyclic analogs (e.g., aza-arenes). The term 'polynuclear' is frequently used for 'polycyclic.' Hundreds of PAHs may be formed. Over 100 PAHs have been identified in atmospheric particulate matter and about 200 in tobacco smoke. PAHs have very low water solubility, and are soluble in many organic solvents and highly lipophilic.

The nomenclature codified by the International Union of Pure and Applied Chemistry (IUPAC) is also used by the Chemical Abstract Service. Some compounds, however, are commonly reported in literature with nonsystematic names. Table 1 lists the PAHs considered for this review. The selection is based on their occurrence data (as being the most frequently determined in environmental and food analysis) and their toxicological concern. Benzo[*a*]-pyrene (BaP) is the most widely studied compound and most information on occurrence and toxicity of PAHs is related to it. In the comparison of different matrices, BaP has frequently been (and still is) used as an indicator for the PAH class, as regards both the levels of contamination and the carcinogenic risk.

Formation and Sources

PAHs are formed during incomplete combustion or pyrolysis of organic material, such as coal, wood, oil products, and garbage. Consequently, their formation is typically associated to the processing of coal and crude oil, power generation plants, incinerating plants, various industrial processes, domestic and residential heating (especially by wood and coal), motor vehicle exhaust, fires (forest, agricultural, cooking), and tobacco smoking. Volcanoes may represent a natural source with a locally relevant impact. Because of these numerous and widespread sources, PAHs are ubiquitous and occur in all environmental

compartments, which they enter mostly via the atmosphere.

During any formation process, and subsequently in the matrices to which the population is exposed (air, water, soil, and food), PAHs are always present as a class and not as individual compounds, in complex mixtures also containing other chemical classes.

Most PAHs have no use other than for research purposes. Exceptions are limited to an occasional use of some PAHs as intermediates in the production of plasticizers, pigments, dyes, and pesticides; naphthalene is used as a moth-repellant for clothing.

Sources in Foods

In nonprocessed foods, the occurrence is mainly attributed to the environmental contamination: deposition of airborne particles (e.g., grain, fruits, and vegetables), uptake from contaminated soil (e.g., potatoes), absorption from contaminated fluvial and marine waters (e.g., mussels, fish, and shellfish). Common sources in processed foods are thermal treatments (namely grilling, roasting, baking, and frying), and processing procedures. The latter include especially the drying process by combustion fumes, e.g., vegetables oils, and the smoking process by traditional methods.

PAHs may leach into drinking water from coal-tar or asphalt coatings on storage tanks and water distribution pipes.

Toxicological Effects

Carcinogenicity of PAHs

The toxicological concern for PAHs is due to their carcinogenicity; other effects turn out to be by far less important. The International Agency for Research on Cancer (IARC) evaluated the carcinogenic evidence for 43 PAHs. The evidence in experimental animals was evaluated as 'sufficient' for 12 of them, and 'limited' for 12 others. No individual PAH could be evaluated conclusively as a human carcinogen. This is a consequence of the fact that human exposure, via both inhalation and ingestion, always occurs simultaneously with complex mixtures containing a large number of PAHs (with variable composition) and other potentially carcinogenic compounds. Based on an overall evaluation of available data, however, the IARC could classify three PAHs (including BaP) as 'probably' carcinogenic to humans and nine as 'possibly' carcinogenic (Table 1; five possibly carcinogenic PAHs are missing from the table and are not considered in this review, due to the scarcity of their occurrence data and to their very low, or undetected, concentrations reported in any matrix). For a number of PAH mixtures (also containing other potentially carcinogenic chemicals) occurring in occupational environments, there is epidemiological evidence of increased risk for lung cancer and, in some cases, for skin (following dermal exposure) and bladder cancers; it is plausible to attribute these risks partially or predominantly to PAHs.

Carcinogenic Risk of BaP by Ingestion

No adequate epidemiological data are available concerning carcinogenicity by ingestion of PAHs or PAH mixtures. The experimental data are scarce and limited to BaP. The latter has been shown to be carcinogenic in experimental studies when given by diet. Oral administration of BaP to mice induced gastric papillomas and squamous-cell carcinomas and increased the incidence of pulmonary adenomas. Other studies in mice indicated that it can cause carcinomas distal to the point of application. The incidence of gastric tumors was 70% or more in mice fed 50–250 ppm BaP for 4–6 months. In another study with rats, which were fed diets containing BaP, tumors were observed in the forestomach, esophagus, and larynx.

Based on these experiments, the US Environmental Protection Agency made a quantitative assessment of carcinogenic risk for oral exposure to BaP which gave a unit risk of 7.3×10^{-3} ($\mu g\,kg^{-1}$) day^{-1}. This involves an increased risk of 1×10^{-5} for the daily ingestion of about 100 ng BaP per person (1.4 ng BaP kg^{-1} body weight). This ingestion value is roughly in the order of magnitude of the actual BaP intake as estimated in different studies; the actual BaP intake, however, may exceed the value of 100 ng by up to fourfold.

The ingestion of food is by far the major source of PAH exposure for nonsmokers. It has been estimated as contributing up to about 90% of total BaP intake, excluding occupational and tobacco exposure. The remaining is attributed to air inhalation and (about or less than 1%) to drinking water. However, while there is a great deal of evidence which stresses the hazard of inhalation and skin contact as routes of PAH intake, it is less clear what the risk of ingestion is. (*See* **Smoked Foods**: Principles; Applications of Smoking.)

Limit Values of PAH Concentration in Foods

Owing to the potential carcinogenicity of foods contaminated by PAHs, some measures have been taken to limit the PAH content, in particular that due to food processing. They include legal limits associated with smoked foods and water, and recommended limits for refined oils and fats.

Smoked food Germany, Austria, and Poland set a limit of 1 $\mu g\,kg^{-1}$ for BaP in smoked meat and meat

products. The same limit was also set in Germany for smoked cheese and cheese products. In the European Union, the maximum BaP concentration permitted in foodstuffs as a result of using flavorings, including smoke flavorings, is 0.03 μg kg^{-1} (Council directive 88/388/CEE of 22-06-1988). In addition, another Council directive (91/493/CEE of 22-07-1991) concerning fishery products lays down some health conditions under which these products must be smoked, and lists wood materials which cannot be burned in smoking foods. (*See* **Vegetale Oils**: Types and Properties; Composition and Analysis.)

Waters The following limits were set in the European Union to PAH presence in water intended for human consumption (Council directive 98/83/EC of 3-11-1998): 0.010 μg l^{-1} for BaP, and 0.10 μg l^{-1} for the sum of benz[*e*]acephenanthrylene, benzo[*k*]fluoranthene, benzo[*ghi*]perylene, and indeno[1,2,3-*cd*]pyrene. BbFA, BkFA, BghiP, and IP.

Refined oils and fats Some European oil industries set their own guideline values for refined oils and fats: 5 μg kg^{-1} for the sum of seven higher-molecular PAHs (BaP, benzo[*e*]pyrene (BeP), BghiP, dibenz[*a,h*]anthracene (DBahA), perylene, anthanthrene, coronene), and 25 μg kg^{-1} for the sum of 13 PAHs, including the previous seven, plus another six lower-molecular PAHs. (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography; Supercritical Fluid Chromatography; **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Analysis
