These renal adjustments are an adaptive or training response rather than a countermeasure to the perturbations of acute exercise. In humans an aldosterone-mediated retention of sodium and water seems to cause a net retention of water.[82–84] Until recently, the mechanism behind the hypervolemic response was not as clear in the horse. An early study did not demonstrate any change in renal mechanisms affecting the retention of sodium and water, and instead suggested that urea rather than sodium may be the solute responsible for the renal retention of water that leads to a training-induced expansion of plasma volume in the horse.[14] However, the authors paradoxically demonstrated that there was a highly significant increase in plasma sodium content that paralleled the increase in plasma volume.[14] Interestingly, this net increase in retained sodium and water occurred despite increased losses via sweating.[14] As the rate of sodium intake was held constant, the only other routes for a training-induced retention of sodium would have been either a more efficient uptake of electrolytes and water from the gut and/or a net retention by the kidneys early in the first days of training, as seen in humans, where most of the response occurs in the first days of training. To solve this mystery, a more recent paper[78] focused on the first days of training and demonstrated dramatic reductions in urine output and excretion of sodium during the first days of training. Thus, like humans, the horse appears to undergo a similar aldosterone-mediated retention of sodium and water by the kidneys.[78]

However, it was also found that renal retention of sodium and water did not fully counter losses seen in the sweat during the first days of training and the authors suggested that an enhanced aldosterone-mediated uptake of sodium and water from the large intestine may also contribute to the retention of electrolytes and water.[78] This makes sense because the horse's large intestine serves as a fluid reservoir. Such an additional response in the horse may be a warranted species-specific adaptation in response to the relatively larger electrolyte deficits associated with the production of hypertonic sweat. Enhanced intestinal uptake of sodium and water is supported by other published studies[85] demonstrating that aldosterone may enhance the transport of electrolytes and water from the digestive tract of the horse.

Concurrent with the aforementioned retention of water, sodium, and other vital electrolytes (which keeps the retained fluid isotonic), is an increase in the plasma protein content.[14,48,78] This increase in protein functions to keep the plasma iso-oncotic; thus, holding water within the vascular space. Human studies suggest that the early increase in plasma protein content comes about from inward shifts of protein from the lymphatics and interstitial space, and later from an overall net increase in plasma protein synthesis.[48] The hypervolemic response to training in the horse also appears to involve an increase in the content of plasma protein, most likely through a net increase in synthesis.[14,78]

One aspect of the effect of training yet to be studied in the horse is whether there are alterations in the cardiopulmonary baroreceptors that allow for the retention of the extra vascular volume. Human studies have shown that training results in a down regulation of the ANP and neuroendocrine response to exercise, quite possibly to accommodate the hypervolemia associated with exercise training.[48] Future research should determine if down regulation of these important control mechanisms also occurs in horses.

It is important to note that short term horizontal studies of humans, dogs, and horses have demonstrated that the increase in plasma volume occurs early in training and is followed by a subsequent slow increase in red blood cell volume (Fig. 38.7).[86] Thus, early in training, if one only looks at hematocrit there is a false impression of a 'sports anemia'.[86] Interestingly, in humans there appears to be an overshoot in the expansion of plasma volume.[86] As red cell volume slowly increases, the early increases in plasma volume appear to level off and even decrease.[86] Thus, after weeks and months of training there is a greater blood volume, with both plasma and red cell volume remaining greater than pretraining levels,[86] most likely at a level that optimizes both blood viscosity and oxygen-carrying capacity.[87]

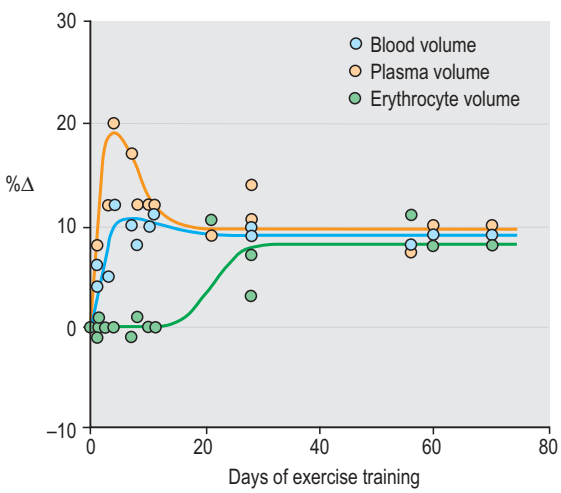

Fig. 38.7 Estimated time course of relative (%) changes in blood volume (blue line), plasma volume (orange line), and erythrocyte volume (green line) during exercise. Each point represents the average change reported in a group of (human) subjects from one investigation. Data were extracted from 18 investigations in which all three vascular volumes were reported. (Reproduced with permission from Sawka et al.[86])

Effects of aging on the acute and chronic response to exercise

A limited number of data have been reported comparing the thermoregulatory responses of older and younger men and

women during exercise in the heat.[88,89] It has been concluded that age influences thermoregulatory function during exercise.[88] Suggested reasons for this age-related decline in the ability to thermoregulate properly during exercise in humans include lower cardiovascular capacity due to the age-related decrease in cardiac output, alterations in mechanisms associated with the control of skin blood flow, and a possible state of hypohydration in the elderly.[88]

While there are an abundance of papers that have examined thermoregulation in young horses, few studies have addressed the effects of age on the thermoregulatory response to exercise in the horse.[90,91] McKeever and co-workers[90,91] exercised young and old horses at the same submaximal absolute work intensity of 1625 watts until they reached a core body temperature of 40°C. Older horses reached a core temperature of 40°C in almost half the time required by the younger mares.[90,91] The heart rates of the older mares were also substantially higher than the heart rates of the younger mares at 40°C.[90,91] Interestingly, both groups had similar heart rates and core temperatures by 10 min after exercise.[90,91] Even with the more rapid heart rate, older horses were still unable to dissipate the heat generated from exercise as quickly as younger mares, therefore leading to a faster increase in core temperature after the onset of exercise. Age-related changes in fluid and electrolyte balance and cardiovascular function may contribute to the impaired thermoregulatory capacity. Older humans commonly have lower total body water, plasma volume and reserves of fluid for sweating. [88] In the above mentioned studies of aged horses the changes in markers of fluid status suggested that acute fluid shifts were of a similar magnitude when compared to younger animals. However, a subsequent study[92] demonstrated that older horses had a substantially lower pre-exercise plasma volume compared to younger animals. A lower plasma volume could result in lower venous return, stroke volume, and cardiac output and a compromise of thermoregulatory stability.

Summary

Exercise places large demands on the cardiovascular system, and is further complicated by environmental factors. Performance is limited in many respects by fluid and electrolyte stores and the ability to maintain cardiovascular and thermoregulatory stability in the face of severe sweat losses. Studies of the exercising horse have been primarily descriptive and/or associative with only a limited number seeking to identify physiological mechanisms associated with the control of fluid and electrolyte balance. More mechanistic studies are needed to fully understand the integration of the cardiovascular, endocrine and renal systems in the defense of plasma osmolality, blood volume, and blood pressure.

CHAPTER 39

Acid–base physiology during exercise and in response to training

Michael I. Lindinger

Introduction

The aim of this chapter is to provide an introduction to acid–base assessment in clinically normal horses at rest and performing exercise of different intensities and durations. The physicochemical approach to acid–base assessment will be introduced and used to exemplify the origins of acid–base disturbances during exercise. Also, the impact of diet, alkalinizing agents, frusemide, and selected clinical conditions on acid–base status will be explored briefly. An update on acidosis and skeletal muscle fatigue will be provided and it is hoped that this will help to dispel some of the myths and confusion surrounding lactate, H^+, and muscle fatigue. At the outset, it is also important to dispel another myth. We often read that plasma and intracellular pH are maintained within narrow limits. This contention is not supported by the research literature in any animal so far studied, including horses. In clinically normal humans and horses, plasma pH can vary from 7.0 to 7.6, although the norm lies close to 7.4. The large range of change in pH represents a four-fold change in $[H^+]$, specifically 25 to 100 nEq/L, with normal plasma $[H^+]$ of 40 nmol/L. While this range of plasma $[H^+]$ can be tolerated, it is true that such changes are eventually accompanied by the activation of mechanisms that return $[H^+]$ back towards 40 nEq/L. Let us now consider reasons for the changes in acid–base status in the horse at rest and during exercise.

Overview of acid–base responses to exercise

Moderate- to high-intensity muscular exercise results in acidification of muscles and blood. The acidification that occurs primarily results from the generation of protons (H^+) within contracting skeletal muscle. The protons are generated from a series of biochemical and physicochemical reactions associated with increased rates of anaerobic energy production. These proton-generating reactions will be detailed below. The protons that are generated continue to be involved in a series of chemical reactions involving carbonic anhydrases and membrane transport proteins that results in the net movement of acid-equivalents out of the contracting muscle cells into the interstitium, and from there into the lymphatic system and venous capillary circulation. It is this large and rapid efflux of acid equivalents from contracting muscle that produces the systemic metabolic acidosis associated with moderate- to high-intensity exercise.

In the exercising horse, whole-body acid–base balance is dependent on the integrated responses of the muscular, respiratory, vascular, hepatic, cutaneous, and renal systems. The muscular system, in addition to providing the locomotory force requirement for activity, generates considerable amounts of acid equivalents, resulting in acidification of the intracellular and extracellular fluid compartments. Non-contracting skeletal muscle also provides the largest tissue mass within the body for the removal of lactate and acid equivalents during high-intensity exercise and the initial recovery period. The respiratory system plays a key role in eliminating acid equivalents as CO_2 at the lung, in addition to extracting the O_2 needed to fuel aerobic cellular metabolism. The vascular system plays an integral role in the transport and distribution of acid and base equivalents throughout the

body – this system provides for the 'buffering' of the acid–base disturbance by distributing acid equivalents from acid-generation sites (contracting skeletal muscle) to other sites (non-contracting skeletal muscle and other tissues). Within the vascular system itself, bicarbonate, plasma proteins and hemoglobin within red blood cells are also involved in the transport and temporary storage (buffering) of acid equivalents. The hepatic system is a major tissue mass involved in the removal of lactate from the vascular system, thereby removing acid equivalents from the circulation. The cutaneous system is heavily involved in the production and secretion of sweat to the surface of the skin during and immediately following moderate to high intensity exercise. Sweat contains large amounts of Na^+, K^+ and Cl^- and different rates of excretion of each ion affects acid–base state of blood leaving the skin. The kidneys are capable of excreting H^+ and lactate at greatly elevated rates during recovery from high intensity exercise, aiding in the process of recovery from the acidosis of exercise.

Each of the systems described above is capable of modifying the water, electrolyte and acid–base composition of the extracellular (blood plasma, lymph, interstitial fluids) and intracellular fluid compartments. It must therefore be appreciated that the acid–base status of the blood depends greatly on where and when the blood is sampled. Blood draining intensely contracting skeletal muscle has very high concentrations of H^+, lactate, K^+, and CO_2, whereas blood that drains relatively inactive tissues (jugular venous blood, for example) has markedly lower concentrations of these metabolites and ions; arterial blood is intermediate in composition. Also, the magnitude of change is proportional to the intensity and duration of exercise, and the concentrations of these and other substances change with time of exercise and recovery.

Why is acid–base balance important? A detailed analysis of acid–base balance provides a biochemical and physicochemical description of the state of the organism, or of individual organs and tissues within the body. Furthermore, severe acid–base disturbances are often associated with high-intensity exercise, with prolonged duration exercise, and with many pathologies. Therefore an understanding of the origins of acid–base disturbances is of interest to both basic and clinical physiologists. Within the context of the present chapter, exercise physiologists remain keenly interested in acid–base balance because of a close association between acidification and muscle fatigue.[1,2] Considerable research over the past century has identified many effects of increased $[H^+]$ within skeletal muscle (Box 39.1; for reviews see Jones and Heigenhauser,[3] Fitts[4]). The content of this chapter is primarily directed to moderate- to high-intensity exercise because exercise at these intensities produces a significant acid–base disturbance, while exercise at low intensities does not (unless markedly prolonged with underlying dehydration and metabolic abnormalities). Hultman and Sahlin's 1980 paper still provides the best, detailed review of skeletal muscle acid–base balance during exercise.[5] Previous treatments of muscle acid–base balance emphasizing a physicochemical approach include Lindinger[6] and Lindinger and Heigenhauser.[7,8]

Box 39.1 Effects of increased intramuscular $[H^+]$ and functional consequence(s) in muscle

Decreased glycogenolytic (phosphorylase) activity[33,162] → decreased anaerobic ATP production → ATP supply is limited → fatigue

Decreased glycolytic (phosphofructokinase) activity[33,163,164] → decreased anaerobic ATP production → ATP supply is limited → fatigue

Decreased pyruvate dehydrogenase activity[33] → decreased aerobic ATP production → ATP supply is limited → fatigue

Decreased sarcolemmal and sarcoplasmic reticulum Ca^{2+} ATPase activity[59,165,166] → elevated cytosolic $[Ca^{2+}]$ → decreased myosin ATPase activity[59] → decreased rate of actin–myosin cross-bridge cycling → slowed rate of muscular contraction → fatigue

Increased $[H^+]$ increases the [diprotonated inorganic phosphate] → Inhibition of actin–myosin cross-bridge interaction resulted[36,167,168]

Inhibition of Ca^{2+} binding to troponin C,[59,169,170] resulting in decreased number of actin–myosin cross-bridges formed → decreased strength of force production → fatigue

Increased acetyl CoA, indicative of increased intramuscular triacylglycerol hydrolysis[33] → increased citric acid cycle dehydrogenase activities → stimulate aerobic metabolism

Decreased lactate efflux from muscle cells[171] → prolongation of intracellular acidification by retaining a strong acid anion

Thorough reviews on plasma acid–base status have been provided by Constable,[9] Kowalchuk and Scheuermann,[10] Lindinger et al[11,12] and Johnson et al.[13] Clinical primers on assessing and treating acid–base disturbances are provided by Whitehair et al,[14] Constable,[15] Carlson,[16] and Corley and Marr.[17] Hyyppä and Pösö[18] and Kingston and Bayly[19] provide brief reviews on the effects of exercise on acid–base status in horses.

In traditional terms, many of us remember being taught that acid–base balance is represented by the relationships among P_{CO_2}, pH and the HCO_3^- in blood plasma.[20,21] While this is true, using only these three variables provides for only a very limited understanding of the factors that contribute to acid–base imbalances. The approach taken within this chapter is to use a comprehensive, physicochemical approach to identify the causes or origins of acid–base disturbances during exercise, and to discuss how the disturbance is resolved during recovery from exercise.

While the traditional variables of acid–base – P_{CO_2}, pH and the HCO_3^- – are useful in identifying whether an acid–base disturbance is metabolic or respiratory in nature,[20–22] they are insufficient to identify the physicochemical origins of the acid–base disturbance. It is nonetheless important for the student of acid–base physiology to be familiar with the concepts presented using the traditional approach, and to be able to use these concepts as an important foundation on which to apply the physicochemical approach. This chapter will emphasize the use of the physicochemical approach as this method provides for a detailed physiological and clinical

assessment of acid–base disturbances. It is worth pointing out that the traditional approaches to assessing acid–base status are not incorrect, but rather they were a simplification introduced in the 1960s to make use of readily available and relatively simple measurements of Pco_2 and pH. Technological developments from the 1970s have simplified the measurements of the other important acid–base variables in blood plasma and skeletal muscle, allowing us to take a more comprehensive approach.

The physicochemical approach presented here was detailed by Peter Stewart,[23,24] bears many similarities to earlier work by Peters and Van Slyke,[25] and builds on the work of many others, including Hastings, Dill, Lawrence, Henderson, and Siggaard-Andersen. This approach is based on the defined physicochemical properties of electrolyte solutions as detailed in textbooks of physical chemistry.[26] Helpful books and reviews include those by Stewart,[23,24] Kowalchuk and Scheuermann,[10] Lindinger,[6] Heigenhauser,[27] Jones and Heigenhauser,[28] Constable[15] as well as software developed by Watson.[29]

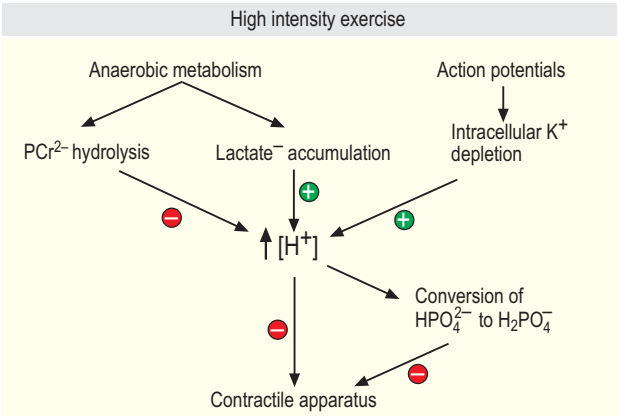

Fig. 39.1
Overview of events contributing to the intracellular acidosis and fatigue of skeletal muscle during high intensity exercise. A – indicates a decrease in accumulation of function, while a + indicates a positive contribution to the increase in $[H^+]$.

Acidosis and skeletal muscle fatigue

There is no question that high-intensity muscle contraction results in intracellular acidification[2,30] that generates an extracellular, systemic acidosis in the whole organism that can be very pronounced and long lasting.[11] It is also clear that intracellular acidosis and fatigue are associative during high-intensity exercise, with mounting evidence that increased $[H^+]$ reduces the calcium sensitivity of the contractile proteins.[30] Furthermore, acidosis imposed prior to the period of high-intensity exercise results in an earlier onset and more pronounced skeletal muscle fatigue.[31,32] Intracellular acidosis may, however, only exert these effects during high-intensity muscle contraction and recent evidence has shown that the contributions of intracellular acidosis to fatigue process have yet to be fully understood.[30,33–35] Indeed, Westerblad and colleagues[36] have suggested that increased intracellular concentrations of inorganic phosphate may be a more important contributor to muscle fatigue than the increase in $[H^+]$.

Skeletal muscle fatigue is also associated with an increased interstitial $[K^+]$ as a result of rapid rates of K^+ loss through sarcolemmal K^+ channels during the recovery phase of action potentials.[37] This increase in interstitial $[K^+]$ results in a marked depolarization of the sarcolemma and decreased contractile force.[38,39] In contrast to the dogma that we have long been taught, Nielsen et al[34] demonstrated that the loss in both sarcolemmal excitability and tetanic force resulting from elevated interstitial $[K^+]$ (8–12 mEq/L) was actually *reversed* when intracellular acidosis (either 20 mmol/L lactic acid or 50% CO_2) was imposed![34] While these muscles were only stimulated to perform one contraction every 10 min, this allowed a separation between the fatigue associated with repetitive contraction versus that associated with sarcolemmal depolarization and intracellular acidification.

As summarized by Fitts[4] and Chin and Allen,[30] increased $[H^+]$ does contribute to decreased force production during high-intensity muscle contraction (Fig. 39.1), and there is reasonably good evidence that these effects occur at the level of: (i) impaired Ca^{2+} binding to troponin C, which therefore impairs the ability of actin to form cross-bridges with myosin; (ii) slowing sarcoplasmic reticulum (SR) Ca-ATPase activity; (iii) increasing the leak of Ca^{2+} from the SR; and (iv) a key site of biochemical control within glycogenolysis (decreased glycogen phosphorylase a activity) and glycolysis (decreased phosphofructokinase activity).[33] The latter study also demonstrated an increased reliance on fat metabolism to meet the energy demands of contracting muscle during exercise in humans made acidotic by ingestion of 0.3 g/kg ammonium chloride.

It may be concluded that intracellular acidosis may have two main effects that, when taken together, are of long-term benefit for muscle function and survival (prevention of destruction resulting from over use). First, acidification restores the sarcolemmal excitability and contractility resulting from elevated interstitial $[K^+]$, and the former is very important for cells maintaining the composition of their intracellular environment within physiological limits. Second, the muscle retains the ability to contract while the force and rate of contraction and rates of glycogenolysis/glycolysis are slowed as a result of the acidosis. This in turn slows the demand for energy and the production of acid equivalents, while allowing the animal to continue to move if need be.

Assessment of acid–base balance and factors that affect acid–base regulation

The only method capable of fully assessing acid–base balance is the physicochemical approach, therefore it is this system that is detailed below and used within this chapter.

Box 39.2 Disadvantages and advantages of the physicochemical approach to determination of acid–base balance

Disadvantages

- Requires accurate measurement of many variables including plasma P_{CO_2}, $[Na^+]$, $[K^+]$, $[Cl^-]$, [lactate$^-$], [plasma protein] and, in muscle, additionally $[A_{tot}]$.[40]
- Requires advanced calculator or computer to perform calculations.
- Requires consideration of physical chemistry, biochemistry and physiology – it is truly an integrative approach.

Advantages

- Provides for detailed analysis of why changes in $[H^+]$ and $[HCO_3^-]$ occurred, giving insight into the pathophysiology of any type of acid–base disorder.
- Allows for the determination of the individual independent variables, i.e. $[Na^+]$, [lactate$^-$], [plasma protein] . . . that is, the origin of the acid–base disturbance.
- Identification of the origins of the acid–base disturbance allows one to determine the physiological or biochemical mechanism(s) responsible for the alteration(s) in independent variables.
- Knowledge of the physicochemical origins and physiological/biochemical mechanism(s) behind the acid–base disturbance allows for the development and administration of effective treatment strategies for correcting the acid–base disturbance with minimal untoward side-effects.

Physicochemical characteristics refer to those properties and reactions that are physical and chemical in nature; they proceed in the absence of enzymes and life and occur as a result of the physical and chemical properties of the solvent and solute molecules. Also, biochemical reactions, those catalyzed by enzymes, may alter the physicochemical properties of a solution. However, for the purposes of discussing acid–base balance biochemical reactions may be considered distinct from physicochemical reactions. The main physicochemical reactions are detailed below.

The advantages and disadvantages of the physicochemical approach are listed in Box 39.2. The development and widespread use of ion-selective electrodes and combination blood gas–electrolyte analyzers has greatly simplified the process of obtaining the necessary measurements with the accuracy needed to perform detailed assessments of acid–base balance.[9,11,40–43] The advantages of this approach lie in the ability to quantitatively determine the physical and chemical origins of acid–base disturbances. This is therefore a very powerful approach and an important step towards understanding acid–base physiology and pathophysiology. This approach provides an essential foundation for the effective treatment of pathological acid–base disorders.

Physicochemical determinants of acid–base balance

Prior to detailing the physicochemical reactions that increase $[H^+]$ within contracting skeletal muscle, it is necessary to provide an introduction to the physicochemical system of acid–base balance. This approach is founded on three underlying physical premises:

1. A dissociated proton molecule (H^+) is only in physical existence for a fleeting instant of time, approximately 10^{-5} s. The proton is highly reactive, associating briefly with negative charges on proteins, $^-$OH molecules, HCO_3^- molecules and amino acids to name a few. The proton is therefore very unlike inorganic electrolytes such as $Na,^+$ K^+ and $Cl,^-$ which are relatively unreactive.
2. Protons are a main constituent of water, the most prevalent molecule within the body. Water thus provides an almost limitless source of H^+ for biochemical and physicochemical reactions. Protons are part of the solvent that comprises the milieu of the body. It is because of the ability of water to so rapidly dissociate and reassociate H^+ and $^-$OH water is the 'universal' solute.
3. Because of these physical attributes of protons and water, it is physically impossible to add protons to a physiological solution without adding water. Take hydrochloric acid (HCl) as an example. HCl exists in aqueous form and is characterized by very high concentrations of Cl^- and H^+ in solution. The H^+ is an integral part of the aqueous system. As described below, it is the strong acid anion Cl^- that makes this solution so acidic. The strong acid anion Cl^- can be neutralized by the addition of an equivalent amount of the strong base cation Na^+ to the solution, but without an accompanying acid anion such as $Cl,^-$ $HCO_3,^-$ or $H_2PO_4.^-$ Thus NaOH would be added – the strong anions Cl^- and Na^+ remain fully dissociated in solution while there occurs a rapid reaction between H^+ and $^-$OH that decreases $[H^+]$. The resultant solution is saline at neutral pH.

The physicochemical approach to acid–base balance recognizes that three groups of independent variable determine the concentrations of the traditional acid–base variables pH and $[HCO_3^-]$: (i) the strong ion difference (SID), which represents the sum (charge considered) of the strong acid anions and strong base cations; (ii) the total weak acid concentration (A_{tot}), which represents the sum (charge considered) of the weak acids and bases; and (iii) the carbon dioxide (CO_2) concentration, which is usually measured and used as the partial pressure of CO_2 (P_{CO_2}) (Fig. 39.2).

Strong ions and strong ion difference

The terms 'strong acid anion' and 'strong base cation' were introduced in the preceding section and they will be defined here. The term 'strong' refers to the fact that the ion will be fully, or nearly so, dissociated in aqueous solutions (Fig. 39.2). Most of the inorganic ions are 'strong' and hence nearly fully dissociated within the body fluids (Box 39.3). Some organic ions are also strong, such as lactate$^-$ (acid dissociation constant of 3.9) and phosphocreatine^{2-} (PCr^{2-}, acid dissociation constant of 4.5). Anions possess negative charge whereas cations possess positive charge. An anion is an acid by definition because the addition of that strong anion, in the absence of an accompanying strong base, will result in acidification of the solution. Using the example of HCl above, the addition of HCl to plasma will result in acidification. Similarly, the addition of Hlactate will

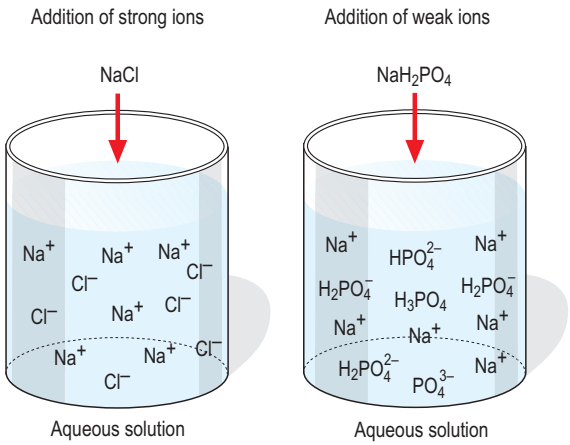

Fig. 39.2
Representation of strong ions and weak ions in an aqueous solution. The addition of NaCl to an aqueous solution results in the complete dissociation into the strong ions Na^+ and Cl^-. In contrast, the addition of sodium phosphate results in the complete dissociation of all of the sodium into Na^+, but the phosphate is capable of reacting with H^+ in solution to form the following weak ions: H_3PO_4, $H_2PO_4^-$, HPO_4^{2-} and PO_4^{3-}.

Box 39.3 A summary of acid–base terminology

The following definitions are placed in order of functional similarities, as opposed to alphabetical order:
Base: any cation in biological fluids[22]
Buffer base: base equivalent to the sum of buffer anion concentrations (including $[HCO_3^-]$) in mEq/L[22]
Base excess/deficit: represents the accumulation of non-volatile base/acid in the blood (excludes plasma $[HCO_3^-]$ and blood hemoglobin concentration)[172]
Alkali (alkaline) reserve: the proton-buffering ability of plasma bicarbonate when bases or non-volatile acids are added to or taken from the body fluids[22]
$[A_{tot}]$: a physicochemical term that defines the *total* concentration of weak anions in solution[23]
[SID]: a physicochemical assessment term that refers to the sum of all strong base cations minus the sum of all strong acid anions:[23]

$$[SID] = \Sigma[\text{strong base cations}] - \Sigma[\text{strong acid anions}]$$

Strong ion: those ions that are fully, or nearly so, dissociated in physiological solutions. In general, if the dissociation constant is ≤ 4.5, then the molecule is considered to be a strong anion; if the dissociation constant is greater than 9, then the molecule is considered to be a strong cation.
Anion gap: a traditional term that is defined as:

$$\text{anion gap} = ([Na^+] + [K^+]) - ([Cl^-] + [HCO_3^-])$$

Strong ion gap: a term coined by Constable et al[173] as an alternative way of determining the concentration of unmeasured strong ions in plasma:

$$\text{Strong ion gap} = 2.24 \times \text{total [protein] (g/dl)}/(1 + 10^{(6.65\text{-pH})}) - \text{AG},$$
where AG is the anion gap

Unmeasured anions: unmeasured anions contribute to the anion gap, strong ion difference and strong ion gap. The unmeasured anions include both strong (SO_4^{2-}, some amino acids, pyruvate) and weak (inorganic phosphate, carbonate, carbamates, some amino acids) anions. The negative charges on plasma protein contribute to the anion gap, and strong ion gap, but this is usually a 'measured' anion.

also result in acidification. In contrast, the addition of the strong base Na^+ in the absence of accompanying strong anion (as $NaHCO_3^-$) will result in alkalinization. The values for the key variables used in the physicochemical assessment of acid–base balance, for resting horses, are provided in Table 39.1.

The concentrations of strong acid anions and strong base cations within a fluid compartment are summed, with consideration of the charge, to yield the strong ion difference [SID].

Within plasma and the extracellular fluid compartment the [SID] can be calculated as:

$$[SID]\ (mEq/L) = ([Na^+] + [K^+] + [Mg^{2+}] + [Ca^{2+}]) - ([Cl^-] + [lactate^-] + [SO_4^{2-}])$$

Note that it is the free or ionized concentrations of the divalent ions that must be used, and not the total concentration; considerable amounts of the divalent ions are bound to plasma proteins or to each other. The concentrations measured using ion-selective electrodes are those of the free or ionized or dissociated ion in the aqueous portion of the solution (i.e. mEq/L of plasma water), so long as the instrument does not use a calculation to modify the 'concentration' to total (not free) concentration in units of mEq/L of plasma. Thus, while these divalent ions are 'strong', the interactions with charged moieties on protein molecules remove some of the ion from solution. In practice, the free concentrations of the divalent cations and anions are approximately equivalent and can be ignored, leaving:

$$[SID]_{plasma}\ (mEq/L) = ([Na^+] + [K^+]) - ([Cl^-] + [lactate^-])$$

In some treatments of acid–base balance using the physicochemical approach, $[lactate^-]$ is also ignored. However, $[lactate^-]$ cannot be ignored in the exercising and recovering animal.

Within skeletal muscle, PCr^{2-} and Mg^{2+} must be used within the equation because their free concentrations are large and change substantially during exercise:

$$[SID]_{muscle}\ (mEq/L) = ([Na^+] + [K^+] + [Mg^{2+}]) - ([Cl^-] + [lactate^-] + [PCr^{2-}])$$

The strong ions are important determinants of the concentrations of $[H^+]$ and $[HCO_3^-]$ because they directly affect the associated state of H_2O, and thereby determine the concentrations of H^+ and ^-OH.

A decrease in the SID (without concurrent change in pCO_2 or A_{tot}), due to either a decrease in strong cation concentration or an increase in strong anion concentration, will increase $[H^+]$ and decrease $[HCO_3^-]$ – an acidification occurs. Conversely, an increase in SID has an alkalinizing effect and decreases $[H^+]$ and increases $[HCO_3^-]$.

Weak acids and bases, and $[A_{tot}]$

The term 'weak' refers to those anion acids and cation bases that are not fully dissociated in solution. Thus when sodium phosphate (Na_2HPO_4) is added to an aqueous solution two Na^+ are added and fully dissociate and a weak anion HPO_4^{2-} is added. In contrast to Na^+, the HPO_4^{2-} cannot achieve full dissociation due to reactions of the molecule with H^+ within

Table 39.1 Physiologically important acid–base variables, and their concentrations, in arterial plasma and skeletal muscle of horses at rest

	Plasma		Skeletal muscle	
	'Normal' value	Normal range	'Normal' value	Normal range
Dependent variables				
$[H^+]$ nanoEq/L	40	33–45	100	71–126
pH	7.40	7.35–7.48	7.0	6.90–7.15
$[HCO_3^-]$ mEq/L	28	22–34	10[a]	8–12[a]
Independent variables				
pCO_2 mmHg	40	35–45		
[total CO_2] mmol/L	30	23–36	10[a]	8–12[a]
Strong ions				
[SID] mEq/L	40	37–43		
$[Na^+]$ mEq/L	140	132–146		
$[K^+]$ mEq/L	3.7	2.7–4.7		
$[Ca^{2+}]$ mEq/L	2.5	2–3		
$[Mg^{2+}]$ mEq/L	1.0	0.5–2.0		
$[Cl^-]$ mEq/L	105	99–109		
$[lactate^-]$ mEq/L	1.0	0.5–1.5	1.5	1.0–2.0
$[PCr^{2-}]$ mEq/L	na	na	15	12–18
$[SO_4^{2-}]$ mEq/L	0.5	0.3–0.7		
Weak ions				
$[A_{tot}]$ mEq/L	12	11–13		
[plasma protein] g/dL	5.5	5.0–6.0		
[albumin] g/dL			na	na
[globulins] g/dL			na	na
$[HPO_4^{2-}] + [H_2PO_4^-]$ mmol/L	2.7	2.0–3.5	8[b]	7–9[b]
carnosine mmol/L			6[b]	–
Protein histidine concentration mmol/L			46[b]	–

[a] Sahlin et al[174] – human muscle.
[b] Hultman & Sahlin[5] – human muscle.

the solution. Thus the HPO_4^{2-} is also partially and instantaneously transformed into H_3PO_4, $H_2PO_4^-$ and PO_4^{3-} (see Fig. 39.2). This physical attribute of phosphate is what makes phosphates, and many other weak acid anions such as bicarbonate and albumin, good proton 'buffers'. The predominant weak acid anion in plasma and extracellular fluid (ECF) is albumin, while the predominant weak acid anions within skeletal muscle cells are the histidine residues on proteins.

The main weak acids and bases within the extracellular fluid compartment are albumin, globulin, phosphate, and bicarbonate. Bicarbonate, however, is part of the CO_2 system and thus is not used in the calculation, or estimation, of $[A_{tot}]$. As with the strong ions, the weak ions also directly affect the concentrations of H^+ and HCO_3^- in solution. Within skeletal muscle it is primarily the histidine moieties on proteins that contribute to $[A_{tot}]$, with creatine, Pi, ATP and other molecules also contributing.[6] While it is theoretically possible to measure the concentration of weak acids and bases in both extracellular and intracellular fluid compartments, this tends to be prohibitive and appears not to be necessary to be able to effectively estimate acid–base state. Rather, an effective $[A_{tot}]$ and apparent dissociation constant K´a have been determined in equine plasma and rat skeletal muscle (Table 39.2). A value for $[A_{tot}]$ has not been determined in equine or human skeletal muscle. Muscle $[A_{tot}]$ is equivalent to the non-bicarbonate proton-buffering capacity of adult rat plantaris muscle,[7,8] and is similar to that of human vastus lateralis.[5] When rat plantaris values for $[A_{tot}]$

Table 39.2 Values of the constants used within the acid–base equations

Parameter	Constant	Reference
K_A – plasma	2.11 or 2.12×10^{-7} Eq/L	9,43
K_A – resting muscle	1.64×10^{-7} Eq/L	7,8
K_A – exercised muscle	1.98×10^{-7} Eq/L	7,8
K_3	6.0×10^{-11} Eq/L	23
K_C	2.46×10^{-11} $(Eq/L)^2/mmHg$	23
K'_w	4.4×10^{-14} $(Eq/L)^2$	23

and K´a were applied to human muscle, reasonable data were generated.[6] Equine muscle, compared to human muscle, has a much greater non-bicarbonate proton-buffering capacity: 43 mEq/kg dry muscle^{-1}.pH^{-1} in trained humans, versus 58 and 93 mEq/kg^{-1}.pH^{-1} in untrained and trained equine skeletal muscle.[44] Assuming proportionality with rat hindlimb skeletal muscle (buffer capacity of ~40 mEq/kg.pH^{-1} = [A_{tot}] of ~140 mmol/L,[6] this translates to an [A_{tot}] of ~315 mmol/L in trained equine muscle.

The carbon dioxide system

The concentration of CO_2 is the third independent variable of acid–base balance. Carbon dioxide is effectively a strong acid, and because it is a major end-product of cellular respiration is often referred to as a respiratory acid. Also, the primary means for eliminating excess CO_2 from the body is through the respiratory system.[13,28]

Carbon dioxide is a strong acid by virtue of its ability to combine with water to increase the concentration of H^+ while at the same time increasing the weak acid [HCO_3^-]. This reaction effectively acidifies the solution to which CO_2 has been added. The majority (about 95%) of the total CO_2 within the body is in the form of HCO_3^-, with much smaller amounts of H_2CO_3, CO_3^{2-}, dissolved CO_2 ($CO_{2(d)}$), and some that is bound to amino groups on protein to form carbamino compounds. The chemical reactions involved in the hydration and dehydration of CO_2 are:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2H^+ + CO_3^{2-}$$

Solving equations to determine acid–base balance

With this background, the following five mass action equations and one equation expressing electrical neutrality of solutions describe the physicochemical characteristics of any aqueous, physiological solution:[23,24]
Water dissociation:

$$K'_w = [H^+] \cdot [^-OH]$$

Weak electrolyte system:

$$K_A \cdot [HA] = [H^+] \cdot [A^-]$$
$$[A_{tot}] = [HA] + [A^-]$$

Carbon dioxide system:

$$K_c \cdot P_{CO_2} = [H^+] \cdot [HCO_3^-]$$
$$K_3 \cdot [HCO_3^-] = [H^+] \cdot [CO_3^{2-}]$$

Electrical neutrality:

$$[SID] + [H^+] - [HCO_3^-] - [A^-] - [CO_3^{2-}] - [^-OH] = 0$$

It is noteworthy that $[H^+]$ appears in each of these equations and its dependence on the concentrations of strong and weak acids/base and CO_2 is evident. These six equations can be combined into a single equation that may then be solved for $[H^+]$ when the three independent variables and the constants are known:[23,24]

$$[H^+]^4 [\{K_A = [SID]\}] [H^+]^3 = \{K_A ([SID] - [A_{tot}]) - (K_C P_{CO_2} + K'_w)\} [H^+]^2 - \{K_A (K_C P_{CO_2} + K'_w) + K_3 K_C P_{CO_2}\} [H^+] - K_A K_3 K_C P_{CO_2} = 0$$

Contracting skeletal muscle: proton-generating and removing reactions

When considering the acid–base changes that occur in blood during exercise, it is important to have an understanding of the changes that occur within skeletal muscle because that tissue forms 40–60% of the mass of the horse.[45] Contracting skeletal muscle generates the disturbance[11,41] and non-contracting cells are capable of ameliorating the disturbance.[42,46] The role of non-contracting muscle may be small to negligible in horses performing moderate- to high-intensity exercise because most skeletal muscles are used for locomotion and maintenance of posture. That is in contrast to bipedal humans, where many activities require leg muscles and leave many other muscles relatively inactive. This section will thus focus on the time course and magnitude of changes that occur within contracting skeletal muscle, primarily gluteus medius, during moderate- to high-intensity exercise.

Exercise is a consequence of muscular contraction, and muscular contraction results in an increase in cellular energy demand compared to the resting state. The increased energy demand is due to activation of myosin ATPase needed for release of actin–myosin cross-bridge interaction, increased activity of SR Ca^{2+}-ATPase activity resulting from increased cytosolic [Ca^{2+}] and increased rates of Na,K-ATPase activity needed to maintain transmembrane Na^+ and K^+ gradients and repolarization of the muscle membrane potential.

The acid–base changes that occur within contracting skeletal muscle and in blood during exercise are the results of the biochemical (metabolic) and physicochemical reactions that occur within contracting muscle cells. The onset of muscular contraction sets into motion a series of biochemical events that result in stimulation and inhibition of numerous metabolic pathways. Those pathways within the aerobic energy systems are relatively slow to increase, whereas those of the anaerobic pathways (ATP utilization, phosphocreatine degradation, glycolysis) increase rapidly.[47] Thus the onset of exercise (rest to work transition) may be associated with muscular acidification for reasons described below. Similarly, transitions from low to high work rates, as well as exercise at moderate to high intensities, result in increased rates of anaerobic metabolism. Full activation of aerobic pathways may be achieved within minutes of the onset of exercise, but until this is achieved anaerobic pathways continue to supply ATP. Activation of aerobic metabolism results in increased mitochondrial respiration with CO_2 production – while this CO_2 is acidic, its rate of production and removal from the cell can easily be matched by CO_2 elimination rates at the lung.[13,28] Therefore aerobic CO_2 production can be ignored in most discussions of the acid–base changes of exercise.

Muscle characteristics and acid–base

Skeletal muscle is composed of different fiber types, some of which produce acid equivalents at high rates (the anaerobic, fast twitch, glycolytic fibers) and others that do not (the aerobic, slow twitch, oxidative fibers). Fiber types continue to be classified on the basis of their twitch characteristics, oxidative/glycolytic capacities and on their myosin heavy chain composition[48] (and see Chapter 5). The acid–base changes that occur reflect the fiber type composition of the contracting muscles, and thus reflect breed differences and type of activity performed.

Within individual muscle groups, such as the well-studied gluteus medius of equids, skeletal muscle fibers of different composition are in close proximity and form integrated functional units that are selectively recruited by appropriate motor units depending on the locomotory requirements of the animal. Muscle fibers with high oxidative capacity that have low glycoytic capacity, slow contractile properties with low myosin ATPase activity, are fatigue resistant and primarily function in the maintenance of posture (Table 39.3). These slow-twitch oxidative fibers have the ability to oxidize all the pyruvate generated from glycolysis and, during exercise, they have the ability to take up and oxidize lactate released into the interstitium from nearby glycolytic muscle fibers – the intramuscular lactate shuttle.[49] At the other extreme, fibers of high glycolytic capacity with low oxidative capacity have fast contractile properties with high myosin ATPase activity. These fibers function to generate power at high rates for high intensity sprinting, jumping, and pulling activities. The majority of the acid–base disturbance that occurs during high-intensity exercise is generated within the fast-twitch glycolytic (type IIB or type IID/X) that are endowed with a high glycogen content, high activities of glycogen phosphorylase and lactate dehydrogenase, and a high content of carnosine to buffer metabolically generated H^+. These fibers also fatigue rapidly due to the loss of membrane excitability, as well as their high rate of intracellular acidification[8] that effectively downregulate muscle fiber function at multiple membrane and intracellular sites.[4]

It is noteworthy that Quarter Horses and Thoroughbreds, the two fastest horse breeds, have the lowest proportion of slow oxidative (type I) fibers and high proportions of both fast-twitch oxidative glycolytic (type IIA) and fast-twitch glycolytic (type IIB, also known as type IIX) fibers. These fast-twitch fibers are also known to have high activities for glycogen phosphorylase,[50] catalyzing the initial reaction in glycogenolysis, and lactate dehydrogenase[51,52] for converting pyruvate to lactate. Indeed, in racing Thoroughbreds and Standardbreds there is a high degree of correlation between type IIB fiber proportion and lactate accumulation:[51] fiber-type-specific lactate content 6 min *after* the end of 1200–2700 m races was greater in gluteus medius type IIB fibers (97.3 ± 2.1) than in type I (82.6 ± 3.8 μmol/kg dry muscle; $n = 8$), with type IIA fibers intermediate (93.6 ± 2.1). This is consistent with observations that type IIB fiber proportion is positively correlated with elevated plasma [$lactate^-$] during submaximal and maximal exercise in Standardbred trotters.[52–54] Of interest and importance to muscle acid–base regulation is the observation that in type I fibers [$lactate^-$] was only 15 mEq/kg dry muscle (equivalent to about 3 mEq/L) less than in type IIB fibers. This supports the idea that lactate produced in type IIB fibers diffuses out of these fibers into the interstitium where the lactate can be taken up by oxidative fibers[49,54,55] to be used as a fuel source both during and following exercise.

The fast-twitch fibers are also endowed with an important physicochemical feature that aids in the regulation of intracellular acid–base balance: there is an increasing content of the histidine dipeptide, carnosine, with increasing glycolytic capacity. Carnosine has a pKa ~6.9 and, as such, is an effective H^+ buffer and contributes substantively to the non-bicarbonate H^+ buffer capacity of muscle, particularly in fast-twitch glycolytic fibers.[56] Indeed, if the contribution of carnosine to non-bicarbonate buffering is removed, then each of the different fiber types have similar non-bicarbonate

Table 39.3 Skeletal muscle fiber types in horses and relationship to acid–base balance

	Fiber type		
	SO – type I	**FOG – type IIA**	**FG – type IIB**
% of total fibers[a,b]	15	45	40
Total H^+ buffer capacity[a]	88	98	130
Carnosine H^+ buffer capacity[a]	18	58	60
Carnosine % of total[a]	20	29	45
Carnosine content[a]	54 ± 15	85 ± 15	180 ± 15
Glycogen phosphorylase activity[b]	122 ± 20	71 ± 20	172 ± 20
Citrate synthase activity[b]	168 ± 15	167 ± 15	37 ± 15
Glycogen content[c]	+	++	++

SO, slow oxidative; FOG, fast-twitch oxidative glycolytic; FG, fast-twitch glycolytic.

[a,b] Averaged data from Sewell et al[57] (n = 20 2–3-year-old racing Thoroughbreds); Sewell et al[50] (n = 50 2–3-year-old racing Thoroughbreds).

H^+ buffering capacities; thus carnosine confers all of the fiber type difference in non-bicarbonate H^+ buffering capacity.[50,57] Quarter Horses have a higher carnosine content (39.2 ± 1.8 mmol/kg wet muscle; $n = 6$) than Thoroughbreds (31.3 ± 2.9 mmol/kg wet muscle; $n = 6$) and Standardbreds (27.6 mmol/kg wet muscle; $n = 5$).[58] The high H^+ buffering capacity of glycolytic fibers is important given the high rates of metabolic H^+ production resulting from ATP hydrolysis, glycogenolysis, and glycolysis (described above). Without the ability to buffer this rapidly produced H^+ during exercise, cellular $[H^+]$ would rapidly increase to concentrations inhibitory for actin–myosin cross-bridge cycling[4,59] and for many metabolic reactions.[4,60,61] Buffering of H^+ within the cells in which it is produced also reduces the extent of extracellular acidification that occurs. Cessation of activity and resynthesis of ATP and glycogen results in a lowering of intracellular $[H^+]$ and a decrease in the quantity of H^+ buffered by histidine groups within the cell.

Biochemical origins of H^+ changes: anaerobic metabolism and muscle acidification/alkalinization

Muscular acidification occurs as a necessary consequence of providing ATP at high rates, using anaerobic metabolic pathways.[62,63] Rapid increases in anaerobic metabolism are needed during rest-to-work transitions and during transitions from work of lower intensity to higher intensity work, such as occurs during cutting and jumping. The rate-limiting enzymes of anaerobic metabolic pathways are rapidly activated compared to the duration required for peak activation of key rate-limiting enzymes of the aerobic metabolic pathways.

ATP hydrolysis by myosin ATPase, Ca^{2+}-ATPase and the $Na,^+K^+$-ATPase results in the net production of H^+:[62]

$$ATP + H_2O \rightarrow ADP + Pi + 0.425H^+$$

The anaerobic reactions of glycogenolysis and glycolysis are also rapidly activated, resulting in the production of 3 ATP for each lactate$^-$ produced; lactate$^-$ is produced because of an accumulation of pyruvate at the end of the glycolytic pathway, resulting in conversion of pyruvate to lactate by the enzyme lactate dehydrogenase:

$$\text{Glycogen} \xrightarrow{\textit{glycogenolysis}} \text{glucose-1-phosphate} \xrightarrow{\textit{glycolysis}} \text{pyruvate} \xrightarrow{\textit{lactate dehydrogenase}} \text{lactate}^-$$

For each mole of lactate$^-$ produced from glycolysis, 0.36 moles of H^+ are produced, while for each mole of lactate$^-$ produced from glucose-6-phosphate (arising from glucose transport into the cell, with the production of 2 ATP), 0.575 moles of H^+ are produced.[62]

The ATP produced from these anaerobic reactions is rapidly hydrolyzed, resulting in the production of 0.425 H^+ for each ATP hydrolyzed (see above). This reaction, combined with those that produce lactate$^-$, results in a nearly 1:1 stoichiometry for lactate$^-$:H^+.[62]

When ATP utilization rates are high, phosphocreatine (PCr^{2-}) is hydrolyzed, resulting in the consumption of H^+:[62]

$$PCr^{2-} + MgADP^- + H^+ \rightarrow MgATP^{2-} + H_2O + \text{creatine}$$

The rates of hydrolysis of ATP and PCr^{2-} are closely coupled and occur simultaneously as long as there is PCr^{2-} to hydrolyze; in simplified form, the combined ATP hydrolysis reaction and the PCr^{2-} hydrolysis reaction is:[62]

$$1\ PCr^{2-} + 1\ MgADP^- + 0.85\ H^+ \rightarrow 1\ MgATP^{2-} + \text{creatine}$$

Thus, for each mole of PCr^{2-} hydrolyzed to regenerate a mole of $MgATP^{2-}$, 0.85 moles of H^+ is generated.

Examination of this sequence of biochemical reactions shows that the H^+ produced by ATP hydrolysis is more than counteracted by the H^+ consumed by PCr^{2-} hydrolysis, resulting in the well-known increase in intracellular $[H^+]$ at the onset of exercise. Within the first few minutes of exercise there occurs a decreased reliance on PCr^{2-} hydrolysis to regenerate ATP, as ATP is increasingly produced from glycogenolysis/glycolysis as well as from aerobic sources. When exercise is continued above the lactate threshold, the combined reaction of ATP hydrolysis and lactate$^-$ production produce nearly equivalent amounts of lactate$^-$ and H^+ within skeletal muscle.

Most of the H^+ produced does not remain free in solution but binds to negatively charged sites, primarily histidine residues, on weak acids and bases such as intracellular proteins and is thus buffered.[5] Therefore, despite micromolar and millimolar changes in the concentrations of intracellular metabolites and strong ions, proton buffering by intracellular proteins limits $[H^+]$ changes to the nanomolar range.

In addition to reacting with intracellular proteins, H^+ also readily reacts with HCO_3^- (bicarbonate buffer system):

$$H^+ + HCO_3^- \xrightarrow{\textit{carbonic anhydrase}} CO_2 + H_2O$$

When intracellular $[H^+]$ increases as a result of increased anaerobic metabolism, this reversible reaction catalyzed by carbonic anhydrases produces CO_2 and water. The CO_2 itself is acidic and is removed from the cell by carbonic anhydrases and possibly by diffusion. As may be appreciated, during high-intensity exercise, when proton generation rates are very high, the bicarbonate buffer system is very limited with respect to its ability to remove H^+ from solution.

Because increased intracellular $[H^+]$ contributes to skeletal muscle fatigue, prevention or delayed onset of fatigue can only occur if H^+ is removed. Both the bicarbonate and non-bicarbonate (protein) buffer systems are limited. However, the cell can transport $Na,^+$ a strong base cation, into the cell (in exchange for H^+) using the Na^+–H^+ exchanger, and possibly augment intracellular HCO_3^- using a Cl^-–HCO_3^- exchanger.[64] In addition to these mechanisms, the outward transport of lactate$^-$ also contributes to an alkalinizing effect, as detailed below.

In summary, H^+ is produced from the hydrolysis of ATP and from the production of lactate$^-$. In contrast, the hydrolysis of PCr^{2-} at the onset of muscle contraction consumes H^+ to a greater extent than the H^+ produced through ATP

hydrolysis, resulting in intracellular alkalinization. With continuation of moderate- to high-intensity muscle contraction, H^+ and lactate$^-$ continue to be produced, resulting in intracellular acidification. Much of the H^+ is buffered by intracellular proteins or reacts with HCO_3^- to produce CO_2 and H_2O. CO_2 is removed from the cell by diffusion across the plasma membrane and by carbonic anhydrases.

Physicochemical origins of [H^+] changes in skeletal muscle during exercise

In addition to the biochemical reactions summarized above, physicochemical changes within the intracellular compartment of contraction muscle also contribute to the acid–base changes of exercise. There is involvement of each of the three independent physicochemical variables, although the changes in the concentrations of strong ions predominates, as will be exemplified below. The physicochemical descriptions complement the biochemical descriptions provided above.

Muscle [SID] during exercise

The time course and magnitude of changes in muscle [SID], and of the factors contributing to it, have not been well studied in horses. This is due in large part to the fact that muscle biopsies cannot truly be taken during exercise – the exercise must be stopped and the horse restrained to safely obtain a useful piece of muscle. Also, most studies have taken postexercise muscle biopsies between 2 and 20 min after cessation of exercise, during which time there are substantial changes in organic and inorganic strong ions. Accordingly, studies that measured muscle [K^+] showed no change[65] or a small increase[66] after brief periods of high-intensity exercise and this may be attributed to rapid recovery processes. The limited equine data will be used with what is known from human experiments to profile the changes occurring within muscle during exercise and recovery. The focus will be on high-intensity exercise because the changes are more pronounced and hence somewhat easier to follow. Changes with moderate-intensity exercise are attenuated compared to those occurring with high-intensity exercise.[54,67,68] Muscle acid–base responses to low intensity exercise have not been specifically studied and, indeed, changes in metabolites that affect acid–base state are minimal.[69,70] With prolonged endurance exercise it is expected that the major players would be [SID] changes resulting from net K^+ loss, with Na^+ and Cl^- gain, water loss or gain[71] and changes in [A_{tot}] primarily resulting from changes in intracellular water content.

The main variables changing within muscle during exercise that affect [SID] are [PCr^{2-}], [lactate$^-$], [K^+][6] and water content.[72] The osmotic shift of water from plasma and noncontracting tissues into contracting muscle at the onset of exercise is very large and rapid and can be attributed to the accumulation of osmolytes such as creatine, inorganic phosphate, lactate$^-$.[73] This fluid shift produces a large decrease in plasma volume (see below) and the 10% increase in intracellular volume at the end of 2 min of high-intensity exercise in horses[72] effectively dilutes intracellular metabolites and electrolytes and reduces [A_{tot}]. It is the actual concentrations of these variables that determine the acid–base state of the cell at any given point in time.

When working from metabolite or electrolyte data expressed in mmol/kg dry muscle or mmol/kg wet muscle it is necessary to convert to units of mmol/L or mEq/L of intracellular water. The water content of resting, non-exercised skeletal muscle is 0.75 L/kg wet muscle[74] and increases by about 10% with high-intensity exercise;[72] resting muscle thus has a wet:dry weight ratio of ~4, which increases to ~4.5 with high-intensity exercise. Therefore, a resting PCr^{2-} content of 85 mmol/kg dry muscle equates to 21 mmol/kg wet muscle (85/4) and 28 mmol/L (21/0.75) or 56 mEq/L. The doubling from 28 mmol/L to 56 mEq/L recognizes the divalent negative charge on PCr^{2-}.

With the onset of exercise, the initial few seconds of contraction results in the rapid hydrolysis of PCr^{2-} to regenerate ATP being used by myosin-, Ca- and Na,K-ATPases. The hydrolysis of PCr^{2-} effectively removes a strong acid anion from solution, which increases intracellular [SID] and has an alkalinizing effect (Fig. 39.3). The alkalizing effect resulting from PCr^{2-} hydrolysis is short lived. With high-intensity exercise, the high rates of H^+ and lactate$^-$ (a strong acid anion that decreases [SID]) production rapidly acidify the intracellular environment. Concurrent increases in [lactate$^-$][41,61,67] and decreases in [K^+][75] effectively decrease [SID], which accounts for the majority of intracellular acidification during high intensity exercise.[8] As may be expected, the accumulation of muscle lactate$^-$ contributes substantially to the exercise-induced acidosis because lactate$^-$ is a strong acid anion that increases [H^+]. Intracellular lactate$^-$ concentrations greater than 60 mEq/L (234 mmol/kg dry weight) have been reported in the gluteus medius of trained Standardbreds after trotting 1600 m at a high speed of 11 m/s.[76] With lower intensity exercise, PCr^{2-} is resynthesized during the subsequent period of steady-state exercise, thus contributing to decreases in [SID] and increased intracellular acidification.

The physicochemical factors contributing to intracellular acidification will now be examined in more detail.

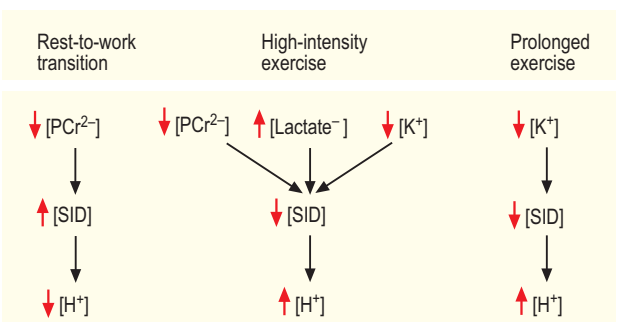

Fig. 39.3 Factors that affect muscle [SID], and the impact on muscle [H^+], during exercise.

Thoroughbreds exercising at high intensity hydrolyzed 32% of PCr^{2-} in 40 s (600 m sprint),[61] and 42% after 5 min at 100% of peak Vo_2.[68] In these studies, muscle biopsies were obtained within 60 s of stopping exercise and thus the amount of postexercise PCr^{2-} resynthesis was low at the time of muscle sampling. In resting equine muscle, $[PCr^{2-}]$ of 21 mmol/kg wet muscle[61,67,74] equates to 56 mEq/L (21 mmol/kg wet muscle/0.75 L/kg intracellular water).[74] Thus, after 40 s of sprinting, muscle $[PCr^{2-}]$ was reduced by 18 mEq/L, which effectively raises [SID] by 18 mEq/L; by virtue of this increase in [SID] it is evident that PCr^{2-} hydrolysis has an alkalinizing effect. This effect, however, is completely offset by the accumulation of $lactate^-$, with muscle $[lactate^-]$ reaching 45 mEq/L.[61] Very similar results for PCr^{2-} degradation were reported by Lindholm and Saltin[67] in five racing Standardbreds completing 2100 m in 178 s; however, these trained race horses experienced considerably less muscle $lactate^-$ accumulation (~ 20 mEq/L), a likely training adaptation.

Combining the effects of changes in $[PCr^{2-}]$ and $[lactate^-]$ decreases [SID], which has a net acidifying effect. This effect alone, however, only accounts for about 50% of the observed decrease in muscle intracellular pH from 7.01 to 6.86;[61] this is equivalent to an increase in $[H^+]$ from 98 to 138 mEq/L. The other contributor to the decrease in [SID] is the rapid and pronounced decrease in $[K^+]$ during high-intensity exercise.[71,75] In the gluteus medius of Standardbreds at rest, intracellular $[K^+]$ is 122 + 7 mEq/L (92 + 5 mEq/kg wet weight, with a water content of 75%).[74] There are no reports of equine muscle $[K^+]$ during exercise[65,66] and, on the basis of the large increases in plasma $[K^+]$ seen during exercise in horses,[77] it is expected that horses experience similar rates and magnitudes of muscle K^+ loss as do humans. In humans, 30 s of high-intensity exercise decreased muscle $[K^+]$ by 20 mEq/L and, with increases in muscle $[Na^+]$ and $[Cl^-]$ balancing each other, the decrease in [SID] is thus approximately 20 + 11 = 31 mEq/L. Based on titrimetric studies conducted on rat fast-twitch skeletal muscle, the 31 mEq/L decrease in [SID] is sufficient to account for about 75% of the increase in $[H^+]$.[6] In summary, using this example of muscle after 40 s of high-intensity exercise, the decrease in [SID] can account fully for the increase in $[H^+]$. Coincidently, the decrease in [SID] approximates the increase in $[lactate^-]$, and the decrease in $[PCr^{2-}]$ was similar to the decrease in $[K^+]$. Further study is needed to determine if this relationship holds during high-intensity exercise. If it does, it means that decreases in [SID] during high-intensity exercise may be estimated from the increase in $[lactate^-]$ alone. Changes in muscle [SID] account for the majority of the change in muscle $[H^+]$ (Fig. 39.4).

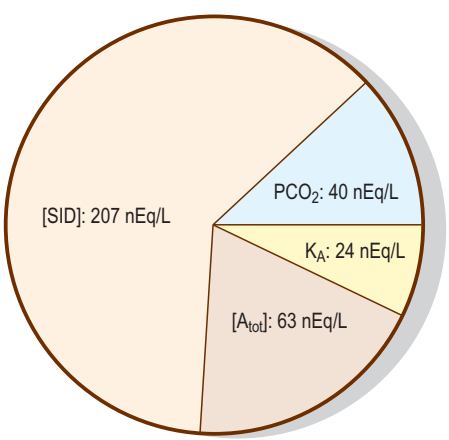

Fig. 39.4
Effects of changes in independent physicochemical variables on muscle $[H^+]$ after high-intensity exercise. The example provided is a brief period of very high-intensity exercise resulting in a decrease in muscle pH from 7.00 to 6.48, equal to an increase in $[H^+]$ from 100 to 334 nEq/L. Data from Lindinger.[6]

Muscle $[A_{tot}]$ during exercise

Exercise affects the intracellular protein portion of $[A_{tot}]$ (which has units of concentration) primarily through changes in cell volume or intracellular water content.[72] These volume changes are pronounced during the first several minutes of exercise[73] and also much later during prolonged exercise resulting in intracellular dehydration. The impact of cell volume changes on skeletal muscle $[A_{tot}]$ and acid–base state has not been studied, although it appears that the total capacity to buffer protons may not be appreciably affected because the content of carnosine remains constant.[78]

With high-intensity exercise, a number of the minor variables contribute to changes in $[A_{tot}]$, including an increase in [creatine] resulting from PCr^{2-} hydrolysis, a decrease in [ATP] and an increase in [Pi]. The increases in [creatine] results from PCr^{2-} hydrolysis, while increases in Pi are due to ATP hydrolysis, increases in glycolytic phosphates, and decreases in ATP.[46] Taken together, the increases in [creatine] and [Pi] account for all of the increase in $[A_{tot}]$ during high-intensity contractions in rat skeletal muscle.[46] The production of H^+ with increase in $[H^+]$ does not affect $[A_{tot}]$ but does decrease $[A^-]$ and increase [HA], as H^+ is buffered by this nonbicarbonate buffer system. Because the concentrations of the constituents comprising $[A_{tot}]$ changes during exercise, the K_A also changes. The increases in $[A_{tot}]$ and K_A accounted for 19% and 7%, respectively, of the increase in $[H^+]$ during 5 min of high-intensity exercise in rat muscle;[6] these have yet to be determined in equine muscle.

Muscle CO_2 during exercise

During high-intensity exercise CO_2 is produced primarily as a result of H^+ buffering by HCO_3^-, with a minor although increasing amount from tricarboxylic acid (TCA) cycle activity. Within the TCA cycle, the dehydrogenation of oxalosuccinate to α-ketoglutarate and of α-ketoglutarate to succinyl CoA produces one molecule of CO_2 for each carbon entering the cycle.

Muscle $[H^+]$ responds in near linear manner to increases in intracellular Pco_2, with a 90 mmHg increase in Pco_2 (40 to

130 mmHg) increasing [H^+] from 100 to 140 nEq/L.[6] Therefore, increases in CO_2 contribute relatively little to contraction-induced changes in intracellular [H^+], compared to the relatively large effect of CO_2 on plasma [H^+] (see Fig. 39.4). The contribution of CO_2 to intracellular acid–base state during exercise can only be estimated using venous plasma P_{CO_2} in blood draining intensely contracting muscles; this estimate assumes that intracellular muscle P_{CO_2} is similar to muscle venous P_{CO_2}.[79] This is reasonable given that CO_2 is highly diffusible and that there is substantial carbonic anhydrase within the interstitium, cells and on the sarcolemma to catalyze the conversion of HCO_3^- to CO_2. It is likely that the majority of the increase in P_{CO_2} results from the reaction of metabolically and physicochemically produced H^+ with HCO_3^- to produce CO_2 and water.

Draught exercise

While the responses described above are typical of racing horses, very similar responses appear to occur in horses pulling heavy loads. As occurs with racing, increasing exercise intensity results in increasing recruitment of fast motor units and fast glycolytic fiber types. Standardbreds performing incremental draught-loading exercise while trotting slowly (4.8 m/s) showed a similar muscle metabolic profile[80] to that seen during racing.[61] Indeed, after 10–12 min of incremental draught loading, muscle [PCr^{2-}] decreased by 15 mEq/L and [$lactate^-$] increased by 20 mEq/L, with one horse achieving a muscle [$lactate^-$] of 57 mEq/L.[80] This study is noteworthy in that the muscle biopsies were obtained 10 s after cessation of the exercise.

Changes in plasma during exercise and recovery

As noted previously, the acid–base disturbance within the plasma during exercise is generated within contracting skeletal muscle. It must therefore be appreciated that the venous plasma draining contracting muscles display the greatest and most rapid changes in metabolite, electrolyte, and gas concentrations compared to mixed venous or arterial plasma. The changes in mixed venous plasma will be greater than those in arterial plasma, and those in arterial plasma will be greater than those seen in venous plasma draining non-contracting tissues (i.e. jugular vein).[81–83]

These differences in blood sampling site are important considerations when evaluating the acid–base and electrolyte profile of exercised horses. In laboratory conditions, acid–base determinations are best performed on arterial and on venous plasma draining contracting skeletal muscle. While blood samples have been collected from the iliac vein in resting horses,[84] the technique does not yet appear to have been applied to exercising horses. The only real difference in acid–base composition between mixed venous and arterial plasma is due to CO_2 loss at the lung but this, together with associated measures of P_{O_2}, provides valuable information on the respiratory system during exercise and recovery.[13] When an acid–base assessment is performed on jugular venous plasma (as it often must be due to ethical or field considerations) then it must be kept in mind that a less severe and somewhat erroneous picture of whole body acid–base status will be the result.

As with muscle, it must also be appreciated that the rapid loss of water and some electrolytes from the plasma compartment with the onset of exercise is among the factors that produces changes in measured concentrations of electrolytes, metabolites protein and red cells (hematocrit or packed cell volume; PCV).[85,86] Indeed, about 50% of the increase in plasma [K^+], all of the increase in [plasma protein] and 50% of the increase in PCV is due to loss of water from the plasma compartment.[85,86] The remainder of the increase in plasma [K^+] is due to net loss of K^+ from contracting skeletal muscle and the remaining increase in PCV is due to splenic contraction resulting in discharge of red cells into the circulation.

Assessment of acid–base status in the blood is performed on constituents measured within the plasma compartment. Therefore concentrations of metabolites measured on samples of lysed whole blood cannot be used because the concentrations of these substances within red cells differs from that measured in plasma. The differences between plasma and red cell intracellular concentrations diminish within the syringe after blood sampling.[87] It is therefore important to separate red cells from plasma immediately after sampling the blood from exercising horses so that the plasma sample is as close to a true reflection of what was in the plasma of the horse at the exact time of blood sampling. As noted above, the P_{CO_2} at different blood sampling sites varies considerably and is an important consideration when determining whole-animal acid–base status, and some of this can be due to marked temperature differences. Determination of the actual pH, P_{CO_2} and P_{O_2} (as opposed to that measured by an instrument at 37°C), and hence [HCO_3^-], requires a non-linear correction of the blood gas and pH values to the temperature within each blood sampling site.[82,88] Increases in temperature results in increases in P_{CO_2}, P_{O_2} and [H^+] (decreased pH).

As in contracting muscle, the main changes that affect plasma [SID] during moderate- to high-intensity exercise are increases in [K^+], [$lactate^-$][77] and [Na^+] but not [Cl^-][81,82] due to the greater rate of loss of water (than of Na^+) from plasma into contracting muscle. Examples of these types of exercise include incremental exercise to fatigue, maximal intensity sprints, and constant rate submaximal exercise tests.

The arterial P_{CO_2} responses to exercise are highly dependent on running velocity and, during incremental exercise tests, on the duration of time spent at each running velocity. Arterial P_{CO_2} remains unchanged during low to mild intensity exercise. During incremental exercise to fatigue, arterial P_{CO_2} decreased slightly but mixed venous P_{CO_2} increased markedly from 50 mmHg at rest to 80–95 mmHg at the highest work load, corresponding to 100%$\dot{V}O_{2peak}$.[81] In Fenger et al's study[81] running velocity was increased in small increments (0.5 to 1 m/s) and each velocity sustained for 90 s to achieve near steady-state of cardiovascular and

respiratory responses.[89] When velocity was consistently increased at 0.5 m/s increments with 4 min at each speed, increasing exercise duration was associated with a marked and progressive hypocapnia[82] indicative of increasing alveolar ventilation.[90] In contrast, when velocity is increased in large (2 m/s) increments with only 1 min at each speed[91,92] or when single high-intensity (running at > 10 m/s) exercise bouts are performed the increase in P_{CO_2} is similar to that achieved during high-intensity sprint exercise.[91,93] In horses sprinting at 115% of peak $\dot{V}O_2$, arterial P_{CO_2} increased from 42 mmHg at the walk to 48 and 59 mmHg at 45 and 75 s of the sprint, comparable to the 58 mmHg P_{CO_2} seen with rapid, non-steady-state incremental exercise test.[91] From these and other similar results it can be concluded that sprinting or rapid increases in exercise intensity result in elevations in arterial P_{CO_2}, indicating that the respiratory system cannot keep the pace of metabolic and physicochemical CO_2 production. However, if sufficient time (90 s) is allowed at each running velocity, the rate of CO_2 elimination by the respiratory system meets or exceeds the rate of CO_2 production.

Incremental steady-state exercise

With this overview, let us now conduct an acid–base evaluation during the incremental 'steady-state' exercise test of Fenger et al.[81] The reason for choosing this type of a test is because it is a very good design for the controlled, clinical assessment of respiratory and metabolic systems during and following exercise. Although the $[A_{tot}]$ data are incomplete, this particular study provides a reasonably good assessment of acid–base state using arterial plasma.

In arterial plasma, the dependent variable $[H^+]$ increased by 21 nEq/L at maximal exercise, and $[HCO_3^-]$ decreased from 32.8 to 16.2 mEq/L. The independent variable [SID] remained unchanged (36.8 at rest and 35.5 mEq/L at maximal exercise) and thus had no effect on the changes in $[H^+]$ or $[HCO_3^-]$. Arterial P_{CO_2} decreased from 44 at rest to 35.5 mmHg at maximal exercise; this reduction appeared to be due to an increase in alveolar ventilation during the progressive exercise test and effectively reduced the mixed venous P_{CO_2} of 83 mmHg to below resting values. By solving for $[H^+]$ with this decrease in P_{CO_2}, but holding [SID] and $[A_{tot}]$ constant at resting values, the decrease in P_{CO_2} alone (independent of any other changes) contributed to a 7.7 nEq/L decrease in $[H^+]$, indicative of considerable sensitivity of $[H^+]$ to changes in P_{CO_2}. Because this decrease in P_{CO_2} caused a decrease in $[H^+]$, it means that increases in either or both of $[A_{tot}]$ and [SID] had to contribute to the increased $[H^+]$ (acidosis). The numerical (although not statistically significant) 1.3 mEq/L decrease in [SID] accounts for only 5.3 nEq/L of the 21 nEq/L increase in $[H^+]$. Therefore, the increase in $[A_{tot}]$ accounts for the difference between measured change in $[H^+]$ and the decrease in $[H^+]$ due to decreased P_{CO_2}, as well as the difference between change in measured $[H^+]$ and the increase in $[H^+]$ due to the increase in $[A_{tot}]$ (Table 39.4). It may appear unusual that [SID] was unchanged at maximal exercise, compared to rest, so we will examine this in more detail. As expected, the main contributor to a decrease in [SID] during exercise is an increase in $[lactate^-]$, and indeed lactate increased to 17 mEq/L at maximal exercise; the 16 mEq/L increase in $[lactate^-]$ thus contributed to a 16 mEq/L decrease in [SID]. This effect of increased $[lactate^-]$ (from 1 to 17 mEq/L), however, was offset by a simultaneous 11 mEq/L increase in $[Na^+]$ and a 3 mEq/L increase in $[K^+]$, with no change in $[Cl^-]$.

The important points about arterial acid–base balance during this type of exercise is that the increases in plasma total weak acids (primarily albumin) and inorganic phosphate are the primary contributors to the acidosis. While the 16 mEq/L increase in the strong acid anion $[lactate^-]$ did have a pronounced acidifying effect (the increase in $[lactate^-]$ alone effectively increased $[H^+]$ by ~55 nEq/L) this effect is offset by the increases in plasma strong base cations $[Na^+]$ and $[K^+]$. The increase in $[Na^+]$ results from the net movement of a low $[Na^+]$ plasma filtrate into skeletal muscle while the increase in $[K^+]$ arises from net K^+ loss by contracting skeletal muscle.[73,75] Finally, within mixed venous plasma the increases in $[A_{tot}]$ and P_{CO_2} both contribute substantially to the acidosis, and this P_{CO_2} effect is abolished upon transit of the blood through the lungs.

Table 39.4 Contributions to increases in arterial plasma dependent variables $[H^+]$ and $[HCO_3^-]$ by each of the independent variables [SID], P_{CO_2} and $[A_{tot}]$ during incremental 'steady-state' exercise in horses, using data from[80]

Variable	Resting	Maximal exercise	Change from rest	Contribution to change in $[H^+]$ (mEq/L)
$[H^+]$ mEq/L (pH)	33 (7.47)	54 (7.26)	+21	–
$[HCO_3^-]$ mEq/L	32.8	16.2	–16.6	–
[SID] mEq/L	36.8	35.5	–1.3	+5.3
PCO_2 mmHg	44.0	35.5	8.5	–7.7
$[A_{tot}]$ mmol/L	Not given	Not given		+23.4*

* calculated as $[H^+]$ change from rest (21) – ([SID] and P_{CO_2} effects)

High intensity sprint exercise

The second example to be illustrated is using high-intensity sprint exercise. We will specifically examine the second and ninth sprints of a series of nine sprints performed by trained Arabian horses, as described by Kronfeld and colleagues (1999).[93] Each sprint lasted for 60 s, with a 4-min active recovery between sprints. After a warm-up, the first sprint was performed at 7 m/s (6% incline) and the remaining eight sprints at 10 m/s. Another noteworthy feature of this study is that jugular venous plasma was used, and this raises some points of interest that will be addressed as we work through the data.

At the end of sprint 2, as in Fenger's et al's study,[81] there was only a small, 1 mEq/L decrease in [SID] that theoretically contributed 1 nEq/L to the 5 nEq/L increase in $[H^+]$ (Tables 39.5 and 39.6). In these tables, this is reported as –0.6 nEq/L because this more accurately represents the

Table 39.5 Contributions to increases in jugular venous plasma dependent variables [H^+] and [HCO_3^-] by the independent variables [SID], P_{CO_2} and [A_{tot}] at the end of the second sprint, using data from Kronfeld et al[93]

Variable	Resting	Second sprint	Change from rest	Contribution to change in [H^+] (nEq/L)
[H^+] nEq/L	38.7	43.7	5.0	–
[SID] mEq/L	48.6	47.6	–1.0	–0.6
P_{CO_2} mmHg	51.6	57.5	+5.9	4.1
[A_{tot}] mmol/L	18.5	19.5	+1.0	1.5

Table 39.6 Contributions to increases in jugular venous plasma dependent variables [H^+] and [HCO_3^-] by the independent variables [SID], P_{CO_2}, and [A_{tot}] at the end of the ninth sprint, using data from Kronfeld et al[93]

Variable	Resting	Ninth sprint	Change from rest	Contribution to change in [H^+] (nEq/L)
[H^+] nEq/L	38.7	42.1	+3.8	–
[SID] mEq/L	48.6	45	–3.6	+4.4
P_{CO_2} mmHg	51.6	48.2	–3.4	–2.4
[A_{tot}] mmol/L	18.5	20	+1.5	+2.0

mean of the individual calculations for eight horses. The point is that changes in [SID] are small and do not play a major role in acid–base balance during this type of exercise. Although a 4.3 mEq/L increase in plasma [lactate$^-$] contributed to an acidifying effect, this was offset by increases in plasma [Na^+] (1.7 mEq/L) and [K^+] (1.4 mEq/L). As the number of sequential sprints increased, plasma [lactate$^-$] continued to increase to 9.5 mEq/L at the end of sprint 9; this now offset the increases in [Na^+] and [K^+], resulting in a 3.6 mEq/L decrease in [SID] that could alone account for all of the increase (3.8 nEq/L) increase in [H^+].

P_{CO_2} peaked at the end of the second sprint and then decreased progressively to below resting by the end of sprint 6. This indicates both a lowering of glycolytic metabolism and resultant decrease in metabolic H^+ production[60,68] that reduces the generation of P_{CO_2} (from H^+ combining with HCO_3^-) and an improvement in alveolar ventilation as the exercise progresses. Nonetheless, the decrease in P_{CO_2} to below resting values contributed to alkalinizing effect equivalent to reducing [H^+] by 2.4 nEq/L. A further small increase in [A_{tot}] also contributed to an acidifying affect that offset most of the alkalinizing effect of lowered P_{CO_2}.

In summary, comparing the results of sprints 2 and 9, we see a marked difference in the origins of the acid–base disturbance. The primary acidifying influence at the end of sprint 2 was the increase in P_{CO_2}, whereas at the end of sprint 9 P_{CO_2} had decreased and contributed to an alkalinizing effect. This is an important regulatory aspect, for this later alkalinizing effect of lowered P_{CO_2} markedly reduced the acidifying effects of decreased [SID] (which account for two-thirds of the acidification) and increased [A_{tot}] (one-third of the acidification at the end of sprint 9). In sprint 2, there was negligible effect of [SID] as [lactate$^-$] continued to increase in plasma with repeated sprints and a progressively decreasing [SID] played an increasing role in systemic acidification. In classical acid–base physiology, one can refer to this acidosis at the end of sprint 2 as a primary respiratory acidosis that progresses to a primary metabolic acidosis with respiratory compensation by the end of sprint 9.

It should be noted that repeated sprints result in a sequential lowering of P_{aCO_2} with each successive sprint[93] and that this is attributed to a significant increase in alveolar ventilation and not to increased breathing frequency, which is tightly coupled to stride frequency.[90] After 5 sprints, an increasing arterial hypocapnia was observed with each successive sprint.[93] In a similar vein, when a low-intensity exercise warm-up precedes a bout of high-intensity exercise, there is an increase in $\dot{V}_{CO_2}$ during the first minute of exercise compared to when no warm-up preceded the high intensity exercise.[94,95] Rather than evoking an increase in alveolar ventilation to explain this result, however, these authors suggested that the warm-up resulted in increased tissue CO_2 storage, which then reduced the amount of CO_2 during the subsequent bout of high-intensity exercise – this does not preclude an increase in alveolar ventilation after a warm-up. Furthermore, since the increase in $\dot{V}_{CO_2}$ occurred within seconds of starting the high-intensity exercise,[94] it is unlikely that the rapidity of the augmented $\dot{V}_{CO_2}$ response could be explained by a reduced ability to store CO_2. It can be concluded that the augmented $\dot{V}_{CO_2}$ during high-intensity exercise after warm-up is primarily due to increased alveolar ventilation, similar to that seen with high intensity steady-state exercise. In further support, during heavy exercise (4.5 m/s at a 10% grade = 60% of peak $\dot{V}_{O_2}$) of 30 min duration, a progressive decrease in P_{aCO_2} was primarily due to a progressive increase in alveolar ventilation secondary to increases in both respiratory frequency and tidal volume.[96]

Steady-state submaximal exercise

The final example exemplifies the changes and contributions seen during steady-state, submaximal exercise in well trained horses. A time point of 15 min into exercise was selected because this is well past the rapid changes that occur with the onset of exercise and was at least 10 min prior to the onset of fatigue for this intensity with this group of horses (Lindinger MI et al, unpublished data). One of the most noteworthy features of submaximal steady-state exercise in trained horses is the alkalosis that occurs during the steady-state period (Table 39.7). Plasma pH rose in both arterial (carotid artery) and mixed venous (pulmonary artery). In arterial plasma, the alkalosis was completely due to the decrease in P_{aCO_2}, since there was negligible change in [SID] (2 mEq/L increase in [lactate$^-$] balanced by 1 mEq/L decrease in [Cl^-] and 1.3 mEq/L increase in [K^+]) and a 1.3 mEq/L increase in [A_{tot}] had an acidifying

Table 39.7 Contribution to increases in arterial and mixed venous dependent variables [H^+] and [HCO_3^-] by the independent variables [SID], PCO_2 and [A_{tot}] at 15 min of steady-state exercise prior to onset of fatigue. Data represent averages obtained from four trained Standardbreds (from Lindinger MI et al, unpublished)

Variable	Resting	Exercise	Change from rest	Contribution to change in [H^+]	Contribution to change in [HCO_3^-]
Arterial plasma					
[H^+] nEq/L (pH)	37 (7.43)	26 (7.58)	–10	–	–
[HCO_3^-] mEq/L	28.3	26.3	–2.0	–	–
[SID] mEq/L	39.9	39.6	–0.3	+0.4	–0.3
PCO_2 mmHg	42.7	28.3	14.4	–12.0	–0.6
[A_{tot}] mmol/L	13.5	14.8	+1.3	+1.4	–1.0
Mixed venous plasma					
[H^+] nEq/L (pH)	43 (7.37)	38 (7.42)	–5	–	–
[HCO_3^-] mEq/L	28.4	31.0	+2.6	–	–
[SID] mEq/L	39.9	43.8	+3.9	–4.8	+3.7
PCO_2 mmHg	49.2	48.1	–1.1	–0.9	0.0
[A_{tot}] mmol/L	13.6	14.9	+1.3	+1.6	–1.0

effect. The decrease in arterial plasma [HCO_3^-] is a hallmark of 'metabolic acidosis' in the clinical acid–base sense and, indeed, that is what one would expect to see with exercise. Importantly, however, this decrease is primarily due to the increase in total *weak* acid concentration (primarily plasma proteins) and secondarily to the decrease in $Paco_2$ (despite the marked 14.4 mmHg decrease). It must be emphasized that such modest increases in [K^+] and [lactate$^-$], with the alveolar hyperventilation, are features of well-trained horses.

In mixed venous plasma, there was a small decrease in $Pmvco_2$, indicating that the influence of alveolar hypoventilation persisted within the peripheral circulation and that the rates of metabolic H^+ production were low; metabolism was primarily aerobic, as evidenced by the low plasma [lactate$^-$] of 3.25 mEq/L. The sole contributor to an acidifying effect was the increase in plasma [proteins] ([PP]), resulting from the fluid shift into contracting muscle. The 4 mEq/L increase in [SID] thus accounted for all of the alkalinizing effect. Plasma [SID] increased due to a 2 mEq/L increase in [Na^+], a 1.4 mEq/L increase in [K^+] and a 2 mEq/L decrease in [Cl^-] that offset the 1.9 mEq/L rise in [lactate$^-$]. Mixed venous plasma [HCO_3^-] increased during steady-state exercise, in contrast what was seen in arterial plasma and what would also be seen in jugular venous plasma. Again, this is solely due to the increase in [SID], as the increase in [A_{tot}] had the effect of reducing [HCO_3^-] by 1 mEq/L.

It is evident from this analysis, using relatively small changes in both dependent and independent acid–base variables, that [H^+] has similar sensitivities to physiological changes in the independent variables, however [HCO_3^-] is much more sensitive to changes in [SID] and [A_{tot}] than to changes in Pco_2.

Endurance exercise

Low-speed endurance exercise, such as draught horses pulling loads for 8 h per day for five consecutive days[97] produces no significant acid–base disturbances. When the speed of endurance exercise is increased, with ensuing sweat losses of water and electrolytes occurring at elevated rates, then a slowly progressing metabolic alkalosis develops.[98–100] It is important to point out that when the hydration status of the horses is maintained, through the use of effective strategies of electrolyte supplementation, this alkalosis does not develop.

The metabolic alkalosis associated with dehydration during endurance rides, or indeed during prolonged transport of a horse, is a direct result of sweating. Equine sweat has a tonicity similar to that of plasma[101] in contrast to the very dilute sweat produced by humans. The reason for the high tonicity of equine sweat is that the equine sweat gland does not appear to have the ability to resorb ions from within the lumen of the sweat glands. Rather, some ions, such as K^+ and Cl^- appear to be secreted for their concentrations in sweat are much greater than in plasma and extracellular fluid.[101] Although the electrolyte composition of equine sweat changes over time, in general, sweat [Na^+] ranges from 65 to 170, [K^+] ranges from 25 to 55 and charge balance is made up by [Cl^-] in the range 100–180 mEq/L.[101] The total amount of electrolyte loss during a 100-mile endurance ride can be in excess of 1 mole for Na^+ and Cl^- representing substantial depletion of body stores,[102] so it is instructive to determine the origins of the electrolyte losses. Because the tonicity and [Na^+] of equine plasma and sweat are similar, there is little if any change in plasma osmolality and [Na^+] during prolonged endurance exercise.[70,102,103] Additionally, when plasma [K^+] is measured, after allowing sufficient time after exercise has stopped for re-equilibration of plasma and muscle K^+ pools, there is little change in plasma [K^+] and clearly the K^+ losses are not borne by the extracellular compartment. Therefore, the K^+ appearing in the sweat originates largely from cells, and likely contracting muscle cells that are known to lose K^+ during the period of exercise.[104] It is important to recall that the bulk of the body's Na^+ and Cl^- stores are extracellular, and it is Cl^- that balances

the positive charge on Na^+ and K^+ lost in sweat. Therefore sweat $[Cl^-] = [Na^+] + [K^+]$. Because the extracellular losses of Cl^- exceeds those of Na^+ by a factor ranging between 1.3 and 1.8, extracellular and plasma $[Cl^-]$ must decrease, and indeed does by 10 to 15 mEq/L.[70,98,102,103] It is this large decrease in plasma $[Cl^-]$ that is responsible for the alkalosis, for this results in a large increase in plasma [SID].

A detailed assessment of acid–base status in horses during the time course of an endurance ride has not yet been performed. Using the principles of acid–base assessment provided above, an extreme case of plasma $[Cl^-]$ depletion (–15 mEq/L[103]) will be used to exemplify the effect on acid–base status:

$$[SID] = ([Na^+] + [K^+]) - ([Cl^-] + [lactate^-])$$

Before endurance exercise:

$$38\ mEq/L = (135 + 4) - (100 + 1)$$

After endurance exercise:

$$53\ mEq/L = (135 + 4) - (85 + 1)$$

The increase in [SID] alone has a large alkalinizing effect and can be calculated to decrease plasma $[H^+]$ from 36.6 to 23.9 nEq/L (pH increase from 7.436 to 7.622), with $[HCO_3^-]$ increasing from 26.9 to 41.2 mEq/L. The fact that such large changes do not occur is primarily attributed to the simultaneous increase in plasma $[A_{tot}]$ resulting from the loss of extracellular water which raises [PP]. An increase in [PP] from 60 to 75 g/L, typical of endurance rides, increases $[A_{tot}]$ from 13 to 16.25 mmol/L, and this change alone (independent of change in [SID] or Pco_2) has the effect of raising $[H^+]$ from 36.6 to 40.5 nEq/L. The combined effect of increased $[A_{tot}]$ and decreased [SID] results in an $[H^+]$ of 25.6 nEq/L (pH 7.591) and $[HCO_3^-]$ of 38.4 mEq/L. There is negligible change in Pco_2 during endurance exercise and the small changes that occur can be neglected for the purposes of assessing acid–base status. Therefore, the acidification resulting from the increase in plasma $[A_{tot}]$ only partially offsets the alkalinization caused by the increase in [SID], resulting in the observed alkalosis.

It is very important to note that, in the dehydrated horse, there is little change in plasma $[Na^+]$ and osmolality. Horses can lose 30 L or more of fluid as sweat with minimal alteration of plasma osmolality and $[Na^+]$. This is solely because sweat osmolality and $[Na^+]$ differs little from that of sweat. To complicate the interpretation, the decrease in plasma $[Cl^-]$ is seemingly inconsistent with dehydration. The key hematological variables for diagnosis of dehydration in the horse are a decrease in plasma $[Cl^-]$ coupled with increases in [PP] and PCV.

Other types of exercise

It is worth noting some interesting features of acid–base balance reported in the literature in horses performing different types of activities, ranging from draught work to show jumping. Show jumping competition resulted in a decrease in jugular venous Pco_2, once again illustrating the degree of alveolar ventilation and an ability of lowered Pco_2 to offset the acidifying effects due to increases in $[A_{tot}]$.[105] In these horses [SID] increased by 2 mEq/L, which also had an alkalinizing effect; a 2 mEq/L decrease in $[Cl^-]$ and 3 mEq/L increase in $[Na^+]$ more than offset the 3.8 mEq/L increase in $[lactate^-]$.

The second day of three-day eventing consists of a steeplechase, a roads and tracks phase and a cross-country phase, with each separated by a rest/cool-down period. Rose and colleagues[106,107] assessed the acid–base changes occurring within jugular venous blood during this period. As with the other forms of exercise described above, plasma $[H^+]$ decreased from 42 to 37 nEq/L at the end of the roads and tracks phase, and was subsequently 41 nEq/L at the end of the cross-country phase. The main reasons for the decrease in $[H^+]$ at the end of roads and tracks was a 6 mmHg decrease in Pco_2 with a 2.3 mEq/L increase in [SID]. The increase in [SID] resulted from increases in $[Na^+]$ and $[K^+]$ and decreases in $[Cl^-]$ that offset the 1.5 mEq/L increase in $[lactate^-]$. Together, the combined effects of lowered Pco_2 and increased [SID] more than offset the acidifying effects of the 1.2 mmol/L increase in $[A_{tot}]$, producing the mild alkalosis. At the end of the cross-country, plasma $[lactate^-]$ had risen to 8.2 mEq/L, negating the effects of increased $[Na^+]$ and lowered $[Cl^-]$ and leaving [SID] at resting values (40 mEq/L). The sole contributor to an acidifying effect was thus the 3 mmol/L increase in $[A_{tot}]$ (resulting from dehydration (57%) and exercise-induced fluid shift (43%)) and this was completely offset by a further decrease in Pco_2 to 31.5 mmHg resulting in a normal $[H^+]$ (41.3 nEq/L). As expected, the combined effects of increased $[A_{tot}]$ and reduced Pco_2 lowered $[HCO_3^-]$ from 28 mEq/L at rest and at the end of roads and tracks to 18 mEq/L at the end of the cross-country. Within 30 min of the cross-country both $[H^+]$ and $[HCO_3^-]$ had normalized to pre-exercise values despite an elevated $[A_{tot}]$ (at this point due solely to dehydration), whose acidifying effects were offset by a continued depression of Pco_2.

Polo consists of periods of low to moderate activity interspersed with brief periods of burst activity while carrying the rider. The total duration of activity for individual horses ranges from 1 to 2 h, allowing time for dehydration to occur as a result of sweating (see endurance exercise section below). Polo exercise results in a modest acidosis of metabolic origin (increases in plasma $[lactate^-]$) that lasts during the period of activity.[108] After cessation of exercise a mild alkalosis may develop, concomitant with decreased plasma $[Cl^-]$ resulting from sweat losses (see the 'Endurance exercise section').

Clinical notes

In a clinical vein, the nature of the generation of the acid–base disturbance, and its subsequent regulation during and following the period of exercise, results in its eventual amelioration over a period of minutes to hours depending on the intensity

and duration. Very high-intensity exercise is capable of lowering arterial plasma pH to 7.1.[77] Therefore caution may be required with repeated sprints of very high intensity due to the cumulative effects of increasing [lactate$^-$] and [PP] that may be capable of decreasing arterial pH below 7.1. It must be understood that the severity of the mixed venous acidosis would be measurably greater than the arterial acidosis. At somewhat lower intensity, horses are capable of several repeated sprints without incurring a severe acid–base disturbance.[93] The final caution pertains to dehydration that results from prolonged endurance exercise or prolonged transport without adequate intake of fluids and electrolytes. Dehydrated horses typically have an alkalosis that results in large part from the decrease in plasma [Cl^-] (loss of strong acid anion). The decrease in plasma [Cl^-] is primarily due to the very large losses of Cl^- in the sweat that serves to physicochemically balance the positive charge of Na^+ and K^+ lost in sweat. At the same time, [PP] may be in excess of 8 g/dL (normal is 5–6 g/dL in a euhydrated horse) and this will have a pronounced acidifying effect that also lowers [HCO_3^-]. Proper correction of this combined acid–base disturbance requires oral (preferably) or intravenous (if necessary) administration of a balanced electrolyte solution to replace the water, Na^+, K^+ and Cl^- lost in sweat. Since Cl^- in the administered solution will balance the sum of Na^+ and K^+, as K^+ is taken up by the tissues (and this occurs very rapidly[12]) the Cl^- will be left in the extracellular compartment with Na^+, serving to retain extracellular fluid and thereby lower plasma [protein]. This effectively corrects both the strong ion and weak ion aspects of the acid–base disturbance simultaneously.

Exercise summary

The strength of the physicochemical approach to acid–base balance is that it allows for the determination of each of the known and measured variables that determines the concentrations of H^+, HCO_3^-, and ^-OH in body fluids. Specifically, the method allows us to determine how much of an effect the increase in [PP] has. In most types of exercise, and in many clinical conditions, [PP] is elevated; large increases in [PP] are a hallmark of dehydration in endurance horses and, with other causes of dehydration, has a marked acidifying effect on plasma, and additionally lowers [HCO_3^-]. With high-intensity exercise, increases in plasma [lactate$^-$] play a major role in decreasing [SID], and hence acidifying the plasma and lowering [HCO_3^-]. With submaximal exercise, however, changes in strong ion concentrations are small and their effects on acid–base balance may be less than those exerted by increases in [A_{tot}]. Finally, the very large increases in mixed venous P_{CO_2} that occur with high-intensity exercise have a major acidifying effect, but raise [HCO_3^-]. When this blood is treated by the lungs, the P_{CO_2} is markedly lowered, often to below resting values for P_{aCO_2}. Thus the acidifying effect of P_{CO_2} within the venous plasma may be reversed to an alkalinizing effect within the arterial plasma. The main strong ion changes contributing to the decrease in [SID], and hence acidification and lowering of [HCO_3^-], are increases in plasma [lactate$^-$] and decreases in plasma [Cl^-].

Responses to training

The impact of training, or exercise conditioning, on acid–base balance has not been well studied. It is known, however, that the responses to exercise conditioning for low to moderate-intensity exercise (endurance training) differ from those for high-intensity exercise (sprint training), both at the whole-body metabolic level (see Chapter 34) and within skeletal muscle (see Chapter 5). Perhaps because of relative ease of implementation, endurance-type training studies are more prevalent than sprint training studies.

Endurance training

Endurance training results in a decrease in anaerobic muscle metabolism[109] and an increased oxidative capacity of muscles[110] that results in an increased reliance and capacity for fatty-acid oxidation during exercise. There is a reduced conversion of pyruvate to lactate$^-$ accompanied by improved matching of glycolytic flux with entry of pyruvate into the TCA cycle.[111] Notably, these adaptations result in a reduced rate of lactate$^-$ and H^+ accumulation within contracting muscle and blood, and these responses may be detectable within the first week of training. This is associated with increases in the activities of enzymes of oxidative metabolism that favor an increase in free-fatty acid oxidation. In highly trained, elite human endurance athletes the adaptations for fat oxidation are very pronounced, with fat serving as the main energy source at exercise intensities as high as 85% of peak $\dot{V}O_2$[112] with concomitant decrease in muscle glycogen utilization at submaximal exercise intensities. At present, it is not known if the elite equine endurance athlete can achieve a similarly high capacity to utilize blood-borne fatty acids.

These intramuscular biochemical adaptations are associated with improvements in the cardiovascular function (increased stroke volume and cardiac output)[89] but there appears to be little change in functional parameters of the respiratory system.[89,92,113] With low-intensity exercise, endurance training appears to have no effect on measured acid–base variables,[114] probably because the metabolic and cardiorespiratory systems are not sufficiently taxed by low work rates.

Sprint training

The effects of sprint training on the ability of skeletal muscle or the whole body to regulate acid–base state have not been studied. None the less, a number of inferences may be made from the limited results available. Within skeletal muscle, sprint training results in a large increase in non-bicarbonate buffering capacity[44] that appears to be due primarily to increases in muscle carnosine content.[56]

Seven weeks of race training in Thoroughbreds increased skeletal muscle non-bicarbonate buffering capacity by 60%, from 58 ± 7 to 93 ± 7 μmol/kg.pH^{-1}.[44] Similar increases have been reported in humans[5,115] but sometimes not in other equine studies.[116,117] In the latter studies, however, the untrained horses were likely somewhat active, making difficult the detection of significant differences. Buffering capacity, even in untrained equine muscle, is substantially greater than in trained humans, and is 43 μmol/kg.pH^{-1}.[115,118] The increased buffering capacity with sprint training is very important in view of the fact that sprint training (in humans) results in increased activities of the glycogenolytic and glycolytic enzymes phosphorylase, phosphofructokinase, glyceraldehyde phosphate dehydrogenase, and lactate dehydrogenase.[119] Indeed, a high degree of correlation between carnosine content and glycogen phosphorylase activity has been shown.[50] Increased activities of these enzymes would be associated with a capacity to increase the rates of lactate$^-$ and H^+ production within contracting muscle. Despite increased rates of production, there was actually a decrease in lactate accumulation within muscle after training compared to before training both in horses[117] and in humans,[115] suggesting decreased reduction of pyruvate to lactate and enhanced pyruvate conversion to acetyl CoA. Additionally, increased amounts of lactate$^-$ could be transferred out of contracting muscle cells by training-induced increases in the monocarboxylate transporter MCT,[120] to be taken up rapidly by other tissues,[49] keeping plasma [lactate$^-$] relatively low.[117]

Thoroughbred race training resulted in no effects on pH_a, P_{ACO_2}, P_{mvCO_2} and $\dot{V}_{CO_2}$ after 7 weeks[89] or 16 weeks,[92] although arterial[89] and mixed venous pH[92] decreased significantly less than before training during incremental exercise tests.

In summary, from the limited number of sprint training studies, it appears likely that an improved ability to regulate acid–base state with moderate- to high-intensity exercise is primarily due to increases in non-bicarbonate proton buffering capacity and an improved ability to utilize pyruvate.

High altitude

The transition to high altitude results in a number of hematological adjustments that affect acid–base status.[121,122] The decreased atmospheric partial pressure of O_2 results in an alveolar hyperventilation that persists for at least 6 days. During the initial 3 days of transition to 3800 m elevation, P_{CO_2} decreased from 40 to 20 mmHg and [SID] from 44 to 26 mEq/L that, together, accounted for increases in pH (7.43 to 7.48) and decreases in [HCO_3^-] (from 23 to 15 mEq/L).[122] After the third day of altitude, acid–base parameters were normalized over a 3–7-day period.[122] Since [PP] was not measured, the influence of [A_{tot}] on acid–base balance is unknown at this time. From these studies it appears that a minimum of 10 days is needed to complete the adjustments affecting plasma acid–base status. This is an important consideration when horses are brought from low- to high-altitude locations for competition.

Diet and acid–base

Nutrition plays an important role in equine health, performance, and acid–base balance, both at rest and during exercise. Large-animal diets are often characterized on the basis of their dietary cation anion difference (DCAD), defined as the balance between strong base cations (K^+ and Na^+) and strong acid anions (Cl^- and SO_4^{2-}). The reason that dietary DCAD affects acid–base balance in the body is because diets high in cations but low in anions (high DCAD) result in an increased cation content of the extracellular fluids as these cations are absorbed within the small intestine. When a high DCAD diet is sustained, much of the excess cation is excreted by the kidneys, but the cations are accompanied by the weak acid HCO_3^- and the strong acid Cl^-, typically producing a mild systemic alkalosis.[123] In contrast, low DCAD diets produce a systemic acidosis[123–125] with increased renal calcium excretion that could lead to negative calcium balance and weakening of the skeletal system.[126] A DCAD of between 250 and 300 mEq/kg is considered neutral – this will not result in significant alterations of acid–base balance. In contrast, a DCAD > 300 mEq/kg will have an alkalinizing effect, while a DCAD < 250 mEq/kg will have an acidifying effect. High-quality, high-forage diets have a large cation content, primarily K^+, that will often produce a DCAD > 300 mEq/kg. In contrast, unsupplemented grain rations have a high Cl^- and low K^+ content and have a DCAD typically less than 250 mEq/kg.

Resting horses

Plasma pH and [HCO_3^-], and urine pH have been shown to increase in proportion to the DCAD over the range 0 to 407 mEq/kg dry matter.[123,125,126] Diets that have a high protein content are also acidogenic due to the production of SO_4^{2-} (strong acid anion) and inorganic phosphate (weak acid anion), which become elevated in plasma. In Arabian horses, a high protein (HP) diet (DCAD = 182 mEq/kg) significantly decreased [SID] by 7 mEq/L compared to horses fed on a low protein (LP; DCAD = 260 mEq/kg) diet.[127] The decrease in [SID] was due to a 7 mEq/L decrease in plasma [Cl^-] in the HP group. It is likely that the decrease in [Cl^-] was offset by increases in [SO_4^{2-}] and [phosphate], but these were not reported. Plasma P_{CO_2} averaged 3 mmHg higher in the HP group. The resultant changes in dependent acid–base variables was small (increased plasma [H^+] by 2–3 nEq/L), with no effect on [HCO_3^-].

Exercise

Only a few studies have examined the influence of DCAD on exercise performance and on acid–base balance during exercise.[124,125,128,129] Popplewell et al[129] demonstrated that horses fed a high DCAD ran significantly faster and, at the end of exercise, had elevated concentrations of lactate in the blood while plasma [H^+] was unchanged.[129] A similar

response was not seen by Cooper et al where the high DCAD diet was marginal at 306 mEq/kg.[128]

In the study by Graham–Thiers et al[127] horses on the high protein (HP) diet (low DCAD) had a more pronounced lowering of [HCO_3^-] during exercise consisting of 6 sequential 1 min sprints, separated by 4 min rest periods. The lower [SID] and Pco_2 during rest in the HP group persisted during exercise and 30 min of recovery and accounted for the reduced [HCO_3^-]. Of interest, and in contrast to Popplewell et al's study,[129] horses on the HP diet averaged 3 mEq/L higher plasma [$lactate^-$], which was offset by a 3 mEq/L decrease in plasma [Cl^-], than horses on the LP diet.

Dietary protein

The purported effects of dietary protein on acid–base balance in the study by Graham-Thiers et al[127] can at least in part be attributed to the low DCAD of the HP diet. A recent study by the same group[130] maintained the DCAD of the HP diet between 387 and 424 mEq/kg dry matter, whereas the DCAD of the low protein (LP) diet was 345–370 mEq/kg. At rest, horses on the LP diet had a minor lowering of arterial and mixed venous plasma [$lactate^-$] and pH, and increased arterial [HCO_3^-] and [K^+], without change in other variables. With high-intensity sprinting exercise, horses on the LP diet maintained a 0.03 pH-unit higher mixed venous pH than horses on the HP diet, although the physiological significance of such a small, although consistent effect, is questionable. The increased mixed venous pH could be attributed to a 2 mEq/L greater [SID] in LP horses both at rest and during exercise, with no differences in Pco_2 and [A_{tot}] between LP and HP. In contrast, arterial plasma was not influenced by diet during exercise. These limited studies suggest that the LP diet alters the functioning of the contracting muscles sufficiently to produce a modest effect of elevated [SID] and pH in mixed venous blood. The effects are so small to be of questionable physiological significance.

Dietary starch

Dietary starch has been suggested to be the cause of a decrease in plasma pH when DCAD was held constant across diets. However, a recent comprehensive study using three high DCAD (305–333 mEq/kg) and three low DCAD (124–154 mEq/kg) diets, with starch comprising 45–49% of each diet, showed that high-starch diets (from corn, oats or alfalfa) had no effect on plasma acid–base balance.[131] These authors concluded that the potential negative effects of high-grain diets (low DCAD) can be overcome by adjustment of the DCAD with supplemental cations. There was also no effect of alfalfa versus non–alfalfa roughage diets on acid–base status and exercise performance in Thoroughbreds.[132]

Dietary fat

The effect of dietary fat on performance and acid–base balance has received more attention than starch and protein. Graham-Thiers et al found no effect of dietary fat (0 versus 10%) on acid–base balance at rest and during repeated sprint exercise, although there was evidence for an increased reliance of fat as an energy source.[130] In contrast, an earlier study of repeated sprint exercise reported that horses on a 10% fat diet showed an increased plasma acidosis with increased [$lactate^-$][133] and decreased Pco_2 and [SID] than horses on the control diet.[134] Peak effects of the high-fat diet required between 6 and 11 weeks of feeding. When horses were on a high-fat (10%) diet for a relatively short duration of 4 weeks, there was a tendency for the high-fat diet to increase plasma [$lactate^-$] during exercise.[135] This was associated with faster gallop speeds during the third and fourth repeated gallops, which Duren et al[135] attribute to an increased activation of glycolysis and glycogenolysis[136] with associated increases in power output with repeated sprint exercise. It appears that, with high-intensity exercise, horses must be maintained on a high-fat diet for at least 6 weeks and that the chronic high-fat diet results in an increased reliance on glycolysis to produce the ATP needed to generate the high power outputs. The effects of a high-fat diet on acid–base balance during high-intensity exercise appear to be minor. The effects of dietary fat on acid–base balance during prolonged low- and moderate-intensity exercise do not appear to have been studied.

Selected clinically relevant issues for seemingly 'normal' horses

Age

A recent study[137] provided a detailed comparison of plasma acid–base status in young (< 9 years) and old (> 19 years) horses. The only differences were a reduced (by 1.5 mmHg) arterial Pco_2 that resulted in a lower pH (7.428 versus 7.404) and this was associated with a lower Po_2 (90 versus 102 mmHg); there were no differences in measured weak and strong ion concentrations. A similar effect of age on arterial Pco_2 has previously been reported.[138] Aguilera-Tejero et al suggest that the apparent hypoxemia in older horses results in an increased ventilation that would thereby reduce arterial Pco_2.[137]

Idiopathic laryngeal hemiplegia

A number of race horses, both Thoroughbred and Standardbred, may perform poorly[138] due, in part, to a syndrome known as idiopathic laryngeal hemiplegia (ILH).[139] ILH is a peripheral neuropathy characterized by dysfunction of the left recurrent laryngeal nerve innervating most of the left laryngeal muscles.[140] Haynes indicated that about 50% of large breed horses have some degree of laryngeal synchrony and asymmetry at rest.[141]

Impaired regulation of acid–base balance occurs during exercise in horses with grade 4 or 5 laryngeal function,[140] where grade 5 is complete hemiplegia. The primary manifestation during a standard exercise test to fatigue is a marked elevated in arterial P_{CO_2} (grade 4, 69 mmHg; grade 5, 75 mmHg) compared to grade 1 (normal laryngeal function, 58 mmHg) that is associated with a reduced arterial P_{O_2} (by 8 mmHg) and increased (by 5–6 mEq/L) plasma [lactate$^-$].[139,140]

Small airway inflammation and exercise-induced pulmonary hemorrhage (EIPH) also commonly occur in racehorses, leading to decrements in performance.[142] Poorly performing horses with these respiratory diseases manifested a pronounced and sustained hypocapnia with lower arterial P_{O_2}, [HCO_3^-] and pH and higher blood [lactate$^-$] during recovery from high intensity exercise. The more pronounced increase in [lactate$^-$] is consistent with impaired blood oxygenation at the lungs, resulting in a greater reliance on anaerobic mechanisms to produce energy during high-intensity exercise. The authors' conclusion that the hypocapnia was due to the lactic acidosis[142] cannot be supported. While the hypocapnia itself would blunt the arterial chemoreceptor drive to ventilate, this may be offset by the increased [H^+]. The hypocapnia can be explained in terms of alveolar hyperventilation, which would facilitate rapid release of CO_2 at the lungs while maintaining compromised ability to extract oxygen.

Administration of alkalinizing substances and other purported ergogenic aids

Alkalinizing substances

There is an extensive literature on the administration of bicarbonate salts and other alkalinizing agents in both horses and humans, and the interested reader is referred to reviews by Schott and Hinchcliff[143] and Heigenhauser and Jones.[144] There is also evidence that the administration of alkalinizing agents will result in enhanced performance with exercise at moderate to high intensities, and that this is due to increased rates of strong acid (i.e. lactate$^-$) removal from contracting muscle. This section will focus on the physicochemical aspects of inducing and correcting the acid–base disturbance resulting from the administration of bicarbonate-, citrate-, and phosphate-containing compounds.

At the outset it must be explained that the administration of HCO_3^- does not in and of itself result in an increase in plasma [HCO_3^-]. When sodium bicarbonate, or baking soda, is dissolved in water, all of the Na^+ completely dissociates from HCO_3^- by virtue of Na^+ being a strong ion; by definition strong ions are completely dissociated in solution.[23,26] The HCO_3^- in solution readily participates in physicochemical reactions with H^+, CO_2 and H_2O, as described above. In this simple solution consisting of water and added baking soda, the [HCO_3^-] will be determined by the [Na^+] and by the P_{CO_2}. Since this solution will come into equilibrium with the CO_2 in the air, the resulting P_{CO_2} will be very low once equilibrium is achieved. The addition of carbonic anhydrase to this solution would greatly increase the speed of the reaction, establishing equilibrium.

When a freshly mixed baking soda solution is administered nasogastrically into the stomach of a horse, which is an acidic environment, acid within the stomach and upper intestinal tract reacts rapidly with the HCO_3^- in solution. The HCO_3^- that was in solution rapidly dissipates, producing CO_2 and H_2O:

$$HCO_3^- + H^+ \rightarrow CO_2 + H_2O$$

The CO_2 diffuses readily into the blood, where most is transformed by the action of carbonic anhydrase to HCO_3^-, transported to the lungs, reconverted to CO_2 and eliminated in expired air. The ingested water and Na^+ are absorbed within the small intestine, resulting in increased plasma water content and [Na^+] – the excess is ultimately removed from the body through normal renal processes. Since the ingested HCO_3^- becomes part of the open CO_2 system, which is in a dynamic equilibrium with inspired air and the tissues, P_{CO_2} is rapidly normalized through ventilation. Therefore the only changes remaining within the plasma (and extracellular) compartment are increased [Na^+] and decreased concentrations of other plasma ions, both strong and weak. Notably, the concentrations of the predominant weak acid, protein, and strong acid Cl^- are decreased, resulting in decreased [A_{tot}] and [Cl^-]. Both the decrease in [Cl^-] and the increase in [Na^+] contribute to an increase in [SID]. Both the increase in [SID] and the decrease in [A_{tot}] contribute to increased [HCO_3^-] and decreased [H^+]; P_{CO_2} remains unchanged.

Because of the nature of these physicochemical reactions, it does not matter which cation salts of bicarbonate are dissolved in water and administered to the horse – all will result in a very similar extracellular alkalosis, at least initially. If calcium salts are used, these are absorbed slowly and the onset of the alkalosis will be slow. If a sufficient amount of calcium is used to induce an alkalosis, it is likely that this would be toxic. Potassium bicarbonate has also been used. Potassium, in contrast to Na^+, does not remain in the extracellular compartment but is rapidly taken up by the tissues, reducing the extent of the extracellular alkalosis presumably at the expense of alkalinizing the intracellular compartment.[12]

Time course

The administration of an alkalinizing agent results in a lowering of plasma and extracellular [H^+], with a concurrent increase in [HCO_3^-], with peak effects appearing to depend on the volume of water administered with the dose. When 1 L of water was administered with a $NaHCO_3$ dose of 0.4 g/kg body mass, peak effects occurred 2–4 h after administration.[145] In contrast, when 2–4 L of water was used to administer doses ranging from 0.25 to 1.5 g/kg, peak effects occurred only 6–8 h after administration.[146–149] Similar time courses occurred with a range of alkalinizing agents (sodium citrate, sodium acetate, sodium lactate, sodium acetate) administered at a dose of 0.5 g/kg in 2 L of water.[150]

As noted above, the administration of an alkalinizing agent with 4 L of water should result in a transient increase

in plasma volume. The time course of PV change has not been studied, although it is known that any early changes in PV that would occur are corrected 6 h after administration.[151] Therefore, after this 6-h period the sole cause for the acid–base disturbance is the increase in extracellular [Na^+] (or other administered cation).

Mechanism for enhanced lactate efflux

The rate of lactate$^-$ facilitated diffusion across the sarcolemma by the monocarboxylate transporter (MCT1), of which there are at least four isoforms in muscle,[49,120] depends on the chemical gradient and driving force for H^+ and lactate$^-$. Extracellular [lactate$^-$] is very low compared to muscle [lactate$^-$] in horses performing moderate- to high-intensity exercise,[152,153] providing a high driving force for lactate$^-$ diffusion out of contracting muscle cells. Similarly, extracellular [H^+] is low compared to intramuscular [H^+], and this is increased for a prolonged duration (up to 16 h) after administration of alkalinizing agents.[150] This combination of chemical changes results in an enhanced rate of removal of lactate$^-$ from contracting muscle during high-intensity exercise, producing a higher plasma [lactate$^-$] and lower muscle [lactate$^-$] at the end of exercise.[153] In order to be able to detect these changes, the dose administered may be important: Greenhaff et al used an $NaHCO_3$ dose of 0.6 mg/kg,[153] and when a dose of 0.4 mg/kg was used no differences in muscle and blood lactate were found.[152]

Creatine supplementation

The practice of creatine supplementation is used in humans to improve performance associated with short-term, high-intensity exercise.[154] Attempts to replicate similar effects in horses with a dose of 25 g creatine monohydrate twice daily have shown no effect on performance, metabolism, and related acid–base variables.[155]

Furosemide

Furosemide is a loop diuretic that is extensively used to treat race horses exhibiting symptoms of exercise-induced pulmonary hemorrhage (EIPH) in some racing jurisdictions.[156] There is evidence that furosemide administration improves racing performance[157] despite the pronounced diuresis with loss of water and electrolytes.[158] The mechanism by which furosemide induces a long-lasting mild alkalosis is through reductions in plasma [Cl^-] due to marked increases in renal Cl^- excretion without concomitant increases in renal strong cation excretion[158] and movement of plasma, Cl^- into red blood cells.[159] Because furosemide results in a pronounced loss of water, Na^+, and titratable acid from (primarily) the extracellular fluid compartment, this results in increased plasma [Na^+] (by 8 mEq/L) and decreased plasma [Cl^-] (by 8 mEq/L) between 5 and 10 h after intramuscular administration of 1 mg/kg.[160] In this study, it appears that plasma [SID] increased by 13 mEq/L 8 h after administration. More recently, a 7 mEq/L increase in plasma [SID] 4 h after administering 1 mg/kg furosemide has been reported.[161] This large increase in [SID] fully explains the increase in pH (7.383 to 7.445) and increase in [HCO_3^-] (3 mEq/L) in arterial plasma.[161] The effect of increased [SID] alone would have been greater, however, the concomitant increase in [PP] and hence [A_{tot}], due to the extracellular dehydration, results in an acidifying effect. Arterial and mixed venous P_{CO_2} remains unchanged in resting horses.[161] During high-intensity treadmill running exercise (4 h after 0.5 or 1 mg/kg furosemide administration), the elevations in arterial and mixed venous pH and [HCO_3^-] were maintained in furosemide-treated horses through to the last minute of maximal exercise; furosemide did not appear to result in increased lactate accumulation within blood.[161] Similar responses were reported by Hinchcliff and McKeever.[162]

In many ways, the alkalosis resulting from furosemide administration qualitatively resembles that resulting from administration of $NaHCO_3$ and related alkalinizing agents. The main feature in common that produces the increased plasma pH and [HCO_3^-] is the pronounced decrease in plasma [Cl^-]. The main differences are elevations in [PP] and [Na^+] with furosemide, while these variables remain largely unchanged with alkalinizing agents. The alkalosis resulting from even high-dose furosemide (1 mg/kg) is relatively mild compared to the moderate alkalosis resulting from high-dose $NaHCO_3$ (> 0.5 mg/kg), although the effects appear to be similar in duration.

CHAPTER 40

Abnormalities of body fluids and electrolytes in athletic horses

Eduard Jose-Cunilleras

The cardiovascular system delivers oxygen and nutrients to all tissues. During exercise the cardiovascular system is also involved in transferring the heat load generated in working skeletal muscles to the skin. Heat is lost by convection (transfer between media of different temperatures), conduction (direct transfer between surfaces in contact), radiation (energy absorbed or emitted at the body surface), and evaporation (conversion of a liquid to vapor and consequent cooling effect at the surface at which the change of state occurs). In equine athletes, the most important route of heat transfer during exercise is the evaporation of sweat,[1] accounting for approximately two-thirds of heat dissipation. Therefore, sweating is an essential mechanism to avoid hyperthermia during exercise. Equine sweat is an isotonic to slightly hypertonic fluid with electrolyte concentrations equal or higher than that of plasma. Consequently, horses performing athletic events of several hours duration, in which thermal balance is maintained by evaporation of sweat, will lose considerable amounts of water and electrolytes. When fluid and electrolyte deficits are not partially or totally replaced during and/or after exercise horses may develop clinical signs of dehydration and exhaustion. Clinical disorders associated with fluid, electrolyte and acid-base imbalances are most commonly observed in horses competing in different modalities of endurance rides and three-day events.

Fluid and electrolyte balance is not only important from a medical perspective but also because it relates to exercise performance. The reduction in plasma volume associated with dehydration can impair the ability to maintain adequate perfusion to the working skeletal muscle, potentially leading to fatigue, and to the skin, which may lead to excessive hyperthermia and fatigue. The relationship between hydration status and/or fluid and electrolyte supplementation and exercise performance has not been formally investigated in horses. It has been established that horses dehydrated prior to exercise will have compromised thermoregulatory function, and fluid and/or electrolyte supplementation during and immediately after exercise will hasten recovery. However, the effects of dehydration prior to exercise or fluid/electrolyte supplementation upon direct measurements of athletic performance in endurance exercise have not been formally addressed. In human athletes it is well established that exercise performance, assessed as an increase in time to exhaustion at a given exercise intensity or as a decrease in time to complete a given distance, is enhanced by ingestion of electrolyte containing solutions during exercise.[2]

Understanding of some concepts related to fluid composition is necessary for discussion of fluid and electrolyte disturbances. Concentrations of electrolytes in plasma or fluids are commonly reported in a variety of forms: weight per volume (mg/dL, g/L or %), or number of mols, osmols or equivalents per volume (mmol/L, mOsm/kg or mEq/L). One mol of any substance is the molecular weight of the substance in grams (Na^+ 23 g/mol, K^+ 39.1 g/mol, Cl^- 35.5 g/mol, Ca^{2+} 40.1 g/mol, Mg^{2+} 24.3 g/mol). Electrolytes in body fluids combine based on their charge, the number of positively charged particles (cations) and negatively charged particles (anions) is always equal, and it is often useful to express electrolyte concentrations as mEq/L. One equivalent is defined as the number of mols times its valence or number of ionic charges (valence is 1 for Na^+, K^+ and Cl^-, and 2 for Ca^{2+} and Mg^{2+}). Osmolality refers to the number of dissociated particles per kg of solvent (e.g. water) and osmolarity refers to the number of dissociated particles per liter of solvent. Those particles in solution that cannot freely diffuse across cellular membranes will exert an osmotic effect, and are referred to as effective osmols. The effective osmolality of a solution is referred to as tonicity. Isotonic fluids are those with a concentration of osmotically active particles similar to that of plasma (osmolality of equine plasma is 270–300 mOsm/kg). Hypotonic and hypertonic fluids are those with an osmolality much lower or much higher than 300 mOsm/kg, respectively.

Exercise-associated dehydration/exhaustion

- Most commonly seen in horses competing in endurance events (e.g. endurance races, competitive trail rides and three-day eventing).
- Exhaustion is due to the compound effects of heat accumulation, alterations in electrolyte, fluid and acid–base, and substrate depletion.
- Therapeutic strategy: stop exercise, cool the horse, and provide access to water and hay in mild cases. In more severe cases administration of oral electrolyte solutions via nasogastric tube and/or intravenous fluids is a must.
- Prevention: acclimatization to environment in the case of extreme heat, humidity, or altitude. Administer electrolytes and offer water to horses during endurance exercise. Avoid competitive endurance exercise with unfit or otherwise unsuitable horses (e.g. overweight Quarter Horses). Provide supplementary electrolytes in the diet to compensate for electrolyte losses in sweating.

Recognition of the disease

History and presenting complaint

Exercise-induced dehydration/exhaustion is most commonly recognized as a condition that requires medical intervention in horses exercising for protracted periods in hot environments. It is most commonly observed in horses competing in endurance rides and less frequently in horses undertaking three-day events or combined training competitions. The presenting complaint is severe depression, and lack of thirst and appetite despite apparent dehydration.

Physical examination

Clinical signs observed in horses suffering exercise-induced dehydration/exhaustion include depression, anorexia, lack of thirst despite persistent dehydration, persistently elevated rectal temperature, heart rate and respiratory rate.[3,4] Other clinical signs related to dehydration and poor cardiovascular function include dryness of mucous membranes (gums, conjunctiva), delayed capillary refill time, decreased pulse pressure, and persistent skin-fold test. Dry feces, minimal urine production, poor gastrointestinal motility, poor anal tone, ileus, and colic may also be observed. Other less common signs associated with dehydration and exhaustion include cardiac arrhythmia, muscle cramps, and/or synchronous diaphragmatic flutter.

The severity of dehydration can be subjectively assessed based on the clinical signs observed (Table 40.1). Dehydration below 5% is not detectable clinically, whereas acute dehydration above 10–12% is considered incompatible with life.

In endurance competitions, horses are evaluated at regular intervals in an attempt to assure that only those capable of safely continuing to exercise remain in the competition. At each mandatory rest period ('vet gates'), fitness to continue is assessed based on examination of general appearance, attitude, gait, pulse and respiratory rates, and evaluation of dehydration, capillary refill time, color of mucous membranes, and gastrointestinal motility. The cardiac recovery index is performed routinely in some countries during the veterinary examination at a mandatory stop. The cardiac recovery index involves taking a resting heart rate, the horse is then trotted 30 m (33 yards) out and back and the heart rate is taken again 1 min later. Generally, if the resting heart rate is low (50 bpm or less) and the heart rate taken after trotting is equal or lower than the resting heart rate the horse is considered fit to continue.[5,6] Close examination of horses at the mandatory stop and use of the cardiac recovery index may help to identify those horses with early stages of significant dehydration/exhaustion.

Table 40.1 Clinical signs observed depending on severity of dehydration

	% of body weight	Volume deficit (L) in 450 kg horse	Clinical signs
Mild	5–6	≈ 20–30	Tacky mucous membranes, decreased skin turgor
Moderate	7–9	≈ 30–40	Dry mucous membranes, depression, sunken eyes
Severe	> 9	> 40	Cold extremities, recumbency, moribund

Laboratory examination

Routine hematology reveals alterations related to dehydration and stress, which include increased plasma total protein, packed cell volume, red blood cell count, and hemoglobin; and the total white blood cell count and differential generally show neutrophilia and lymphopenia.[7–9]

Plasma electrolyte concentrations in dehydrated/exhausted horses are variable. Moderate hypochloremia is most commonly observed after endurance exercise in exhausted and non-affected horses. However, the degree of dehydration and hypochloremia, with consequent metabolic alkalosis, is generally more pronounced in affected horses. Although the characteristic acid–base abnormality is hypochloremic metabolic alkalosis, it is also reported that the fastest horses in an endurance race may develop mild metabolic acidosis due to lactate production,[8,10] which probably results in a mixed acid–base disorder with concurrent lactic acidosis and hypochloremic metabolic alkalosis. Other abnormalities can include hypokalemia, hypocalcemia, hypomagnesemia and hypo- or hypernatremia. Substantial decreases in total body electrolyte content due to sweating will be poorly reflected by changes in plasma electrolyte concentrations, because fluid and electrolyte losses are isotonic and of similar composition to plasma. Plasma electrolyte concentrations observed in horses performing endurance rides and three-day events are shown in Tables 40.2 and 40.3.

Table 40.2 Plasma electrolytes concentrations (from jugular venous blood unless specified otherwise) observed in horses competing in endurance rides (average ± SD, except Lindinger[14] average ± SE)

	Before ride	32–50 km	80–100 km	160 km	Reference

Plasma glucose concentrations in dehydrated/exhausted horses are quite variable. Hyperglycemia can occur in exhausted horses and those with heat-stroke due to high concentrations of stress hormones, such as the catecholamines and cortisol. Hypoglycemia can also occur during protracted exercise because of depletion of liver glycogen, which will lead to fatigue and altered mentation due to lack of glucose availability to neurons.

Dehydration and possibly renal disease may be apparent by elevation in blood urea nitrogen and creatinine concentrations in horses performing protracted exercise. If urine can be obtained, it may be highly concentrated due to severe dehydration, or may be poorly concentrated despite severe dehydration in cases of ischemic renal tubular damage. The use of urinary specific gravity, urinary to plasma creatinine ratios and fractional excretion ratios of electrolytes in the diagnosis and management of acute renal failure is discussed below under the heading 'Acute renal failure' (page 914).

Plasma concentrations of creatine kinase (CK) and aspartate aminotransferase (AST or GOT) may be elevated as a consequence of recent muscular activity, and in case of exertional rhabdomyolysis these enzymes are elevated 20–100-fold or more.

Treatment and prognosis

Prognosis varies from favorable to very grave depending upon severity of clinical signs, promptness of medical therapy, and potential complications. Exercise-induced dehydration and exhaustion is responsive to medical therapy if fluid therapy is aggressive. Unfortunately, loss of horses competing in endurance events still occurs, and the importance of close veterinary supervision and diligent therapeutic intervention cannot be overemphasized.

Immediate care should include stopping exercise and, if possible, moving the horse into the shade. If available, fans should be placed close to the horse to promote cooling. The horse should be cooled by repeated rinsing/bathing with abundant volume of cold water over the entire body. In studies performed under field and laboratory conditions, repeated application of cold water over the entire body surface decreases rectal temperature more quickly than no bathing or bathing with water at ambient temperature.[11,12] These treatments do not cause muscle cramps or myopathies. Wet sheets or towels left in place over the horse's neck or trunk should be avoided, unless cold water is sprayed repeatedly because wet towels will only serve to provide unneeded insulation in a heat-compromised patient.[4]

The choice of oral versus intravenous fluid administration or a combination of both should be based mostly on severity of the clinical signs, but cost and manpower may be other considerations. Oral fluid therapy may be considered in mildly affected horses that may not drink sufficiently on their own. It is generally recommended to administer isotonic electrolyte

Table 40.4 Composition and tonicity of homemade recipes for electrolyte solutions for nasogastric administration

	1 liter	1 gallon (3.8 liters)	Electrolyte composition (mEq/L)	Tonicity
0.45% NaCl	4.5 g (0.16 oz)	17 g (0.6 oz, 1 tbsp)	Na^+ 77, Cl^- 77	Hypotonic
0.9% NaCl	9 g (0.32 oz)	34 g (1.2 oz, 2 tbsp)	Na^+ 154, Cl^- 154	Isotonic
Dr Carlson's formula[3]	–	1 tbsp table salt + 1 tbsp Lite salt in 4 liters	Na^+ 107, K^+ 28, Cl^- 135	Isotonic
Dr Smith's formula[90]	–	1 part $CaCO_3$ (ground limestone) + 3 parts Lite salt; 2 oz per gallon	Na^+ 96, K^+ 75, Cl^- 154, Ca^{2+} 75, HCO_3^- 25	Slightly hypertonic

Lite salt: mixture of KCl:NaCl at 50:50, Morton Lite salt mixture, Morton International, Rohm and Haas, Philadelphia, PA, USA; tsp, teaspoon (5 ml); tbsp, tablespoon (15 ml); oz, ounce (28.35 g); 1 US gallon = 3.8 L.

solutions at a rate of 6–8 L every 30–60 min via nasogastric tube. Contraindications for oral fluid therapy are nasogastric reflux and signs of colic. If the patient's clinical condition does not improve within the following 2–4 h, intravenous fluids should be administered as soon as possible. Table 40.4 lists some recipes for homemade isotonic solutions.

A balanced polyionic solution that is approximately isotonic is recommended. To that effect, Carlson[3] described the following formula, which is similar in composition to electrolytes lost in sweat and is close to isotonic:

> Mix 1 level tablespoon of table salt (16.6 g NaCl) and 1 level tablespoon of Lite salt (16.9 g of 50:50 mixture of NaCl:KCl) in 4 L (≈ 1 gallon) of water (Na^+ 107 mEq/l, K^+ 28 mEq/l and Cl^- 135 mEq/l, 270 mOsm/l).

The effect of tonicity, glucose supplementation and temperature of oral electrolyte solutions is discussed below under the heading 'Rehydration after exercise'.

Intravenous fluid therapy

Intravenous fluids are classified as crystalloids or colloids. Crystalloid fluids are solutions containing electrolyte and non-electrolyte solutes capable of distributing among the body compartments. Colloid fluids contain large-molecular-weight particles, which do not normally pass through capillary membranes, and some smaller more diffusible particles. Colloid fluids include dextrans, glucose polymer mixtures of low (dextran 40) or high-molecular-weight (dextran 70 and dextran 75), gelatins, modified bovine collagens (oxypolygelatin), and hydroxyethyl starch preparations (hetastarch and pentastarch). Colloid fluids are indicated in those patients suffering increased capillary permeability and hypoproteinemia. Exhausted and dehydrated athletic horses will not generally require colloid fluids. Therefore, the following discusses the administration of crystalloid fluids that are used commonly in field situations for treatment of athletic horses.

The ionic composition, pH and osmolality of commonly used crystalloid fluids are presented in Table 40.5. The composition of polyionic fluids resembles that of extracellular fluid. Note that Ringer's solution and 0.9% saline solution have a relative excess of sodium and especially chloride when compared to extracellular fluid concentrations. Exhausted/dehydrated horses generally have greater deficits of electrolytes relative to water (i.e. hypotonic dehydration) because fluid loss (sweat) is isotonic to slightly hypertonic and fluid intake (fresh water) is hypotonic. Therefore, the relative excess of sodium and chloride in Ringer's and saline solutions works to our advantage in treating exhausted/dehydrated endurance horses.

Anions used as buffers in some fluids are added as a source of base because their metabolism in the body yields bicarbonate:

$$\text{Lactate: } C_3H_5O^-_3 + 3\ O_2 \rightarrow 2\ CO_2 + 2\ H_2O + HCO^-_3$$

$$\text{Acetate: } C_2H_3O^-_2 + 2\ O_2 \rightarrow CO_2 + H_2O + HCO^-_3$$

Horses involved in endurance rides and those in the cross-country test (speed and endurance test, second day) of a three-day event competition will commonly suffer substantial fluid and electrolyte depletion, and hypochloremic metabolic alkalosis is the characteristic acid–base disorder. On occasion, in an attempt to dissipate heat, some horses have persistently elevated respiratory rate, which may lead to hypocapnia (low CO_2 tension in the blood) and mixed respiratory and metabolic alkalosis. Therefore, the primary goal is to correct the volume deficit with chloride-rich fluids, such as Ringer's solution or 0.9% saline solution supplemented with potassium and calcium. A suggested amount of calcium supplementation is 10–20 mL of 23% calcium gluconate per liter of saline solution (10–20 mEq Ca^{2+}/L or 5–10 mmol Ca^{2+}/L). It is contraindicated to administer potassium at rates higher than 0.5 mEq/kg/h because of potential for cardiotoxicity. Unless cardiovascular function is closely monitored, potassium supplementation in intravenous fluids should not exceed 15–20 mEq/L. Ringer's solution is preferred over lac-

Table 40.5 Electrolyte composition of selected common sterile intravenous fluids

	Na^+ (mEq/l)	K^+ (mEq/l)	Cl^- (mEq/l)	Ca^{2+} (mEq/l)	Mg^{2+} (mEq/l)	Buffer* (mEq/l)	pH	mOsm/L
0.9% NaCl	154	0	154	0	0	0	5.0	308

tated Ringer's solution because, as mentioned above, lactate is metabolized to bicarbonate and may have an alkalinizing effect, which is contraindicated in an already alkalotic patient. However, in dehydrated horses the volume of fluid administered is more important than the actual acidifying/alkalinizing nature of the fluid, and one should not forego fluid administration if the only available fluids are alkalinizing, such as lactated Ringer's solution.

Volume of intravenous fluids and rate of administration

In general, calculation of the volume of intravenous fluids to administer is based on estimation of daily maintenance requirements, current fluid deficits, and assessment of ongoing losses. However, in practical terms, maintenance requirements and ongoing losses can be ignored in exhausted/dehydrated horses unless the horse develops diarrhea, ileus with abundant nasogastric reflux, or polyuric renal failure. The goal of intravenous fluid therapy in exhausted/dehydrated horses is to replace water and electrolyte deficits to improve cardiovascular function and allow the horse to regain homeostasis, and to stimulate normal food and water intake.

Horses engaged in prolonged strenuous exercise events, like endurance competitions of 80 to 160 km or more, are reported to lose 4–8% of body weight (as much as 10% in a few horses) during the competition.[9,13–15] Horses undertaking the speed and endurance test of a three-day event or a combined test may lose an average of 2–4% of body weight, which increases to up to 6–9% in a few horses in certain competitions.[16–19] However, sweating rates and consequently fluid and electrolyte losses depend upon environmental conditions, and horses exercising in hot or hot and humid conditions develop greater deficits when compared to more temperate conditions.[20] If 90% of the body weight loss is fluid loss, then an estimated 20–40 L of fluids are lost in a 450-kg horse (≈ 1000 lb) (Table 40.6). A simple estimation of the fluid deficit can be calculated as:

$$\text{Fluid deficit (L)} = \%\ \text{dehydration} \times \text{body weight (kg)}$$

The rate of administration will be calculated as the fluid deficit divided by the duration of i.v. infusion. If one is to replace the volume deficit in 6–12 h the infusion rates will be 0.5–2.5 mL/s, depending on fluid deficit and duration of infusion. For example, if we intend to replace fluid deficits in a 450-kg horse with 7% dehydration over 6 h:

$$\text{Fluid deficit (L)} = 7\% \times 450\ \text{kg} = 32\ \text{L}$$

Table 40.6 Fluid deficits (L) depending on body weight (kg) and estimation of dehydration (%)

% dehydration	350 kg	400 kg	450 kg	500 kg	550 kg
5%	18 L	20 L	23 L	25 L	28 L
7%	25 L	28 L	32 L	35 L	39 L
9%	32 L	36 L	41 L	45 L	50 L

$$\text{Infusion rate (mL/s)} = \frac{32\ \text{L}}{6\ \text{hours}} \times \frac{1000\ \text{mL}}{1\ \text{L}} \times \frac{1\ \text{h}}{60\ \text{min}} \times \frac{1\ \text{min}}{60\ \text{s}} \simeq 1.5\ \text{mL/s}$$

The flow rate can be estimated by counting the number of drops/s in the drip chamber of the administration set. Most fluid administration sets commercially available for large animals deliver 10 drops/mL. In practical terms, to administer 5–10 L/h simply requires full open intravenous administration through a 14-gauge catheter placed in one or both jugular veins. For exhausted horses with hypovolemic shock, large-bore catheters (10–12 gauge) and wide-bore administration sets that allow rapid intravenous fluid administration (up to 30–40 L in 1–2 h) are recommended for resuscitation.

Prevention

Horses competing in endurance exercise events develop substantial body fluid losses, mostly in the form of water and electrolytes lost in sweat, which is manifest as a 3–6% loss in bodyweight by the end of the competition.[13–18] In addition, weight loss persists after an overnight recovery period, which may be detrimental for horses performing multiday events. In an attempt to decrease the risk of thermoregulatory failure consequent to dehydration and to enhance recovery of horses performing endurance-type exercise it has been recommended to supplement electrolytes in drinking water, with concentrate feeds or as hypertonic oral pastes. These and other strategies are discussed below.

Strategies of water and electrolyte replacement/supplementation before, during, and immediately after exercise

Before exercise In horses performing strenuous prolonged exercise, administration of isotonic oral electrolyte fluids via nasogastric tube prior to exercise has been advocated to maintain adequate levels of hydration during exercise and in an attempt to improve cardiovascular and thermoregulatory function during exercise. In man, hyperhydration prior to prolonged exercise results in better cardiovascular function and heat dissipation than if exercise is performed in the euhydrated state.[21] However, the benefits of pre-exercise fluid loading in horses in controlled laboratory conditions have been equivocal. In a recent study of hyperhydration on physiological strain of horses exercised in the heat, administration of 10 L of water or isotonic carbohydrate–electrolyte solution before and between two 45-min bouts of trotting exercise, when compared to no fluid, resulted in maintained cardiovascular function and sweating rate and decreased heat storage.[22] The effect of fluid administration was observed during the second bout of exercise and was attributed to maintenance of euhydration by oral fluid replacement.[22] In a series of laboratory studies, Sosa León et al determined the effect of oral electrolyte fluid administration prior to either a 90-min bout of trotting exercise or a standardized exercise test (SET) intended to simulate the second day of a three-day event.[23–25] Administration of ≈ 26 L of isotonic electrolyte fluid prior to SET, or ≈ 18 L of

hypotonic carbohydrate–electrolyte solution prior to trotting exercise, when compared to no fluid, resulted in maintained plasma volume but cardiovascular (i.e. cardiac output, stroke volume) and thermoregulatory (i.e. core temperature) function were not improved, and fluid administration resulted in arterial hypoxemia. Marlin et al[26] showed that administration via nasogastric tube of 4 L of isotonic fluids to resting horses caused a modest plasma volume expansion when compared to administration of same volume of water. However, administration of the same isotonic electrolyte solution prior to a 40-min low-intensity treadmill exercise bout did not alter the exercise-induced plasma volume expansion.[26] Relevant differences between the study by Geor et al[22] and the rest of the previous studies are that oral fluids were administered not only before but also in between two bouts of exercise and, more importantly (and unlike the rest of the studies), horses exercised in hot environment. Therefore, the purported beneficial effect of hyperhydration before exercise on thermoregulatory and cardiovascular function may be more critical in the heat when heat dissipation is most dependent on sweat evaporation. In summary, the benefits of fluid loading prior to exercise have not been clearly established in horses, and direct measurements of exercise performance have not been performed.

The efficacy of hyperhydration in human subjects is limited when water or hypotonic carbohydrate–electrolyte solutions are ingested due to rapid renal excretion of excess fluid. Administration of solutions containing glycerol is another strategy that has been studied in order to induce a state of hyperhydration before exercise. In resting human subjects and in horses, glycerol administration induces a state of hyperhydration by enhancing fluid retention due to delayed urinary excretion of the excess fluid.[27,28] However, using glycerol, rather than water, as the liquid base to mix sodium chloride and potassium chloride administered during and after exercise is no more effective than electrolytes alone in maintaining euhydration during endurance exercise in horses.[29,30]

Administration of a salt supplement and free access to water prior to exercise may be a practical alternative to intragastric administration of electrolyte solutions. Coenen et al[31] reported greater water intake during and after a 2-h treadmill exercise bout when horses were fed a salt supplement prior to exercise. Similarly, Schott et al[30] reported that administration of salt pastes before and during a 60-km simulated endurance resulted in greater water intake and lower body weight loss.

During exercise Allowing horses to drink salt water during and/or immediately after exercise appears to be beneficial because it enhances total fluid intake during the early recovery period and attenuates the magnitude of weight loss observed during the overnight recovery.[32,33] In a recent laboratory study, horses received furosemide 2 h prior to a 45-km (28-mile) treadmill exercise bout.[32] The combined effect of diuretic administration and endurance exercise resulted in bodyweight losses of 5.2–5.7% (20–22 kg or approximately 18–20 L), which is similar to that observed in competitive endurance rides.[15] When horses were offered water, 0.45% saline, or 0.9% saline immediately after exercise and then given free access to water, total fluid intake during the first hour after exercise was 11.4 L, 16.6 L, and 18.5 L, respectively.[32] However, these interventions did not result in complete replacement of fluid deficits by the next day. Therefore, it appears to be beneficial to offer salt water (0.9% NaCl, 9 g in 1 L water, 1.2 oz [2 level tablespoons] in 1 US gallon), rather than fresh water, immediately after exercise to stimulate a greater water intake during the recovery period.

Electrolytes can be supplemented by mixing them in grain, beet pulp or pelleted feeds, or by direct oral administration instead of offering salt water during or immediately after exercise, which may not be accepted by some horses. Endurance riders commonly supplement their horses with electrolytes as a top dressing on grain or as an oral paste. Electrolyte supplementation as an oral paste before and during a simulated 60-km (37.5-mile) endurance ride on a treadmill resulted in attenuated weight loss after exercise due to greater voluntary water intake during and after the ride. Furthermore, bodyweight loss recovered by 48 h after exercise in supplemented horses, whereas the bodyweight of non-supplemented horses remained decreased.[29,30] In this study, total electrolyte supplementation in horses of mean body weight of 370 kg was 75 g of potassium chloride and 150 g of sodium chloride (≈ 2500 mEq Na^+, ≈ 1000 mEq K^+, and ≈ 3500 mEq Cl^-) given as smaller doses divided before and during treadmill exercise. This supplementation regimen was estimated to replace electrolyte losses in 20–25 L of sweat.[29,30] Similarly, Coenen et al[31] reported greater water intake during and after a 2-h treadmill exercise bout when horses were fed a salt supplement prior to exercise that provided one-half of the sodium and chloride and one-fifth of the potassium administered in the study of Schott et al.[30]

Some field studies have attempted to address the effect of oral electrolyte supplementation during endurance rides. During a 62-km endurance ride, horses were offered either water, water and a salt paste (30 g NaCl), or a 0.9% saline solution at 20-km, 42-km, and the end of the ride.[33] Total fluid intake was highest and body weight loss was lowest when horses were offered 0.9% saline solution during and immediately after the ride. Administration of salt paste had an intermediate effect but the amount of sodium chloride administered in this manner was also half as much as that by the 0.9% saline drink. Ralston et al[34] investigated the effect of oral electrolyte administration during a 96-km endurance race. In this study, a 60-g oral paste (1.6 g NaCl, 3 g K^+, 0.9 g Ca^{2+} per dose; the rest was amino acids and molasses) was given the night before and at 19 and 50 km during the race. The authors reported that supplemented horses recovered slightly faster at the 50-km checkpoint, and serum potassium concentration decreased to a lesser extent in supplemented horses.[34] However, interpretation of this study is complicated by the low number of unsupplemented horses (3 not supplemented versus 14 supplemented) and the relatively low electrolyte content of the product used.

Rehydration after exercise The composition and temperature of oral electrolyte solutions have been shown to

influence fluid absorption in man.[35,36] Similarly, the effectiveness of oral rehydration solutions given to horses via nasogastric tube after exercise or after diuretic-induced isotonic dehydration depends on the nature of the fluid.[37–39] It is generally recommended in horses to administer water with electrolytes with or without carbohydrates as an isotonic solution, rather than water alone.

It has been observed in humans that fluid absorption is optimal if the oral electrolyte solution is hypotonic, contains glucose, and is below room temperature.[36,40] Addition of glucose to electrolyte solutions for oral rehydration in human athletes appears to enhance electrolyte absorption. This effect is argued to be due to the mechanism of sodium absorption in the small intestine. Sodium is absorbed in the small intestine coupled to absorption of glucose. Sodium absorption is an active process mediated by the concentration gradient generated by Na^+, K^+-ATPase pumps that maintain low intracellular sodium and high extracellular sodium concentrations. Sodium in the intestinal lumen is absorbed by facilitated diffusion with a transport protein that cotransports glucose and sodium. Therefore, glucose in the intestinal lumen facilitates intestinal sodium absorption. Absorption of chloride follows sodium due to the electrical gradient generated by sodium absorption. However, addition of glucose to oral electrolyte solutions in horses dehydrated by furosemide administration does not facilitate fluid and electrolyte absorption.[38,39]

Several models of dehydration have been used to study rehydration strategies. These include controlled treadmill exercise, the administration of the loop diuretic furosemide, and a combination of the furosemide administration and exercise. Although it has been argued that the isotonic dehydration induced by furosemide administration mimics exercise-associated fluid and electrolyte disturbances, it should be realized that the overall physiologic perturbations are quite different. Nonetheless, the furosemide model has provided some insight into the effectiveness of different rehydration solutions. For example, in horses dehydrated by administration of furosemide, hypertonic electrolyte solutions (628 mOsm/kg) appear to delay gastric emptying and impair electrolyte absorption, possibly due to the drawing of water into the gut.[39] However, gastric emptying and fluid absorption is not altered when isotonic fluid is administered at temperatures of 5–37°C (41–98.6°F).[39] Concerning exercise studies, Hyyppä et al[41] administered either 8 L of isotonic carbohydrate and electrolyte solution or water to horses after treadmill exercise intended to simulate the second day of a three-day event. Compared to water alone, the carbohydrate–electrolyte solution resulted in better recovery of body weight and lower body weight loss in a subsequent exercise bout the following day.[41] Administration via nasogastric tube of 6 L of isotonic carbohydrate–electrolyte solution immediately after 40-min of low-intensity treadmill exercise resulted in plasma volume expansion when compared to administration of same volume of water.[37] In summary, administration of and oral isotonic rehydration solution after exercise, when compared to water administration or no fluid, results in more effective rehydration and lower weight losses in a subsequent bout of exercise.

Administration of oral electrolyte pastes to horses with free access to water may be an equally effective and more practical form of rehydration after exercise, when compared to the administration of isotonic fluids via nasogastric tube or allowing horses to drink salt water. The effects of electrolyte paste administration on rehydration after furosemide-induced dehydration has been studied.[42,43] Diuretic-induced dehydration caused a body weight loss of 4.1–5.2%. The administration of 0.5 g/kg of NaCl or 0.25 g/kg of NaCl plus 0.25 g/kg of KCl or 0.3 g/kg of NaCl plus 0.1 g/kg of KCl in these horses increased voluntary water intake and improved rehydration when compared to no oral electrolyte administration.[42,43]

Diet, fiber content and the large intestine as a fluid and electrolyte reservoir

It is generally accepted that the large intestine functions as a reservoir of fluid and electrolyte for horses engaged in prolonged exercise. However, there is a paucity of direct measurements or estimations of the volume of fluid and electrolyte content in the large intestine, as well as a quantitative assessment of the contribution of fluid and electrolyte absorption from the large intestine during exercise or in the recovery period. Methodological limitations are probably the main reason for our limited knowledge of fluid and electrolyte contents of the different body compartments. Estimations of the major components of the extracellular fluid are: plasma (4–6% of bodyweight), interstitial and lymph fluid (8–10% of bodyweight) and transcellular fluids (6–10% of bodyweight), the largest component of which is the gastrointestinal fluid.[44] However, only extracellular fluid volume and plasma volume can be measured in the living horse. A limited number of studies have determined the water or gastrointestinal content of ponies and a small number of horses at post-mortem. From these studies one can estimate the water content in the large intestine of the horse to be 8–18% of the bodyweight, depending on diet and the time between feed ingestion and euthanasia. It is also important to note that the large intestine of 150-kg ponies has a higher water content (as a percentage of body weight) compared to 500-kg horses.[45–48] In a recent study, Warren et al[49] obtained direct measurements of extracellular fluid volume (226 mL/kg) and plasma volume (55 mL/kg) and estimated the gastrointestinal fluid volume of 550-kg horses to be 47–54 L (9–10% of bodyweight) assuming that interstitial fluid accounted for 8% of the bodyweight.

The amount of dietary fiber is thought to influence the size of a horse's large intestinal fluid reservoir. In 100–300-kg ponies, Meyer et al[50] demonstrated that feeding a high-fiber diet (hay), when compared to low-fiber diet (complete feed made with grains, bran, and beet pulp), resulted in greater water and electrolyte content in the large intestine (183 and 101 mL water/kg bodyweight, and 398 and 212 mg Na^+/kg bodyweight in high- and low-fiber diets, respectively). However, in the study by Warren et al[49] dietary fiber content did not significantly alter large intestinal water content (99 versus 86 mL water/kg bodyweight in high- versus low-fiber diet, respectively). Meyer et al[46] also described that, when

comparing five paired groups of exercised ponies and rested ponies on the same diet, low intensity exercise (2.8–3.3 m/s for 1–3 h) resulted in absorption from the gastrointestinal tract of 22 ± 7 (mean ± SD) ml of water, 43 ± 30 mg Na^+ and 23 ± 14 mg Cl^- per kg of bodyweight. These averages extrapolated to a 450-kg horse would suggest that during exercise ≈ 10 L of water, ≈ 19 g Na^+ (840 mEq Na^+), ≈ 10 g Cl^- (290 mEq Cl^-) may be absorbed from the ≈ 45 L present in the gastrointestinal tract.

In summary, based on the limited data available at this time, it appears that water and electrolytes absorbed from the gastrointestinal tract of non-supplemented horses may play an important role during exercise but that quantitatively the amounts absorbed are at best modest compared to losses in the form of sweat. As an example, estimated losses in sweat during an exercise bout lasting 2 h are ≈ 20 L of fluid and ≈ 58 g Na^+ [2500 mEq Na^+], ≈ 106 g Cl^- [3000 mEq Cl^-] and ≈ 27 g K^+ [680 mEq K^+], which is two-fold, three-fold and 10-fold higher than the amounts of water, sodium and chloride, respectively, that are potentially available by absorption from the gastrointestinal tract.

Electrolyte requirements in athletic horses

The electrolyte requirements of adult horses vary widely depending upon the level of physical activity. Horses performing protracted exercise bouts may lose large amounts of Na^+ and Cl^- because their sweat has a high NaCl content, similar to that of plasma (Table 40.7). In addition, as the sodium and chloride content of horse feedstuffs is low, salt supplementation is required to offset sodium and chloride losses in sweat. In contrast, potassium losses in sweat are lower and some feedstuffs (i.e. most forages) have a high content of potassium, which makes potassium balance less of a concern.

Electrolyte supplementation is generally provided by giving free access to a salt block. However, it has been shown that there is great individual variation of voluntary sodium intake from a salt block. In a study using Standardbred trotters in racetrack training, total sodium intake of some horses did not even meet the suggested maintenance requirement of 20 mg/kg/day (10 g of sodium or 25.4 g of table salt in a 500-kg horse).[51,52] In contrast, Houpt et al[53] found that salt intake from salt blocks was excessive (over 100 g) in furosemide-treated horses. It appears that salt intake in horses may not be closely regulated to balance losses. Therefore, it has been recommended to provide supplemental loose salt in the diet rather than allow horses to compensate for their electrolyte losses by voluntary intake from salt blocks.

Few studies have addressed the requirement of electrolytes based on dietary intake and direct measurements of electrolyte losses in sweat during training and performance exercise. Although dietary intake can be measured easily, it is more difficult to make a complete assessment of ongoing fecal and urinary losses to account for stimulation of compensatory mechanisms. Some studies have attempted to estimate ion losses based on changes in extracellular fluid volume and plasma electrolyte concentrations, but this approach underestimates ion losses in sweat by over 50% when compared to direct measurement of sweating rates and sweat electrolyte concentrations.[54] Studies that have measured sweat ion losses during training in various environmental conditions and exercise bouts intended to simulate the second day of a three-day event and prolonged low-intensity exercise have demonstrated that a balanced ration and appropriate ion

Table 40.7 Suggested electrolyte requirements (mg/kg bodyweight daily) of adult horses depending on physical activity and sweat losses

	Maintenance	Slight loss (≤ 5 L sweat)	Moderate loss (10–15 L sweat)	Intense loss (≥ 20 L)	Reference

Slight loss (≤ 5 L sweat), e.g. 30 min of trotting in summer.
Moderate loss (10–15 L sweat), e.g. Thoroughbred and Standardbred training and racing in temperate climates.
Intense loss (≥ 20 L), e.g. speed and endurance of three-day event in summer and endurance rides.
Note: horses suffering moderate and intense sweat losses should receive above amounts as salt supplements in days of exercise. Otherwise they should receive maintenance requirements. Fresh water should always be available, especially when salt is supplemented.

supplements can replace sodium and chloride losses in sweat. McCutcheon et al[54] demonstrated that dietary intake of sodium, potassium, and chloride was adequate to replace daily electrolyte losses due to sweating during training in hot and cool conditions when the diet of 450-kg horses was supplemented with a salt supplement that provided 40 g sodium, 26 g of potassium, and 84 g of chloride. However, these same horses, when performing a simulated speed and endurance test of a three-day event in hot environment, had sodium losses more than twice those incurred during more temperate conditions and about 30% higher than the sodium daily intake.

In summary, continued salt supplementation in the form of salt water, oral electrolyte pastes, or electrolytes top-dressed on the ration appears to be necessary in athletic horses because of increased requirements related to loss of electrolytes in sweat.[32,54] A number of commercial electrolyte supplements and homemade recipes are available to supplement the diet of horses that sweat profusely during training and competition. However, the composition of such products is very different and one should carefully examine the composition before choosing any one product (Table 40.8). It is rather common to recommend the addition of 50–75 g (1.8–2.6 oz) of common table salt to the diet of horses exercised heavily in hot environments.

Etiology and pathophysiology

Dehydration will occur during exercise as a consequence of sweating. Sweating allows heat dissipation during exercise, however, protracted fluid losses can result in compromised cardiovascular function, which impairs thermoregulatory function and may eventually lead to fatigue or exhaustion if

Table 40.8 Comparison of the electrolyte content of selected commercially available electrolyte supplements and homemade recipes when administered at the recommended dose

M: Kraaft salt, Kraaft, Sweden.
* Recommended total amount to be given divided in smaller doses.
[a] Flaminio[93] and personal communication Flaminio 2002. Preparation: 3 parts NaCl, 1 part KCl, 1/4 part of calcium (calcium acetate) and 1/8 part of magnesium (magnesium citrate) dosed as 20 g [0.7 oz] before ride, every 30 km and after ride.
[b] Bryant, 1993, personal communication in Schott.[95] Suggested preparation by author (EJC): 1 part of NaCl, 2 parts of Lyte salt (NaCl:KCl of 50:50), 1 part of calcium carbonate, dosed as 57 g [2 oz] increments.
[c] Frazier.[94] Preparation: 2 parts of Lyte salt (NaCl:KCl of 50:50), 1 part of calcium carbonate and 1 part of magnesium oxide dosed as 57 g [2 oz] at each veterinary checkpoint.

Table 40.9 Electrolyte composition (in mEq/L) of horse plasma, sweat and skeletal muscle

	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	Ca^{2+} (mmol/L)
Plasma	132–146	3.0–5.0	98–110	2.8–3.4
Sweat[20]	117–134	26–42	142–156	2–3
Muscle, horses				
mEq or mmol/kg dw (ww)[60]	40 (10)	305 (76.3)	120 (30)	10 (2.5)
mEq/L[59]		147		
mEq/kg wet weight[61]		91		
mEq/kg dw (ww)[62]		222 (74)		
Muscle, humans mEq/L[63]	10	142	4	2

Gottlieb-Vedi et al[60] and Wilson et al[62] reported as values in dry weight (dw), transformed to wet weight (ww) values by dividing by 4 (water of muscle is ~ 750 mL/kg, therefore 1 kg of dry weight is 4 kg of wet weight).

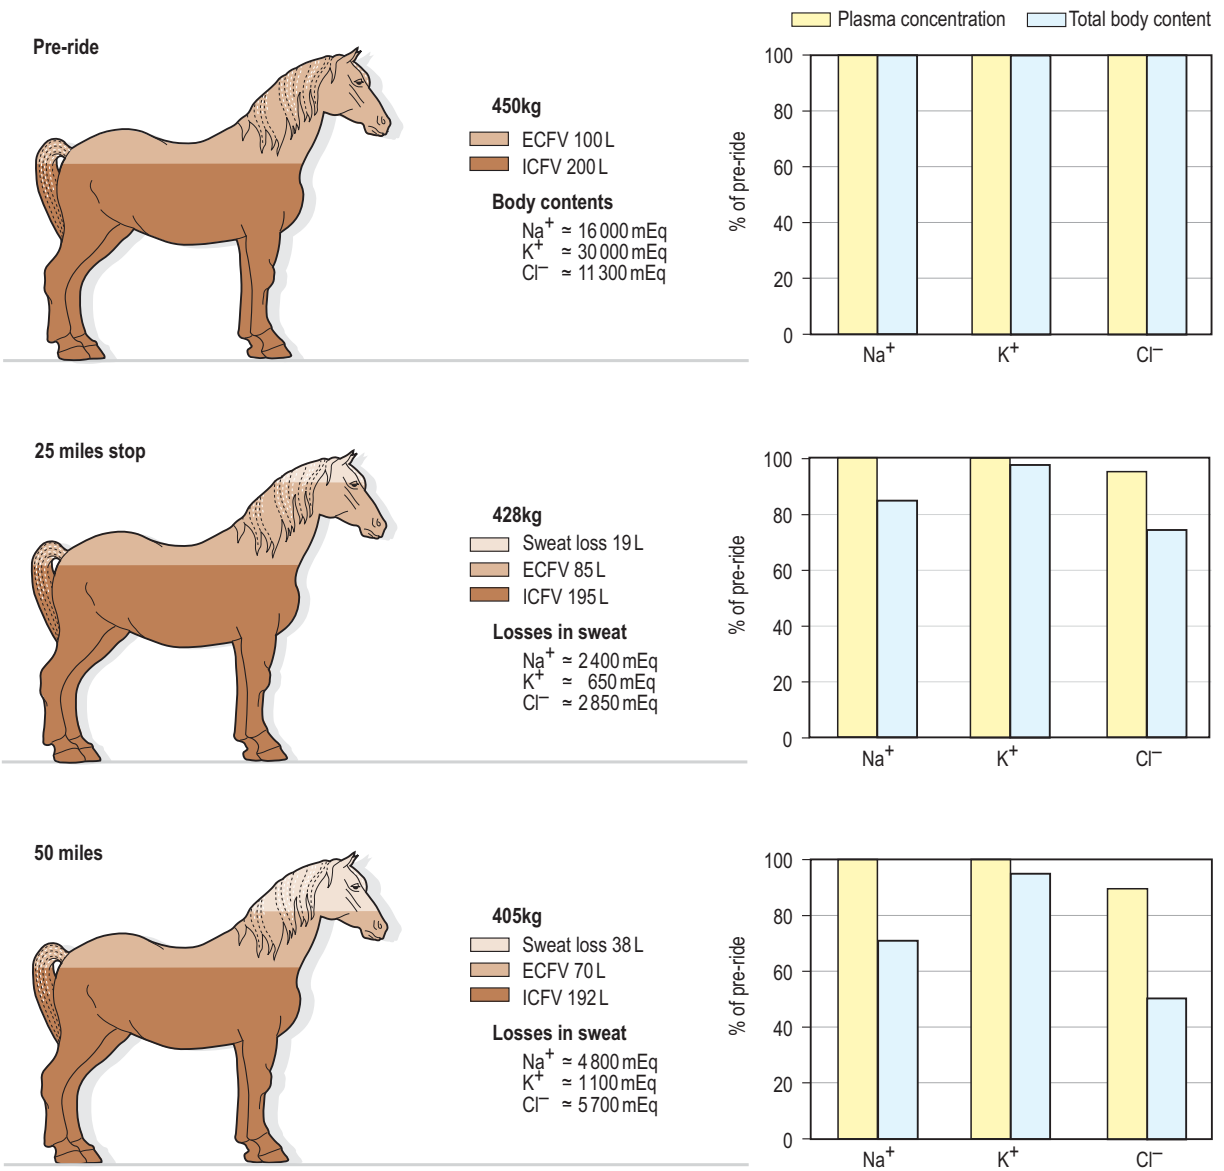

Fig. 40.1
Estimates of fluid and electrolyte losses during an 80-km (50-mile) endurance ride. ECFV, extracellular fluid volume; ICFV, intracellular fluid volume. (Adapted from Schott and Hinchcliff[57] with permission).

fluid and electrolyte losses are not replaced. We should probably keep in mind that evolution has equipped the horse to maintain body temperature during short sprints, although hyperthermia can occur with short bouts of exercise. However, no wild or feral horse will run several hours at high speeds, as we force endurance horses to do.

Rehydration becomes necessary after prolonged exercise or after episodes of water deprivation and intense sweating, as may occur during transportation in summer months. Effective rehydration may improve performance and reduce the risk of illness in subsequent exercise events. It is well established in horses that hypertonic dehydration due to water deprivation and isotonic dehydration due to furosemide administration will impair thermoregulation during a subsequent low-intensity treadmill exercise bout even in favorable ambient temperature and humidity (21–22°C, 25–40%).[55] In both forms of dehydration, the sweating rates were similar to the euhydrated state but heat transfer from the core to the periphery was decreased in horses dehydrated prior to exercise when compared to euhydrated state which was hypothesized to be caused by decreased blood flow to the skin.[55] This hypothesis is supported by the observation of decreased plasma volume during exercise in dehydrated horses compared to the euhydrated state.[56]

Losses of fluid and electrolytes in sweat during prolonged strenuous exercise induce a state of isotonic dehydration because electrolyte concentrations in sweat are similar to those in plasma (Table 40.9). Because an increase in plasma osmolality is a more potent stimulus for thirst than hypovolemia, a thirst response is not triggered until a significant state of dehydration occurs. This concept is referred to as 'involuntary dehydration', a state in which mild to moderate dehydration (2–5%) develops without triggering voluntary water consumption. Although involuntary dehydration has not been well documented in horses, it is commonly observed that endurance horses drink little during the first half of a ride.

Figure 40.1 shows estimates of fluid and electrolytes losses in horses during low-intensity protracted exercise (e.g. 80-km [50-mile] endurance ride). Note that the magnitude of these deficits is poorly reflected by changes in plasma concentrations of electrolytes due to the nature of the losses. The following assumptions were used to calculate total fluid and electrolyte deficits during a 50-mile ride:

- a 450-kg horse has lost 5% of the bodyweight (BW) (22.5 kg) at the 25-mile checkpoint and 10% of BW (45 kg) at the end of the ride
- total body water (TBW) is 666 ml/kg of body weight (BW), extracellular fluid volume is 222 mL/kg BW, intracellular fluid volume is 444 mL/kg BW, and plasma volume is 5 mL/kg BW
- 100% of the bodyweight losses represent body water losses (which includes urinary, fecal, respiratory, and sweat losses)
- after accounting for water and feed consumption, and losses in urine, feces and via the respiratory tract sweat fluid losses were 85% of body water losses, as described by Kingston et al[58]
- similarly to values reported in Table 40.2, plasma sodium and potassium concentrations did not change and plasma chloride concentration decreased from 105 mEq/L to 100 mEq/L by 40 km (25 miles) and to 95 mEq/L by 80-km (50 miles)
- sweat, and intramuscular potassium concentrations are as reported by McCutcheon & Geor[20] and Pickar et al[59] (see Table 40.9)
- intracellular electrolyte concentrations are assumed to be equal to those measured intramuscularly.

Note that intramuscular K^+ concentrations reported by Gottlieb-Vedi et al,[60] Johnson et al,[61] and Wilson et al[62] appear to be excessively low and intramuscular Cl^- concentrations excessively high when compared to well-established values in other species,[63] therefore intramuscular Na^+ and Cl^- concentrations were used from Rose[63] and intramuscular K^+ concentrations were used from Pickar et al[59] (see Table 40.9).

Epidemiology

After lameness, metabolic conditions (dehydration, synchronous diaphragmatic flutter, exhaustion, etc.) are the most common medical reason for elimination of horses from endurance events. As an example, 10–30% of non-finishing

Table 40.10 Completion rates and causes of disqualification in the Tevis Cup

Year/no. horses	% Non-finishers	% Lame	% Metabolic	% Rider	% Over time
2002/216	57	32	30	21	17
2001/225	60	60	15	19	6
2000/259	51	67	21	19	17
1999/224	49	61	10	17	12
1998/219	45	59	22	9	9

From: Tevis Cup Ride Home Page (www.foothill.net/tevis).
Note: Non-finishers, horses that did not complete the race; lame, horses disqualified due to musculoskeletal injury; metabolic, horses disqualified due to dehydration, synchronous diaphragmatic flutter, or other medical condition; rider, horses removed from competitions by rider's decision; over time, horses disqualified at a checkpoint due to being over time.

horses in the Tevis Cup have been disqualified during the last 5 years because of metabolic reasons (Table 40.10). The Tevis Cup is a one-day 160-km (100-mile) endurance race that takes place in the Sierra Nevada mountains of California. The completion rate in the Tevis Cup during the last 20 years has varied between 40–66%. The number of horses starting the race during the last 20 years has varied between 157 and 271.

In a study of the reasons for elimination in endurance competitions that take place in Europe and in Arabic countries (n = 7117 horses) it is reported that, on average, lameness accounts for 63% of the disqualifications and metabolic conditions account for 24%.[64] Endurance competitions of 80–110 km were reported to have the highest percentage of horses disqualified due to metabolic conditions (37%). However, some competitions that take place in Arabic countries may pose a greater metabolic challenge to endurance horses, as reflected by 68% of the disqualified horses suffering some metabolic condition,[64] perhaps a reflection of higher racing speeds and harsher environmental conditions.

Complications associated with exercise-induced dehydration and electrolyte imbalance

Acute renal failure

Due to decreased renal perfusion and ischemia, horses may develop renal tubular damage. This condition is discussed in more detail on page 913.

Cardiac dysrhythmias

Horses subjected to exhaustive endurance exercise may occasionally develop atrial fibrillation or ventricular premature depolarizations.[4,65] It is well described that alteration in electrolyte gradients across cellular membranes may alter membrane resting potential or excitation threshold (see Fig. 40.3 and the rest of the section 'Synchronous diaphragmatic flutter'). The electrolyte and acid–base disturbances associated with exhaustive exercise apparently result in abnormalities of impulse generation in the sinus node or impulse conduction across the atrial myocardium. Cardiac dysrhythmias seen in athletic endurance horses generally respond rapidly to cessation of exercise and intravenous administration of fluids to replace fluid and electrolyte deficits.[4]

Laminitis

Some horses with exercise associated dehydration/exhaustion may initially respond positively to oral and/or intravenous fluid therapy only to develop in the following hours or days mild to severe signs of laminitis. Hypoxic damage, reperfusion injury, endotoxemia and subsequent increased vascular permeability, microvascular thrombosis, administration of corticosteroids, and large intestinal absorption of exotoxins released by *Streptococcus bovis* with consequent activation of matrix metalloproteinases have all been incriminated in the pathogenesis of laminitis. It is likely that a combination of these events plays a role in the cases of laminitis observed after exhaustive exercise. Suggested therapy for horses that develop laminitis after exhaustive endurance exercise include replacement of fluid and electrolyte deficits, keeping the horse in a stall with soft deep bedding, and administration of non-steroidal anti-inflammatory drugs (NSAIDs). Capsaicin ointment applied on the skin overlying the palmar digital nerves has recently been shown to significantly decrease lameness in a reversible model of equine foot soreness.[65b] Judicious use of capsaicin ointment may prove to be an effective adjunctive therapy in laminitic horses after exercise-associated dehydration/exhaustion, which may be at risk of acute renal failure due to dehydration, myoglobinuria and/or administration of NSAIDs. Other medications used in laminitic horses include: (i) aspirin (acetylsalicylic acid), heparin, and warfarin to minimize platelet aggregation; (ii) acepromazine, phenoxybenzamine, isoxuprine, pentoxifylline, and nitroglycerine ointment to vasodilate and improve laminar blood flow; and (iii) dimethylsulfoxide for its anti-inflammatory effects. None of these drugs has been consistently demonstrated to be effective in the treatment of laminitis and the author does not recommend any of them.

Synchronous diaphragmatic flutter (thumps)

- Not a problem in and of itself but is indicative of severe electrolyte disturbances.
- The contraction of the diaphragm and flank coincides with cardiac contraction.
- Typically seen in horses with hypochloremic metabolic alkalosis; hypokalemia and/or ionized hypocalcemia is also commonly observed.
- Responsive to calcium-enriched fluids.

Recognition of the disease

History and presenting complaint

Most commonly seen in endurance horses, (SDF) is associated with dehydration and exhaustion. It has also been described in horses with other clinical disorders associated with ionized hypocalcemia and/or alkalosis, such as impending enteritis, colic, and uterine torsion.[66] There is no apparent breed, age, or sex predilection, but horses known to develop SDF should be watched more closely because there is a tendency for recurrence.

Physical examination

Easily diagnosed by placement of one hand over the flank and simultaneous cardiac auscultation, which will demonstrate that thumping in the flank is synchronous with cardiac contraction, specifically with atrial depolarization. Muscle contractions may be more apparent on one side only, may be continuous or intermittent and the intensity of contraction may vary from barely perceptive to an obvious thumping sound.

Other clinical signs related to dehydration and electrolyte disturbance may be present, such us depression, dry congested mucous membranes, delayed capillary refill time, weak arterial pulse, and persistently elevated heart rate and/or respiratory rate after exercise. Many exhausted endurance horses develop SDF along with the abovementioned signs of dehydration and exhaustion, however other horses develop SDF with few other indications of exhaustion.

Laboratory examination

Consistent abnormalities in horses afflicted of SDF include hypokalemia, hypochloremia, and alkalosis.[66] Hypocalcemia is not as common, however ionized calcium concentrations in horses with SDF have not been reported. Ionized calcium should decrease as a consequence of alkalosis and increased protein binding of calcium.

Treatment and prognosis

Mild cases may recover without specific treatment once the horse is allowed to rest and has free access to water and hay. In horses with clinical signs of dehydration and SDF, oral or intravenous fluids are indicated as discussed in the section on exercise induced dehydration/exhaustion.

Specific therapy for SDF involves intravenous administration of calcium solutions like 23% calcium gluconate. The general recommendation is to slowly administer (over 15–30 min) 250–500 mL of 23% calcium gluconate that has been diluted 1:4 with saline or 5% dextrose. Close monitoring of the cardiovascular response by cardiac auscultation and electrocardiography, if available, is recommended. Dilute calcium infusion should be discontinued if alterations in heart rhythm or rate are observed. Increased alertness of the patient, cessation of SDF, and return of gastrointestinal motility and appetite are evidence of a favorable response to calcium-rich fluids. Bicarbonate administration is contraindicated. In fact, bicarbonate administration in volume and electrolyte depleted horses causes SDF.[67]

Prognosis for SDF is favorable. However, other complications associated with dehydration and electrolyte disturbances can occur, such as laminitis, rhabdomyolysis, or acute renal failure.

Prevention

Development of hypocalcemia and lack of compensatory mechanisms for calcium mobilization from osseous deposits is often argued as the main cause of synchronous diaphragmatic flutter. It is suggested that excessive dietary calcium intake may impair the normal response of the parathyroid gland to hypocalcemia. Therefore, switching from alfalfa hay (1.2–1.4% of calcium in dry matter) to grass hay (0.3–0.45% of calcium in dry matter) has been advocated to decrease dietary calcium intake and possibly to increase the sensitivity of the parathyroid gland to release parathyroid hormone in response to hypocalcemia. However, the effect of ingestion of different hay types or calcium dietary intake on secretion of parathyroid hormone has not been investigated in horses. Another possible dietary manipulation would be to provide anionic diets, which are those with excess of anions over cations. In dairy cattle, it is proven that prevention of parturient paresis ('milk fever', hypocalcemia of lactating dairy

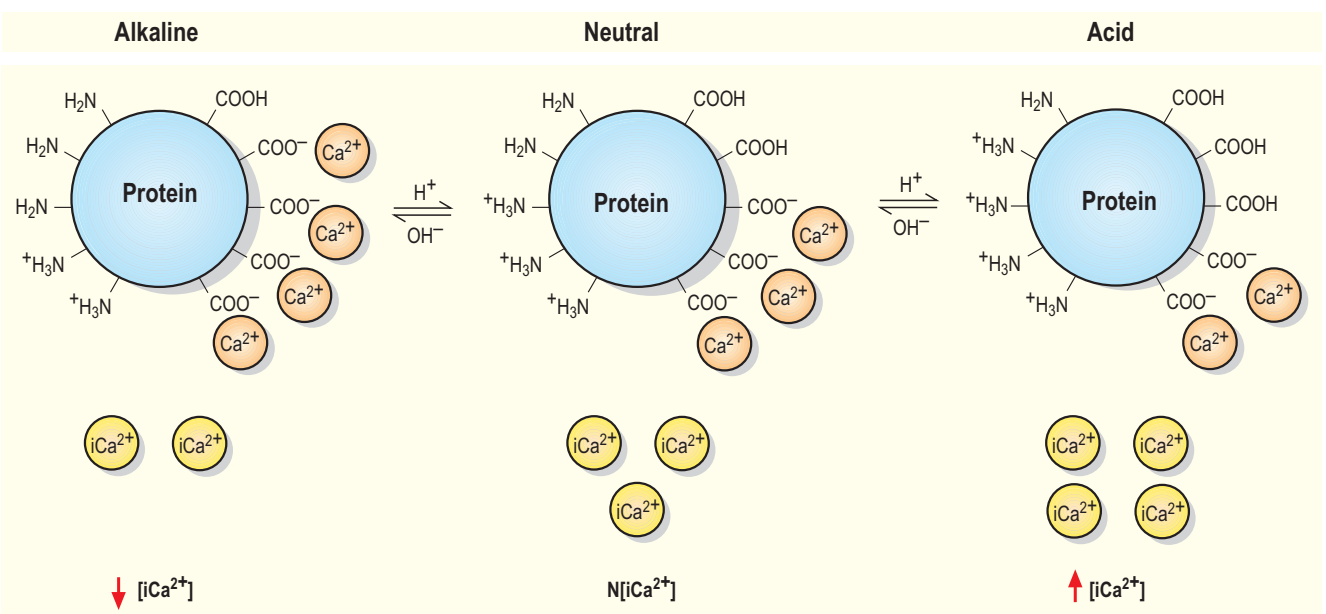

Fig. 40.2
Relationship between pH, protein-bound calcium and plasma ionised calcium. Alkalosis increases protein-bound calcium because of the increased number of negatively charged plasma proteins. (Adapted, with modifications, from Pitts[96].)

cows) is more effective by feeding anionic diets than by lowering dietary calcium intake.[68] Anionic excess apparently enhances calcium absorption from the gastrointestinal tract and resorption of calcium from bone. Whether diets with anionic excess would prove beneficial for the management of SDF in endurance horses is not known.

Provision of supplemental electrolytes before, during and after the athletic event to avoid electrolyte imbalances and development of alkalosis may help prevent development of SDF.[69]

Etiology and pathophysiology

It is suggested that fluid, electrolyte and acid–base derangements alter the normal resting potential and/or action potential of the phrenic nerve, which results in stimulation of the phrenic nerve as it runs over the atria and consequent diaphragm contraction each time the atria depolarize.

Hypochloremic metabolic alkalosis is the most consistent metabolic derangement. It is worth noting that SDF can be reproduced experimentally in horses that are volume and electrolyte depleted by administration of furosemide followed by oral administration of hypertonic sodium bicarbonate.[69]

Alkalosis increases protein-bound calcium due to increased number of negative charges of plasma proteins (Fig. 40.2). Ionized hypocalcemia may be responsible for increased neuromuscular irritability by decreasing the threshold potential (e.g. from –65 mV to –75 mV) (Fig. 40.3), which brings it closer to the membrane resting potential (e.g. –90 mV) and facilitates depolarization and nerve conduction, which in the case of the phrenic nerve stimulates the diaphragm to contract. Conversely, ionized hypercalcemia decreases neuromuscular irritability because it increases the threshold potential. Alterations in the ratio of intracellular:extracellular potassium concentrations may also make cells more or less excitable by altering the membrane resting potential. Hypokalemia (low $K^{+[ECF]/[ICF]}$) hyperpolarizes the cell membrane (makes it more negative), which decreases neuromuscular irritability; and hyperkalemia and/or intracellular potassium depletion (high $K^{+[ECF]/[ICF]}$) increases the resting potential (e.g. from –90 mV to –80 mV), which makes the cells more excitable (Fig. 40.3).[63]

The role of multiple electrolyte alterations in the development of neuromuscular disorders has been described using a formula of neuronal irritability (NI).[70] The formula illustrates how neuronal irritability, and signs of SDF or muscle fasciculations, will develop in hyponatremia, ionized hypocalcemia, hypomagnesemia, alkalosis, or with an increase in the ratio of extracellular to intracellular potassium concentration:

$$N = \frac{Na^{+} + K^{+[ECF]/[ICF]}}{Ca^{2+} + Mg^{2+} + H^{+}}$$

The typical alterations observed in endurance horses are concurrent total body potassium depletion, alkalosis and consequent increase in binding of calcium to albumin, and ionized hypocalcemia. It is likely that multiple electrolyte and metabolic disorders are responsible for development of SDF.

Epidemiology

The incidence of SDF in horses competing in endurance competitions is not well established. It is generally described to be more common in poorly conditioned horses and in competitions that take place in hot climates. In Tevis Cup races between 1962 to 1971, 974 horses started the race, 44% failed to finish, and SDF was observed in 42 of those eliminated.[66]

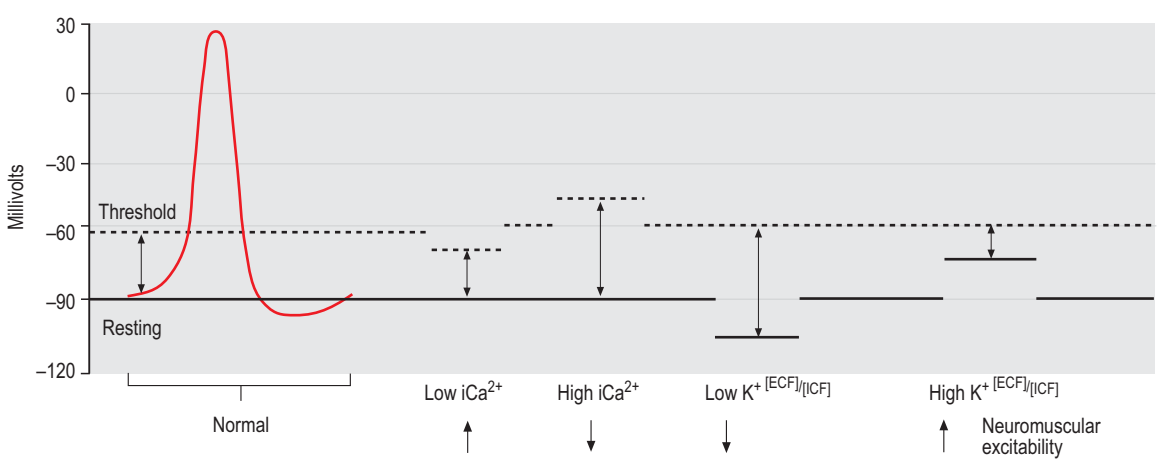

Fig. 40.3
Relationship between resting membrane potential, threshold potential, and plasma ionized calcium concentration; and the ratio of extracellular to intracellular potassium. Ionized hypocalcemia decreases the threshold potential (e.g. from –65 mV to –75 mV), which brings it closer to the membrane resting potential (–90 mV) and facilitates depolarization and nerve conduction. (Adapted, with modifications, from Leaf and Cotran[97].)

Acute renal failure

- Inability to concentrate urine despite clinical signs of dehydration.
- Oliguria in the initial stages of renal failure. Polyuria and/or polydipsia observed as acute renal failure progresses to chronic renal failure.
- Due to decreased blood flow/ischemia or nephrotoxic compounds. Most common nephrotoxins are non-steroidal anti-inflammatory drugs, aminoglycoside antibiotics, vitamin K_3, hemoglobin, and myoglobin.
- Therapy is directed to replacement of fluid, electrolyte and/or acid–base abnormalities. Other drugs indicated for treatment of renal failure (diuretics and renal vasodilators) should only be used after correction of fluid and electrolyte deficits.

Recognition of the disease

History and presenting complaint

Horses afflicted with acute renal failure (ARF) will generally have a history of participating in an athletic event that induced moderate or severe dehydration and frequently concomitant NSAID administration. The presenting complaint may be oliguria (decreased urine production), although urine production may be variable.

Physical examination

Acute renal failure is generally suspected in horses showing marked depression, anorexia, and a lack of urine production within the first 6–12 h of initiation of fluid therapy. Alternatively, affected horses are unable to concentrate urine despite clinical signs of dehydration. However, clinical signs observed are most often those related to the inciting condition.

Renal ultrasonography may be of use in diagnosing acute renal failure. Nephrolithiasis and congenital renal disorders may be ruled out by renal ultrasonography. Ultrasonographic findings described in horses with ARF include perirenal edema, loss of detail of the corticomedullary junction, or dilation of the renal pelvis.[71]

Laboratory examination

Plasma biochemical measurements of horses with acute renal failure will demonstrate increases in plasma urea nitrogen (also referred as BUN) and creatinine concentrations (i.e. azotemia). However, azotemia is only indicative of decreased glomerular filtration and may be solely a consequence of dehydration (prerenal ARF). Determination of the specific gravity of the urine by refractometry is one of the few readily available tests in the field to determine presence of ARF in horses. In cases of oliguria due solely to dehydration, urine specific gravity is usually above 1.025; however, in cases of intrinsic ARF it is generally below 1.020. These cut-off values will only be valid when performed in urine collected before initiation of fluid therapy or administration of diuretics (e.g. furosemide) or α_2-agonist sedatives (e.g. xylazine).

Hyponatremia and hypochloremia are fairly common in horses with renal failure due to increased loss of sodium and chloride in urine because of decreased renal tubular reabsorptive function. Hypocalcemia and hypophosphatemia are often found in horses with acute renal failure.

Urinalysis and urine sediment evaluation

Urine can be collected as a midstream catch during voiding or via urethral catheterization. It is recommended to obtain a urine sample for urinalysis assessment whenever renal failure is suspected in athletic horses.

Horse urine is normally alkaline (pH 7 to 9). However, aciduria may develop as a consequence of exercise-induced fluid and electrolyte losses. In an attempt to maintain plasma volume in the face of dehydration, renal tubular reabsorption of sodium is maximal and sodium is reabsorbed in exchange for potassium. When potassium depletion occurs due to continued losses in sweat, sodium continues to be reabsorbed in the renal tubules in exchange for hydrogen ions. This results in paradoxic aciduria, which describes a state of alkalosis in which the kidneys do not compensate by urinary elimination of an alkaline urine but rather maintain sodium reabsorption at the expense of elimination of inappropriately acidic urine.

Reagent strip analysis is useful to obtain an estimate of pH and the presence or absence of blood, protein, glucose, ketone bodies, and bilirubin. A positive result for blood indicates presence of red blood cells, hemoglobin, or myoglobin. To distinguish between these pigments one can examine the urine sediment for presence of red blood cells, examine plasma to assess if it appears hemolytic (pink or red tinge in normally light yellow plasma) and measure the activities of creatine kinase (CK, normal 145–380 units/L) and aspartate aminotransferase (AST, normal 220–600 units/L) as indicators of rhabdomyolysis and thus the potential for myoglobinuria. A false-positive result for urine protein is common in alkaline urine, and the presence of protein in urine is better assessed with other more specific biochemical assays. Proteinuria and hematuria may transiently follow exercise.[72] Proteinuria is a characteristic finding in glomerulonephritis due to filtration of albumin and other proteins into the urine. A urine protein to urine creatinine ratio above 2:1 is indicative of clinically significant proteinuria in a patient. Glucose should not be detected in normal equine urine and glucosuria may be observed in cases of acute renal failure. Ketones are rarely detected in equine urine, even in cases of catabolic states. Bilirubinuria may be observed in cases of hemolysis and liver disease, however other plasma biochemical data (total and conjugated bilirubin, bile acids, alkaline phosphatase, aspartate aminotransferase, γ-glutamyl transferase and sorbitol dehydrogenase) may be more useful in assessing liver disease.

Sediment examination of equine urine is a simple and very useful technique to evaluate presence and magnitude of renal tubular disease and to determine presence or not of infectious or inflammatory disorders. However, sediment examination should be performed within 1 h of collection,

because casts are unstable in alkaline urine. A normal horse urine sediment should not contain casts, fewer than five red blood cells and fewer than ten white blood cells should be seen per high power field. Briefly, a urine sediment examination is performed by centrifugation of a 6–10 mL urine sample at 1000 rpm for 5 min. The supernatant is discarded and the sediment is resuspended in a couple of drops of sediment staining solution and transferred to a glass slide with a coverslip on top. The sediment is examined first at low power to evaluate for casts (long cylindrical molds of protein and cells shed from the renal tubules; Fig. 40.4). The presence of casts is indicative of renal tubular necrosis. Increased numbers of red blood cells can result from inflammation, infection, and neoplasia, and it is transiently observed after exercise.

Renal tubular function is assessed by clearance rates of electrolytes. However, the clearance rate of a substance in urine requires volumetric urine collection, which is not practical in clinical settings. Fractional creatinine clearance values, more commonly referred to as fractional excretion ratios, allow a similar assessment of renal tubular function by comparing the clearance of an electrolyte to creatinine clearance. Fractional excretion ratios are calculated after measurement of electrolytes in plasma and urine, and obviate the need for volumetric urine collection. Fractional excretion ratio of substance X (i.e. Na^+) is calculated as:

$$\frac{Cl_x}{Cl_{Cr}} = \left(\frac{\text{Urine [X]}}{\text{Plasma [X]}} \Big/ \frac{\text{Urine [Cr]}}{\text{Plasma [Cr]}} \right) \times 100$$

Normal fractional clearance values are less than 1% for sodium, less than 1.6% for chloride, 20–60% for potassium, less than 1% for phosphorus and 2–6% for calcium.[73] However, the results of these calculations must be interpreted taking into consideration fluid therapy and dietary intake.

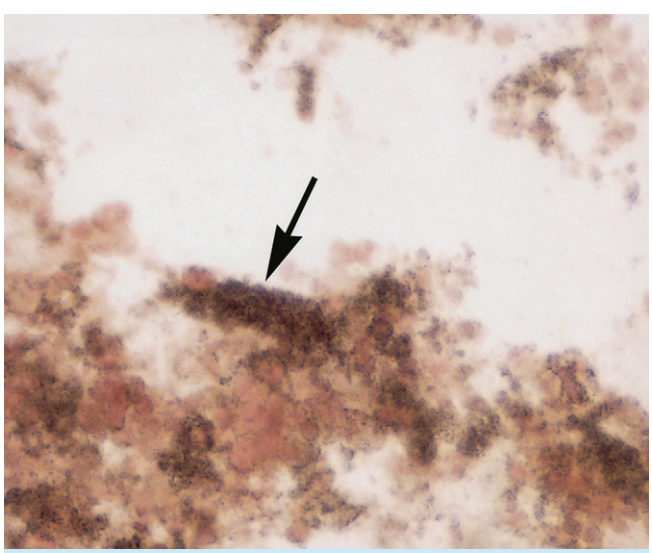

Fig. 40.4
Microscopic evaluation of urine sediment from a horse with acute renal failure. Note the presence of granular casts, one of them in the center of the image (arrow) (×42).

Fractional clearances of potassium, calcium, and phosphorus will vary greatly depending upon dietary intake. Potassium intake is generally adequate and excessive amounts are readily excreted in the urine. The kidneys also play an important role in calcium and phosphorus homeostasis and urinary loss of these electrolytes varies with dietary intake.

Once fluid therapy has been initiated, urine specific gravity and fractional excretion ratios will not be useful because the results are altered by fluid diuresis. However, urine sediment microscopic evaluation will still be useful in assessing ongoing renal damage.

Treatment and prognosis

Therapy for acute renal failure is aimed at removing the primary cause and restoring normal fluid balance by correcting dehydration and electrolyte and acid–base disorders. The prognosis will depend upon the initiating cause and the severity of renal damage. In those cases due to hypoperfusion or ischemia, the prognosis is favorable when the condition is treated promptly. In cases where fluid replacement has been delayed and/or the kidneys suffer multiple simultaneous insults from different nephrotoxins, as in a dehydrated horse that is 'tying-up' (rhabdomyolysis) and is given phenylbutazone, the prognosis is guarded to poor.

Fluid therapy

Regardless of the cause of acute renal failure, initial therapy should include replacement of fluid deficits (preferably by intravenous administration) and correction of any electrolyte or acid–base abnormalities. After these have been corrected, one should attempt to monitor urinary output. Other than subjective assessment of frequency and volume of urination, monitoring of bodyweight will be useful in assessing excessive fluid retention in cases of oliguric renal failure. As described under the heading 'Exercise-induced dehydration/exhaustion', the fluid of choice in horses after prolonged endurance type exercise is Ringer's solution, although other balanced polyionic solutions also are suitable.

Adjunctive medications

When urine output remains reduced after replacement of fluid deficits over the first 6–12 h, administration of drugs that increase renal blood flow, glomerular filtration, and urinary flow may be indicated.

1. Diuretics: Furosemide is a loop diuretic, it blocks the $Na^+/K^+/2Cl^-$ cotransporter in the ascending limb of the loop of Henle, which promotes natriuresis and diuresis. The aim of furosemide administration is to turn oliguric renal failure into non-oliguric renal failure, which facilitates the management of fluid and electrolyte status. The efficacy of furosemide in treating horses with acute renal failure is not documented. In human patients with ARF administration of furosemide does not affect the long-term outcome. The use of

furosemide is contraindicated in horses with suspected urinary tract obstruction or rupture.

Manitol is an osmotic diuretic that increases intravascular osmolality, causing an increase in intravascular volume and as a consequence it increases renal blood flow and glomerular filtration rate. These osmotic effects cause an increase in urinary output and may be effective in the treatment of ARF characterized by tubular obstruction and swelling of the tubular cells.[74]

2. Renal vasodilators: Dopamine activates dopaminergic receptors present in the renal cortex and induces increased renal blood flow and urine output when infused at 5 μg/kg/min, without significant alteration in arterial blood pressure and heart rate. However, some horses develop dysrhythmias with dopamine infusion.[75] Fenoldopam is a selective, α_1-dopaminergic agonist that, in animal models and humans, increases renal blood flow, glomerular filtration rate, and urinary output without unwanted side-effects.[76,77] The effect of fenoldopam on renal hemodynamics in horses is unknown.

Prevention

Acute renal failure in athletic horses will be prevented using those strategies that minimize the risk of development of clinically significant dehydration that may compromise renal perfusion. Avoidance of commonly used nephrotoxic drugs is of the utmost importance in horses that show clinical signs of dehydration/exhaustion. If administration of an NSAID is considered necessary, it is advisable to delay administration until fluid and electrolyte deficits have been at least partially corrected by administration of oral and/or intravenous fluids.

Etiology and pathophysiology

Acute renal failure in the horse results from toxic causes or from ischemic or hemodynamic causes.[74,78] Causes of nephrotoxic acute renal failure include aminoglycoside antibiotics (neomycin being the most nephrotoxic), nonsteroidal anti-inflammatory drugs, vitamin K_3, myoglobin, vitamin D, heavy metals, mycotoxins, and acorns.

Aminoglycoside antibiotics (gentamicin, amikacin, neomycin, streptomycin, kanamycin, and tobramycin) are toxic to the tubular epithelial cells. These antibiotics are reabsorbed from the urine and accumulate in tubular epithelial cells, which causes disruption of the cellular metabolism resulting in tubular swelling and sloughing.[79]

Phenylbutazone and other NSAIDs exert their analgesic and anti-inflammatory effects by inhibition of cyclo-oxygenase, an enzyme responsible for prostaglandin and thromboxane synthesis. However, NSAIDs inhibit also the synthesis of local protective vasodilator prostaglandins in the kidney, thereby reducing blood flow to the renal medulla and inducing renal papillary necrosis.[80,81] Acute renal failure is more likely when NSAIDs are administered in abnormally high doses or when administered to hypovolemic or dehydrated horses. Ketoprofen may be less nephrotoxic when compared to other NSAIDs.[81]

Vitamin K_3 (menadione sodium bisulfite) had been a common cause of acute renal failure in the US before its withdrawal from the market. The development of ARF appears to be an idiosyncratic reaction.[82]

Acute tubular necrosis may occur in cases of moderate or severe myoglobinuria or hemoglobinuria.[74] The pathogenesis for this condition is not completely understood; hemoglobin or myoglobin casts present within the renal tubules may result in ischemic injury, and these pigments also reduce renal blood flow by direct vasoconstrictor effects. In addition, myoglobin deposited in the renal tubules appears to induce oxidative damage of components of tubular cell membranes.[83]

Dehydration and decreased renal blood flow may cause acute renal damage due to hypoxic damage of tubular epithelial cells. Tubular epithelial cells are more susceptible to hypoxia because these cells are involved in solute reabsorption, which demands a high metabolic rate and high demand for oxygen. However, due to unique physiologic and anatomic features of the kidneys, only about 10–20% of the total renal blood flow reaches the medullary portion of the kidney. The low medullary blood flow is required to provide a functional countercurrent mechanism; however, it also renders the medulla relatively hypoxic and more susceptible to ischemic injury.

Epidemiology

Incidence of acute renal failure in the general horse population and specifically in athletic horses is not well documented. The more common causes of acute renal failure are described to be ischemic renal tubular damage due to renal hypoperfusion or NSAIDs (most commonly phenylbutazone and flunixin meglumine), and gentamicin nephrotoxicity.

CHAPTER 41

Thermoregulation and exercise-associated heat illnesses

L. Jill McCutcheon and Raymond J. Geor

Body heat is produced by metabolism and is also gained from the environment. In homeotherms, internal temperature is normally maintained within a narrow range (37–40°C) by integrated neurophysiologic mechanisms that balance heat production and heat loss. Thermoregulation is the process by which the internal temperature is regulated to maintain body temperature within this thermoneutral zone. For example, during heat exposure or exercise, when heat gain occurs, the thermoregulatory system will provoke mechanisms for heat loss such that the rise in internal (or core) body temperature is mitigated. It is the most important regulation system in homeothermic animals.[1]

In horses, as in humans and other mammalian species, an excessive elevation in body temperature limits performance capacity. Therefore, a thorough understanding of thermoregulation and means for enhancement of these mechanisms is crucial to management of the athletic horse. The fact that horses often train and compete in hot weather, ambient conditions that substantially increase the risk of thermal injury, further underscores the importance of such understanding.

Heat production and dissipation

Core body temperature is a dynamic equilibrium between factors that add or remove heat. This balance is maintained by integration of mechanisms that vary the body's rate of heat production, alter the transfer of heat to the periphery (e.g. skin), and regulate evaporative cooling. The hypothalamus contains the central coordinating center for the various processes of thermoregulation. Specialized neurons within the hypothalamus act as a thermostat that initiates thermoregulatory adjustments to deviations from normal body temperature. Heat-regulating mechanisms are activated by thermal receptors in the skin that provide input to the hypothalamus, or by direct stimulation of the anterior hypothalamus via changes in the temperature of blood perfusing the area.

The greatest disequilibrium in heat balance occurs during exercise. Conversion of chemical energy (i.e. stored substrates) to mechanical energy (e.g. muscular contraction) is inefficient with approximately 75–80% of the total chemical energy released as heat rather than physical work.[2] As such, the rate of metabolic heat production increases markedly with the onset of exercise and is accompanied by increases in muscle and core body temperatures. The increase in core temperature provokes activation of heat dissipatory mechanisms such that increases in body temperature are mitigated. However, whether balance between heat gain and heat loss can be re-established will depend on the duration and intensity of exercise and the efficiency of heat dissipation. The latter is primarily influenced by ambient conditions but also modified by physiological adaptations (e.g. conditioning, heat acclimatization) in heat dissipatory mechanisms.

Heat production

For living organisms, biologic work is either external, which includes moving the body or other objects through muscular contraction, or internal work that would include all other forms of biologic work, such as smooth muscle contraction, synthesis of molecules and compounds, or active transport within cells. With the exception of periods of growth, ultimately all this work is transformed into heat that is either stored or liberated. Energy expenditure by the body can therefore be expressed by the following equation:

$$\text{Total energy expenditure} = \text{internal heat production + external work performed + energy stored}$$

The body has a basal level of energy expenditure or basal metabolic rate (BMR) that is lowest when environmental temperature range is within a thermoneutral zone. This BMR minimizes energy expenditure required to maintain normal body temperature. The BMR is altered by numerous factors, both internal and within the environment, which increase or decrease energy expenditure. Metabolic rate is normally lowered during sleep and increases with any form of work or stress. Perturbations of BMR such as exercise, fever, catecholamine release, feed consumption (thermic effect of feed), or dealing with a cold environment can therefore affect heat balance. In mammals, there have been extensive investigations of the relationship between bodyweight and heat production,[2,3] which have demonstrated that resting heat production is proportional to body mass to the power of 0.75 in adults but not in growing animals. There are, however, differences between species and it could be expected that within a species such as the horse with extensive variation in size and weight based on breed, lighter breeds may have a significantly lower resting heat production when compared to heavier breeds.

Heat production in horses is influenced by dietary factors, including the quantity and quality of feed and water intake. Replacing hay in the diet with grains has been demonstrated to decrease heat production,[4] with a further reduction in heat production possible with fat supplementation.[5] When exposed to hot or cold environments, water restriction and dehydration can also reduce heat production.

During exercise, the workload or speed is the main determinant of the rate of heat production. Other factors such as the weight of rider and tack, and the nature of the terrain and footing will also contribute to the overall workload.[6,7] Heat production during exercise can be estimated from oxygen consumption data:

$$\text{Metabolic heat} = \dot{V}O_2(\text{liters per min}) \times k \times \text{exercise duration (min)}$$

where $\dot{V}O_2$ = oxygen consumption and k = amount of heat liberated per liter of oxygen consumed. Values for k range from 4.7 kcal to 5.1 kcal depending on the substrate oxidized (lowest value for pure fat oxidation, highest value for pure carbohydrate oxidation).[3]

Metabolic rate in horses is 40- to 60-fold higher during exercise at maximum oxygen uptake ($\dot{V}O_{2max}$) when compared to the resting state. For a 500-kg horse with a $\dot{V}O_{2max}$ of 80 L/min, this equates to metabolic heat production in excess of 400 kcal/min (~ 1.3 MJ/min) of exercise. Production of this quantity of heat without any ability for heat dissipation would result in an increase in body temperature of approximately 1°C per minute during exercise. Although the rate of metabolic heat production is lower during endurance exercise, the overall heat load is substantially higher because of the longer work duration. For example, it has been estimated that the metabolic heat production of an endurance horse running at 8 m/s is about 150–200 kcal/min; if no heat was dissipated, this heat load would result in an increase in core temperature of approximately 21°C per hour. These hypothetical measurements emphasize that effective heat-loss mechanisms are crucial and serve to further underline the additional impact severe ambient conditions will impose on the horse's ability to lose heat to the surrounding environment.

In contrast to most other large domestic species in which skeletal muscle comprises 30–40% of total bodyweight, half the total bodyweight of the Thoroughbred is working muscle. This higher percentage of bodyweight from muscle contributes to the horse's higher mass-specific $\dot{V}O_2$ when compared to other athletic species, including man. Furthermore, a running horse uses a greater proportion of its body mass for locomotion than does a human performing running or leg cycling exercise. Thus, the mass-specific heat load for the exercising horse is as much as two- to three-fold higher compared to that of exercising humans. Despite a substantially higher rate of heat production in the horse, the ratio of surface area to body mass is approximately 50% less than that of humans (man = 1:35–40 m^2/kg; horse = 1:90–100 m^2/kg).[6,7] As a result, the horse has a significantly smaller surface area over which to dissipate a relatively larger metabolic heat load and, at any given workload, must dissipate approximately four times more heat per unit of body surface area during exercise than human athletes. The disadvantage posed by a smaller surface-area:body-mass ratio can be partially offset by higher rates of cutaneous and respiratory heat loss. However, it is apparent that exercise is a considerable thermoregulatory challenge to the horse, with prolonged exercise representing one of the most demanding situations.

Mechanisms of heat transfer

Conductive, convective, radiative, and evaporative heat loss are the four basic mechanisms for heat transfer. Heat loss by *conduction* involves direct transfer of heat through a liquid, solid, or gas from one molecule to another. Although most of the body heat is transferred to the periphery by the circulation, a small amount moves by conduction directly through the deep tissues to the cooler surface. Heat loss by conduction then occurs by the warming of air molecules and cooler surfaces in contact with the skin. The rate of conductive heat loss is directly proportional to the temperature gradient between the skin and surrounding surfaces, and inversely proportional to the thickness of the hair coat. Heat loss by conduction from the surfaces of the head, neck and distal limbs is more effective due to a higher surface area to mass ratio in these regions when compared to proximal limbs, thorax and abdomen.

Convection represents the transfer of heat between two media, such as the skin surface and surrounding air. The effectiveness of heat loss by convection depends on how rapidly the air near the body is exchanged once it is warmed. Conductive heat loss is most effective when the warm air surrounding the body is continually replaced by cooler air, as occurs as a running horse moves through the air and/or wind speed is moderate to high. On the other hand, the trap-

ping of air within a long hair coat will impede convective heat transfer to the environment. Convective heat transfer also occurs in the respiratory tract, the rate of which is dependent on pulmonary ventilation and the temperature difference between inspired and expired air.

Radiative heat transfer occurs when electromagnetic radiated is emitted or absorbed at the skin surface. As body temperature is normally higher than the environment, there is a net loss of radiative heat energy at the skin surface. However, in hot ambient conditions, when the temperature of objects in the environment exceeds skin temperature, radiant heat energy is absorbed from the surroundings. Under these conditions, the only avenue for heat loss is evaporative cooling. A gain of radiant heat energy also occurs via direct (or reflected) sunlight. It has been suggested that solar radiation can contribute up to 15% of the heat gain in horses during exercise in sunny conditions.[8]

For the horse, the most important mechanism for heat loss is *evaporative* cooling including the evaporation of sweat from skin surfaces and water from the respiratory tract. The efficacy of this mechanism is dependent upon the extent of the vapor pressure gradient between body surface and environment. Calculations of the estimated heat loss are based on the latent heat of vaporization of water (from a liquid to a vapor – 598 kcal [2501 kJ] for each gram of water at 0°C).[9] After accounting for possible variations in the thermodynamic properties of sweat when compared to water, it is estimated that the evaporation of 1 L of sweat from the skin surface will dissipate approximately 580 cal (2428 kJ or 2.4 MJ) of body heat.[10] The quantity of heat (~ 2.4 MJ) dissipated in association with the evaporation of 1 L of sweat in thermoneutral conditions is approximately equivalent to the heat generated by 2 min of high-intensity exercise or 6 min of moderate-intensity exercise. In optimum conditions, (i.e. when relative humidity is low) the evaporation of sweat is a very efficient mechanism of heat loss and can account for as much as 65% of total heat loss during exercise. However, several environmental factors will influence the efficacy of evaporative heat loss. These include ambient temperature and relative humidity, the extent of the vapor pressure gradient between the skin surface, and the rate of air movement.[11–13] At high ambient humidity, the vapor pressure gradient between the body surface and the environment narrows thereby constraining evaporative cooling and increasing the rate of heat storage.

The extensive surface area of the respiratory tract also provides a mechanism for heat dissipation. This process relies upon the difference in vapor pressure between the inspired air and that of the epithelial surface of the respiratory tract. The external nares of the horse contribute considerable surface area for heat exchange. Similarly, the extensive surface area of the upper respiratory tract, including the internal nares and nasal turbinates provide an environment in which air entering the nasal passages contacts the highly vascularized epithelium of the upper respiratory tract. Horses also have a unique anatomical arrangement by which their internal carotid arteries are enveloped by a pair of air-filled guttural pouches. Preliminary studies suggest that exercising horses can use their guttural pouches to cool blood en route to the brain.[14] It is surmised that this heat loss from the upper respiratory tract contributes to selective brain cooling, whereby the temperature of blood reaching the brain is lower when compared with that measured in mixed venous (pulmonary artery) blood or within skeletal muscle.[15] Heat loss from the respiratory tract is dependent upon relative humidity and minute ventilation. Under cool, dry conditions, the extent of heat loss via this mechanism is estimated to be between 15 and 25% of total heat loss. In hot, humid conditions, when cutaneous evaporative cooling is compromised, respiratory heat loss may account for a relatively higher proportion of total heat loss and therefore represent 25% or more of total heat loss. While elevations in the respiratory rate increase the proportion of heat loss from the respiratory tract in these conditions, mechanical limitations imposed during exercise (e.g. the coupling of stride to respiration during canter and gallop) may ultimately limit heat loss from the respiratory tract.

Mechanisms of sweat formation

In only a limited number of species, including some bovidae, primates and equidae, is the sweat gland primarily a thermoregulatory organ.[4,16] In the horse, sweat glands are present in both haired and relatively hairless skin with regional variation in the density of glands that is not dependent on the presence of a haircoat. Structurally, the gland is similar to that of many other domestic species, consisting of a fundus and a duct connecting the fundus with the skin surface. Throughout most of its length, the duct lining is composed of two layers, with a single layer of keratinocytes lining the duct at the skin surface. Located within the dermis, the fundus is lined by an inner layer of secretory epithelium interspersed with myoepithelial cells and surrounded by a fenestrated sheath of fibrocytes that encloses a layer of connective tissue. Although sweating appears to be under sympathetic nervous control, there is no evidence of direct sympathetic innervation of the sweat gland. Rather, sweating appears to occur via humoral stimulation of β_2-adrendergic receptors on sweat glands. As a result, sweating can be initiated by epinephrine (adrenaline) release in advance of any stimulus related to an increase in core temperature.

As most studies to date have investigated sweating rate and composition in Thoroughbred horses, the degree to which sweating rate and composition varies between breeds is unknown. To date, it appears that the basic composition of sweat is similar between breeds. Equine sweat, unlike that of humans, is isotonic to slightly hypertonic relative to plasma.[11,15,17] Sweat ion concentrations are largely a reflection of sweating rate and therefore are subject to alteration based on environmental conditions and exercise intensity (Table 41.1). Although there is some variation in sweat ion composition of equine sweat, individual differences in sweat composition do not appear to be as extensive in horses when compared to human athletes. Epinephrine (adrenaline) infusion will produce a more dilute sweat and may account for the less concentrated sweat produced during high intensity exercise when compared to low intensity exercise.[11,15,18]

Table 41.1 Sweating rate, ion concentrations, and osmolality in horses at two exercise intensities and three different ambient conditions after 10 min exercise (data from[11,90])

Variable	CD high	CD low	HD low	HH low
Sodium (mmol/L)	124.0 ± 6.7	116.7 ± 6.1	133.6 ± 2.3	130.6 ± 1.7
Potassium (mmol/L)	25.8 ± 2.1	32.6 ± 1.4	41.5 ± 1.1	28.1 ± 0.9
Chloride (mmol/L)	142.0 ± 5.6	144.3 ± 4.3	155.8 ± 3.2	149.5 ± 2.9
Osmolality (mOsm/kg)	313 ± 18	303 ± 6	339 ± 6	327 ± 5
Sweating rate (mL/m^2/min)	40.4 ± 3.7	21.1 ± 5.2	32.8 ± 5.1	27.0 ± 6.2

CD, cool, dry (room temperature [T] = 20°C, relative humidity [RH] = 45–55%); HD, hot, dry (T = 32–34°C, RH = 45–55%); HH, hot, humid (T = 32–34°C, RH = 80–85%); high, exercise at 90% of maximum oxygen consumption ($\dot{V}O_{2max}$); low, exercise at 50% of $\dot{V}O_{2max}$.

During exercise, an increase in body temperature as a result of metabolic heat production is the primary stimulus for sweating. Normally, sweating is initiated at a specific core temperature and continues in proportion to the increase in core temperature. Hodgson et al[19] demonstrated that increases in sweating rate at three different exercise intensities (40%, 65%, and 90% of $\dot{V}O_{2max}$) were closely related to elevations in carotid artery blood temperature (Fig. 41.1). Rate of rise in body temperature and the concentration of circulating catecholamines associated with different exercise intensities could also contribute to the determination of sweating rate.

Thermoregulation during exercise

During exercise, metabolic heat from working muscles must be transferred to the skin surface to be lost to the environment. Peripheral thermoreceptors in skin, spinal cord, skeletal muscle, abdomen, and hypothalamus detect changes in thermal load and produce a proportional output that is integrated in the hypothalamus to allow adequate thermoregulatory effector activity, particularly by the circulatory system and sweat glands. The primary physiologic mechanisms driving heat loss are an increase in the proportion of cardiac output directed toward the cutaneous circulation and an increase in the rate of sweat secretion. The increase in cardiac output and blood flow to contracting muscles enables a substantial increase in convective heat transfer away from the muscle. The circulation carries the heat to the body core, resulting in an increase in core temperature. Increasing core temperature and, to a lesser extent, increasing skin temperature provides the afferent signal for reflex increases in skin blood flow and sweating, thereby facilitating heat transfer to the skin surface and its dissipation to the environment.

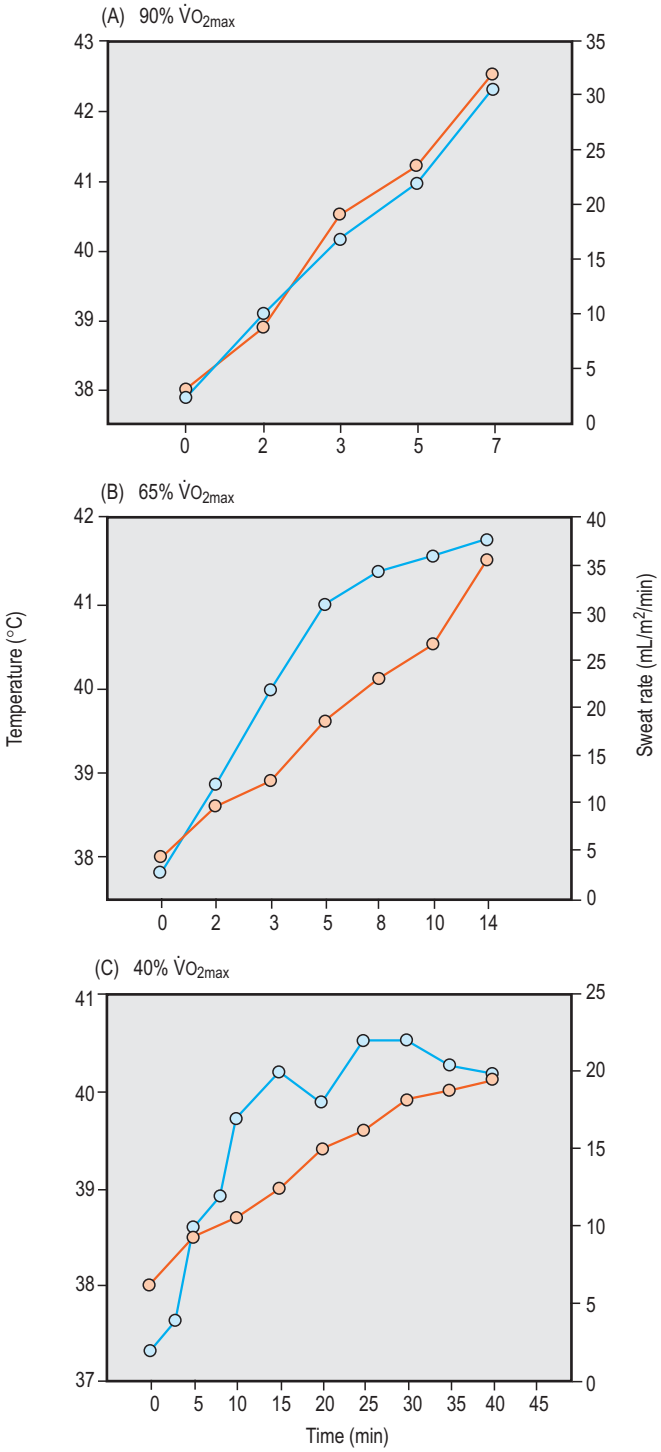

Fig. 41.1
Carotid artery temperature (orange circles) and sweat rate (blue circles) in horses exercising at 90% (A), 65% (B), and 40% (C) of maximal O_2 uptake ($\dot{V}O_{2max}$). Ambient temperature was 21–23.5°C. (Adapted from Hodgson et al.[19])

Skin blood flow is substantially increased by the opening of capillary beds that are normally bypassed by arteriovenous anastamoses that connect arteries directly to veins. The increase in blood flow through the vascular beds of the skin

allows heat to be lost to the environment via convection and direct radiation of heat from the skin surface. The efficacy of transfer of heat by convection and radiation varies according to the rate of air movement across the skin (wind speed) and the gradient of skin temperature to environmental temperature. Increased skin blood flow also provides the latent heat for vaporization of sweat and as well as the fluid required for sweat production. The attempt to maximize blood flow for increased activity and thermoregulation is also reflected in decreased splanchnic and adipose tissue blood flow.[20] Greater oxygen demand increases respiratory rate and respiratory blood flow and both activities will enhance the extent of evaporative cooling by the respiratory system.

Sweating rates of ~ 20 to 55 mL/m^2/min have been measured on the necks and backs of horses exercising on a treadmill in a laboratory.[19,21–23] Assuming a body surface area of 4.5 to 5.0 m^2 for a 500-kg horse, these sweating rates correspond to fluid losses of 6–15 L per hour. This estimate of hourly sweat fluid loss is in agreement with sweat rates calculated on the basis of the decrease in body mass during prolonged exercise under field conditions.[24] When expressed in terms of sweating rate per unit area of skin, these sweating rates are two- to three-fold greater than those reported for human subjects.

At any given point in time during exercise, core body temperature reflects the balance between heat production and dissipation. Soon after the onset of exercise, the rate of heat production greatly exceeds the rate of heat dissipation such that there is a rapid increase in muscle temperature.[25] During short-term, high-intensity exercise (e.g. racing), the rate of heat production will exceed the rate of heat loss throughout exercise and body temperature will continue to increase until the cessation of exercise. In this circumstance, a large proportion of the metabolic heat load will be dissipated during the recovery period. Conversely, during more prolonged low- to moderate-intensity exercise in temperate ambient conditions, activation of heat dissipatory mechanisms progressively attenuates the rate of rise of body temperature. Eventually, the rate of heat loss increases sufficiently to balance metabolic heat production, allowing a near steady-state core temperature to be achieved.[25]

Effects of environmental heat load on exercise responses

Not surprisingly, the thermal response to exercise is affected by the ambient conditions. As environmental temperature increases, the thermal gradient between the skin and the environment is reduced, and sensible heat loss (i.e. convective and radiative heat transfer) is impaired. When ambient temperature exceeds skin temperature (> 35–36°C), the gradient for heat transfer is reversed and the body gains heat from the environment. If humidity is low, a decrease in sensible heat loss can be offset by an increase in sweating rate and evaporative cooling. As humidity rises, the gradient between skin and ambient dew point is reduced and evaporative heat loss is also impaired. The decrease in sweat evaporation is manifested by excessive wetting of the skin surface and drippage of sweat from the body. Sweat that drips from the body only removes 5% to 10% of the heat that can be dissipated by evaporation of sweat. Therefore, during exercise under conditions of high ambient heat and humidity, the rate of heat dissipation may be inadequate to prevent the progressive rise in body temperature. The impact of the environment on the rate of rise of core body temperature in exercising horses is depicted in Fig. 41.2. The rate of heat storage when exercising in hot, humid conditions may be more than twice the rate occurring during exercise at the same intensity in cool, dry conditions.[13,26–28]

Increased demands for respiratory heat loss are reflected by an increase in respiratory rate and during and after exercise. Kohn and Hinchcliff[29] reported a 20% to 25% increase in the respiratory rate of horses during speed and endurance tests in hot when compared to cool conditions. In laboratory experiments, an approximately two-fold increase in post-exercise respiratory rate has been observed in horses under hot, humid when compared to cool, dry environmental conditions.[13,26] When ponies were exposed to heat (41°C dry bulb temperature), there were three-fold increases in respiratory rate and blood flow to tissues of the upper respiratory tract,[30] reflecting the role of the respiratory system in heat dissipation. Similarly, during moderate intensity (~ 30% $\dot{V}O_{2max}$) exercise respiratory rate was five-fold greater in hot than in thermoneutral conditions.[20]

An important consequence of the impairment to heat dissipation during exercise in the heat is a decrease in the time to attainment of a critical upper limit in core body temperature. In humans, it is clearly established that time to exhaustion in trained subjects during exercise in the heat is inversely related to the initial level of body temperature and directly

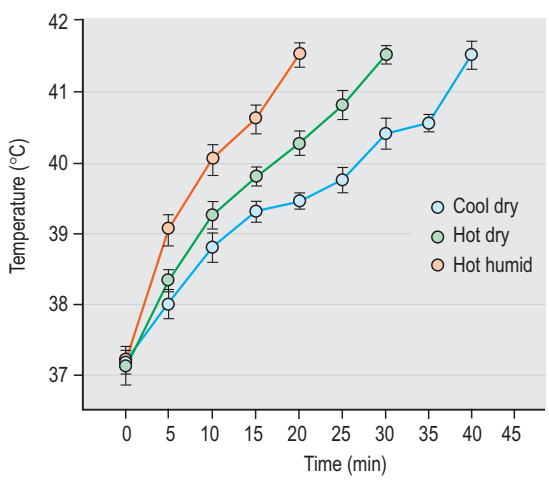

Fig. 41.2
Time course of rise in pulmonary artery blood temperature (T_{pa}) during exercise at 50% of maximal O_2 uptake in cool, dry (room temperature [T] = 20°C; relative humidity [RH] = 45–55%), hot dry (T = 32–34°C, RH = 45–55%), and hot, humid (T = 32–34°C, RH = 80–85%) ambient conditions. Exercise was discontinued when T_{pa} reached 41.5°C. (Adapted from Geor et al.[13])

related to the rate of heat storage.[31] That the lowering of core temperature prior to the start of exercise[32] or cooling the body during the period of exercise[33] will delay attainment of the critically high body temperature and extend exercise duration is further evidence for the relationship between body temperature and exercise performance.

Several factors may contribute to a decrease in performance when exercise is undertaken in hot versus cool conditions. These include the effects of hyperthermia on brain and muscle function, and compromise of cardiovascular and respiratory function. There appears to be a critical body temperature above which mammals will not continue to exercise voluntarily, likely a protective mechanism to protect the human or animal from reaching tissue temperatures that harm cell function.[28] Thus, a more rapid attainment in critical body temperature will translate to a reduction in exercise duration. In trained humans exercising over a range of work intensities in the heat, voluntary fatigue occurs at a core (esophageal) temperature of 39.7–40.0°C.[31,34–36] Furthermore, following heat acclimation procedures that enhance thermoregulatory mechanisms and reduce the rate of heat storage during exercise, the core temperature at the onset of fatigue is unchanged.[35,37] Measurements of central blood (pulmonary artery) temperature in horses during heavy exercise have demonstrated that fatigue occurs as blood temperature approaches 42.5–43°C;[19,38] muscle temperature may reach 44–45°C during such high-intensity exercise. Hypothalamic blood temperature, on the other hand, is approximately 1°C lower than central blood temperature in horses during heavy exercise in moderate ambient conditions.[15] The difference between the temperatures in these two regions provides evidence for the existence of a mechanism for selective brain cooling in the horse. Particularly during exercise in the heat, the onset of fatigue at some critical upper limit in brain temperature may represent a mechanism to avoid heat stroke.

Human studies, dating back to the work of Asmussen and Boje,[39] have indicated that a moderately elevated, but steady-state core body temperature is advantageous to muscle function and to the dissociation of oxygen from red blood cells within muscle tissue. The increase in muscle temperature acts on glycolytic and glycogenolytic enzymes, altering flux rate through these pathways.[40,41] This Q_{10} effect is accentuated during exercise in the heat. However, at high muscle temperature (> 46°C) deleterious structural and functional alterations in skeletal muscle proteins can be induced.[42] These proteins play essential roles in mitochondrial respiration, regulation of calcium by the sarcoplasmic reticulum and the subsequent interactions of myosin and actin, and control of electrolyte movement across the sarcolemma.[31,43] As a consequence, substantial detrimental alterations to skeletal muscle metabolism may occur with elevation of muscle temperature to this critical range.

During exercise heat stress, circulatory adjustments must be regulated to maintain adequate blood flow to contracting muscle and to the thermoregulatory tissues, particularly the skin and the upper respiratory tract.[10] Given a finite cardiac output, the increased demands for blood flow to these thermoregulatory tissues may compromise blood flow to skeletal muscle, thereby limiting oxygen delivery and, possibly, exercise duration. Recent studies in ponies have provided data on the effects of environmental heat load (41°C dry bulb) on the redistribution of cardiac output during exercise.[20] Blood flow to the fore and hind limbs during moderate (~ 30% $\dot{V}o_{2max}$) and high-intensity (~ 65% $\dot{V}o_{2max}$) exercise was reduced by as much as 25–30% when compared to similar exercise in thermoneutral conditions. This reduction in muscle blood flow during exercise heat stress is likely to restrict performance and contribute to an early onset of fatigue.

A reduction in maximal aerobic power is another potential reason for decreased physical performance during exercise in the heat. A reduction in peak oxygen uptake has been demonstrated in human subjects exercising in the heat.[44–46] When non-heat acclimatized horses performed an incremental treadmill exercise test in hot, humid conditions (temperature 30°C, relative humidity 75%), peak expired minute ventilation, oxygen uptake and oxygen pulse were significantly lower and plasma lactate concentrations higher when compared to exercise in temperate conditions (15°C, 55% relative humidity).[47] Although the mechanism of the reduction in peak oxygen uptake in horses exercising in heat and humidity has not been determined, it is possible that alterations in breathing strategy that favor heat loss from the upper respiratory tract (dead space ventilation) and compromise of skeletal muscle blood flow result in decreased oxygen uptake and delivery. Regardless of mechanism, such a reduction in peak oxygen uptake is likely to impair performance relative to exercise performed in temperate conditions.

Physiologic factors affecting thermoregulatory capacity

The term 'exercise heat tolerance' refers to an ability to withstand high internal and external heat loads during exercise. In humans it is well recognized that high aerobic fitness and a period of acclimatization in the heat improves both physiological and psychological responses to the challenge of exercise in the heat.[48] Adaptations in heat dissipatory mechanisms improve cardiovascular stability, decrease the rate of heat storage, and increase the duration of exercise before volitional fatigue. However, highly trained athletes are also able to tolerate higher levels of hyperthermia when compared to untrained individuals, that is, volitional fatigue occurs at a higher core temperature.[49] Conversely, regardless of training or heat acclimatization dehydration decreases exercise heat tolerance, as evidenced by an increase in the rate of heat storage and the development of volitional fatigue at a lower level of hyperthermia. There is now evidence that these physiological factors also modify the thermoregulatory capacity of horses. Specifically, conditioning and heat acclimatization improve tolerance to exercise in the heat,

whereas dehydration adversely affects heat dissipation in horses during exercise.

Other factors that can influence thermoregulation in exercising horses include coat color and the density of the hair coat. Coat color will affect the quantity of solar heat absorbed, while a long hair coat will limit evaporative heat loss.

Conditioning

Physical training in a cool environment is broadly accepted to improve exercise heat tolerance. The extent to which heat dissipatory effector mechanisms are stimulated and the duration of that stimulus will determine the effectiveness of training in improving exercise-heat tolerance. Detectable changes in heat tolerance are evident in human athletes after 1 to 2 weeks of training but are much more substantial if regular training is sustained for 8 to 12 weeks.[50–53] In human subjects, the stimulus must be sufficient to elevate core temperature by approximately 1.5 to 2.0°C for a minimum of 30 min/day.[50,52,53]

At a given percent of maximal oxygen uptake ($\dot{V}O_{2max}$), trained athletes have a higher metabolic rate and, hence, greater heat production at any given relative exercise intensity. Despite this higher metabolic rate, the trained individual is able to maintain a similar core temperature when compared to the untrained subject indicating an enhanced ability to dissipate heat. Improved cutaneous blood flow and whole-body sweating has been measured in trained individuals and are the main contributions to more effective heat dissipation in human subjects.[54] However, highly trained human athletes have been shown to have less extensive sweat fluid losses during exercise[55,56] and there is evidence for similar sweating economy in horses following training.[57] Specifically, 8 weeks of moderate intensity treadmill conditioning resulted in a 1.6-fold increase in sweating sensitivity and an approximately 0.7°C decrease in sweating threshold in horses during exercise in hot, dry conditions (temperature 32–24°C, relative humidity 45–55%). Despite higher sweating rates for a given core temperature during exercise, decreases in recovery sweating rates resulted in an overall reduction in sweat fluid losses (Fig. 41.3).[57] This enhancement in sweating economy as a result of training may assist in minimizing demands placed on the circulatory system by reducing the extent of dehydration associated with fluid losses. Alterations in sweat composition following training in horses appear to reflect changes in the rate of sweat production rather than a modification of the sweat gland itself.[23,57]

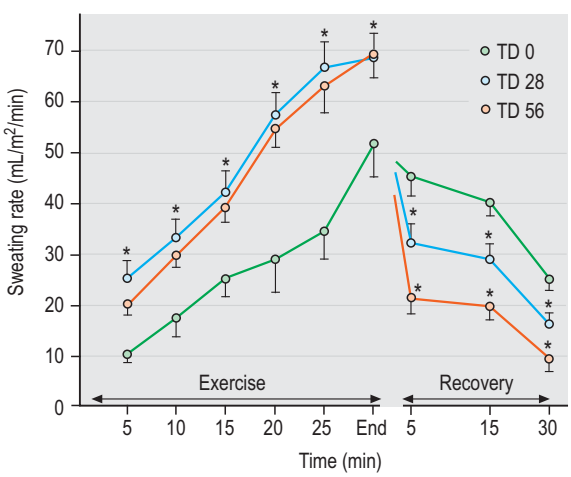

Fig. 41.3
Mean sweating rate for five horses averaged for 5-min intervals during an exercise test in hot, dry conditions (32–34°C and 45–55% relative humidity) at 50% of maximal O_2 uptake ($\dot{V}O_{2max}$) on training days (TD) 0, 28, and 56 of an 8-week training regimen. *Significantly different from TD 0 ($P < 0.05$). (Data from McCutcheon and Geor.[57])

Improvements to cardiovascular function are one of the hallmarks of training. The increase in plasma volume, stroke volume and cardiac output all contribute to increased cardiac stability during exercise and in particular, a lower heart rate at the same work output.[58] Expanded plasma volume in the trained athlete also improves thermoregulatory capacity by reducing the extent to which cutaneous blood flow is compromised. Increased resting plasma volume reduces the risk of a fall in cardiac output during exercise in the face of the decline in plasma volume associated with sweat fluid losses. In studies of human subjects, Roberts et al[59] observed earlier onset of cutaneous vasodilation in trained individuals. Similarly, in more recent work, Fritzsche and Coyle[54] demonstrated that cutaneous blood flow was higher in trained than in untrained individuals at the same relative work load despite similar core (esophageal) body temperatures. In the horse, as in human subjects, enhanced capacity for heat dissipation is, in part, a reflection of an expansion of blood volume[60] and likely a higher proportion of blood flow directed to the skin surface.

The time course of decay in training-induced thermoregulatory adaptations after the onset of detraining has not been determined in horses. In humans there is a strong association between aerobic fitness and exercise-heat tolerance, and the decline in thermoregulatory function with detraining tends to parallel the reduction in aerobic fitness.[49,50]

Heat acclimatization

The term 'acclimatization' is used to describe adaptive changes that occur when a subject undertakes repeated, prolonged exposure to severe environmental conditions (*acclimation* refers to the adaptations produced in controlled laboratory conditions). In the context of the present discussion, hot conditions are normally considered those that will induce the greatest thermoregulatory challenge for horses. As indicated previously, exercise training in a cool environment improves physiological responses when horses exercise in hot conditions. The adaptive responses to training and acclimatization are qualitatively the same. However, the more profound thermal stimulus used during acclimatization will

result in thermoregulatory adaptations of a greater magnitude.[60,61] Furthermore, factors that modify the environment in which acclimatization is undertaken will influence the extent of alterations. These differences are apparent in the higher rate of sweat production during exercise when acclimatization occurs in hot, dry versus hot, humid conditions.[62]

Human studies have demonstrated that the process of heat acclimation begins within a few (3–5) days of regular exposure to and exercise in the heat, with most adaptations complete within a 14-day period.[35,37,50,52,61] The most notable changes are an increase in plasma volume, a decrease in heart rate and core temperature during exercise, an increase in sweating rate and initiation of sweating at a lower body temperature, and redistribution of cardiac output such that there is an increase in blood flow to capillary beds of the skin. In general, the cardiovascular adaptations are complete during the first week of acclimation, whereas alterations in sweating responses require 10 to 14 days of repeated heat exposure.[60,61] Heat acclimation also may result in an improved efficiency of biochemical energy transformation in contracting muscles, thereby attenuating heat production in the acclimated versus unacclimated state.[26]

In horses, there is evidence that regular exercise in the heat results in physiological adaptations that are consistent with thermal acclimation. Marlin and coworkers[38] subjected 5 horses to 15 consecutive days of treadmill exercise in 30°C and 85% relative humidity. Training consisted of a combination of low, medium and high intensity exercise, with a total duration of exercise-heat exposure of 80 min per day. Before and after acclimation, horses undertook a treadmill exercise test designed to simulate the speed and endurance test of a three-day event at 30°C and 85% relative humidity. Following acclimation, four of the five horses were able to complete a significantly greater amount of phase D in the exercise test (pre: 6.3 ± 0.3 min; post: 7.3 ± 0.3 min; target time = 8 min), suggesting an improvement in heat tolerance. Resting body temperatures (rectal, pulmonary artery, tail skin) were lower after acclimation, whereas plasma volume was unchanged.[38]

In another study, six conditioned horses were exposed for 4 h to heat and humidity (temperature 33–35°C, relative humidity 80–85%) for 21 days.[63–66] One hour of low- and moderate-intensity treadmill exercise (30–60% $\dot{V}O_{2max}$) was completed during daily heat exposure. At regular intervals during the 21-day period, horses undertook a standardized submaximal (50% $\dot{V}O_{2max}$) exercise test in the same environmental conditions. In addition, before and after 18 days of acclimation, the horses performed the same exercise test in hot, dry conditions (relative humidity 45–50%). Exercise duration was defined as the time taken for attainment of a pulmonary artery blood temperature of 41.5°C. Similar to the findings of Marlin et al[38] there were significant decreases in resting body temperatures after 5–7 days of heat acclimation. However, in contrast to Marlin's findings, there was a 7–10% increase in plasma volume during the first week of heat acclimation. Thereafter, plasma volume tended to decrease and was not different from preacclimation values at the end of the experimental period.[65] There was a 25% increase in exercise duration when comparing trials performed in the hot, dry conditions before and after acclimation (Fig. 41.4). However, heat acclimation did not increase

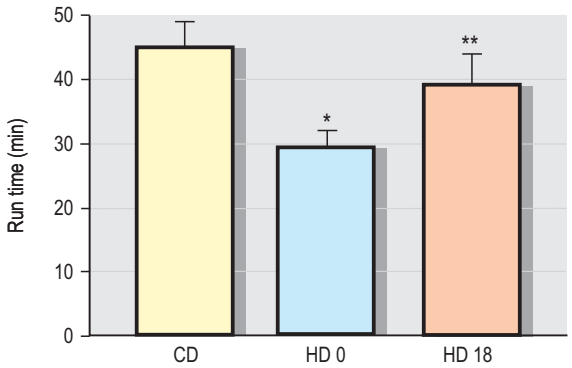

Fig. 41.4
Mean ± SE exercise duration during a standardized exercise test (SET) at 50% maximal O_2 uptake ($\dot{V}O_{2max}$) in cool dry (CD; room temperature [T] = 20°C; relative humidity [RH] = 45–55%) and hot dry conditions (T = 32–34°C, RH = 45–55%) before (HD 0) and after 18 days of heat acclimation (HD 18). *Significantly different from CD and HD 18; **significantly different from HD 0 ($P < 0.05$). (Data from Geor et al.[64])

Table 41.2. Run time during treadmill exercise in hot and humid conditions, pre-exercise body mass and change in body mass on days 0, 3, 7, 14 and 21 of heat acclimation in trained Thoroughbred horses

	Run time (min)	Body mass (kg)	Total sweat fluid loss associated with SET (L)	Sweat loss during exercise (mL)	% of total loss (exercise)	Sweat loss during recovery (ml)	% of total loss (recovery)
Day 0	19.09 ± 1.41	454.1 ± 11.7	11.67 ± 1.23	3844 ± 380	33.8 ± 2	7413 ± 953	66.2 ± 2
Day 3	20.92 ± 1.98	452.0 ± 12.0	12.00 ± 0.86	4179 ± 645	38.0 ± 4	6452 ± 818	62.1 ± 4
Day 7	19.59 ± 1.70	449.5 ± 11.5	11.50 ± 0.99	4324 ± 756	39.8 ± 3	5772 ± 875	59.8 ± 3
Day 14	20.42 ± 1.78	449.7 ± 10.1	10.08 ± 1.31	4451 ± 577	41.7 ± 3*	5323 ± 444	58.0 ± 3*
Day 21	19.61 ± 1.86	445.7 ± 8.7	8.67 ± 0.71*	4452 ± 490	50.7 ± 3*	4193 ± 435*	49.1 ± 3*

Values are mean ± SE for six horses. Run time represents duration of exercise at 50% $\dot{V}O_{2max}$ to attainment of a pulmonary artery temperature of 41.5°C. Total sweat fluid loss includes exercise and 1 h of recovery. Exercise includes exercise at 50% $\dot{V}O_{2max}$ only. Recovery includes 1 h of recovery only.
SET, standardized exercise test. *Significantly different from *day 0*, $P < 0.05$.

exercise duration in the hot, humid environment,[64] further emphasizing the biophysical limitations to heat dissipation in such conditions ('uncompensable heat stress').

Sweating rates greatly exceeded evaporative capacity throughout the 21-day period of humid heat exposure, as evidenced by profuse drippage of sweat from the body. In contrast to the findings of some studies in human subjects, whole-body sweat loss was attenuated with repeated heat exposure. Although sweating rates were slightly higher during exercise after acclimation, a more rapid abatement of sweating during the recovery period after exercise resulted in a significant reduction in overall sweat losses (Table 41.2). Similarly, calculated sweat ion losses were 26% lower after acclimation, for the most part a result of a 10% decrease in mean sweat sodium concentration. The more rapid decline in sweating rate during recovery may represent an adaptive mechanism for conservation of water and ions. An increase in respiratory heat loss as a result of humid heat acclimation, evidenced by an increase in postexercise respiratory rate, may have partially offset the decrease in cutaneous heat loss during the recovery period.[63,64]

In summary, horses undergo a number of physiological adaptations to repeated cycles of exercise heat stress that are consistent with a heat acclimation response. These adaptations are evident after 7–14 days and appear to confer a modest improvement in tolerance for exercise in the heat although, similar to observations in man,[37] this improvement is largely negated when exercise is performed in uncompensable heat stress conditions (high heat and humidity).

The physiologic adaptations associated with acclimatization to heat will diminish in the absence of the thermoregulatory stimulus. In human subjects, the rate of decay is reported to vary from one to several weeks[61,62] In physically fit individuals, there is a slower rate of decay of the thermoregulatory adaptations emphasizing the importance of exercise training in augmenting the benefits of heat acclimatization.[63] The time course of the decay in thermoregulatory adaptations in horses has not been reported.

Hydration state

Prolonged exercise, particularly when it is performed in hot and humid ambient conditions, can result in large fluid deficits that limit thermoregulatory and cardiovascular function. Studies in humans have demonstrated that dehydration of as little as 2–3% of body weight can impair heat transfer from the body core to the periphery, decrease sweating sensitivity (the increase in sweating rate per unit increase in core temperature), and increase the rate of rise in core body temperature during exertion.[67–69] Furthermore, dehydration decreases exercise heat tolerance such that fatigue occurs at a lower core temperature when compared to exercise undertaken in the euhydrated state.[70,71] In horses during 40 min of exercise eliciting 40% $\dot{V}O_{2max}$, pre-exercise dehydration (4% of body weight) induced by water with-holding or furosemide administration decreased cardiac output and increased pulmonary artery blood and middle gluteal muscle temperatures (by approximately 1°C) when compared to the euhydrated state. Peak sweating rates during exercise were not affected by hydration state.[72] The authors concluded that the dehydration-induced impairment of thermoregulation was primarily due to a decreased transfer of heat from core to periphery.

The effects of dehydration on thermoregulatory function in horses are magnified during exercise in the heat. During 90 min of treadmill running at 50% $\dot{V}O_{2max}$ under hot ambient conditions (room temperature 33–35°C; relative humidity 50–55%), progressive dehydration equivalent to 6–8% of body weight was associated with decreases in stroke volume, cardiac output and sweating rate, and higher blood, muscle and rectal temperatures when compared to trials in which hydration state was maintained by the administration of oral fluid equivalent to approximately 85% of the incurred sweat fluid losses.[27] In summary, pre-exercise dehydration or the progressive dehydration incurred as a result of sweat fluid losses during prolonged exercise will impair thermoregulation in horses. This impairment of thermoregulation will be reflected by a more rapid rise in body temperature. Such an exacerbation of hyperthermia would be expected to reduce exercise capacity due to earlier attainment of a critical upper limit in core and brain temperatures.

Old age

Almost all the studies that have addressed thermoregulatory responses to exercise in horses have used young subjects.[6,13,19,38,57] As a result, there are very limited data on the effects of age on thermoregulatory function during activity in older horses. McKeever and coworkers[73] demonstrated the older horses had higher heart rates and attained a core body temperature of 40°C in approximately 50% less time than younger mares when both groups were required to work at the same absolute work output (1625 watts). Despite their inability to dissipate heat load at a similar rate during exercise when compared to the younger mares, the older horses had similar heart rates and core temperatures 10 min post exercise.[73,74]

In human studies, older subjects have been shown to have lower total body water and plasma volume and, as a result, will have a smaller fluid volume that is available to produce sweat.[75,76] There is some suggestion that older subjects are chronically hypohydrated and that these age-related alterations in fluid and electrolyte status will add to an age-related reduction in thermoregulatory capacity. However, based on the limited data available regarding older horses, it appears that the fluid shifts during exercise are of similar magnitude in the aged and young horses.[73,74]

The sweating rate in older horses has been determined to be higher when working at the same absolute work intensity as younger mares. However, it would appear that this increased sweating rate did not improve the ability of the older horses to dissipate heat when compared to their younger counterparts. This could suggest that higher sweating rates occurred in the presence of lower skin blood flow in

older versus younger horses.[73] An apparent decline in maximal heart rate and stroke volume measured in older horses may contribute to this reduced heat dissipatory capacity.[77,78] While skin blood flow measurements were not undertaken in these studies, impaired cutaneous blood flow has been demonstrated in older human subjects in response to exercise.[76] The mechanism for this age-related change in skin blood flow has not been determined. Chronic hypohydration and a concomitant decrease in plasma volume have been suggested as a contributing factor for differences in thermoregulatory capacity in older versus young human subjects.[75,76] In one study, pre-exercise plasma volume was lower in old when compared to younger mares.[73] This relative hypovolemia could impair the thermoregulatory responses of older horses.[74]

Recommendations for preparation for exercise or competition in hot conditions

Although it is not possible to eliminate the effects of adverse effects of environmental conditions on exercise performance, there is evidence from human and animal (including equine) studies that a thorough exercise training program together with a subsequent period of acclimatization will mitigate the impact of the environment. Careful planning is needed for horses transported from a temperate to a hot, humid climate, and then required to train and compete in the hot environment. These horses should attain a high level of event-specific fitness before the trip, and be given adequate time for acclimatization to exercise in the hotter conditions. The hair coat should be clipped to facilitate cutaneous heat loss.[79] For the 1996 Olympic Games in Atlanta, Georgia, the International Equestrian Federation recommended that horses arrive approximately 3 weeks in advance of the events. This recommendation was based on research studies[38,63–66] that demonstrated physiological adaptations consistent with heat acclimatization after 14 consecutive days of exercise conditioning in heat and humidity. Minimal training was recommended in the first week, to allow horses to recover from the effects of prolonged transportation. There should not be the expectation of conducting the major portion of a horse's conditioning during this period.

Initially, only light exercise should be undertaken during the heat of the day, with harder workouts performed during cooler periods, e.g. early morning. Subsequently, there should be a gradual increase in the duration and intensity of exercise performed in the heat. It is important that some exercise be performed at the intensity required of the horse during competition. Careful clinical monitoring is required to assess successful adaptation to the environment. Collection of detailed clinical data should begin 1 to 2 weeks before travel to the hotter climate. These data will provide baseline information against which to compare clinical responses during initial days of training in the hot conditions. In addition, evaluation of this information will provide an objective assessment of how well the horse is adapting to the hot environment. Water and feed intake should be measured on a daily basis. Heart rate, respiratory rate, and rectal temperature should be recorded before and after training sessions. The intensity of work efforts can be estimated by use of a heart rate monitor. Daily weighing is useful for estimation of the extent of fluid losses associated with travel and training.

Assuming similarity in the duration and intensity of exercise bouts undertaken in both cool and hot ambient conditions, the exercise-induced increase in rectal temperature will serve as an indicator of the added thermal burden associated with the hotter conditions. The monitoring of post-exercise rectal temperature is critical to early detection of heat exhaustion and other heat illnesses. As there is a lag in the rise in rectal temperature, particularly after heavy exercise in hot and humid conditions, it is important to continue to monitor rectal temperature during the first 5 to 10 min after exercise. A rectal temperature that exceeds 42°C (108°F) indicates the need for immediate and vigorous cooling. Hyperthermia of this magnitude also may signal the need for a reduction in the intensity or duration of exercise in the hot ambient conditions. There may be an increase in resting respiratory rate following the transition from cool to hot ambient conditions. This increase reflects the thermoregulatory role of the respiratory system. Similarly, the postexercise respiratory rate is typically 30–40% higher following exercise in hot ambient conditions than in cool to moderate environments. In very hot and humid conditions (temperature of 33–35°C, relative humidity 60–75%), particularly when the horse is not cooled by the application of cold water, the respiratory rate may remain increased (up to 80–100 breaths/min) for 20–30 min after exercise. Persistence of tachypnea after the horse is placed in a cooler environment or is vigorously cooled may indicate that body temperature is still markedly elevated.

Maintenance of fluid and electrolyte balance is important for successful adaptation to a hot environment. Indeed, studies in humans have demonstrated that any thermoregulatory benefits derived from heat acclimation are overwhelmed by the elevated heat stress imposed by hypohydration.[61,71] The first concern is the fluid deficit resulting from the period of transport to the new location. Even when access to food and water is maintained during travel, horses typically incur a substantial loss of weight (approximately 3 kg/h of transport). Fluid losses will be higher during road transport in hot weather. As many horses drink poorly during the initial days in a new environment, this dehydration may persist for 3 to 4 days after arrival. Oral or intravenous fluid support is often provided to recently transported horses in an attempt to hasten correction of fluid balance. Dehydration of as little as 2–3% of body weight not only impairs thermoregulation and exercise performance but also prevents the expansion in plasma volume that typically occurs during the early phases of heat acclimatization. Thus, it is imperative that dehydration is corrected before commencement of training in the heat.

Given the increased fluid losses associated with a period of exercise training in a hot climate, an increase in daily water

consumption is to be anticipated. A 30 to 50% increase in 24-h water consumption was observed in horses undergoing heat acclimation; this change occurred within 10 days of the start of heat exposure and largely reflected an increase in water consumption in the 1-h period after exercise.[63]

Electrolyte or salt supplementation is recommended for horses training and competing in hot climates (see Chapter 40). Fat supplementation has been advocated as a means for reducing thermal stress in horses exercising in hot climates. A high-fat diet (8–10% on a total diet basis) may reduce the heat generated by colonic fermentation when compared to a more traditional diet that is higher in roughage.[5] In addition, lower roughage intake may decrease 'bowel ballast', which may be beneficial during high-intensity exercise. However, the actual effects of these dietary manipulations on thermal load in exercising horses have not been quantified. A limited number of studies have demonstrated that fat supplementation has no effect on fluid and electrolyte balance in horses performing daily exercise in hot conditions (mean daily temperature of 29.2°C).[80,81]

Diseases caused by inadequate thermoregulation

In human medicine, several terms are used to describe syndromes associated with environmental heat exposure or exercise-induced hyperthermia; these include heat stress, heat exhaustion and heat stroke. Heat stress is defined as 'perceived discomfort and physiological strain associated with exposure to a hot environment, especially during physical work', whereas heat exhaustion and stroke refer to mild-to-severe illness that result from exposure to high environmental temperatures or strenuous physical exercise.[82]

As discussed above, heat stress can occur when horses are exercised in warm ambient conditions, wherein physiological strain is evidenced by a more rapid rise in core body temperature, more severe exercise-induced dehydration, and higher heart and respiratory rates during recovery when compared to similar exercise in cool or moderate environments. The horse's prodigious capacity for sweating comes at a cost; high rates of sweat fluid loss can result in moderate to severe dehydration and electrolyte abnormalities that predispose to development of muscle cramping, rhabdomyolysis and synchronous diaphragmatic flutter (SDF). Furthermore, dehydration can impair heat dissipation and contribute to the progression from heat stress to heat exhaustion or heat stroke.

Anhidrosis ('dry coat')

- Defined as an inability to sweat effectively in response to suitable stimuli such as heat or exercise.
- Occurs almost exclusively in horses living in hot or hot and humid climates.
- The mechanism of anhidrosis is not understood, but may involve down regulation of sweat gland β_2-receptors.
- Clinical signs include patchy and inadequate sweating, marked hyperthermia in response to exercise, and delayed recovery of rectal temperature, heart rate and respiratory rate after exercise. Horses with long-standing anhidrosis may exhibit dry and flaky skin with alopecia.
- Exercise during cooler periods of the day, housing the horse in an air-conditioned stall, or relocation to a more temperate climate are possible preventive strategies.

Recognition

History and presenting complaint

Affected horses often present with a history of poor or decreased exercise performance or exercise intolerance. On occasion, a dermatologic abnormality is the initial presenting complaint. An absent or inappropriate sweating response is often not detected by owners and trainers. Instead, they report poor exercise performance, labored breathing after exercise, and deterioration of the hair coat. The condition is normally more evident during hotter summer months.

Physical examination

Affected horses develop the problem in the summer months and usually recommence sweating in the winter. The primary clinical signs of anhidrosis reflect inadequate cutaneous evaporative heat loss, and include failure to sweat, tachypnea at rest, elevated rectal temperature, and a delayed postexercise recovery in rectal temperature and respiratory rate. Tachypnea (> 60–80 breaths per min) with marked nostril flare can persist for 60 or more minutes after exercise. Affected horses may seek shade or attempt to cool themselves with water (e.g. stand in water troughs), particularly during the heat of the day.

The degree of anhidrosis is variable, ranging from partial sweat production to complete absence of sweating. Body areas that may retain the ability to sweat include under the mane, the saddle and halter regions, and the axillary, inguinal and perineal regions. Sweat gland density is highest in these regions, and these areas appear to the last affected prior to onset of complete anhidrosis. Dermatologic abnormalities in horses with long-standing anhidrosis include a dry, sparse hair coat with excessive scaling and alopecia, particularly of the face, neck and shoulders.

Diagnosis

The diagnosis of anhidrosis is predominantly based on history and repeated demonstration of inadequate sweating in response to adequate thermogenic stimuli. Semiquantitative data on sweating response may be obtained by intradermal skin testing using injection of a specific β_2-agonist such as terbutaline or salbutamol. Serial dilutions (10^{-3} to 10^{-8} [w/v]) of the β_2-agonist and a control saline solution are injected into shaved

areas over the neck. Normal horses sweat in response to all dilutions, usually within 15–20 min of injection. Horses with partial anhidrosis sweat only in response to the highest β_2-agonist concentration, whereas horses with more severe anhidrosis may be refractory to all concentrations. Histological examination of skin sections may be unrewarding, although ultrastructural changes in the sweat glands and surrounding tissues may be evident. These changes include thickening of the basal lamina and connective tissues, and a marked reduction in the number of secretory cell vesicles. The lumen of sweat gland ducts may be obstructed with cellular debris, and luminal microvilli are often absent.

Anhidrosis should be differentiated from respiratory diseases that result in an increase in respiratory rate.

Treatment and prognosis

Therapy

Given the paucity of knowledge as to the underlying mechanisms for the altered pattern and intensity of sweating, no effective treatment has been determined. However, the risk of heat stress and heat stroke can be mitigated by a combination of environmental and management strategies. The only recognized effective treatment is to remove affected horses to a cooler environment, either physically (i.e. move to a more temperate climate) or by the use of air conditioning or other means of assisted cooling. Some change in exercise routine is required. Heavy training and competition during the summer months should be discouraged. On the other hand, anhidrotic horses that are rested during the summer may train and compete successfully during the cooler winter months. Anecdotally, affected horses resume a more normal sweating response as night-time temperatures begin to decline. For horses maintained in exercise training during the summer, workouts should be conducted during cooler periods of the day (e.g. early morning) and they should be cooled aggressively after exercise (e.g. the liberal and repeated application and removal of cool water over the entire body).

A variety of nutritional supplements have been advocated in the treatment of anhidrosis, but objective data on the efficacy of these products is not available. Anecdotally, some veterinarians and trainers have reported that horses with a history of anhidrosis that are treated with electrolyte supplements (especially sodium and potassium) before the onset of hot weather and during the summer months do not develop further episodes of anhidrosis. As tyrosine is thought to be important for the resensitization of β_2-receptors, supplementation with this amino acid has been recommended for horses with anhidrosis. Similarly, some veterinarians have claimed success when affected horses are supplemented with vitamin E (1000–3000 U/day) or iodinated casein (10–15 g/day for 4–8 days).

Prognosis

There is anecdotal evidence that most affected horses respond favorably to a change in environment and begin to sweat normally after a few days to weeks. A complete return to normal sweating function may take 3–4 months in some horses. There are no published reports on the long term follow-up of horses with anhidrosis. However, it is generally believed that horses with a history of anhidrosis will become anhidrotic when again exposed to hot, humid conditions.

Etiology and pathophysiology

The pathophysiological mechanisms underlying anhidrosis are not known. Various factors have been suggested, including electrolyte imbalances, hypothyroidism, sweat gland exhaustion, plugging or blocking of the sweat gland ducts to the surface, failure of secretory function, and a downregulation of glandular sensitivity. The most plausible cause is altered sweat gland receptor function. It is thought that overstimulation of sweat gland β_2-receptors results in diminished function via desensitization or downregulation of the receptors. Even apparently normally sweating horses have reduced sensitivity to intradermal epinephrine (adrenaline) in a hot and humid environment.[83] That many anhidrotic horses once again achieve adequate sweat production upon removal to a cooler climate emphasizes the importance of environmental conditions to the development of clinical disease. One hypothesis is that increased circulating epinephrine (adrenaline) concentrations result in overstimulation of the sweat glands. Beadle et al.[84] reported higher resting epinephrine (adrenaline) concentrations in anhidrotic horses compared with control horses in the same hot and humid climate. However, other studies[83,85] did not detect a difference in epinephrine (adrenaline) concentrations between control and anhidrotic horses.

For the equine athlete, the loss of an adequate sweating response translates into a reduction in the efficacy of heat loss through evaporation and an early and excessive increase in core temperature in response to moderate exercise. Exercise intolerance and poor performance can be attributed to hyperthermia. Increased respiratory rate, both at rest and after exercise, reflect an attempt to dissipate heat via the respiratory tract.

Epidemiology

Anhidrosis is almost exclusive to horses living in hot or hot and humid climates. It is estimated that as much as 20% of the population of athletic horses exercising in hot humid climates experience some degree of anhidrosis. However, more severe signs of anhidrosis are recognized in a smaller percentage of horses.[86] Anecdotally, greater susceptibility is evident in horses bred and raised in cooler climates and transported to a warm and humid climate for training or competition.

Prevention

There is no proven strategy for the prevention of anhidrosis in horses kept in hot and humid climates. However, further

episodes of anhidrosis may be prevented by relocation to a cooler climate. When physical removal from the hot climate is not possible, exercise and environmental management can prevent excessive hyperthermia and minimize the risk of heat stress or stroke.

Heat exhaustion/heat stroke

- Heat illnesses can result from exposure to high environmental temperature (non-exertional heat stroke) or, more commonly, from strenuous exercise (exertional heat stroke) undertaken in hot and/or humid ambient conditions.
- Heat exhaustion is a mild-to-moderate illness characterized by hyperthermia, tachypnea, dehydration, and fatigue. A more severe exhaustion syndrome attributed to the combined effects of hyperthermia, fluid and electrolyte deficits, and substrate depletion occurs in horses undertaking endurance exercise.
- Heat stroke is a severe illness in which there is thermoregulatory failure and development of multiorgan dysfunction, including encephalopathy.
- Clinical features common to heat exhaustion and heat stroke include hyperthermia, tachypnea with panting, tachycardia, evidence of dehydration, and fatigue. Other signs may include reduced sweat production with dry hot skin, synchronous diaphragmatic flutter (SDF), muscle cramps, and colic. With heat stroke, these signs are accompanied by neurologic abnormalities including weakness, ataxia progressing to collapse, convulsions, coma, and death.
- Exhausted horses that have sustained large sweat fluid losses may develop a 'postexhaustion syndrome' characterized by renal failure, laminitis, hepatic failure, myonecrosis and a high mortality rate.
- Therapy includes rapid assisted cooling, intravenous fluids for correction of dehydration and electrolyte and acid–base abnormalities, and judicious use of anti-inflammatory drugs.

Recognition

History and presenting complaint

Heat exhaustion and heat stroke can occur in any environmental condition but are more likely to occur in a hot and humid environment. These conditions should be viewed as a continuum; a state of heat stress can progress rapidly to heat exhaustion or heat stroke. Most often, heat stroke is recognized in association with exercise, particularly when undertaken in hot and humid ambient conditions. Affected horses may have a history of anhidrosis or prior episodes of heat exhaustion. Less commonly, heat stroke may develop in horses confined in closed trailers or buildings during hot weather. Affected horses may present with complaint of fatigue, depression, weakness, stilted gait, respiratory distress, and neurologic abnormalities including seizures.

Physical examination

The clinical signs of heat exhaustion reflect the deleterious effects of hyperthermia, dehydration, hypovolemia, and electrolyte disturbances on the function of many body systems. Hyperthermia (rectal temperature > 41–42°C), elevated heart rate (> 60–80 bpm), rapid, shallow respirations (> 80–100 breaths/min), dehydration, and evidence of fatigue are often present. Horses that have completed prolonged exercise in hot weather (e.g. an endurance race) are often dehydrated and hypovolemic. Therefore, skin elasticity may be decreased, capillary and jugular refill time delayed, and mucous membranes tacky or dry. Cardiac auscultation or electrocardiographic examination may indicate a tachyarrhythmia. Horses may be unwilling to drink despite moderate to severe dehydration. While fatigued, these horses do not necessarily appear depressed, although they might exhibit a slightly stiff gait and possibly lameness in association with muscle cramping or soreness. High metabolic heat load is often reflected in a delayed postexercise recovery of heart and respiratory rates (more than 20–30 min) and excessive sweating. Rectal temperature may continue to rise during the 5–10 min period immediately following the cessation of exercise. Decreased anal tone, muscle cramping and SDF may be evident.

By definition, both hyperthermia and central nervous system dysfunction must be present for a diagnosis of heat stroke. Signs of heat stress or exhaustion are accompanied by evidence of brain dysfunction, including a weak, staggering gait, depression or poor mentation, convulsions and coma. There may be excessive sweating with a uniformly wet hair coat or, especially in dehydrated animals, a hot dry skin with dilated cutaneous vasculature.

A number of serious complications can develop in horses with heat exhaustion or stroke. In horses undertaking prolonged exercise that results in exhaustion, glycogen depletion, and marked fluid and electrolyte deficits, such as endurance rides of 50 to 150 miles, a 'postexhaustion syndrome' characterized by multiorgan dysfunction or failure may develop. These horses may develop laminitis, colic, renal and/or hepatic failure, or myonecrosis in the 1–3-day period after the strenuous exercise. Similarly, horses that recover from the acute phases of heat stroke may develop a syndrome of multiorgan dysfunction characterized by renal and hepatic failure, laminitis, pulmonary edema and respiratory distress, and disseminated intravascular coagulation.

Diagnosis

A number of clinicopathologic abnormalities may be present in horses with heat exhaustion or stroke. Respiratory alkalosis due to hyperventilation is usually present. Metabolic alkalosis or acidosis (lactic acid accumulation) may be present depending on the nature of the exercise performed. There is an increased PCV, Hb, red cell count, and TPP and elevated creatine kinase and aspartate aminotransferase activity and decrease serum electrolytes (P, Cl, Ca [total and ionized], Mg, and possibly Na). A stress neutrophilia and lymphopenia with possible

degenerative left shift and leukopenia in face of impending diarrhea may be evident. Severe dehydration and the possible onset of renal disease may be reflected in elevated blood urea nitrogen and creatinine. Urinalysis may reveal high specific gravity (with dehydration and normal renal function) or low specific gravity when renal disease is present with or without evidence of protein or blood in urine. A clotting profile may indicate disseminated intravascular coagulation (thrombocytopenia, increased fibrin degradation products, and prolonged prothrombin time).

Treatment and prognosis

Therapy

Horses exhibiting signs of heat stroke require immediate and aggressive use of cooling techniques and intravenous fluid administration. The horse should be removed from direct sunlight to minimize further radiative heat gain. Unnecessary tack should be removed and the horse left unblanketed. If available, the horse should be positioned in front of high-output fans to increase convective heat loss. Cold water should be applied to the head, neck and body; this will increase the temperature gradient between the skin and the environment, and therefore increase conductive heat loss. The applied water must be quickly removed by use of a skin scrapper with subsequent application of further cool water to maintain this gradient. Misting fans are sometimes available at competitions held during the summer months; these also assist heat dissipation. Internal cooling techniques, such as the intragastric or rectal administration of cold water may be attempted. However, the latter obviates use of the rectum for monitoring the temperature response to therapy. Assisted cooling should be continued until rectal temperature is less than 39°C.

Large volume intravenous fluid replacement is indicated. Normal saline (0.9% NaCl) is the fluid of choice in cases of metabolic alkalosis, but any balanced polyionic solution (e.g. lactated Ringer's solution) is suitable in the face of hypovolemia and dehydration. As much as 60–80 L of fluid may be required over a 6- to 12-h period in severely dehydrated horses. Subsequent fluid therapy should be guided by clinical assessment and the results of serum biochemical analysis. Supplemental calcium may be required in horses with SDF. Oral fluid therapy may be considered providing the horse has normal gut sounds and no clinical evidence of colic or gastric reflux. Further details on the correction of exercise-induced dehydration and electrolyte disturbances are presented in Chapter 40.

The role of antipyretic and anti-inflammatory agents (e.g. non-steroidal anti-inflammatory drugs [NSAIDS]) in the management of heat stroke is unknown. Animal studies have demonstrated that the correction of hyperthermia after the onset of heat stroke may not prevent inflammation, coagulation, and progression to multiorgan dysfunction. On the other hand, treatment with glucocortocoids and immunomodulators such as interleukin-1 (IL-1) receptor antagonists improves survival in animals with heat stroke.[83] Other studies have shown that salicylates and NSAIDs enhance cellular protection against heat stress via induction of the transcription and translation of heat-shock proteins.[87] Accordingly, there may be rationale for the judicious use of NSAIDs (e.g. flunixin meglumine, 1.0 mg/kg) and glucocorticoids (e.g. methylprednisolone sodium succinate, 2–4 mg/kg i.v.) in horses with heat stroke. NSAIDs should also be administered if the horse has pain associated with colic, exertional rhabdomyolysis, or laminitis.

Rest is paramount and therefore it is advisable to transport the horse back to a stabling area once their condition has been stabilized to avoid the requirement for further exercise. Close clinical monitoring is required for a 3–5-day period after an episode of heat exhaustion or heat stroke. This should include clinical assessment of attitude, appetite, hydration status, gastrointestinal function and digital pulses. Serial measurements of serum biochemistries should also be performed. These evaluations will guide further therapy.

Prognosis

There are no reports of long-term follow-up of horses that have suffered an episode of heat stroke. Clinical experience has indicated that the prognosis for heat stroke is variable depending on severity. The recovery of central nervous system function during cooling is a favorable prognostic sign. On the other hand, persistence of neurologic abnormalities and/or the development of complications such as pulmonary edema, laminitis, renal or hepatic failure and disseminated intravascular coagulation indicate a much poorer prognosis.

Etiology and pathophysiology

A complex interplay of physiological alterations that accompany hyperthermia including circulatory failure, hypoxia, increased metabolic demand, and inflammatory and coagulation responses result in the development of heat stroke and the associated progressive multiorgan dysfunction.[82] Heat stress induces thermoregulatory, heat shock and acute phase responses. Thermoregulatory failure, altered expression of heat-shock proteins and an excessive acute phase response individually or collectively contribute to the development of heat stroke. Studies in animal models have demonstrated increased production of nitrogen or reactive oxygen species with splanchnic hypoperfusion, the result of the diversion of blood flow to the cutaneous circulation and away from the gut.[82] Subsequent mucosal injury and hyperpermeability allows the escape of endotoxin into circulation, further stimulating the acute phase response and the production of pyrogenic cytokines and nitric oxide, both of which can further interfere with thermoregulatory mechanisms. The production of these cytokines and nitric oxide can therefore precipitate hyperthermia, hypotension, and heat stroke (Fig. 41.5).

In addition to the leakage of endotoxin from the intestine, hyperthermia can also lead to the release of IL-1 and IL-6 proteins from muscle. A high level of activation of leukocytes and endothelials cells with subsequent release of pro- and anti-

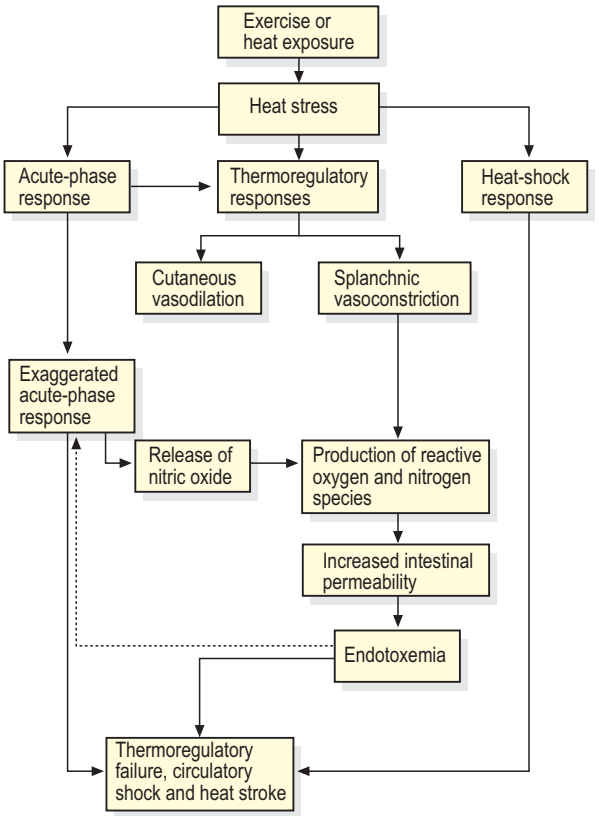

Fig. 41.5
Proposed sequence of events in the development of heat stroke in mammals. Heat stress induces thermoregulatory, acute-phase, and heat-shock responses. The redistribution of cardiac output to accommodate cutaneous heat loss results in splanchnic hypoperfusion and ischemia and the increased production of reactive oxygen and nitrogen species. These mediators may induce intestinal mucosal injury and an increase in permeability that allows the entry of endotoxin into circulation. Endotoxin enhances the acute-phase response, leading to production of pyrogenic cytokines and nitric oxide. These mediators can disrupt thermoregulation and precipitate heat stroke. Solid arrows indicate pathways for which there is experimental evidence; broken arrows indicate putative pathways. (Adapted from Bouchama and Knochel.[82])

inflammatory cytokines (IL-1, IL-6, IL-10, tumor necrosis factor α), upregulation of cell-surface adhesion molecules, and shedding of soluble cell-surface adhesion molecules as well as activation of coagulation and inhibition of fibrinolysis. Direct cytotoxic effects to cells and the inflammatory and coagulation responses result in endothelial injury and microthrombosis.[82]

A critical thermal maximum beyond which lethal injury occurs has been determined in several mammalian species.[88] In humans, critical thermal maximum is a core body temperature of 41.6°C to 42°C for 45 min to 8 h. The critical core temperature for horses has not been determined. However, exercise-associated elevation in muscle temperature above 43°C (109.4°F) results in alterations in muscle mitochondria and sarcoplasmic reticulum in horses.[89] As previously discussed, the onset of volitional fatigue in humans occurs at a core (esophageal or rectal) temperature of approximately 40°C, whereas studies in horses indicate that voluntary exhaustion does not occur until core or rectal temperatures of 42°C or greater. It is possible that horses have higher heat tolerance when compared to humans. Alternatively, the thermal limit to exercise may be very similar to that associated with the induction of heat stroke,[28] further emphasizing the need for the close monitoring of horses exercising in warm conditions.

Epidemiology

Epidemiological data on risk factors for heat stroke in horses are not available. However, poor physical conditioning, lack of heat acclimatization, prolonged exercise in hot and humid ambient conditions, dehydration, long hair coat, and obesity are factors that may increase the risk of exertional heat stroke. Horses with a history of anhidrosis are obviously at higher risk for heat stroke. In addition, the heavily muscled breeds (e.g. Warmbloods) may be at higher risk because of a low body mass to surface area ratio.

Prevention

One of the most important criteria for the prevention of heat stress is ensuring that horses have undertaken a training program that is adequate for the level of exercise or competition that will be demanded of them. However, it should be recognized that it is possible to overwhelm the thermoregulatory capacity of horses with a high level of physical conditioning when exercise is prolonged and/or there are adverse environmental conditions that will impair heat dissipatory mechanisms. Under such conditions, seeking shade at stops to reduce solar heating, using fans to improve convective cooling, and frequent, copious application of cool water will reduce the rate at which heat is stored.

As stated previously, an adequate training program will substantially improve thermoregulatory efficiency during exercise. When there is a requirement to compete in severe (i.e. hot) environmental conditions, then acclimatization to hot conditions will further enhance the horse's ability to thermoregulate in adverse conditions. Under such conditions greater attention needs to be paid to ensuring that there are an adequate number of stops during which cooling can take place. The extent of fluid losses can be ameliorated if horses are trained to drink fluids at rest stops during competition. Early recognition of hyperthermia and heat exhaustion with aggressive medical intervention will prevent development of heat stroke.

CHAPTER 42

Hematologic and serum biochemical responses to exercise and training

Janene K. Kingston

Blood consists of many components that play an essential role in supporting the increased metabolic rate during exercise by transporting oxygen, water, electrolytes, nutrients, and hormones to working muscles. In addition, carbon dioxide and other waste products produced during exercise are removed from muscle by the circulation. Finally, blood components are important in buffering the acid–base changes associated with exercise. The cellular components of blood include erythrocytes, leukocytes, and platelets, whereas the plasma component is made up of water, electrolytes, plasma proteins, and various hormones and enzymes.

Over the years, evaluation of the hemogram and plasma or serum biochemistry has been used to assess the health status or function of a range of body systems in the athletic horse. These tests are commonly used to assess fitness and performance potential, as well as to investigate poor performance in horses. However, there is a wide degree of variation in values of various blood constituents depending on, among other things, whether a horse is at rest or is exercising when the sample is collected. Additionally, the training status of a horse, as well as sampling techniques, can directly affect the hemogram and serum or plasma biochemistry. It is important that the veterinarian is aware of how such factors may impact test results. In this chapter, those factors that can affect the interpretation of hematology and serum or plasma biochemical profile will be detailed.

Methods

Blood samples should be collected using appropriate equipment and techniques. The jugular vein is commonly used for blood sampling and blood is collected into evacuated glass collection tubes. For routine hematology, blood samples should be collected into tubes containing ethylenediaminetetra-acetic acid (EDTA) as an anticoagulant. Given that EDTA can cause a pseudothrombocytopenia,[1] an additional sample may be collected into sodium citrate to ensure an accurate assessment of platelet numbers. Samples for serum or plasma biochemistry can be collected into tubes that do not contain an anticoagulant (serum) or into tubes containing lithium or ammonium heparin (plasma). Some laboratories prefer serum to plasma samples; it is therefore wise to ascertain the laboratory's preference prior to collection of blood samples. It is also important to note that samples collected into EDTA are unsuitable for plasma biochemistry measurements whereas samples collected into heparin are unsuitable for hematology. In addition, if plasma glucose or lactate values are to be measured, blood should be collected into tubes containing sodium fluoride/potassium oxalate as an anticoagulant.

When assessing hematology, the technique of collection, the horse's attitude and degree of excitement, relationship to feeding, and time of day can all have a profound effect on values. In addition, storage of blood samples overnight may result in a slight elevation of hematocrit and mean cell hemoglobin (MCH), probably due to enlargement of erythrocytes.[2] Storage of blood samples can also result in alterations in plasma or serum biochemistry. Therefore, it is important to standardize collection and handling techniques as much as possible.

The temperament of the horse and the technique used by the sample collector can have an important effect on both the erythrocyte and leukocyte values.[3–5] Excited horses that resist venepuncture and move about forcefully have higher

erythrocyte and leukocyte counts.[4] This may relate to the time taken to collect a blood sample in more fractious horses. It takes 30–60 s to mobilize erythrocytes from the spleen following the administration of intravenous epinephrine (adrenaline).[6] It is likely that samples collected within 30 s from less excited horses have fewer or less marked alterations in the hemogram.[4,7] At the other end of the spectrum, it is possible that very placid horses have values for red cell indices that are lower than the mean for values for the breed.[8] Therefore, it is important to note the attitude of the horse during blood collection so that the results can be correctly interpreted.

Other important factors that affect the hemogram and serum or plasma biochemistry are the diet and time of feeding. For example, in the hours after ingesting a hay meal there is a substantial increase in hematocrit and plasma protein concentration (Fig. 42.1).[9] These changes are a result of increased salivary fluid production[9] and fluid shifts from the circulation to the gastrointestinal tract.[10–12] Furthermore, feeding a large concentrate meal results in a 12% increase in plasma protein concentration with significant reductions in plasma volume.[12,13] Therefore, one should avoid collecting blood samples within 3 h of feeding a large concentrate meal or hay ration, or at least ensure that samples are collected at the same time each day and that feeding status is noted to allow for appropriate interpretation of values.

Following exercise it takes 1 to 2 h for hemogram changes to return to pre-exercise values. If blood samples are collected in the afternoon after morning exercise, there is a higher proportion of neutrophils and higher leukocyte numbers than in blood samples collected in the morning before exercise.[14] However, there does not appear to be a significant difference between hemograms for samples collected from resting horses either in the morning or afternoon.[15] It is therefore recommended that blood samples are collected either prior to exercise in the morning or on days when horses do not exercise to avoid exercise-induced effects on the hemogram.

Hematology

Structure and function

Erythrocytes

Erythrocytes are anucleate cells that normally circulate for several months in blood. Their primary purpose is to carry hemoglobin, a heme-containing protein that accounts for 95% of the total protein in erythrocytes. Erythrocyte functions include oxygen transport to the tissues, carbon dioxide transport to the lungs, and hydrogen-ion buffering, all of which are inter-related.

Oxygen transport

Oxygen is carried in the blood in two forms. Most oxygen is carried in combination with hemoglobin but some is carried as dissolved oxygen. Under normal conditions in arterial blood, 0.3 mL of dissolved oxygen is carried per 100 mL of blood.

The amount of oxygen transported by hemoglobin is much greater than that carried in the dissolved form. Hemoglobin is a tetrameric protein consisting of four polypeptide globin chains, each of which contains a heme prosthetic group. Each hemoglobin tetramer can bind four molecules of oxygen when fully saturated. Under normal circumstances, the presence of hemoglobin-containing erythrocytes increases the oxygen-carrying capacity of blood to approximately 70 times more than that that would be transported dissolved in plasma.[16] The oxygen molecule combines loosely and reversibly with the heme portion of hemoglobin. The partial pressure of oxygen (Po_2) affects the quantity of oxygen bound with hemoglobin. When the Po_2 is high, as in the pulmonary capillaries, oxygen binds with the hemoglobin, but when the Po_2 is low, as in the tissue capillaries, oxygen is

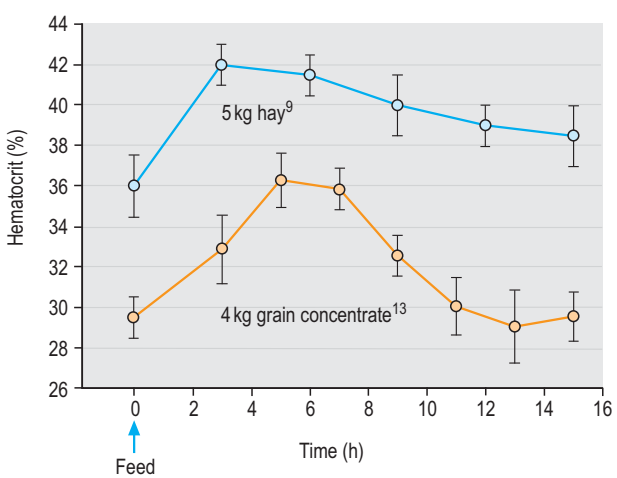

Fig. 42.1
The effect of a single feed of 5 kg of hay[9] or 4 kg of grain concentrate[13] on the hematocrit.

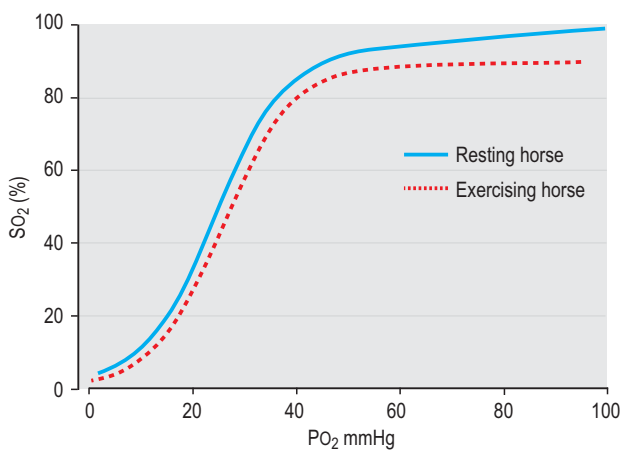

Fig. 42.2

released from the hemoglobin. There is a progressive increase in the percentage of hemoglobin that is bound with oxygen as Po_2 increases, yielding the oxygen–hemoglobin dissociation curve (Fig. 42.2).[17] The curved nature of the oxygen–hemoglobin dissociation curve has several physiological advantages. The flat upper portion means that even if the alveolar gas Po_2 falls somewhat, loading of oxygen will be little affected. In addition, as the red cell takes up oxygen along the pulmonary capillary, a large partial pressure difference between alveolar gas and blood continues to exist when most of the oxygen has been transferred, hastening diffusion. The steep lower portion of the dissociation curve means that the peripheral tissues can withdraw large amounts of oxygen for only a small drop in capillary Po_2. This maintenance of blood Po_2 assists the diffusion of oxygen into the tissue cells.[16]

The oxygen–hemoglobin dissociation curve can be displaced such that the affinity for oxygen is altered. Factors that shift the curve include changes in carbon dioxide concentration, blood temperature, blood pH, and the concentration of 2,3-diphosphoglycerate (2,3-DPG). Changes in blood carbon dioxide and hydrogen ion concentration have a significant effect in enhancing oxygenation of blood in the lungs and enhancing the release of oxygen from the blood to the tissues through the Bohr effect.

Carbon dioxide transport

Carbon dioxide is transported in blood as either dissolved carbon dioxide (5%), bicarbonate ions (70–90%), or as carbamino compounds (5–10%). The majority of carbon dioxide is transported as bicarbonate ions. This is because erythrocytes have a high activity of carbonic anhydrase, an enzyme that catalyzes the reaction between carbon dioxide and water. This reaction makes it possible for water to interact with large quantities of carbon dioxide, enabling transport of carbon dioxide from the tissues to the lungs in the form of bicarbonate. This is particularly important during exercise as working muscles release large quantities of carbon dioxide.

As described earlier for the Bohr effect, the partial pressure of carbon dioxide and pH can loosen the binding of oxygen with hemoglobin. Conversely, oxygen can also act to displace carbon dioxide and hydrogen ions from hemoglobin; this is termed the Haldane effect. Both the Bohr and Haldane effects can be explained by the fact that deoxyhemoglobin is a weaker acid than oxyhemoglobin. Hence, deoxyhemoglobin more readily accepts hydrogen ions liberated by the dissociated form of carbonic acid at the tissue level when carbon dioxide is released into the blood from the tissues. This allows more carbon dioxide to be transported in the form of bicarbonate ions. At the same time, the association of hydrogen ions with hemoglobin lowers the affinity of hemoglobin for oxygen causing a shift of the oxygen–hemoglobin dissociation curve to the right, facilitating the unloading of oxygen at the tissue level.[16]

Leukocytes

Leukocytes have a primary role in immune function. There are normally six different types of leukocytes found in the circulating blood: neutrophils, eosinophils, basophils, monocytes, lymphocytes, and occasional plasma cells. In resting blood samples, the white cell count does not reflect the total intravascular pool, as this consists of both the circulating and marginal pools, the latter being sequestered in capillary beds and the spleen.[18] Therefore, any factors that cause mobilization of cells from the marginal pool will increase the numbers of leukocytes in the circulating pool. Such factors include plasma catecholamine and cortisol concentrations. Therefore, recent stress such as transportation or exercise of a horse can alter the white cell count in blood samples.

Platelets

Platelets are anucleate cell fragments derived from megakaryocytes in the bone marrow that normally circulate in the bloodstream for 4–5 days. Platelets interact with the endothelium and circulating coagulation factors in the maintenance of normal hemostasis. In addition, platelets are also thought to be involved in inflammatory and immunological processes.[19] Platelets are also sequestered in the spleen and are subject to increases in circulating numbers with splenic contraction. Platelets are also subject to activation following injury of the endothelium, through inappropriate handling in vitro and potentially through sheer stress in the vascular system. For the exercising horse, each of these factors is a consideration when evaluating both platelet numbers and activation status.

The normal resting hemogram

For the normal resting hemogram, the normal range for an individual horse is quite narrow, whereas there are much broader ranges across horse breeds, with further variation due to age and state/type of training. The normal ranges for various breeds, age groups, and horses in training are given in Appendices 1 and 2. The red cell indices show the greatest variation amongst breeds. This relates to factors such as plasma volume expansion seen in endurance-trained animals but not in Thoroughbred or Quarter Horse race horses. In addition as mentioned earlier, the temperament of a horse can significantly affect red cell indices.

Hematologic responses to exercise

Erythrocyte indices

Exercise has variable effects on the hemogram depending on work intensity (Fig. 42.3).[20–28] Exercise generally results in mobilization of splenic erythrocytes and, therefore, increases the oxygen transport capacity. The extent of the potential increase in circulating red cell mass is quite remarkable, as the spleen has the capacity to store up to 50% of the total red blood cell pool.[29] The release of splenic erythrocytes is under the influence of catecholamines. Both the intensity and duration of exercise are important in determining the magnitude of the catecholamine response.[30] The extent of the increase in hematocrit is a function of exercise intensity, with a linear

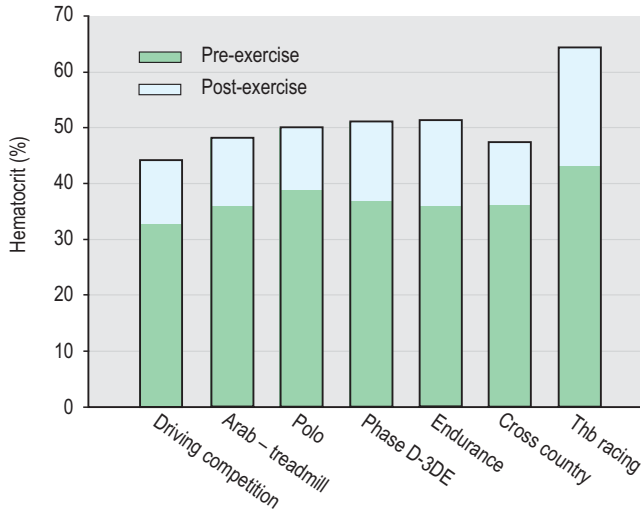

Fig. 42.3
The effect of different types of exercise including the cross-country phase of driving trail competition,[21] low-intensity treadmill exercise,[28] during a polo match,[26] phase D of a three-day event,[25] an 80-km endurance ride,[24] the cross-country phase of a three-day event,[22] and Thoroughbred racing[20] on the hematocrit.

relationship between hematocrit and speed,[23,31] up to a maximum hematocrit of approximately 60–65%.[7] There are, however, variations in splenic capacity in association with breed of the horse as well as age. Draught horses have lower relative splenic weights compared to Thoroughbred horses[32] and it appears that splenic capacity alters in response to increasing age (from 1 to 3 years) in Trotters.[31,33]

While the majority of the increase in hematocrit during high-intensity exercise is attributable to splenic contraction, exercise-induced fluid shifts also play a role. For horses performing moderate short-term incremental exercise there is a 5–10% decrease in plasma volume.[34] However, given the substantial fluid losses incurred during prolonged endurance exercise, it is likely that reductions in plasma volume play a greater role in changes in hematocrit observed in endurance exercise.

In association with the increases in hematocrit are increases in the erythrocyte count and hemoglobin concentration. As a consequence of the increase in hemoglobin concentration there is an increased oxygen transport capacity, an important factor in the horse's high aerobic capacity.[35] Indeed, studies of splenectomized horses have shown a marked reduction in exercise capacity.[29,36] However, the increase in blood viscosity associated with exercise and increased hematocrit[37–39] likely reaches a point that offsets improved oxygen-carrying capacity. This probably accounts for the marked reduction in performance in horses with red cell hypervolemia.[31]

Other erythrocyte changes associated with high-speed exercise include small increases in mean corpuscular volume (MCV) and decreases in MCH and mean corpuscular hemoglobin concentration (MCHC). In addition, erythrocytes in blood samples obtained after exercise are more resistant to osmotic stress.[40] However, although Smith et al[40] did not detect any differences in erythrocyte deformability, Geor et al[39] detected reduced erythrocyte deformability during exercise. The difference between these two studies may be attributable to the techniques used to assess erythrocyte deformability. Deformability of erythrocytes is considered to be the major determinant of resistance of blood to flow in the microcirculation,[41] with reduced erythrocyte deformability potentially increasing blood flow resistance. However, horses are remarkably resistant to changes in blood viscosity associated with increases in hematocrit, likely because of changes in red cell deformability.[42,43]

It has been reported that there are large numbers of echinocytes released during exercise.[44] However, other studies of horses exercising for shorter durations at higher intensity have found the concentration of echinocytes to be quite low.[39,40] These differences might relate to exercise intensity and duration or possibly to the breed of horse. The significance of echinocytes is unclear, however for short duration, high-intensity exercise, they are probably not of physiologic importance in changing oxygen delivery.[40] Their role in prolonged low-intensity exercise is yet to be defined.

There is a four-fold increase in oxygen extraction from blood during exercise. This increase in extraction ratio is facilitated by a rightward shift of the oxygen–hemoglobin dissociation curve. The shift occurs because of acidosis, hypercarbia, and hyperthermia in the local muscle environment.[45] There are also increases in the levels of 2,3-DPG during exercise.[46] This causes a rightward shift in the oxygen–hemoglobin dissociated curve further enhancing the release of oxygen from hemoglobin to the tissues. Low blood Po_2 stimulates erythrocyte glycolysis and the formation of 2,3-DPG. The increased oxygen extraction during exercise also makes blood more effective in the transport of carbon dioxide due to the presence of increased amounts of deoxyhemoglobin for formation of carbamino products.[45]

Leukocytes

There are significant differences in the response of leukocytes to exercise of differing intensities and duration (Fig. 42.4). Following high-intensity exercise, significant increases in leukocyte numbers are not seen. Immediately after galloping, there is a change in the neutrophil:lymphocyte ratio, but little change in the total leukocyte count. There is a transient lymphocytosis with a decrease in the neutrophil:lymphocyte ratio.[20,47] These changes are likely secondary to catecholamine release and splenic contraction. At 3 h after exercise there is an increase in the neutrophil:lymphocyte ratio, caused by an increase in neutrophils and decrease in lymphocytes due to increased plasma cortisol concentrations. However, the neutrophil:lymphocyte ratio returns to normal by 6 h after exercise.[20]

In contrast to high-intensity exercise, endurance exercise is associated with a leukocytosis, resulting from a neutrophilia and lymphopenia.[24,48] This is probably due to an increase in circulating corticosteroids,[49–51] with speed significantly affecting the extent of the neutrophilia and lymphopenia. Horses that complete an endurance ride at a faster speed have a higher neutrophil:lymphocyte ratio than slower

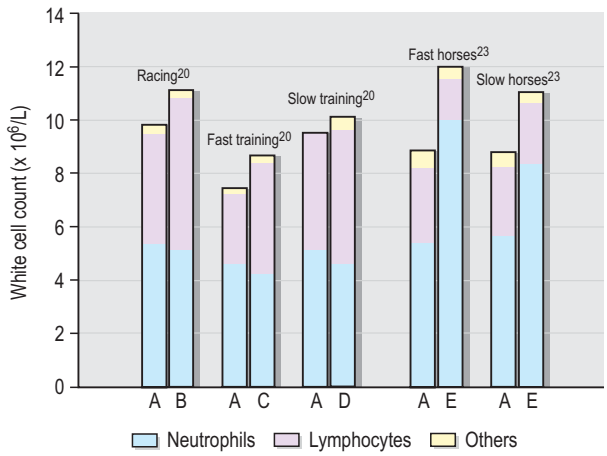

Fig. 42.4
The effect of different types of exercise on the leukocyte numbers. Data from Snow et al[20] and Rose.[23] A, resting; B, immediately after racing; C, immediately after fast training (11–12 m/s); D, immediately after slow training (13 m/s); E, immediately after a 160-km endurance ride.

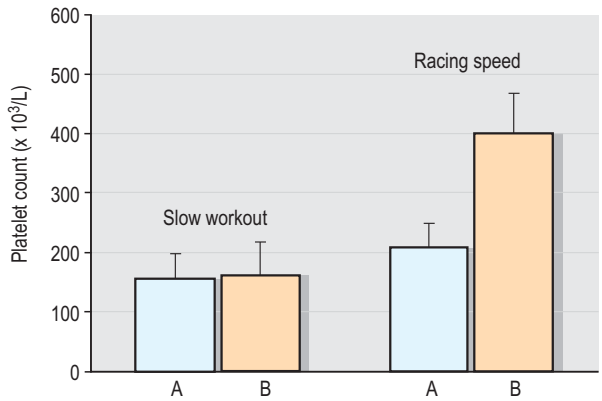

Fig. 42.5
The effect of exercise on platelet numbers. A, before exercise; B, after exercise. (Data from Johnstone et al,[55] and Bayly et al.[53])

horses.[23] Additionally, Carlson et al[52] showed that exhausted endurance horses had a significant left shift in the neutrophils when compared to clinically normal horses, even though the total white cell count was similar to that reported by Rose.[23] For samples collected the day after an endurance ride, a slower group of horses still had a significantly increased white cell count compared to a group of fast horses. However, this could be associated with the time the samples were collected, 14 h versus 21 h postexercise for the slow and fast horses, respectively.[23]

Platelets

Similar to erythrocytes, exercise has a variable effect on platelet numbers that appears to be exercise intensity dependent (Fig. 42.5). High-intensity exercise results in significant increases in circulating platelet numbers[53] whereas moderate exercise does not significantly increase platelet numbers.[54,55] With regards to platelet activation and aggregability, some studies report reduced platelet aggregability in response to high-intensity exercise,[53,55] however, others have reported increased aggregability[56] and activation of platelets.[57,58] It is likely that increases in the sodium citrate concentration associated with hemoconcentration of blood samples resulted in reduced ionized calcium concentration[59] and platelet aggregability.[53,55] No studies have looked at the effect of exercise duration, age or breed of the horse on the response of platelets to exercise.

Hematologic responses to training

Erythrocyte indices

There has been a large number of studies investigating the response of the hemogram to various types of training. The most common finding for horses undergoing high-intensity training has been significant increases in the resting red blood cell count, hematocrit, and hemoglobin concentration.[20,60–62] The increased erythrocyte numbers observed in horses training at higher intensities is thought to result from a greater demand for oxygen carriage, which stimulates erythrocyte production. Interestingly, in one study, horses with higher hematocrits (> 40%) at the start of training did not show any significant change in red cell indices compared to horses starting with a lower hematocrit.[60] This highlights some of the problems in trying to interpret the resting hemogram. Variations exist with the demeanor of the horse, as well as time of blood collection. The increased excitability of a horse as it gets fitter could result in elevations of resting red cell indices rather than the training per se and might account for the results reported by Clarkson and others.[8] Regular monitoring of the hemogram during training has little value for assessing a horse's fitness.

Despite the variability of the resting hemogram, there does appear to be an increase in total hemoglobin and total red cell volume with training. However, due to variability in individual plasma volume, an assessment of postexercise hematocrit or hemoglobin alone lacks accuracy for determination of the total erythrocyte mass.[33]

In Standardbred Trotters, prolonged training can result in an excessive increase in the red cell mass and the phenomenon known as red cell hypervolemia.[31,63] This results in reduced racing performance and appears to be due to overtraining. These horses have lower oxygen consumption. It has been hypothesized that increased blood viscosity leads to reduced capillary perfusion and inadequate utilization of oxygen by the working muscles. This phenomenon has not been observed in other breeds of performance horses, so it is unclear if it plays a role in overtraining in other breeds.

Endurance-trained horses have lower resting red cell indices than race horses. Similar to race horses, the effects of training on red cell indices are variable. In a group of Standardbred horses, after 7 weeks of low-intensity exercise training there were no significant effects on the resting or recovery hemogram.[27] Similarly, in a group of endurance horses (predominantly Arab crosses) there was no change in the resting hematocrit over 12 weeks of training, although

quieter horses had significantly lower hematocrits throughout the training period compared to more apprehensive horses. None the less, it is possible that there could be a reduction in hematocrit in endurance horses due to expansion of plasma volume.[64] It is clear from the results of these studies that hematological measurements are of little value in assessing the fitness or progress of horses during training.

Blood gas transport

Several studies have examined the effect of exercise training on blood oxygen transport properties in horses.[46,61,65] The results have been variable, although an increase in circulating blood oxygen capacity at rest, and an increase in blood oxygen affinity due to decreases in erythrocyte 2,3-DPG concentration, have been described.[61] With regards to 2,3-DPG concentration, Lewis and McLean[65] and Lykkeboe et al[61] showed a reduction in red cell 2,3-DPG concentration in response to training, whereas Pelletier et al[46] showed no change in 2,3-DPG concentration. This could potentially be due to the different training programs used in those studies. A reduced 2,3-DPG concentration could potentially impair unloading of oxygen. However, this has not been further evaluated and detrimental effects on work performance have not been reported.

Leukocytes

The total leukocyte count is unchanged during training of race horses and horses used for endurance racing. In addition, there are no alterations in the proportions of the different leukocytes. While there have been anecdotal reports of alterations in the neutrophil:lymphocyte ratio in horses that are overtrained, this was not observed by Tyler-McGowan et al.[66] However, several horses in that study developed an absolute eosinopenia together with clinical signs of illness. It was hypothesized that eosinophils may be a more sensitive indicator of training stress than other members of the leukocyte series.

Platelets

Although a large number of studies have investigated changes in the hemogram in response to training in horses, no studies have documented platelet numbers during training. Furthermore, given many of the technical problems when working with equine platelets, it is currently unknown if exercise training alters platelet function.[59]

Plasma or serum biochemistry

Muscle-derived enzymes

Creatine kinase (CK) is a relatively muscle-specific enzyme with a plasma half-life of approximately 2 h.[67] In muscle, CK makes ATP available for contraction by phosphorylation of ADP from creatine phosphate. Apart from skeletal muscle, CK activity is also present in gastrointestinal tissue, uterus, urinary bladder, kidney, heart, and thyroid gland.[68] Increased serum CK activity may be due to muscle damage, injury to organs containing smooth muscle, and be falsely increased with in vitro hemolysis.[69]

Aspartate aminotransferase (AST) has a much longer half-life (approximately 7 to 8 days)[67] than CK and is less specific for muscle, being found in most tissues.[70] It is a cytoplasmic and mitochondrial enzyme that catalyzes the deamination of aspartate to form oxaloacetate, which can enter the Kreb's cycle. Increases in plasma AST activity may be due to hepatocyte damage, muscle damage, or in vitro hemolysis.[69]

Lactate dehydrogenase (LDH) is a cytoplasmic enzyme that catalyzes the conversion of pyruvate to lactate at the end of glycolysis. Activities of LDH are high in various tissues of the body. Therefore, measurements of LDH are not organ specific. There are five isoenzymes of LDH, which can be separated by electrophoresis.[68] The isoenzyme LDH5 is the predominant form in skeletal muscle and has a plasma half-life of less than 6 h.[69] Increases in LDH activity may be due to hepatocyte damage, muscle damage, or hemolysis.

Liver-derived enzymes

γ-Glutamyltransferase (GGT) is a membrane-associated enzyme that catalyzes the transfer of glutamyl groups between peptides and is involved in glutathione reactions. Many cells have GGT activity but biliary epithelial cells, pancreas, and renal tubular cells are classically considered to have the greatest activity.[69] The half-life of GGT in horses is approximately 3 days and it is stable in serum for 2 days at room temperature, or 30 days if frozen.[71] The primary source of increased plasma GGT activity in horses is cholestasis or biliary hyperplasia.

Alkaline phosphatase (AP) catalyzes the hydrolysis of monophosphate esters and is bound to the mitochondrial membrane. Tissues that contain AP include liver, bone, intestine, kidney, placenta, and leukocytes. Increases in the serum activity of this enzyme in adult horses are secondary to induction. Cholestasis and certain drugs will cause production and the release of AP.[72]

Sorbitol (iditol) dehydrogenase (SDH) is a cytoplasmic enzyme that catalyzes the conversion of fructose to sorbitol. It has a short plasma half-life with blood levels declining within 4 h of transient hepatic necrosis. Its short half-life necessitates analysis within 12 h of collection, or 48 h if the serum is separated from blood and refrigerated.[73]

Glutamate dehydrogenase (GLDH) is found in hepatocytes, renal tissue, brain, muscle, and intestinal cells. Like SDH, GLDH has the highest tissue concentration in the liver and increases of this enzyme in blood can be considered specific for acute liver disease. The half-life for GLDH is 14 h.[71]

Plasma proteins

Albumin is synthesized by the liver and is the most prominent of the plasma proteins constituting 35–50% of total plasma

protein in animals. It is the most osmotically active plasma protein due to its abundance and small size and accounts for about 75% of the oncotic activity of plasma. A major role of albumin is as a general binding and transport protein.[74] The plasma concentration of albumin is affected by changes in plasma water content and intravascular water volume.

Globulins include α-globulins, β-globulins, γ-globulins, and immunoglobulins. Changes in the concentration of globulins generally reflect inflammation and disease, although hydration can also impact globulin concentration.

Fibrinogen is an acute phase protein, the concentration of which increases in response to inflammation. Dehydration can increase plasma fibrinogen concentration.

Changes in plasma or serum biochemistry associated with exercise

Muscle-derived enzymes

Increases in plasma CK, AST[25,70,75–78] and LDH[79] activities have been seen in response to exercise. These increases are believed to relate either to overt damage or to a change in the muscle fiber membrane causing a transient increase in permeability.[79,80] Physiological increases have been shown to occur without any tissue destruction.[81] The extent of this increase depends on the nature of the exercise.[70,79] It has been suggested that sampling at least 24 h after exercise may facilitate the differentiation between those animals showing a normal physiological response to exercise and those with an abnormal or pathological response.[70]

Liver-derived enzymes

In general, a single exercise bout has minimal effect on the activities of liver-derived enzymes. However, increases in serum AP activity have been reported in horses during endurance exercise[77] and in horses competing in three-day event competitions.[78] It is unclear whether these increases in AP are of skeletal or hepatic origin.

Plasma proteins

During maximal exercise, there is a redistribution of fluid and electrolytes from the vascular compartment to the tissue extracellular fluid spaces, with a corresponding increase in total plasma protein and albumin.[22,26,38,82–85] The extent of the fluid shift appears to be related to the duration and intensity of exercise. Less dramatic increases are seen in polo horses[26] and horses performing submaximal exercise[82] than in Thoroughbred race horses[86] and other horses performing maximal exercise.[82] Increases in plasma protein associated with short-duration exercise return to pre-exercise values within 15 to 30 min of exercise.[26,82,83] However, with hot conditions and extensive sweat losses, these fluid shifts may be more dramatic and prolonged.

While acute exercise in horses results in significant increases in total plasma protein concentrations, individual plasma protein fractions increase in a heterogeneous manner, indicating that changes in plasma protein concentrations cannot be simply attributed to changes in plasma water alone.[22,38] In a study by Coyne et al,[38] plasma albumin concentration increased by 22%, whereas fibrinogen concentration increased 12.5% and increases in the various globulin groups ranged from 25.5% to 60%. This resulted in a 10% decrease in the albumin:globulin ratio compared to resting samples. The mechanisms behind heterogeneous alterations in plasma protein fraction concentrations are unclear but could include compartmental redistribution, accelerated biosynthesis, increased degradation, and bolus release.[38] In addition, exercise-induced fibrinolysis could play a role in limiting the increase in fibrinogen concentration.[87] However, given that many laboratories consider a fibrinogen concentration above 4 g/L to be clinically significant, acute exercise does not appear to increase fibrinogen to this extent.[88]

During prolonged, low-intensity exercise, albumin and total plasma protein concentration increases.[50,51,76,77,89,90] However, despite the increase in plasma protein concentration, there is evidence that plasma volume increases during the initial stages of prolonged exercise.[31,91] Although increased plasma volume has been noted in dehydrated horses after 40 min of low-intensity exercise,[91] it is likely that plasma volume decreases in response to the substantial fluid losses incurred during prolonged endurance exercise.[24,92,93] Furthermore, those fluid losses result in increases in albumin and plasma protein concentrations that are much greater than those observed in horses performing short-duration exercise, and it takes longer for plasma protein concentrations to return to normal following prolonged endurance exercise. For horses competing in three-day event competitions[78] and driving trial competitions,[21] there are similar increases in plasma protein concentration, which remain significantly increased 30 min after exercise.

Changes in plasma or serum biochemistry associated with training

In general, there are few changes in resting biochemical values as a result of training. Although there have been some significant changes in a number of biochemical measurements, results have been variable and inconsistent.[23,62,66,94,95] The most consistent change has been in indicators of liver function, with serum GGT activity showing the greatest increase.[66,95,96] In some horses, GGT activity is greater than 100 U/L, but horses have not shown any other evidence of liver disease.[8] However, in other studies high-serum GGT

activities have been associated with poor health and overtraining in some horses.[96] Some performance horses with decreased performance have had three- to four-fold increases in serum GGT activity with no other laboratory evidence of hepatic disease. The source of the increase in GGT has not been determined and reportedly returned to normal within 30 to 60 days.[97]

Conclusion

There is no doubt that hematology and plasma or serum biochemistry are important tools for assessing the health of athletic horses. However, many factors can influence measurements, as have been outlined in this chapter. Each of these factors needs to be considered carefully when interpreting blood results. Hematology and biochemistry measures are unlikely to provide useful information regarding the fitness or performance potential of horses. However, they will continue to be useful in assessing health and disease in individual animals, particularly when samples are collected in a standardized manner and are compared to the results of horses of similar breed and training backgrounds.

CHAPTER 43

Hematologic and biochemical abnormalities in athletic horses

Sidney W. Ricketts

For horses to be successful when they race or otherwise perform they must be healthy, fit, properly prepared, well ridden, competing appropriately, and to some degree lucky. Leaving aside the effects of opposition, jockey, state of training, genetic suitability for athleticism, and how the horse feels 'on the day', this is a matter of constitution, 'heart', courage, and perhaps even intelligence. These are factors that cannot be assessed in the laboratory. This is one of the reasons why neither financial input nor veterinary/scientific endeavor guarantees success and why equine sports remain so popular for the casual punter and such a success for the betting industry. Nevertheless, within the confines of horse-training environments, health and disease remain important factors affecting fitness to compete and athletic performance.

When horses are ill or injured they are less likely to perform to their optimal potential. Therefore, veterinary surgeons attending performance-horse stables spend a great deal of their time diagnosing clinical and subclinical injury and disease, selecting and applying appropriate treatments, and assessing return to normality. The clinical pathology laboratory provides an important aid to diagnosis.[1–14] In addition, the successful race-horse trainer, in association with the attending veterinary surgeon, integrates clinical pathology assessments of individual horses and group trends into the stable's management team strategy. If interpreted with care alongside relevant reference data, specific experience, and clinical and training performance data, laboratory results can provide useful aids to the diagnosis of clinical and subclinical abnormality and therefore to training management.[15–30] As with most aspects of veterinary medicine, this is a process of 'jigsaw puzzling'. The more pieces of the puzzle that are available to the clinical pathologist, clinician, and trainer, the more likely is the team to be able to recognize the picture, make the correct diagnosis, and apply the appropriate treatment and management. If used correctly, the clinical pathology laboratory can provide important pieces of information.

It is clear that individual horses vary considerably not only in their own 'reference' results but also by the effects that variations from reference range and even clinical abnormality will have on their performance. The trainer's assessment of each horse as an individual remains essential and laboratory results should never be used to 'train' performance horses. Different types of horses are used for different forms of exercise and each requires different reference ranges and experienced interpretations.[31–38]

Groups of predominantly immature horses (Thoroughbred flat racing) that are stressed by continual population change and what must be considered unnatural housing and feeding practices, training, transport, and racing suffer a full variety of injuries and diseases for which appropriate veterinary supervision is required. Surveys have confirmed that respiratory, musculoskeletal, gastrointestinal, and skin diseases – both infectious and non-infectious – are of particular concern.[39,40]

Despite many years of clinical research into equine sports medicine, a practical laboratory measure (or measures) of fitness in race horses remains elusive.[18,21,22,25,26,29,30,41–46] Nevertheless, sensible, routine screening for subclinical disease (perhaps better called 'unfitness' tests) can be helpful to trainers and owners and may help with important management decisions, potentially preventing further injury and disease and therefore making an important contribution to the welfare of the individual horse and the others with which it is stabled.

Poor, disappointing or loss of performance[47–49] is a common problem for which owners and trainers request veterinary investigations to help provide explanations and answers to aid future management. The clinical pathology

laboratory can provide information that can be of help in this regard, if only to help rule-out obvious specific injury or illness.

All clinicians who work with performance horses should have direct access to elementary laboratory facilities that can provide quick results in urgent situations. This should include at least a simple hematologic cell counter, an elementary dry serum chemistry analyser, and a method of performing a leukocyte count and cytologic differentiation on synovial fluid samples in emergency situations such as acute collapse, myopathy and septic arthritis. The basic equipment for these tests is comparatively inexpensive, requires minimal space, and the tests can be performed quickly, accurately, and simply, using simple standard operating procedures. The equipment must be properly maintained, the staff using it must be adequately trained, and the results must be subject to elementary internal quality control and external assurance if they are to be reliable. Unreliable results are worse than no results at all because they can result in misdiagnoses and inappropriate managerial decisions.

For more demanding and less urgent laboratory work, a relationship with a specialized referral laboratory should be established. Full, modern, laboratory technology (with all the necessary facilities, equipment, technicians, quality control, and assessment) and experienced interpretations can only be justified, on economic terms, under conditions of high throughput. Referral laboratories should give clear guidance on preferred sample handling so that accurate and repeatable results can be provided efficiently, for reliable interpretation.

Sample collection and handling

Before collecting specimens for laboratory examination, clinicians should make sure that they have the necessary knowledge, experience, and equipment to obtain satisfactory samples safely. The choice of relevant tests will dictate the samples required. Results can only be as good and useful as the samples allow them to be. Samples must be collected at the appropriate time, using suitable techniques with adequate equipment, into suitable containers, and using recommended anticoagulants, preservatives or fixatives where appropriate; they must then be transported to the laboratory under satisfactory conditions. If unsure, the clinician should contact the laboratory to clarify particular sample preferences before attempting collection. In general terms, samples collected into ethylenediaminetetra-acetic acid (EDTA, sequestrene) anticoagulant are ideal for hematologic analyses and clotted (serum) samples are ideal for the majority of biochemical analyses. Adding a sample in sodium citrate anticoagulant will allow the measurement of fibrinogen by the more accurate direct coagulometry method. Therefore, three blood samples collected into EDTA and sodium citrate anticoagulants and a plain tube to allow clotting to occur, will allow the laboratory to perform all of the routinely useful tests for performance horses.

Samples should be analyzed in-house without delay or reach the referral laboratory as soon as possible after collection. Delays in postal services cause deterioration in many samples, sometimes making accurate results impossible to obtain. Ideally, serum should be separated from clotted samples by centrifugation or simple standing and then pouring or pipetting, before transit, to prevent hemolysis, which renders many enzyme analyses inaccurate. Modern blood collection and separation tubes, containing beads or gel to aid serum separation, are particularly helpful in this regard. For urgent or labile samples, rapid courier services should be used.

Samples should be indelibly labeled with full details of the horse's name or identification. Without this simple information, neither the in-house nor referral laboratory can properly certify results. A letter, or preferably the laboratory's own request form should be included, repeating the label details and adding the clinician's name, address and telephone number, either a brief or detailed case history (as appropriate), the tests requested or help required, and any other relevant information or comments. The more information the laboratory receives, the more help can be given to the clinician.

Referred samples should be carefully sealed in inner leakproof containers and securely enclosed in padded and crushproof outer containers so that they conform to relevant legislation and will withstand the handling that packages sometimes receive in the postal services. Packages must be labelled clearly to minimize the risk of going astray.

Sample analysis

It is not the purpose of this chapter to discuss laboratory management and technology. Each in-house or referral laboratory will develop under different circumstances, with different aims and priorities. There are many methods of achieving satisfactory results but it is essential to make sure that samples are received, prepared, examined, and reported as accurately and as quickly as possible. To do this, the laboratory must be well managed, technical equipment must be well maintained, technicians must be adequately qualified and experienced, and test procedures must be quality controlled and externally assured. Specific veterinary laboratory technical education and quality assurance are not universally available and thus each laboratory must make appropriate provision. Medical laboratory science courses provide an excellent foundation upon which to build in-house training in the specific veterinary requirements. Similarly, there are currently no internationally accepted general quality assurance schemes available specifically for veterinary laboratories, although medical schemes are very helpful. A combination of relevant internal and external systems is therefore essential. Modern, sophisticated biochemistry ana-

lyzers can run automatic quality controls for each assay but routine repeat analysis of split samples on different days is also necessary. Efficient secretarial services are essential for results to be reported and transmitted accurately and quickly.

Hematology

A variety of hematologic abnormalities can be recognized in blood samples collected from performance horses.

Erythrocyte abnormalities

Hemoconcentration/dehydration

Hemoconcentration/dehydration (raised total erythrocyte count, hematocrit and hemoglobin concentration) can be interpreted only in samples taken from resting horses that are relaxed at collection, which can be very difficult to achieve in some excitable individuals. Reflex splenic contraction occurs in horses in response to fright, excitement, and exercise, increasing numbers of young macrocytic erythrocytes in the circulating pool.[4,6,13,50,51] Routine sampling sessions in performance-horse stables are therefore often conducted at standard times after a period of rest and quiet, e.g. early morning or late afternoon, before mucking out and feeding, to avoid sampling excited horses and to add a degree of standardization.

Hemoconcentration is sometimes a feature of so-called 'over-trained' horses,[30] who perform poorly; appear stressed; have dry, scurfy, skin coats, lose condition and who drink inadequately. They usually respond well to fluid and electrolyte therapy administered by nasogastric tube followed by a period of rest. Chronic anhidrosis[52] can produce a similar picture.

Dehydration is a feature of horses that are clinically ill with acute enteritis or colitis,[53–55] requiring intensive fluid, electrolyte, acid–base, and supportive therapy to replace losses.[56–58]

Hemoconcentration or dehydration are features of exercise and heat exhaustion in horses performing in hot dry climates and over long distances (typically endurance races), requiring timely diagnosis and appropriate treatment/management.[57,59] The interesting condition of acute anhidrosis,[52] i.e. failure of normal sweating, occurs in some horses who are raised in temperate climates and then perform in hot, dry climates when they have failed to acclimatize, resulting in respiratory distress, labored breathing, pyrexia, collapse, and even death.

Attempts have been made to interpret the significance of results of postexercise blood samples in terms of fitness.[21,22] In terms of hematologic tests, variable degrees of hemoconcentration and leukocytosis (see below) are always a feature and without rigid standard exercise test regimes,[60] which are almost impossible to organize within most performance-horse training environments, results are usually uninterpretable. Specific muscle enzyme tests (see later), performed on serum samples collected before and after exercise, can help with the diagnosis of exertional myopathy.[61] There has been considerable interest in lactate assays[62] before, during, and after exercise to determine aerobic/anaerobic metabolic capacity, with still considerable debate and differences of opinion.

It has been shown that the osmotic fragility of erythrocytes is increased by exercise regardless of release of erythrocytes from the spleen into the peripheral circulation.[51] The precise mechanism for these changes remains unknown but they may be involved in the apparent decrease in mean cell volume (MCV) and increase in mean cell hemoglobin concentration (MCHC), which occur with exercise.

Echinocytes (spiculated erythrocytes) have been demonstrated in equine blood samples[63] in a variety of systemic diseases and in response to exercise, apparently associated with electrolyte shifts, particularly hyponatremia. Their presence decreases erythrocyte sedimentation rate but does not affect whole-blood viscosity. Although horses with echinocytosis have higher plasma lactate levels during exercise and higher serum CK levels after exercise, their presence appears to have no demonstrable effect on exercise potential.

Anemia

In horses, anemia (low total erythrocyte count, hematocrit, and hemoglobin concentration) is less commonly a primary condition and more often occurs secondary to some other primary condition, for example infection (bacterial or viral), parasitism (endo- or ectoparasitism), or metabolic abnormality (e.g. hepatopathy, nephropathy), which requires specific diagnosis and treatment.[55,64] Malnutrition is rarely seen in performance-horse stables but mineral and vitamin imbalances (involving deficiency or excess) may occur.

Acute hemorrhage can cause acute primary blood-loss anemia following accidental injury involving a major blood vessel. The hemorrhage may sometimes be visible externally but more often occurs internally within a body cavity (i.e. intraperitoneal, intrapleural or intrapericardial hemorrhage). Chronic hemorrhage, for example following castration, may cause an anemia and self-perpetuating thrombocytopenia.[55] Platelet transfusion may result in hemostasis without further surgical interference. Guttural pouch mycosis[65] may cause internal carotid artery ulceration, resulting in profound acute, and sometimes fatal, blood-loss anemia. Gastric ulceration.[66] not uncommonly seen in performance horses, can cause anemia from chronic hemorrhage. Examination of fecal samples for the presence of occult blood can be performed but results are frequently positive, most commonly because of the activity of intestinal parasites, even in well managed horses, and are therefore not reliably diagnostic of gastric ulceration. Unfortunately, serum pepsinogen assays[67] are not reliably diagnostic of gastric ulceration in horses. Where suspected, the diagnosis must be made and the significance assessed by gastroscopic examinations.

It has been reported that the repeated administration of recombinant human erythropoietin (rhEPO) to race horses results in the production of anti-rhEPO antibodies that can result in moderate to severe anemia.[68,69]

Intravascular hemolysis (i.e. erythrocyte destruction resulting in hemolytic anemia) has a variety of different causes, which require specific diagnostic testing. Equine infectious anemia[70] (Coggins' agar gel immunodiffusion test), autoimmune hemolytic anemia[55] (Coombs' antiglobulin test), piroplasmosis[71] (babesiosis) (complement fixation test), disseminated intravascular coagulopathy[55] (DIC; prolonged prothrombin and activated partial thromboplastin times) and a variety of plant and environmental toxins[72] are some causes of intravascular hemolysis.

Equine anemia is most commonly macrocytic (raised MCV), reflecting splenic replacement with juvenile erythrocytes, as seen with blood loss, infections, and parasitism. Reticulocytes are not commonly seen in equine blood samples[4,6] and so their presence or absence is not a reliable means of determining regeneration or non-regeneration, as in other species. Normocytic (MCV within the normal range) anemia is sometimes seen in horses that are being challenged by respiratory viruses but show no clinical signs. Microcytic anemia (low MCV) is uncommon but is sometimes seen in immature individuals and has been reported in horses with iron/folate deficiency.[73]

Leukocyte abnormalities

Leukocytosis and neutrophilia

Leukocytosis (raised total leukocyte count) and neutrophilia (raised segmented neutrophil count) most commonly occur in performance horses in association with septic and non-septic inflammatory conditions.[4,6,13,74] Septic inflammation is most commonly associated with bacterial infection. In performance horses this most commonly follows an injury, for example penetrating wounds followed by cellulitis, septic arthritis or tenosynovitis, upper respiratory infections, and less commonly in systemic bacterial infections. Non-septic inflammation most commonly occurs after a non-penetrating injury (e.g. bruising of soft tissues, tendons, ligaments or periosteum and traumatic arthritis or tenosynovitis) and is sometimes associated with degenerative joint disease.

Neutrophilic 'shifts to the left' (juvenile neutrophils or 'band' neutrophils), although diagnostically helpful in foalhood infections, are seldom seen in adult horses unless severely and acutely infected with conditions such as acute cellulitis or lymphangitis.[75] Some cases of acute salmonellosis, endotoxemia, peracute enterocolitis, peritonitis, and pleuritis have neutrophilic shifts to the left, more commonly associated with leukopenia and neutropenia.[76–78]

Leukopenia and neutropenia

Leukopenia (low total leukocyte count) and neutropenia (low segmented neutrophil count) are most commonly seen in adult performance horses during the acute phase of a viral challenge,[4,6,13,79] when there may or may not be clinical signs. These signs include lethargy, pyrexia, nasal discharge, coughing, and edematous legs. Leukocytic changes seen with infection very much depend upon sampling time in relation to the stage of the disease process (Fig. 43.1).

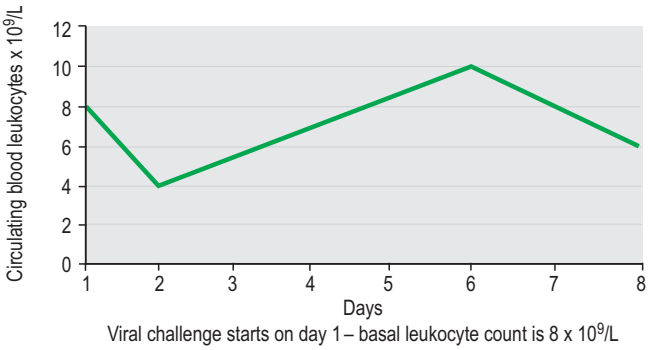

Fig. 43.1
Schematic diagram depicting total circulating blood leukocyte (WBC) response to viral challenge.

If the early acute infectious phase has passed then the leukopenic phase will be missed and hematologic examinations will reflect repair and sometimes secondary bacterial involvement with leukocytosis and neutrophilia. To help with diagnosis, epidemiology, and assessment of recovery blood samples should therefore be taken from symptomless stablemates where viral infections are suspected. Unfortunately, unless equine influenza, herpesvirus, rhinovirus, or adenovirus infections are involved (for which specific serologic assays are available), virologic 'screening' investigations are seldom rewarding.

Profound leukopenia with neutropenia and neutrophilic shifts to the left are sometimes seen in adult performance horses suffering from acute salmonellosis, peracute enterocolitis, peritonitis, and pleuritis/pleuropneumonia.[76–78] This is always a sign of severe illness, indicating the need for intensive care and suggesting a guarded prognosis.

Lymphocytosis

Lymphocytosis (raised lymphocyte count) is seen in horses in response to endogenous catecholamine release during excitement or exercise.[22] Otherwise, it is most commonly seen in response to some chronic viral infections and, more rarely, in autoimmune diseases. Massive leukocytosis (sometimes greater than 100×10^9/L) with lymphocytosis is a feature of generalized lymphoma,[80] in which neoplastic lymphocytes can be demonstrated in peripheral blood, body cavity fluid samples, and tissue biopsy samples.

Lymphopenia

The low lymphocyte count of lymphopenia is seen in horses in response to endogenous glucocorticoid release and in response to exogenous corticosteroid administration.[81] Otherwise, it can be seen in acute viral infections, severe

bacterial infections, septicemia, endotoxemia, and immune deficiency conditions. Profound, persistent leukopenia always carries a poor prognosis.

Monocytosis

Monocytosis (raised monocyte count) reflects increased phagocytic demand, as may occur with chronic suppurative conditions with tissue necrosis.[4,6,13,79] In performance horses, monocytosis is most commonly seen during the postacute or recovery phases following upper respiratory viral infections.

Eosinophilia

A raised eosinophil count occurs with antigen–antibody response in tissues rich in mast cells (e.g. skin, lung, gastrointestinal tract, and uterus) and in parasitically sensitized horses.[4,6,13,82] In performance horses, low-grade eosinophilia is most commonly seen in association with leukopenia or lymphocytosis in the acute phase of responses to viral infections.[13,79] Rare cases of eosinophilic leukemia have been seen with eosinophil counts as high as 2.5×10^9/L (25% of differential leukocyte count).

Basophilia

The raised basophil count of basophilia is very uncommon in horses, as is the presence of basophils themselves. Basophils have been a feature in cases of hyperlipidemia and in some horses that were recovering from colic.

Platelet abnormalities

Thrombocytosis (raised platelet count) is uncommon in adult horses but may occur in bacterial infections.[4,6,13,55]

Thrombocytopenia (low platelet count) may be a reflection of decreased platelet production, increased usage or from various spurious factors, e.g. drug administration, the presence of cold agglutinins in the sample, or platelet clumping in EDTA.[83] Where pseudothrombocytopenia is suspected, platelet counts should be measured on two blood samples collected at the same time, one into EDTA and the other into sodium citrate anticoagulants. If the sodium citrate sample, after correction for dilution, is considerably higher than the EDTA sample, EDTA-induced pseudothrombocytopenia is the likely answer. Decreased production may occur with neoplasia or a toxic insult to the bone marrow, the latter is diagnosable by biopsy.[84] Idiopathic thrombocytopenia is probably an immune-mediated condition and thrombocytopenia is seen in horses with disseminated intravascular coagulopathy (DIC),[55] most commonly a serious complication of acute enterocolitis.

When to use hematologic analysis

The regular, routine use of hematologic examinations to screen horses in training for subclinical disease can be helpful providing the results are interpreted carefully. Depending on the stage of sampling, Hematologic signs of viral infection (leukopenia and neutropenia) or relative lymphocytosis in a clinically normal horse may suggest 'challenge' (i.e. the horse's immune system is responding, but not succumbing, to the infection). In this condition, many horses do not perform to their best athletic potential, their recovery after exertion may be prolonged and they may be more likely to suffer secondary complications such as pneumonia, lung abscess, skeletal and/or cardiac myopathy, and/or exercise-induced pulmonary hemorrhage.

In cases of clinical disease, hematologic variations from 'normality' are often marked and obvious, but more sophisticated analytical equipment is required when screening for less obvious variations and trends. Modern automated cytochemical hematology analyzers (e.g. Bayer Advia 120) provide accurate differential cell counts that correlate closely with traditional manual differential counting techniques. Their automated differentials are highly repeatable and are likely to be more accurate than manual cell counts as they are performed on 10 000 rather than 100 leukocytes. The results provided by these analyzers are more accurate, repeatable, and therefore reliable for the routine monitoring of performance horses. However, when required by clinical history or results obtained, a traditional stained smear is still required to demonstrate erythrocyte or leukocyte abnormalities. In erythrocytes these abnormalities include Howell–Jolly bodies, nucleation, fragmentation, oxidative damage, spherocytes, basophilic stippling or *Babesia* spp. parasites in piroplasmosis. In leukocytes they include left shifts, toxic changes, hypersegmentation, neoplastic change or cytoplasmic inclusions as seen for example in ehrlichiosis.[14,85–87]

Clinical chemistry

Proteins

Total protein, albumin and globulin estimations are useful in the assessment of general bodily condition and nutritional status, and the response to infectious or parasitic disease.[20] Electrophoresis helps determine the significance of raised total globulin levels.[7,13,88] Horses in training, although not at pasture, usually have access to areas of communal grazing that can become contaminated with parasitic larvae. Yearlings usually leave stud farms having received comprehensive worm-control programs and have therefore had little opportunity to develop natural immunity to intestinal parasites. It is therefore essential that adequate worm-control programs are maintained throughout training or problems with large strongylosis, cyathostomiasis, or tapeworm infestations may occur, sometimes with fatal consequences.[89,90] Specific tapeworm ELISA assays are now available commercially.[91] Serum protein assays can be very useful as part of the stable's routine worm-control monitoring program. Low serum albumin and/or rising globulin levels are a 'red flag' warning,

most commonly seen with cyathostomiasis[92] (hypoalbuminemia), large strongylosis[93] (raised β-1 globulin), mixed helminthiasis (hypoalbuminemia and raised β-1 globulin), hepatopathy (hypoalbuminemia and raised β-2 globulin), antibody response to infection (raised γ globulin) or abscess formation (raised α-2 and γ globulins).[13] Globulins can be differentiated by electrophoresis (Fig. 43.2).

Protein electrophoresis

This identifies elevations in specific globulin fractions:

- α-2 globulin: acute-phase inflammatory protein responses (Fig. 43.3).
- β-1 globulin: *Strongylus vulgaris* and mixed strongyle larval activity (Fig. 43.4).
- β-2 globulin: hepatopathy (Fig. 43.5).
- γ globulin: antibody responses to bacterial or viral infections (Fig. 43.6).

Horses with abscesses will often show characteristic α-2 and γ globulin responses. Serum samples should be used for protein electrophoresis, as raised fibrinogen levels in heparinized plasma samples will cause confusing rises in β-2 globulins (Fig. 43.7).

Occasionally, horses with generalized lymphosarcoma[80] or plasma cell myeloma[94] have massively increased total protein and globulin levels, for which protein electrophoresis shows a massively raised, discrete, 'skyrocket' peak, usually in the β-2 globulin range (Fig. 43.8) suggesting monoclonal lymphoma protein production.[95]

presence of tissue damage and this assay may help with diagnosis and prognosis in cases of internal abscessation, chronic infectious or parasitic disease and in cases of exercise-induced pulmonary hemorrhage (EIPH). The test can be performed on fresh, paired, non-hemolyzed EDTA and serum samples by subtraction of serum protein from plasma protein results, but more accurate results are obtained from samples collected into sodium citrate anticoagulant to measure values by direct coagulometric assay. When measured serially with serum amyloid A (see below) the kinetics of the inflammatory response can often be determined (Fig. 43.9) and this can be very helpful when monitoring response to treatment.

Plasma viscosity (PV)

This is a very non-specific measure of inflammation and acute tissue damage, which may help with the diagnosis and prognosis of inflammatory response. Fresh, non-hemolyzed sequestrated or heparinized blood samples are required. Some trainers of performance horses like to monitor PVs as a crude guide to health and fitness. It has superseded the use of erythrocyte sedimentation rate (ESR), which was used in a similar manner. Because of the horse erythrocyte's tendency to form rouleaux, ESR is a highly inaccurate test and it is much more satisfactory to measure PV directly.[97] Plasma viscometers have become difficult to source and fibrinogen and amyloid A assays will probably replace the use of PV assay because their results are inherently more accurate and useful.

Serum amyloid A (SAA)

This is a highly sensitive, rapidly reacting inflammatory protein, which can be very helpful in monitoring early responses to infection and their response to treatment.[98] Most normal horses have zero measurable levels and in the face of acute, particularly septic inflammation, levels increase quickly (within 24 h) to over 20 mg/L and sometimes more than 100 mg/L. Levels peak and fall similarly quickly with subsidence of inflammation when the infection responds to antibiotic therapy (see Fig. 43.9).

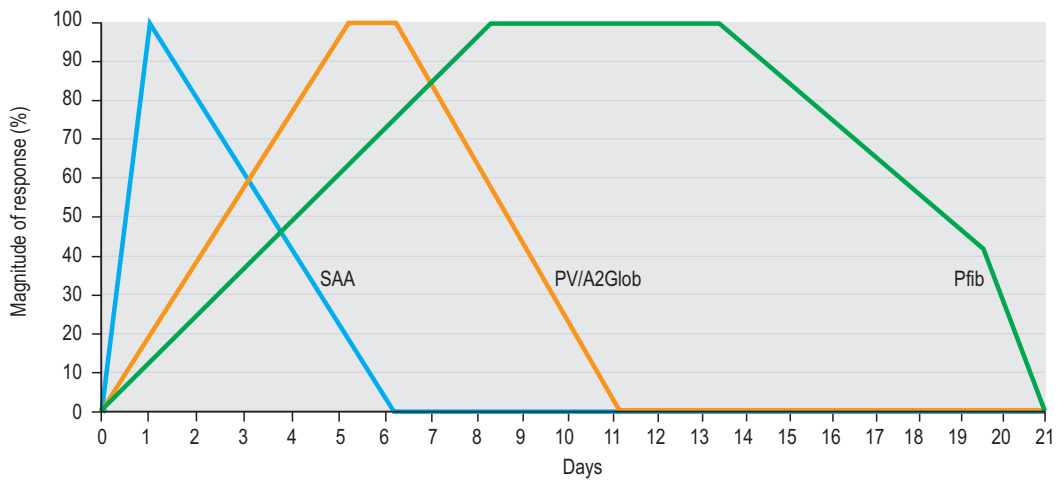

Fig. 43.9 Schematic diagram depicting inflammatory protein (plasma viscosity and fibrinogen, Pfib; serum α-2 globulin and amyloid A, SAA) dynamics during an inflammatory response.

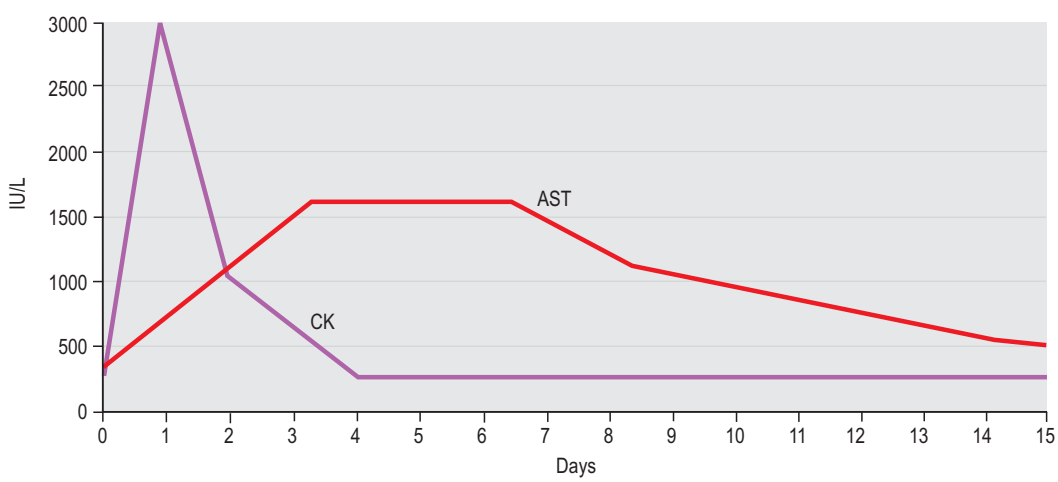

Fig. 43.10 Schematic diagram depicting serum muscle enzyme (AST and CK) levels following a relatively mild episode of exercise-induced myopathy.

Aspartate aminotransferase (AST, AAT, SGOT)

Elevations are seen in the presence of acute myopathy[61,99,100] or hepatopathy.[101–105] After myopathy, levels peak at 24–48 h and return to baseline by 10–21 days, assuming that no further damage occurs. This test, taken with CK at first visit and then 10–14 days later, can therefore be a useful guide to recovery from acute myopathy (Fig. 43.10).

Creatine kinase (CK, CPK)

Elevations are specifically seen in the presence of acute myopathy.[61,99,100,106] CK isoenzyme analysis[107] was (before routine ultrasound diagnosis) used in human medicine to help differentiate cardiac and skeletal myopathy from brain pathology, but has never become routinely established in equine sports medicine. Cardiac troponin assays (see later) are now used to differentiate skeletal from cardiac myopathy in horses.

CK levels peak at 6–12 h and return to baseline by 3–4 days, assuming that no further myopathy occurs. When measured alongside AST, which takes longer to rise, peak and return to normal, the timing and response to treatment of myopathy in horses can be usefully monitored (see Fig. 43.10). Paired CK assays taken before and 2–3 h after strenuous exercise can form a useful diagnostic test for exercise-induced myopathy, in horses where the diagnosis may be in doubt. Some respiratory virus infections, notably equine herpesvirus-1, appear to increase muscle cell membrane fragility and predispose to exercise-induced myopathy in horses in training.[108] This condition is sometimes

associated with clinical signs of fatigue and stiffness in performance horses.[109]

Significant myopathy, demonstrable by higher serum CK and AST levels, occurs more often after exercise in unfit rather than in fit horses. The conditioning process protects equine muscle cells from exercise-induced injury.[106]

Lactate dehydrogenase (LD)

A variety of disease conditions can cause elevations in total LD and more useful differentiation can sometimes be provided by isoenzyme analysis[7,13,110] (Fig. 43.11):

- LD isoenzyme 1: most dramatically increased by intravascular hemolysis (Fig. 43.12).
- LD isoenzyme 2: elevated in some cases of cardiac pathology, an indication for cardiac troponin assay (Fig. 43.13).
- LD isoenzyme 3: no known disease association in the horse.
- LD isoenzyme 4: most commonly elevated by intestinal pathology (Fig. 43.14).
- LD isoenzyme 5: rises seen with skeletal myopathy and hepatopathy, requiring further differentiation with CK and liver enzyme assays (Fig. 43.15).

Cardiac troponin (cTnI)

Two proteins (tropomyosin and troponin) work in concert with calcium to regulate muscle contraction.[111] Troponin is a globular protein complex composed of three single-chain polypeptide subunits: TnI (troponin inhibitory component), which prevents muscle contractions in the absence of calcium; TnT (tropomyosin-binding component), which connects the troponin complex with tropomyosin; and TnC (calcium-binding component), which binds calcium. The cardiac-muscle-specific isoform cTnI (24 kDa) exhibits approximately 60% homology with the skeletal isoforms (sTnI) and has a unique 31-amino-acid extension of the N-terminus. Experience in human medicine has shown that after acute myocardial infarction (AMI), elevated cTnI levels appear in the circulation within 3–6 h. Serum levels peak within 14–20 h and return to normal after 5–7 days. The measurement of cTnI can therefore be a useful diagnostic aid for AMI and an aid for the monitoring of recovery.[111]

Myocardial infarction is rarely diagnosed in horses but myocardial necrosis is seen in conditions such as atypical myoglobinuria.[112] Myocarditis is sometimes suspected on the basis of echocardiographic abnormalities and/or raised serum lactate dehydrogenase isoenzyme-2 levels, most commonly following upper respiratory viral infections, which can predispose to exercise-induced cardiomyopathy. Horses who have suffered in this way will need rest and supportive treatment, followed by follow-up to normality before returning to strenuous exercise if potentially serious complications are to be avoided. Raised cTnI levels in a performance horse in training are an indication for cardiac ultrasound examinations and monitoring.[112]

Cardiac troponin (cTnI) levels are measured in serum samples. Clinically normal horses have serum cTnI levels of less than 0.2 ng/mL. Experience so far suggests that greater than 0.3 ng/mL is abnormal, i.e. suggests myocardial

pathology and 0.2–0.3 ng/mL is currently a 'gray' zone. Levels of 0.9–5.4 ng/mL have been measured in horses with ultrasound-confirmed cardiomyopathy.

Sorbitol dehydrogenase (SDH)

This is an enzyme found in the cytoplasm of hepatocytes and is therefore virtually liver specific,[113] although rises are sometimes seen in horses with skin conditions and enteropathy. It is useful for the identification of acute hepatocellular damage for in-house laboratory conditions, but the enzyme is highly labile. Therefore, samples must be handled with care and assays must be performed within 8–12 h of sampling, making SDH assays unsatisfactory for transported samples.

Glutamate dehydrogenase (GLDH)

Elevations are seen in the presence of acute hepatocellular damage. This is a mitochondrial enzyme found mainly in liver, heart muscle, and kidney. It is a relatively stable enzyme and is a suitable replacement for sorbitol dehydrogenase (SDH) in transported samples.[13] GLDH rises are sometimes seen in horses with skin conditions and enteropathy.

L-gamma glutamyltransferase (GGT)

GGT is found in cell membranes of hepatocytes and biliary epithelial cells, but the enzyme is also found in the pancreas and kidney.[101,102,104,105] Elevations in serum levels are seen in the presence of acute hepatitis, chronic liver cirrhosis, and in very rare cases of pancreatitis. Nephropathy does not usually result in significantly raised serum GGT levels so high levels measured in the horse are usually a sign of biliary or cholestatic disease. Chronic pyrrolizidine alkaloid toxicity (ragwort, i.e. *Senecio jacobea*, poisoning) causes bile duct hyperplasia and biliary stasis and therefore typically results in raised serum GGT and alkaline phosphatase levels.[114] This remains an important cause of hepatopathy in horses and ponies in the UK, who ingest the plant unknowingly in poor-quality hay. Toxicity is uncommon in well-managed performance horses.

Idiopathic GGT elevations are not uncommonly seen in horses in training who appear otherwise healthy but perform poorly. The cause of these GGT rises has not yet been satisfactorily defined, although plant and fungal hepatotoxins have been suspected. In most cases, other liver enzymes are within normal range as are urea and creatinine levels, and liver biopsy reveals insignificant histopathologic findings. It is therefore not certain that primary hepatopathy or nephropathy is involved. Some cases have raised muscle enzymes suggesting an association with myopathy, either directly or secondarily, again perhaps via respiratory virus-induced increased muscle cell membrane fragility. Most cases respond (GGT levels return to normal) to a period of rest from exercise.

Urine GGT:creatinine ratios are elevated (> 4.0) in renal tubular pathology.[115]

Alkaline phosphatase (SAP)

Elevations in this brush-border enzyme are most commonly seen in the presence of chronic biliary obstructive liver pathology (e.g. chronic pyrrolizidine alkaloid toxicity).[101–105] High levels are also seen with abnormalities of bone metabolism and intestinal malfunction.[116]

Intestinal phosphatase (IAP)

Elevations relative to total SAP are seen in the presence of intestinal pathology.[116]

Reference ranges for serum SAP and IAP levels are age-related[10] and apparently high results must be interpreted carefully in immature performance horses.

Bilirubin

The analysis of bilirubin levels is seldom useful in the horse but may aid the classification of anemia and jaundice in some cases.[5,101,102,117] Owing to the horse's unusual biliary excretion system, indirect (unconjugated) bilirubin levels may be higher than those in other species, without clinical disease, and the significance of elevations without other abnormalities may therefore be difficult to interpret. A period of anorexia, inanition, or intestinal malfunction typically increases indirect bilirubin levels spuriously.

Bile acids

This is a much better guide to hepatobiliary status than bilirubin assays. High bile acid levels occur with embarrassed hepatic function[118] and are a useful diagnostic and prognostic liver function guide in horses.

It is important to remember that none of the liver enzymes, measured singly or in a 'profile', give any useful information about liver function.[103] The liver has a large functional reserve and compensatory capacity. Liver enzyme rises suggest hepatopathy that can be differentiated to a degree into acute, chronic, biliary obstructive, or mixed pathology, but bile acid assays and bromsulfalein clearance test results reveal either adequate (normal levels) or impaired (high levels) functional compensation. Impaired hepatic function suggests a guarded prognosis. Liver biopsy and ultrasound examinations are required to confirm an etiologic diagnosis on the basis of histopathologic and echographic features.

Bromsulfalein (sulfobromophthalein, BSP) clearance

Abnormally long clearance half-times for this liver-cleared dye are seen in the presence of gross liver malfunction and results may provide a useful diagnostic and prognostic guide to liver function.[119] Its use has decreased now that bile acid

assays (whose results appear to correlate well) have become available. After a baseline (time zero), jugular venous serum sample is taken, two vials of prewarmed reagent are injected intravenously. Serum samples are then taken from the other jugular vein at 2, 4, 8, and 16 min, after injection. Half-time clearances of more than 90 s are considered abnormal in horses.

Amylase

Elevations occur in the presence of pancreatitis,[120] but this condition is rarely diagnosed in the horse.

Glucose

Other than for oral glucose and xylose absorption tests,[121] useful for the diagnosis and evaluation of intestinal malabsorption cases, the value of this assay in adult horses is limited to cases of pituitary adenoma (equine Cushing's syndrome).[122,123] This condition is seldom seen in young horses in training. Cases are frequently hyperglycemic.

Samples for glucose assay must be taken into fluoride anticoagulant and must reach the laboratory within hours of collection.

Cholesterol and triglycerides

Elevations are seen in the presence of abnormal lipid metabolism and hyperlipidemia.[124] These conditions, which are typically seen in the Shetland and other small ponies, are seldom recognized in well-managed performance horses.

Urea

Urea is produced in the liver from the metabolism of ammonia.[125] Elevations are seen in the presence of abnormal renal function. Urea levels may rise in the hemoconcentrated and 'over-trained' horse, associated with fluid balance shifts rather than renal disease. Many cases of equine dysautonomia ('grass sickness')[126] have a degree of uremia but this is usually caused by catabolism. A period of anorexia can have a similar result.

Creatinine

Creatinine is formed in muscles from creatine breakdown and is excreted via the kidneys.[125] In normal horses, daily production and excretion are remarkably constant, leading to its use as an arithmetic constant for use with urinary fractional excretion rates (see below). Therefore serum elevations reflect renal malfunction (reduced glomerular filtration), levels being controlled by excretion rate. This may occur in horses with prerenal (e.g. circulatory disturbances, dehydration or shock), renal (insufficiency) or postrenal (obstructive) conditions.[7]

Urinary fractional electrolyte and mineral clearance ratios

In horses with normal renal tubular function, urinary excretion rate of creatinine is almost constant. It can therefore be used as an arithmetic constant to produce a measure of the fractional excretion of electrolytes and minerals in equine urine.[7,127–129] Concentrations of electrolytes or minerals are measured in serum and urine samples collected at the same time or at least within 1 h of one another. Diuretics must not be used to stimulate urination.

The percentage excretion of an electrolyte is calculated from the following equation:

$$\text{Fractional urinary excretion (\%)} = \frac{(E)u}{(E)s} \times \frac{(Cr)s}{(Cr)u} \times 100$$

Where: (E)u is the concentration of electrolyte in the urine, (E)s is the concentration of electrolyte in the serum, (Cr)u is the concentration of creatinine in the urine and (Cr)s is the concentration of creatinine in the serum.

Fractional excretion rates for sodium, potassium, chloride, magnesium, calcium, and phosphate are most commonly measured. The result provides an assessment of the horse's homeostatic regulatory status for that electrolyte or mineral, e.g. sodium and chloride may be selectively excreted at an increased rate because of excessive dietary salt intake. Phosphate may be excreted at an increased rate to try to maintain a normal serum calcium:phosphate ratio in the face of inadequate calcium intake.[7] The use of this method applies only to horses with normal renal function. Impaired renal tubular function results in high urine excretion rates for all the electrolytes and minerals, from failure of retention, and in such cases, creatinine is not a valid arithmetic constant.

Electrolyte imbalance may predispose to exercise-induced myopathy in horses in training and so fractional clearance ratios may sometimes be helpful in the investigation and management of recurrent cases.[127,129] Dietary deficiencies, excesses, or imbalances can be corrected and return to normal excretion rates monitored, sometimes with useful results in terms of resolution of myopathy.

In secondary nutritional hyperparathyroidism,[7] which is commonly seen in horses on a high-phosphate training diet, phosphate excretion rate is high, indicating the need for oral calcium supplementation and phosphate reduction, to restore balance. Experience has shown that, in the UK, many healthy, fit, stabled and well-performing horses receiving high cereal training rations have urinary fractional phosphate excretion rates in excess of 9%, emphasizing the need for calcium supplementation. Higher excretion rates are seen in horses with clinical manifestations of secondary nutritional hyperparathyroidism, which include shifting lameness, periosteal thickening, and facial and mandibular swelling.

Sodium, phosphate, and chloride

Electrolyte imbalance and fluid loss may occur with diarrhea, endotoxemia, intestinal crises, and exertional

exhaustion.[46,53–59,130] The latter is of particular importance for endurance horses and for other horses performing in hot and humid weather conditions.[131] Serial assays are helpful with intensive care cases. In other cases, urinary fractional electrolyte excretion rates (see above) are a much better assessment than single serum assays.

Calcium, phosphate and magnesium

Mineral analysis may be helpful in young horses, i.e. yearlings and 2-year-olds coming into training, with signs suggesting abnormalities of bone metabolism.[132] As homeostatic mechanisms are efficient, serum levels are often normal even in the face of whole body abnormality, and thus urinary fractional excretion rates are of greater value.

Plasma lactate

A number of hand-held and bench-top blood lactate analyzers have been used in horses. Most have been designed to help assess the human response to exercise. Results have been used to describe and predict aerobic endurance capacity in horses and it has been suggested that the rate of decline in blood lactate concentration, which occurs after exercise, may be a useful index of fitness.[62,133–136] Persistent high blood lactate concentrations may suggest metabolic fatigue. Anerobic capacity is essential for sprinters and so increases in blood lactate concentrations for fast, short-distance Thoroughbred flat race horses may be an advantage. Successful long-distance endurance race horses need to be able to maintain mainly aerobic metabolism (low blood lactate levels) rather than switching to increased dependence on anaerobic metabolism (high blood lactate levels) for prolonged periods of time.

In horses, high circulating erythrocyte counts, particularly in response to exercise, make measurement of whole blood lactate levels less accurate, repeatable, and meaningful than plasma lactate levels.[137] This necessitates deproteinization and centrifugation before analysis of plasma samples, which is much less convenient than whole blood analyses, which can be performed for human athletes with instant-reading hand-held machines.

For race horses, results are uninterpretable without carefully controlled standard exercise testing conditions,[45,60] which are often difficult to organize, especially under Thoroughbred race horse training conditions.

Serology

Feed allergen precipitin tests

These may be useful in intractable cases of allergic dermatologic or enteric disease. Serum samples can be tested against a panel of equine food allergens prepared previously or specific allergens can be prepared from representative samples of all the individual horse's feed constituents. Bran appears to be the most common feed constituent that produces positive precipitin responses in equine serum. Occasionally, exclusion from the diet has resulted in clinical improvement in sensitized horses.

Fungal allergen precipitin tests

These have been used occasionally in cases of recurrent allergic pulmonary disease.[138]

Blood gas analysis

Analyses are useful in cases of respiratory and intestinal abnormality, where acidosis or alkalosis are suspected, prior to therapeutic correction.[56,58,139] Analyses are helpful, alongside fluid and electrolyte balance assessments, for enterotoxemic and other critically ill horses under intensive care and for endurance horses and others performing in hot, humid conditions, suffering exertional exhaustion and/or heat stress.

Samples must be taken in heparinized, airtight syringes (preferably glass), and transported on ice to the laboratory within an hour or two of collection, so are practically limited to immediate in-house testing.

Interpretation of laboratory results

With a differential diagnosis in mind, the first task is to examine laboratory results in relation to appropriate reference values[10,140] and to decide whether significant variations occur. If all figures lie within reference ranges, this can help to rule out some possibilities, opening paths for further investigation. For example, the horse that is 'stiff' after exercise, yet whose serum AST and CK levels (in a sample collected later the same day or the following day) are not elevated, can be confirmed to be not suffering from exertional myopathy.[61] Further examinations and spinal/pelvic radiographic examinations may be indicated if clinical signs persist. The horse that coughs with normal leukocyte figures may not be suffering from a systemic infection and the next logical step is endoscopic and tracheobronchial wash cytologic examination[141,142] to investigate further.

Where there are variations from reference values, physiologic and pathologic causes must be differentiated.

Physiologic and collection technique effects

Marked elevations in erythrocyte parameters can occur following epimephrine (adrenaline) release and reflex splenic contraction, especially in the temperamentally 'nervous' horse.[4,6,13,50,51] This may occur when the horse is presented

with an unusual situation (e.g. a veterinary surgeon with blood collection equipment) or following exercise. In most cases, such excitement is obvious to the clinician but, if a laboratory interpretation is required, a note should be made on the laboratory request form to avoid misinterpretations. Alternatively, other people, prior to the clinician's arrival and unknown to him or her, may have excited the horse and this may only be apparent on examination of the results. Under these circumstances, marginal effects are difficult to assess. For these reasons, blood samples should be taken from horses following periods of rest, with the minimum of restraint and with a gentle reassuring technique. In UK Thoroughbred racing stables, 4 p.m., before the staff arrive to feed and groom, is usually a convenient time for sampling standardization. Despite all efforts, it is impossible to collect blood from some individual horses without eliciting a degree of excitement that makes the interpretation of erythrocyte parameters impossible.

The delineation between physiologic alterations and pathologic changes can sometimes be indistinct. Exercise, especially strenuous exercise, produces physiologic alterations in circulating leukocyte numbers, the concentrations of circulating muscle cell enzymes, fluid, electrolyte, and acid–base balance, which must be taken into consideration when trying to interpret postexercise laboratory results.[21,22] Excessive alterations in these parameters may occur as the result of pathologic changes in the unfit, overexerting and/or exhausted horse.[46,131] It can sometimes be very difficult to determine where physiologic alteration finishes and pathologic change begins. For example, degrees of exercise-induced myopathy can be diagnosed in serum samples taken from most, if not all, race horses during their training process on the basis of raised serum muscle enzyme levels. Some horses show no clinical signs and perform well whereas others with similar magnitudes of circulating AST and CK appear stiff and perform poorly. It is sometimes difficult to determine where physiologic muscle 'stress' becomes pathologic myopathy. There appears to be considerable individual variation and this is where the veterinarian and trainer must get to know their horses as individuals.

Pathologic abnormalities

Once artifactual and physiologic effects have been considered, the next step is to identify those that suggest pathologic abnormality. In some cases these will be highly specific, for example high serum AST and CK levels in a clinical case of exertional myopathy[61] or the isolation of equine influenza virus from a nasopharyngeal swab sample of an acutely coughing horse.[143] In other cases, the initial results may require clarification by the application of further tests, for example LD isoenzyme analysis, bile acids, BSP clearance test, liver ultrasound imaging and biopsy following high serum AST, LD, GLDH, GGT, and SAP levels.[103] Urine analysis, urinary electrolyte fractional excretion rates, renal and bladder ultrasound examinations, and cystoscopic examinations may be required following high serum urea and creatinine results in cases of weight loss. In some instances, parallel tests must be performed to make accurate interpretations, for example concurrent tracheobronchial cytopathologic and bacteriologic examinations of tracheal wash samples in race horses.[141,142] Without information regarding the presence or absence of septic leukocytic inflammatory change, the interpretation of the ubiquitous equine skin and mucosal aerobe *Streptococcus zooepidemicus* in relation to bronchitis in the absence of obvious clinical signs is impossible.

Where abnormal results indicate organ pathology (e.g. AST, LD, GLDH, GGT, and SAP indicate hepatopathy), it is important to determine its effect on organ function.[103] Normal bile acid results indicate insufficient pathology to compromise liver function and therefore a better prognosis for response to treatment than where raised bile acids confirm sufficient pathology to cause functional impairment.

Once pathologic abnormality has been identified, this must be correlated with the clinical history and an assessment made of primary or secondary significance. In a horse with clinical signs of acute, postexercise myopathy, high serum AST and CK levels are consistent with primary significance.[61] However, in a horse that is collapsed and jaundiced with very high serum SAP and GGT levels and history of ingestion of contaminated hay, suggesting chronic *Senecio jacobea* poisoning, high β-1 globulin levels may be a sign of underlying and perhaps opportunist large or mixed strongyle larval activity. Treatment of the latter case with larvicidal doses of anthelmintics would be unlikely to cure the collapse, jaundice, and hepatopathy and may be deleterious, until the hepatopathy has been treated and resolved. Mixed pathology is not uncommon in young and adult horses and multiple laboratory result abnormalities must be interpreted with care. The 'jigsaw puzzle' analogy is again appropriate.

Response to treatment

Clinicians recognize that clinical examinations alone may be misleading in the assessment of response to treatment. Again, the race horse with exercise-induced myopathy provides a good example. This horse may appear clinically normal after a period of rest and treatment but experience suggests that if exercise is resumed before serum AST levels have returned to within normal reference limits there is a greater risk of immediate recurrence. This especially applies to those fillies who repeatedly 'tie-up'[144] and are suspected to have a genetic predisposition to this condition. Race horses that are returned to strenuous exercise before respiratory viral-induced leukopenia and raised inflammatory protein and cardiac troponin levels have resolved are at significantly greater risks of developing chronic fatigue syndrome[109] and/or cardiopulmonary complications. Horses that have been treated with larvicidal doses of anthelmintics for intestinal parasitism should be re-examined 4 weeks after treatment to look for return to normal β-1 globulin levels. If there is an unsatisfactory response, a change in management, anthelmintic type, repeat treatment, or search for a primary

predisposing factor or other primary disease is indicated. Horses that have been treated for hepatopathy should be re-examined 3 weeks later to look for return to normal liver enzymes and bile acid results.

The future

Equine veterinary research will continue to generate information leading to the development and refinement of laboratory aids to diagnosis, including hematologic and serum biochemical tests, which are of help to the clinician. Clinicians will continue to improve their knowledge and expertise in the application and interpretation of these aids and will require access to efficient laboratory support. Equine diagnostic laboratories will continue to develop to provide this support to the benefit of race horses and their owners and trainers.

For clinical disease diagnosis, tests with improved specificity will continue to develop and find their place in practice. The importance of preventive medicine, in terms of both humane and economic considerations, will continue to increase and developments in knowledge and techniques will improve laboratory support.

Research into equine exercise physiology will continue to provide information, which may help to improve the efficiency of the performance-horse industries. Interest in exercise physiology, involving standardized exercise schedules, on and off treadmills, with pre-, during and postexercise sampling, cardiopulmonary monitoring, and muscle cell histochemical assessments have and will continue to improve our understanding of this subject. Unfortunately, few trainers of race and performance horses have embraced or are even willing to try these techniques. Frequently, trainers covet their art and are suspicious of recommended science. It is to be hoped that scientific progress in equine exercise physiology can be converted into practical and reliable tests that can help veterinarians give advice to trainers with respect to the true assessment of fitness in performance horses and the management of the training process. Once convinced, trainers will be more willing to use these techniques.

CHAPTER 44

Abnormalities of the erythron

Colin C. Schwarzwald and Katarina Schuback

Anemia

Anemia is defined as a decrease in red-cell mass leading to a reduction in measured erythrocyte concentration, hemoglobin concentration, or hematocrit below the reference value.[1,2] As hemoglobin is the major determinant of the arterial oxygen content (Cao_2), anemia is functionally characterized by the reduced oxygen-carrying capacity of the blood.[3–5]

Several compensatory mechanisms serve to increase tissue oxygenation in the presence of anemia.[1,2,6] One of the initial adaptations to anemia is an increase in the 2,3-diphosphoglycerate (2,3-DPG) content of the red blood cells. This is probably caused by a change in intracellular pH and leads to a decreased oxygen-affinity of hemoglobin; oxygen is therefore more readily released to the tissue. Blood viscosity is markedly decreased, with lower erythrocyte concentrations,[7] and tissue hypoxia activates mechanisms of local blood flow regulation and causes peripheral vessels to dilate.[8] This results in a dramatic fall in peripheral vascular resistance, an increase in cardiac output, and improvement in oxygen delivery to the tissues.[1,2,6,9] Individual changes in vascular tone result in redistribution of blood from non-vital areas (skin, intestine) to highly oxygen-dependent tissues (heart, brain, muscles). Finally, diminished oxygen supply to the kidneys leads to increased synthesis of erythropoietin, which accelerates erythropoiesis in the bone marrow and elicits a regenerative response to anemia.[2]

These mechanisms can, at least partially, compensate for the decreased hemoglobin concentration and attenuate the decrease in oxygen delivery to tissues. Even severe anemia is therefore relatively well tolerated at rest, as long as it meets the following criteria:

- it does not occur acutely
- it is not associated with acute hemolysis or blood loss
- there is no loss of blood volume
- no other disease processes or conditions (such as infection, fever, severe injury, exercise, agitation, or advanced pregnancy) are present which increase oxygen demand.

Free hemoglobin in solution, as present in intravascular hemolysis, exerts strong vasoconstrictor effects due to binding of nitric oxide,[10] and has an increased affinity for oxygen due to a loss of 2,3-DPG.[11] The resulting decline of effective oxygen delivery and release into the tissues contributes to the pathophysiologic effects of hemolytic anemia. When tissue oxygen demand is increased, or when anemia becomes severe enough to exceed the compensatory capacity of the organism, the degree of oxygen extraction from the blood cannot be increased and the oxygen uptake by the tissue decreases as the oxygen supply decreases (supply-dependent oxygen uptake; Fig. 44.1). The resulting anaerobic metabolism leads to an accumulation of lactate and metabolic acidosis.[3,4,12] Ultimately, tissue hypoxia and limited metabolic capacity of the affected tissue can lead to tissue damage and organ failure.[2,13]

Diagnosis of anemia

Clinical signs

Decreased oxygen-carrying capacity of the blood and related compensating mechanisms are responsible for most of the clinical signs associated with anemia. The severity and rate of development of anemia determine the efficacy of physiologic compensatory mechanisms. Patients with chronic anemia tolerate a much lower red-blood-cell mass than do patients with rapidly developing acute anemia.

Subtle anemia is difficult to detect and has mild clinical effects. Total red-cell volume and hemoglobin concentration are correlated with the exercise capacity of a horse.[14–16] During exercise, tissue demand for oxygen is increased. Small decrements in red-cell mass lower the level of exercise

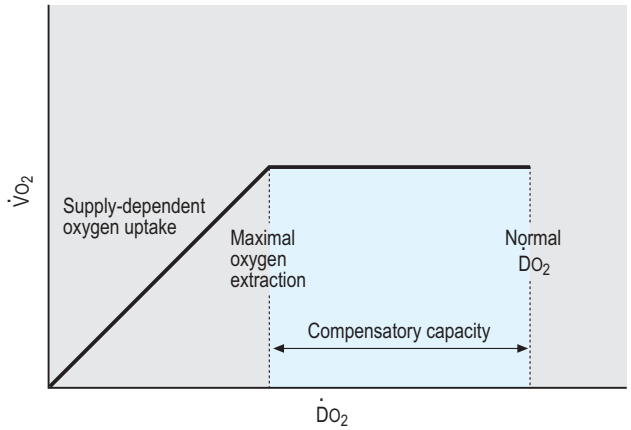

Fig. 44.1
Relationship between oxygen delivery ($\dot{D}O_2$) and oxygen uptake ($\dot{V}O_2$).

intensity at which tissue hypoxia occurs, and therefore result in exercise intolerance.[6]

More severe anemia is characterized by depression, weakness, tachypnea, tachycardia, hyperkinetic pulses, and pale or icteric mucous membranes. Systolic, functional heart murmurs are frequently associated with anemia. Hemoglobinuria or bilirubinuria may be seen in horses with hemolytic anemia. Cardiac arrhythmias may indicate myocardial hypoxia. Abdominal pain and signs of functional intestinal ileus are likely related to splanchnic ischemia, which may lead to sloughing of the intestinal mucosa, endotoxemia, and bacteremia.[12,13]

Hematology

Anemia is diagnosed when hematocrit, hemoglobin concentration, and erythrocyte concentration on a complete blood count (CBC) are below the reference range for the respective breed. The clinical definition of anemia can be problematic, as hydration status and splenic contraction due to exercise, excitement, or stress can also influence the hematologic values. Changes in hematocrit and hemoglobin concentration may therefore not reflect the true change in oxygen-carrying capacity of the blood.[1,17]

The traditional approach to determine the etiology and pathogenesis of anemia is to establish whether the anemia is regenerative or non-regenerative.[18] In horses, assessment of a regenerative response is difficult based on a routine hemogram, because reticulocyte maturation is completed in the bone marrow and release of reticulocytes into the blood is minimal, even in response to severe anemia.[17,19,20] Rarely, reticulocytes and nucleated red blood cells may be found in cases with severe hemolysis.[21] Young erythrocytes are usually larger than normal erythrocytes. Therefore, a regenerative response is in most species characterized by release of macrocytes into the bloodstream, independent of reticulocytosis.[18,19] Macrocytosis and anisocytosis may be the only indicators of regeneration in peripheral blood of horses.[18] It can be detected by determination of erythrocyte indices (mean corpuscular volume and red blood cell distribution width), red blood cell cytograms and volume distribution histograms, or blood smear evaluation.[18]

The mean corpuscular volume (MCV) is not a very sensitive test for the detection of abnormal or variable sizes of erythrocytes. Large numbers of macrocytes are necessary to increase the MCV above the normal range.[18,19,22,23] Macrocytosis is more pronounced in hemolytic anemia than in anemia due to acute blood loss.[24,25] The mixture of pre-existing normocytes and newly produced macrocytes during the recovery period in regenerative anemias leads to anisocytosis.[26] The red blood cell distribution width (RDW) is an index of anisocytosis and is calculated by many automated hematology systems as a coefficient of variation of the erythrocyte volume distribution.[19,23] Significant increases in MCV and RDW are detectable 14 to 20 days after onset of anemia and can persist for several weeks.[19,23] Although the RDW might be somewhat more sensitive than the MCV in detecting a regenerative response in horses, its increase is not a consistent indicator of regeneration, and it does not occur in mildly anemic horses.[19] Therefore, absence of these two findings does not exclude regenerative anemia.

Red blood cell (RBC) cytograms, RBC volume distribution curves, and hemoglobin concentration histograms are more sensitive in detecting changes in erythrocyte size or hemoglobin content and allow earlier detection of abnormal erythrocyte subpopulations than the routine erythrocyte indices (MCV, RDW).[18,19,22,23,27] Most modern automated hematology analyzers will report this information on request (Fig. 44.2).

Single hematologic measurements may be difficult to assess. Series of samples can reveal the severity of anemia and the presence of a regenerative response. The nadir of the hematocrit is reached around 2 to 7 days after acute blood loss and as late as 13 to 22 days after onset of hemolysis.[19,20,23–25] Reported daily increases in hematocrit following hematocrit nadir in regenerative anemias in horses vary between 0.32 and 0.67%, and are slower than reported in other species.[19,20] The rate of erythrocyte and hemoglobin production after hemolysis is higher than after acute blood loss, probably because iron and protein is not lost from the body and is readily available for erythropoiesis.[17,23,25,26]

Concurrent measurements of total plasma protein concentration may also be useful for determination of the type of anemia. Regenerative anemia, associated with a low, increasing plasma protein concentration, is consistent with blood loss, whereas a normal protein concentration more likely indicates hemolysis.[17]

Blood smears Blood smear evaluation is an easy and very important procedure in diagnosing anemia. Autoagglutination, alterations in erythrocyte morphology, presence of blood parasites, or the brown color of methemoglobin cannot be accurately detected by automated hematology analyzers.[18,28]

The physiologic property of equine erythrocytes to aggregate and form rouleaux on the peripheral blood smear (Fig. 44.3) requires special consideration and should be distinguished from pathologic autoagglutination. The latter leads to formation of irregularly shaped erythrocyte clusters of different sizes, whereas rouleaux formation leads to a more

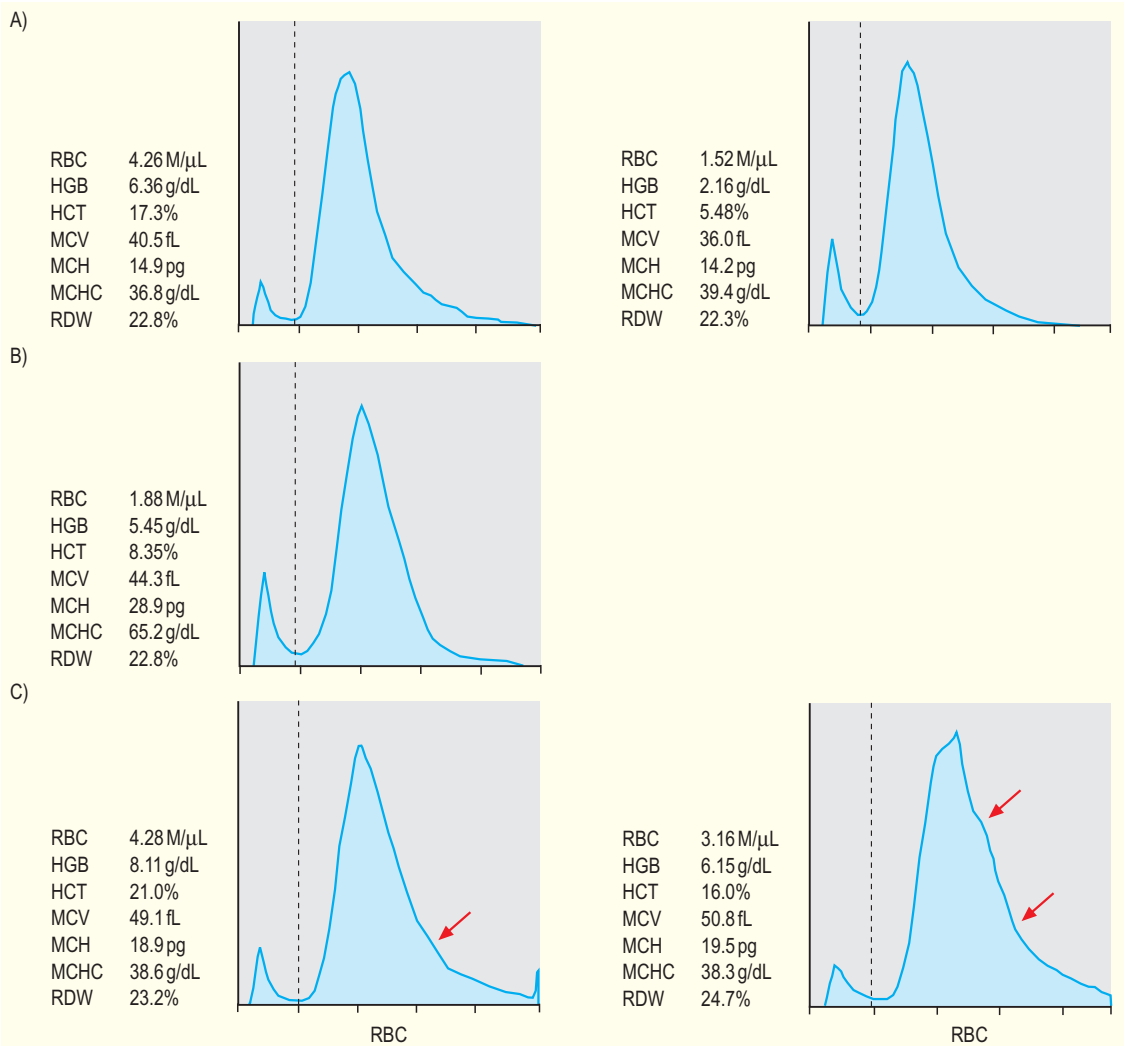

Fig. 44.2
Red blood cell indices and erythrocyte volume histograms.
(A) Pure red cell aplasia associated with administration of rhEPO. The RBC indices and erythrocyte volume histograms of two examinations 80 days apart indicate lack of regenerative response despite decreasing hematocrit (PCV). (B) Heinz body hemolytic anemia due to maple leaf toxicity. RBC indices and erythrocyte volume histograms 4 days after onset of the clinical signs do not indicate regeneration. (C) Erythrocyte volume histograms of the horse in (B) 2 days (left) and 8 days (right) later. Widening of the right tail of the histograms (arrows) indicates increased numbers of macrocytes consistent with a regenerative response. Note that the MCV and RDW are increasing over time but do not exceed the upper limit of the normal range (normal ranges: MCV 43–55 fl; RDW 19.8–25.4%).

orderly association with the erythrocytes lining up in rows. Mixing of the blood with normal saline (in a ratio of 1 part blood to 4 parts saline) will break up rouleaux but not agglutinated erythrocytes.[17,29,30]

Wedge smears of EDTA-anticoagulated whole blood can be made using two clean glass slides. The smears are then air dried and stained with Romanowsky-type stains (e.g. Wright, Giemsa, Diff–Quick).[28] New methylene blue stain can be used to detect Heinz bodies. Normal equine erythrocytes are approximately 5.4 µm in diameter. Changes in erythrocyte morphology may be useful to determine the underlying mechanism of anemia.[28] Table 44.1 summarizes common findings in blood smears of anemic horses.

Bone marrow evaluation

Bone marrow evaluation is the most accurate method for assessment of a regenerative response in horses. It is indicated in cases for which the hemogram does not adequately provide evidence of normal bone marrow function.[18,26,31] Bone marrow aspirate cytology allows evaluation of individual cellular morphology and the use of special stainings and procedures, but may not reflect true cellularity of the bone marrow and can be affected by hemodilution. Core biopsy examination is indicated if repeated aspirates are of marginal cellularity, if hypoplasia, aplasia, inflammation, necrosis, or myelofibrosis are suspected, or when megakaryocyte

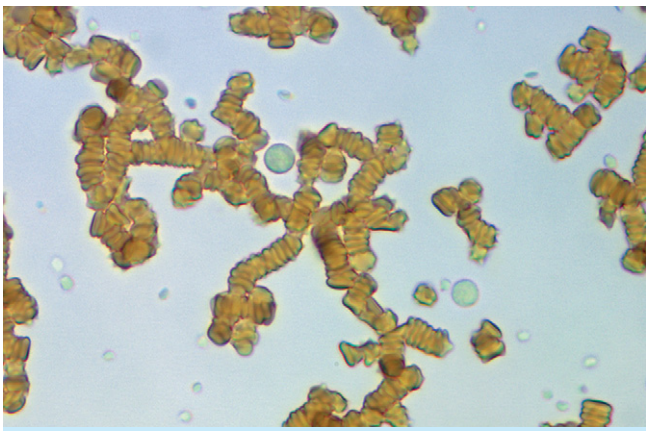

Fig. 44.3
Normal rouleaux formation of equine erythrocytes.

numbers should be determined.[32] In some cases only a combination of both techniques provides the desired information. Both procedures are easy to perform on the standing sedated horse and carry a small risk of complications. Standard techniques for bone marrow collection, sample preparation, and staining have been described.[32–35]

For aspirates, a 13- to 15-gauge, 2-inch needle with stylet is recommended. For core biopsies, a larger needle (11 to 13 gauge) should be used (Fig. 44.4). Several types of bone marrow collection needles are commercially available. An alternative biopsy technique using an electric drilling machine has been described.[36] Possible sites for bone marrow sampling in horses are the cranial sternum, tuber coxae, and the dorsal third of the ribs, where hematopoietic activity is maintained throughout life; the sternum is most frequently used. The sampling is performed in the ventral midline on an

Table 44.1 Common findings on peripheral blood smears in anemic horses[17,18,28]

Finding	Description/appearance	Cause
Rouleaux formation	Erythrocytes lining up in rows, very prominent in equine blood	Normal
Howell–Jolly bodies	Round, basophilic inclusion bodies, found near the periphery of the erythrocytes	DNA remnants, found in 0.1% of normal erythrocytes; more often with severe (regenerative) anemia
Heinz bodies	Pale pink (Romanowsky stain) or dark blue (new methylene blue stain) round protrusions of the erythrocyte membrane or bodies within the cell	Denaturated aggregates of hemoglobin due to oxidative damage (maple leaf, onion, or phenothiazine toxicity)
Eccentrocytes ('hemighosts')	Erythrocytes with small peripheral cytoplasmatic clearing	Alterations in the erythrocyte membrane and condensation of hemoglobin in the remainder of the cell due to severe oxidative damage (maple leaf toxicity)
Schistocytes (erythrocyte fragments)	Small, irregularly shaped erythrocyte fragments with two to four angular or pointed projections	Endothelial damage and alterations in the microcirculation, associated with DIC, neoplasia, or inflammation of very vascular organs (liver, spleen, lung, kidney, bone marrow, placenta)
Autoagglutination	Irregularly shaped erythrocyte clusters of different sizes	Immune-mediated hemolytic anemia, adverse effect of unfractioned heparin, occasionally incidental finding as a result of anti-erythrocyte IgM antibodies present in normal animals
Echinocytes	Uniformly spaced, pointed membrane projections	Crenation artifact, electrolyte depletion
Macrocytosis	Large erythrocytes	Regenerative anemia, prolonged storage of blood
Microcytosis	Small erythrocytes	Iron deficiency, chronic blood loss
Spherocytes	Small round erythrocytes with lack of central pallor (difficult to detect in horses)	Result from partial removal of red cell membrane by macrophages secondary to antibody or complement attachment (immune-mediated) or oxidative damage (maple leaf toxicity)
Parasites	Teardrop-shaped inclusions with two or four ('Maltese cross') organisms per cell	*Babesia caballi* or *Theileria equi*

DIC, disseminated intravascular coagulation; IgM, immunoglobulin M.

imaginary line between the two elbows. The site is clipped, aseptically prepared, and 5 to 10 mL of a local anesthetic is injected into the subcutis down to the periosteum. A stab incision is then made at the sampling site and the bone marrow needle with stylet is inserted through the skin to the sternum. To take a bone marrow aspirate, the needle is then advanced approximately 1 to 1.5 cm with a rotational movement using firm pressure. The stylet is removed, a 10-mL syringe is attached, and aspiration is performed. The risk of extensive contamination of the sample with peripheral blood can be reduced by forceful, rapid aspiration. The suction should be released when blood becomes evident in the syringe. The marrow specimen should be processed immediately to avoid coagulation and to preserve cellular morphology. The sample is transferred through the needle to several glass slides and direct smears are made before the sample clots. Alternatively, bone marrow aspirates can be transferred onto a Petri dish containing 0.5 to 1 mL 2% to 3% EDTA or a citrate–phosphate–dextrose solution for anticoagulation. The marrow particles adhere to the Petri dish and can be easily detected as small, granular, gray particles, even when some blood contamination is present. They are selected and transferred to glass slides using a Pasteur pipette. Bone marrow squash preparations are made using a second slide. The slides are then air-dried. Multiple smears (4 to 10, depending on volume of material obtained) should be submitted for routine stains and for additional special stains.

To obtain a core biopsy, the needle is inserted through the skin and the cortex of the sternum as described above. After removing the stylet, the needle is advanced with a rotating motion an additional 1 to 2 cm into the bone marrow cavity. The needle is then withdrawn rapidly from the sternum, and the biopsy specimen is removed retrograde from the lumen of the needle with a probe or with the stylet. Some needles require particular handling and the manufacturer's instructions should be followed carefully. Core biopsy samples are fixed in 10% neutral buffered formalin. Before placing in formalin, the specimen should be rolled gently across a glass slide to obtain impression smears for cytologic examination.

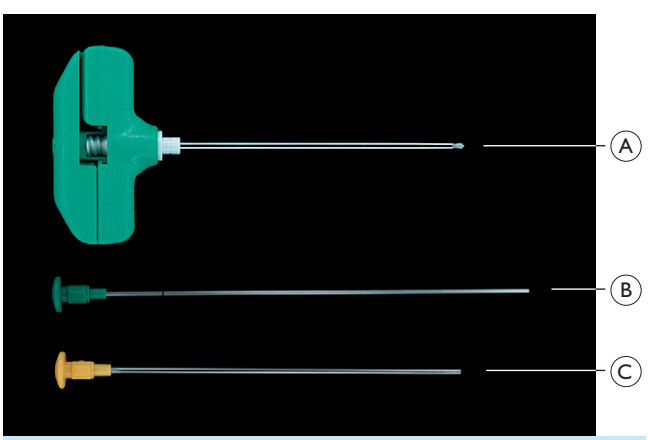

Fig. 44.4
Bone marrow sampling device. (A) Needle with stylet, (B) probe, (C) extraction cannula (optional use). (TrapSystem™ Bone marrow biopsy/aspiration needle.)

Common problems encountered when performing these procedures are failure to obtain a bone marrow aspirate or biopsy, and excessive blood contamination of aspirate specimens. In this case, multiple attempts at slightly different sites should be made to obtain diagnostically interpretable samples. Complications of bone marrow aspiration or biopsy are rare. Iatrogenic infections can be avoided by sterile technique. Excessive bleeding in patients with coagulation disorders, pneumothorax, hemothorax, and cardiac laceration may occur. The risk can be minimized by sedation of the horse, proper restraint, use of a needle guard, and careful monitoring of the needle length during the procedure. Bone marrow collection from the ribs contains similar risks, as the needle can slip off the bone and enter the thoracic cavity. Bone marrow sampling at the tuber coxae appears safer for examiner and horse, and may be associated with less complications. However, it is difficult to obtain bone marrow samples from the tuber coxae of older horses.

Cytologic examination of bone marrow aspirates or histologic examination of bone marrow biopsies should be assessed together with a complete blood count and differential taken on the same day and, if available, with results from previous CBCs and bone marrow evaluations.[18,32,35] Accurate interpretation of bone marrow samples requires training and considerable expertise. Routine bone marrow aspirate cytology is performed using Romanowsky-type stains (e.g. Wright, Giemsa, Diff–Quick). These stains allow the determination of particle cellularity; megakaryocyte numbers and maturity; erythroid and myeloid development, maturation, and morphology; and the presence of lymphoid cells, macrophages, stromal cells, and unusual cell populations.[35]

Normocellular bone marrow particles contain 50% fat and 50% cells (Table 44.2). Hypocellularity is consistent with decreased hematopoiesis, whereas hypercellularity suggests hematopoietic response, infiltrative disease, or neoplasia.[35] Normocellular bone marrow with normal-appearing erythroid cells and increased iron deposits in the marrow is seen in anemia of inflammatory disease.[18,37] Erythroid hyperplasia, accompanied by a lack of hemosiderin in macrophages, is seen in iron deficiency.[18] Aplastic anemia (aplastic pancytopenia) is characterized by peripheral pancytopenia and bone marrow panhypoplasia. The bone marrow space is replaced by adipose tissue.[38] Infiltration and replacement of the bone marrow by inflammatory cells, neoplastic cells, or fibrous tissue (myelofibrosis) is referred to as myelophthisis. The marrow usually appears normocellular or hypercellular.[38] Myelodysplasia is characterized by morphologic abnormalities in hemic cells. Excessive blast cell content of the bone marrow is indicative for leukemia.[18] Severe suppression of only the erythroid cell line is called pure red cell aplasia.[38]

Although subjective microscopic evaluation is a valuable and important method, it is often inadequate to assess regenerative response to anemia. Differential cell counts should be determined to increase the accuracy of quantification of

myeloid and erythroid cells.[31] The myeloid to erythroid ratio (M:E ratio) is commonly used to assess the erythroid compartment. The ratio is determined by counting 200 to 500 cells and dividing the number of cells of the myeloid series by the number of cells of the erythroid series. The normal M:E ratio in horses is between 0.5 and 1.5. A regenerative response leads to a decrease in M:E ratio, whereas a hypoproliferative anemia is characterized by an increased M:E ratio.[31,39–41] The regenerative response after acute loss of 25% of blood volume (20 mL/kg) leads to an expansion of the erythroid compartment within the first 3 days, and the peak erythroid response is reached after 9 days, corresponding with the lowest M:E ratio. The regenerative response in horses is prolonged and may be detected for more than 1 month.[31] Coexisting changes in the myeloid compartment can also influence the M:E ratio and should be taken into consideration. Leukocytosis with left shift, as detected on complete blood count, results from augmented granulopoiesis. In this instance an activation of the myeloid series increasing the M:E ratio may be expected.

In addition to the M:E ratio, determination of the number of young erythrocytes in bone marrow is useful to assess erythropoietic activity.[42] Anucleate erythrocytes in Romanowsky-stained smears are referred to as polychromatophilic erythrocytes (PRBC). In new methylene blue-stained smears, these cells appear as reticulocytes.[35] The presence of more than five PRBCs per high power field (100× oil immersion) and more than 3% reticulocytes (up to 66%) in relation to the total red blood cells confirm a regenerative response.[17,31,42–44]

Prussian blue stain allows semiquantitation of iron storage in the bone marrow. Normal bone marrow particles contain a moderate to large amount of erythroblasts with hemosiderin granula.[40] The amount of stainable iron is decreased in horses with chronic blood loss and iron deficiency.[41] Normoblasts and macrophages containing iron-rich granules (siderocytes, sideromonocytes) can be seen in horses with hemolytic anemia.[45,46] Anemia of inflammatory (chronic) disease leads to increased iron storage,[37,40] whereas iron-deficiency anemia leads to decreased iron storage in bone marrow.[47,48]

Serum biochemistry

Determination of the serum bilirubin concentration may be useful in diagnosis of anemia. Bilirubin is a breakdown product of hemoglobin metabolism. Horses frequently develop mild increases in serum unconjugated (indirect, prehepatic) bilirubin concentrations (up to 6–8 mg/dL [103–137 μmol/L]) as a result of anorexia. Larger increases of unconjugated bilirubin concentrations in anemic horses support the diagnosis of hemolysis. The degree of elevation depends on the rate of red cell destruction and the capacity of the liver to conjugate and excrete the newly formed bilirubin.[49] Monitoring of the serum creatinine and serum urea nitrogen concentrations is critical in horses with hemolytic anemia, as hemoglobinuria and bilirubinuria can lead to acute tubular nephrosis (pigment nephropathy). Hypovolemia associated with acute blood loss is characterized by prerenal azotemia. Furthermore, moderate non-regenerative anemia can occur secondary to chronic renal failure.[49,50] Serum activities of sorbitol dehydrogenase (SDH), other liver-derived enzymes, and bile acid concentrations may be increased with severe acute anemia due to hypoxic or ischemic liver damage or increased iron storage and iron overload with severe hemolytic anemia.[49,51] Increased cardiac troponin I serum concentrations may indicate hypoxic myocardial damage.

Urinalysis

Hemoglobinuria and bilirubinuria are common features associated with severe intravascular hemolysis, potentially leading to acute tubular nephrosis. Monitoring of renal

Table 44.2 Normal and abnormal bone marrow findings used for assessment of anemia in horses

Finding (staining method)	Normal	Regenerative response	Hypoproliferative bone marrow
Cellularity	50% fat, 50% cells	> 50% cells, dense cellular aggregates	< 50% cells, mainly fat
M:E ratio	0.5–1.5	< 0.5	> 1.5
PRBCs (Romanowsky)	< 2/HPF	> 5/HPF	
Reticulocytes (new methylene blue)	0.5–1% of erythroid cells	> 3–5% of erythroid cells	
Stainable iron (Prussian blue)	Many or all erythroblasts contain one to many hemosiderin granules	Normal in blood loss anemia	⇓ or absent in iron deficiency anemia
		⇑ in hemolytic anemia	Normal or ⇑ in anemia of inflammatory disease

HPF, high power field (100x oil immersion); M:E ratio, myeloid-to-erythroid ratio; PRBC, polychromatophilic erythrocytes.

function in cases with hemolytic anemia includes repeated analyses of urine samples.[49]

Blood gas analysis and lactate

Blood gas analysis and measurement of blood or serum lactate concentration may be useful for assessment of tissue oxygenation in horses with severe anemia. Metabolic acidosis, increased anion gap, and elevated blood or serum lactate concentration are consistent with tissue hypoxia or ischemia. A low venous or (preferably) mixed venous oxygen partial pressure (Pvo_2 < 25 mmHg) in association with normal pulmonary function and adequate arterial oxygenation (Pao_2 > 90 mmHg) indicates increased oxygen extraction from the blood secondary to inadequate oxygen delivery.[1,4,52] However, the clinical application of these measurements to assess the severity of anemia, tissue oxygenation, and the need for blood transfusions in horses with anemia has not been established and requires further investigation.

Assessment of minerals, trace elements, and vitamins

Iron Iron exists in several anatomically, chemically, and functionally distinct compartments in the organism.[53,54] The functional pool contains approximately 70% of the total body iron. It consists of hemoglobin, myoglobin, and several iron-containing or iron-dependent enzymes. Iron is stored primarily in bone marrow, spleen, and liver, either in a soluble form (ferritin), or as insoluble, aggregated deposits (hemosiderin). Plasma transferrin is the major iron transport protein.

The iron content of several of these compartments can be determined to assess a patient's iron metabolism. Hemoglobin, the largest iron compartment of the body, is most commonly measured and routinely included in complete blood counts. However, hemoglobin is probably the least sensitive variable for detection of iron deficiencies. Overt anemia occurs only in late stages of severe iron deficiency.[53,54] Serum iron, ferritin, iron-binding capacity, and evaluation of the iron content of bone marrow are more accurate indicators of the iron status.[47,48,53,54] Total serum iron concentration is low with chronic iron deficiency, but it is also decreased in inflammatory disease, hypoproteinemia, and renal disease.[55] Serum ferritin concentration correlates well with body iron stores and is a sensitive indicator of iron deficiency.[55,56] It is also an acute-phase reactant protein and can increase secondary to inflammation or liver disease, leading to an overestimation of total body iron content. Serum ferritin should therefore be assessed together with a complete blood count and plasma fibrinogen concentration.[57] Plasma transferrin is indirectly measured after complete saturation with iron, with the resulting iron content referred to as total iron-binding capacity (TIBC). The TIBC is typically increased in iron deficiency states, but decreased with acute-phase reactions and inflammatory disease. The amount of stainable iron in bone marrow samples correlates well with iron stores[58] and is a sensitive indicator for evaluation of the iron metabolism (see above). The amount of marrow stainable iron is decreased with iron deficiency, and increased with inflammatory disease (Tables 44.3 and 44.4).

Copper Copper deficiency may commonly be overdiagnosed in horses due to inappropriately high reference ranges available for horses. Normal serum copper concentrations in healthy horses probably vary between 0.5 and 1.5 mg/L (8–24 μmol/L).[63–66] Concentrate ration feeding and copper supplementation increase the serum copper concentrations to 1–1.7 mg/L (17–26.6 μmol/L).[67] Serum copper

Table 44.3 Variables used for assessment of iron status in horses[47,48,53,54,57,59]

	Increased	Decreased
Serum iron	Hemolytic anemia Refractory anemia Iron overload Liver disease	Iron deficiency Acute phase reactions Chronic inflammation Hypoproteinemia Renal disease Stress response (transport)

concentrations lower than 0.7 mg/L (11.5 μmol/L) may indicate copper deficiency.[68]

Liver copper concentration and plasma ceruloplasmin activity may be used in addition to serum copper concentration to assess copper status of an animal.[64,68,69] Normal copper concentrations in liver tissue vary between 3.2 and 11 mg/kg (51–176 μmol/kg) fresh weight.[68,70,71] Mean plasma ceruloplasmin activity in mature Standardbreds has been determined to be 39.1 ± 0.5 IU/L (mean ± s.d.),[65] and serum ceruloplasmin concentration in adult horses varies between 4.07 ± 0.41 and 6.06 ± 0.74 mg/mL.[72] Acute-phase reactions may increase copper metabolism and cause the plasma copper concentration and ceruloplasmin activity to rise.[63,69,72] Complete blood count and plasma fibrinogen concentration should therefore be assessed together with serum copper concentrations to detect falsely elevated values.

Folic acid and vitamin B_{12} (cobalamin) Data on normal folate and vitamin B_{12} serum concentrations for horses are limited, and comparison between different studies is complicated by differences in feeding and management regimen. Serum folate concentrations in non-supplemented stabled horses and intensively training Thoroughbreds and Standardbreds (range: 1.5–15.1 ng/mL) are generally lower than in pastured horses (range: 6.4–21.7 ng/mL) or in race horses receiving dietary folate supplements (range: 2.0–21.1 ng/mL).[73–76] Similar differences were found for red cell folate concentrations, with race horses in training having lower values (35–372 ng/mL) than stabled horses (70–630 ng/mL) or horses on pasture (123–986 ng/mL).[76] Measurement of red cell folate concentration may be more accurate for the assessment of the folate metabolism of horses.[76,77] Serum vitamin B_{12} concentrations in non-supplemented horses vary between 1.25 and 5.4 μg/L.[75,76] Vitamin B_{12} levels do not seem to be significantly affected by feeding and exercise. Measurements of serum or red cell folate concentrations and vitamin B_{12} levels may be indicated in horses with macrocytic or normocytic anemia, leukopenia, and hypoplastic bone marrow. However, interpretation of the results may be difficult, as specific cut-off values for determination of vitamin deficiency are not established.

Specific causes of anemia

Anemia is caused by hemorrhage (blood loss anemia), red blood cell destruction (hemolytic anemia), or lack of erythrocyte production (hypoproliferative anemia) (Table 44.5).[17,18] Blood loss anemias and hemolytic anemias are referred to as regenerative anemias, whereas hypoproliferative anemias are non-regenerative.

Table 44.5 Causes of anemia in athletic horses

Regenerative anemia		Non-regenerative (hypoproliferative) anemia
Blood loss anemia	**Hemolytic anemia**	
Acute Trauma Surgery Guttural pouch mycosis Internal abdominal or thoracic bleeding Coagulation disorders **Chronic** Gastrointestinal (ulceration, neoplasia, parasites) Respiratory (ethmoidal hematoma, guttural pouch mycosis, pulmonary hemorrhage) Urogenital Coagulation disorders	**Infectious** Equine infectious anemia (EIA) Piroplasmosis (*Babesia caballi*, *Theileria equi*) **Immune-mediated hemolytic anemia (IMHA)** Secondary IMHA (Clostridial infection, penicillin, lymphoma, purpura hemorrhagica) Autoimmune hemolytic anemia Transfusion incompatibility **Oxidative injury (Heinz body anemia and methemoglobinemia)** Maple leaf toxicity Onion poisoning Phenothiazine poisoning **Others** Terminal liver failure Intravenous administration of concentrated dimethyl-sulfoxide (DMSO) or hypotonic solutions	**Anemia of inflammatory (chronic) disease** Chronic infection Chronic inflammation Severe trauma Neoplasia **Nutritional deficiencies** Iron deficiency Folate deficiency **Immune-mediated hypoproliferative anemia** Recombinant human erythropoietin (rhEPO)-induced pure red cell aplasia Immune-mediated hemolytic anemia affecting erythroid precursors **Infectious** Equine infectious anemia **Others** Chronic organ dysfunction Aplastic anemia Myelophthisic disorders Myelodysplastic syndromes

Blood loss anemia

Acute blood loss

- External or internal bleeding can lead to decreased circulatory volume and hypovolemic shock.
- External bleeding is usually obvious, whereas internal bleeding may be difficult to diagnose.
- Anemia and hypoproteinemia usually become evident within 12 to 24 h of the onset of acute hemorrhage.
- Treatment consists of controlling the hemorrhage and reversing hypovolemia, rather than increasing the hemoglobin content of the blood.
- The prognosis is favorable for controlled hemorrhage, but guarded for uncontrolled hemorrhage.

Acute hemorrhage is defined as major external or internal hemorrhage that occurs within a few minutes to several hours. Severe acute blood loss results in acutely reduced blood volume, cardiovascular collapse, hypovolemic shock, and death.[12,13,78,79]

History and presenting complaint A history of recent trauma or surgery may be obtained. Overt bleeding is a common but not invariate presenting sign. Exercise intolerance, weakness, depression, anorexia, colic, and dyspnea may be present.[80]

Physical examination Clinical signs principally reflect the loss of blood volume rather than the loss of hemoglobin.[78] They vary depending on the underlying cause and rapidity, severity, and duration of blood loss. Depression, weakness, tachycardia, tachypnea, pale mucous membranes, weak peripheral pulses, dehydration, and cold extremities are signs of hypovolemia and hypovolemic shock. Occasionally, anxiety and agitation may occur. Death due to cardiovascular collapse can occur within 30 min with severe acute hemorrhage.[80–82]

Hemothorax is generally associated with dyspnea,[82] whereas hemoperitoneum commonly presents with signs of abdominal pain.[80,81,83] Colic may also arise from malperfusion of the intestine and tissue ischemia resulting from compensatory cardiovascular mechanisms.[81]

Special examination Endoscopic examination of the upper airways and guttural pouches is indicated to determine the cause of severe epistaxis. Rectal examination, ultrasonographic examination of the abdominal and thoracic cavity, followed by abdominocentesis or thoracocentesis, should be performed if internal hemorrhage is suspected.[80,81,84]

Laboratory examination Initially, hematocrit and erythrocyte count are normal due to the simultaneous loss of blood cells and plasma. Splenic contraction may initially increase the hematocrit in horses with acute blood loss. The hematocrit is therefore not an accurate indicator of the severity of blood loss, especially in early stages of hemorrhage.[78,82,84] The severity of blood loss must therefore be estimated from clinical signs or, if possible, from measurement of the volume of blood loss. Blood volume is restored by shifting water from the interstitial fluid compartment to the intravascular compartment and by gastrointestinal and renal reabsorption of fluid. Anemia and hypoproteinemia usually become evident within 12 to 24 h of acute hemorrhage, indicating blood loss anemia.[17,24,78,84] The plasma protein concentration usually begins to increase within 2 to 3 days and reaches normal values within 5 to 7 days, unless there is ongoing blood loss.[78,84] Three to seven days after acute blood loss, regenerative response can be detected by sequential measurements of the hematocrit.[20,23,24,78]

Internal hemorrhage may be more difficult to detect based on measurements of hematocrit and plasma protein concentration, because up to two-thirds of the erythrocytes and most of the plasma proteins are recycled. The hematocrit can therefore increase more rapidly and the plasma protein concentration may be normal or only slightly decreased.[78,80,84]

The diagnostic work-up should include a platelet count and coagulation profile (activated partial thromboplastin time and prothrombin time) if the etiology of the hemorrhage is not obvious.[81] Bone marrow evaluation is rarely indicated, unless inadequate regenerative response to blood loss anemia is suspected. Erythroid hyperplasia and decreased M:E ratio usually become apparent within the first 3 to 5 days after hemorrhage.[78,82] The increase in red cell production reflects the severity of the anemia. However, concomitant iron deficiency, chronic renal disease, inflammation, bone marrow disorders, or blood transfusions may decrease the erythrocyte response.[78]

Diagnostic confirmation Ongoing blood loss or signs of recent hemorrhage are usually evident on physical examination. However, hematologic examination, abdominal ultrasonography, abdominocentesis, and thoracocentesis may be required to detect internal bleeding.

Therapeutic aims Initial treatment is aimed at controlling the hemorrhage and reversing the hypovolemic shock rather than increasing the hemoglobin concentration in the blood.[1,78,84] If blood pressure, circulatory volume, and tissue perfusion are adequate, tissue oxygenation will be maintained even in severely anemic horses.[52,84]

Therapy External hemorrhage can usually be controlled by external pressure or surgical ligation of large vessels. Control of internal hemorrhage can often not be achieved effectively and surgical intervention is rarely practical.[82,84]

The circulatory volume can be restored by rapid administration of crystalloid solutions, hypertonic saline, colloid solutions, or equine plasma (Table. 44.6).[79,81,84] Hypertonic saline[85–87] and colloid solutions[88–92] allow resuscitation with smaller volumes of fluids. A plasma protein concentration of less than 4.0 g/dL indicates the need for colloid solutions or equine plasma. The latter not only contains albumin as oncotic active component but, if fresh frozen plasma is used, also provides coagulation factors.[81]

Excessive volume replacement in the setting of uncontrolled hemorrhage may exacerbate the bleeding tendency and increase blood loss, due to the increased blood pressure and cardiac output.[81,83] The practice of restrictive volume replacement is referred to as hypotensive resuscitation.[93,94] Reduction of stress, placement in a quiet environment, and moderate fluid therapy are essential points of treatment of uncontrolled bleeding. Sedation with acepromazine (0.02–0.055 mg/kg i.v. or i.m.) leads to peripheral

Table 44.6 Therapies for intravenous volume restoration and increase of oxygen-carrying capacity of the blood[81,82,84,85,98,99]

Treatment	Dosage recommendations	Comments
Isotonic crystalloid solutions	3 times estimated volume of blood loss at a rate of 40–80 mL/kg/h	Shock dose
Hypertonic saline (7.2%)	4–6 mL/kg over 10–15 min	Followed by 40 mL/kg of an isotonic solution within 2 h
Hetastarch 6%	10 mL/kg	Colloid solution
Equine fresh-frozen plasma	12–16 mL/kg	Estimate: 7 L plasma (70 g/L) raises plasma protein concentration by 10 g/L in a 500-kg horse
Polymerized ultrapurified bovine hemoglobin (Oxyglobin®)	10–30 mL/kg at a rate of 10 mL/kg per h	Estimated half-life 40 h Shelf life 2 years (room temperature)
Whole blood	12–16 mL/kg or 20–40% of estimated blood loss at a rate of 20 mL/kg per h (initial rate: 0.1 mL/kg for 10 min, monitor for adverse reactions)	May need to repeat due to destruction of transfused red blood cells Estimate: 1 L blood (PCV 40%) raises PCV by 1% in a 500-kg horse

vasodilation and drop in blood pressure, which potentially reduces severity of hemorrhage and permits clot formation. However, acepromazine can exacerbate shock and cause acute collapse. Flunixin meglumine (0.5 to 1.0 mg/kg i.v.) and butorphanol tartrate (0.02 to 0.04 mg/kg i.v.) may be used to control pain, especially in cases with internal hemorrhage.

Several pharmacologic agents are occasionally recommended to treat acute hemorrhage, although clinical efficacy has not been proven in horses. The antifibrinolytic agents aminocaproic acid and tranexamic acid have been used in horses with the intention to stabilize fibrin clots and stop further hemorrhage (Table 44.7).[80,81,84] Intravenous administration of 10% buffered formalin may help to control bleeding,[81,95,96] although no effect on hemostatic variables can be detected in healthy horses.[97] Adverse effects at the recommended doses are rare. The mechanism of action remains unknown.[97] Naloxone hydrochloride, an opiate antagonist with dopaminergic activity may reverse the effects of endogenous opioids on cardiovascular dynamics and attenuate cardiovascular responses associated with acute hemorrhage,[81,84] but can potentially result in increased pain perception.[80]

Table 44.7 Commonly used dosages for anecdotal treatment of acute hemorrhage in horses[80,81,84,95,96]

Treatment	Dosage recommendations	Comments
Aminocaproic acid	20–80 mg/kg i.v., diluted in 1 L 0.9% saline, over 30–60 min	Antifibrinolytic agents Can be redosed as needed Contraindications: thromboembolic disease, DIC
Tranexamic acid	2 mg/kg i.v.	
Naloxone hydrochloride	0.01–0.02 mg/kg i.v.	Opiate antagonist
10% buffered formalin	0.02–0.08 mL/kg i.v., diluted in 1L 0.9% saline	

DIC, disseminated intravascular coagulation.

Following volume replacement and stabilization, the patient should be reassessed for the necessity of whole blood transfusion. The decision for transfusion should be based on clinical and clinicopathologic assessment. Transfusion is indicated if:

- the hematocrit rapidly falls below 15% and continues to decrease
- the hematocrit is below 10%
- there is uncontrolled bleeding
- the quantitated blood loss is more than 30% of the total blood volume
- the tissue oxygen demand increases due to fever or agitation
- gastrointestinal signs (colic, diarrhea) indicate possible intestinal ischemia or hypoxia
- cardiac arrhythmia and increased cardiac troponin I serum concentrations indicate myocardial hypoxia
- tachycardia, tachypnea, depression and weakness persist after initial restoration of the circulatory volume.[82,84,100,101]

The use of blood gas measurements and oxygen extraction ratios (O_2ER) as transfusion triggers has not been well established in horses. However, a low venous oxygen partial pressure ($Po_2 < 25$ mmHg) with normal pulmonary function, the presence of metabolic acidosis, and increased blood lactate concentrations indicate inadequate tissue oxygenation and the need for blood transfusion.[1,4,52] If available, cross-match testing should precede transfusion. Alternatively, blood can be transfused without cross-matching if the donor (preferably a gelding or stallion) and the recipient have not received prior transfusions.[81,82,100,101] Adult horses can safely donate

10 to 16 mL/kg (5 to 8 L for a 500-kg horse) whole blood without fluid replacement, and up to 25 mL/kg (12.5 L for a 500-kg horse) whole blood when the withdrawn volume is replaced with isotonic solutions. Potential adverse effects of administration of whole blood are transfusion reactions, and suppression of the normal bone marrow response to anemia.[100] Blood transfusions are only temporarily effective, and further transfusions may be required, when the transfused erythrocytes are degraded or removed from the circulation.[81,82,100,101]

The transfusion of polymerized ultrapurified bovine hemoglobin (PUBH, Oxyglobin®, Biopure Corporation, Cambridge, MA, USA) can be a valuable, but very expensive, alternative to whole-blood transfusion when compatible whole blood or packed red cells are not available. It increases the oxygen-carrying capacity of the blood, exerts a profound oncotic effect resulting in volume expansion, and causes peripheral vasoconstriction.[10,11,102] The use of PUBH in hemorrhagic shock or as a low-volume resuscitation fluid is currently being investigated in a variety of species but its safety and efficacy in horses has not been completely established and its optimal use is undefined. Treatment with PUBH has been reported in a miniature horse with intra-abdominal hemorrhage[98] and in ponies with experimentally induced normovolemic anemia.[99]

Prognosis Generally, the prognosis for anemias caused by acute hemorrhage is good, provided that the hemorrhage can be controlled and appropriate treatment is initiated.[78] The erythrocyte variables usually return to prehemorrhage levels within 8 to 14 weeks after acute hemorrhage.[24,78] The prognosis for internal, uncontrolled bleeding is usually guarded.[80]

Etiology and pathophysiology Acute blood loss anemia occurs with severe hemorrhage due to trauma or surgery. Infectious, neoplastic, or parasitic lesions can cause erosion of vessel walls. Severe epistaxis can occur due to trauma or guttural pouch mycosis, and less commonly as a result of pulmonary hemorrhage or nasal neoplasia.[82,84] Occasionally, internal hemorrhage can occur into the abdominal or thoracic cavity. It is caused by trauma, vascular abnormalities, neoplasia, abscesses, amyloidosis, parasite damage, or postoperative complications, and originates from large vessels, liver, spleen, kidneys, intestine, reproductive tract, or lungs. However, the underlying cause is often not found.[79–81,83,84] Rarely, coagulation disorders (warfarin intoxication, thrombocytopenia, disseminated intravascular coagulation, hemophilia) lead to significant acute hemorrhage.[84]

While the decreased oxygen-carrying capacity of the blood and the increased cardiac output are the main pathophysiologic effects in other types of anemia (see above), decreased circulatory blood volume, hypotension, decreased cardiac output, and hypovolemic shock are the primary sequelae in severe hemorrhagic anemia.[1,78,84] The total blood volume equals approximately 8% of bodyweight (40 L in a 500-kg horse). A small amount of acute blood loss is well tolerated, while a loss of larger volume may lead to overt clinical signs. Acute blood loss of more than 30% of total blood volume (13 L) results in hypovolemic shock, whereas loss of 50% or more (20 L) leads to death if untreated.[78,84]

Chronic blood loss

- Chronic blood loss is uncommon in horses.
- Diagnosis is made by identification of the source of bleeding and exclusion of other causes of anemia.
- Differential diagnoses of chronic blood loss anemia are anemia of inflammatory disease, iron-deficiency anemia, and low-grade hemolysis.

Recognition of disease Pale mucous membranes and clinical signs associated with the underlying disease may be noted. Physiologic adaptation to the gradually developing anemia usually masks overt signs of anemia until the hematocrit is less than 15%. The anemia is typically regenerative, unless chronic blood loss results in iron deficiency and depletion of the iron stores (see below). Plasma protein concentration is usually normal, although in some cases hypoproteinemia (e.g. intestinal blood and protein loss) or hyperproteinemia (hyperglobulinemia, chronic immunologic stimulation) can be present.

Diagnostic confirmation Diagnosis is based on characterization of the anemia, identification of a source of chronic blood loss, and exclusion of other causes for anemia. Diagnostic procedures may include complete blood count, bone marrow aspirate, coagulation profile, gastroscopy, fecal occult blood test, fecal parasite egg count, abdominocentesis, endoscopy of upper and lower airways, bronchoalveolar lavage, urinalysis and Coggins test for equine infectious anemia. Differential diagnoses for anemia of chronic blood loss are anemia of inflammatory disease, iron-deficiency anemia, and low-grade hemolysis.

Treatment and prognosis Treatment of the underlying cause is the cornerstone in management of chronic blood loss. Treatment of the anemia is rarely indicated, although horses with secondary iron-deficiency anemia may benefit from oral supplementation with ferrous sulfate. The prognosis depends on the underlying disease.

Etiology and pathophysiology Chronic blood loss may result from bleeding gastrointestinal ulcers, parasites, gastrointestinal neoplasia, exercise-induced pulmonary hemorrhage, ethmoid hematoma, guttural pouch mycosis, or urogenital hemorrhage. Coagulopathies should always be considered.[82,84,103] Chronic blood loss can lead to iron depletion and iron-deficiency anemia.

Red cell destruction (hemolytic anemia)

Equine infectious anemia (EIA)

- Equine infectious anemia is a viral disease characterized by development of persistent subclinical infections with possible recrudescence of disease. Chronic carriers remain infectious.
- Transmission occurs most commonly via insect vectors.
- Anemia occurs due to immune-mediated intravascular and extravascular hemolysis and bone marrow suppression.
- Depression, peripheral edema, weight loss, and recurrent episodes of fever are typical clinical signs of EIA. Laboratory abnormalities include anemia and thrombocytopenia.

- The diagnosis is based on serologic testing with agar gel immunodiffusion (Coggins') or ELISA tests.
- EIA is a reportable disease. Prevention and regulatory measures are important for control of the disease.
- No effective treatment is available.

The equine infectious anemia virus (EIAV) is a retrovirus of the *Lentivirinae* subfamily, closely related to caprine arthritis–encephalitis virus of goats, Maedi/Visna virus of sheep, and the human and feline immunodeficiency viruses.[104] Development of persistent infections is characteristic of lentiviruses. Infected animals remain life-long carriers and a potential source of infection for other animals. Performance of chronically infected horses is impaired, despite lack of clinical signs of disease.[105] Equine infectious anemia occurs in all parts of the world and has important implications on horse trading as well as national and international equestrian sports. Equine infectious anemia is a reportable disease (World Organization for Animal Health (OIE) List B of infectious diseases).[106]

History and presenting complaint The clinical signs of EIA depend on the virulence of the virus, the infectious dose, host resistance factors, and environmental stressors.[104,107] Horses with acute EIA are usually presented for depression, anorexia, and fever. Less virulent strains may lead to less severe clinical signs, and infection may remain undetected. The subacute to chronic stage is characterized by recurrent episodes of fever, depression, peripheral edema, and weight loss. Most EIAV-infected horses, however, do not show clinical signs of disease. Periodic exacerbation of clinical disease may be associated with environmental stressors, transportation, strenuous exercise, concomitant diseases, or corticosteroid therapy.

Physical examination The acute form is characterized by high fever, depression, petechial hemorrhages, pale or icteric mucous membranes, and occasionally death within days. Horses with subacute to chronic EIA show additional signs of lymphadenopathy, edema, and weight loss. Recurrent fever is typical. Neurologic signs have been reported.[104,108]

Laboratory examination Thrombocytopenia and marked anemia are seen during active febrile episodes. The Coombs' test may be positive during these periods. Increase in serum bilirubin is present if significant hemolysis occurs. Leukopenia or leukocytosis with lymphocytosis and monocytosis may be present. Platelet counts usually rebound following resolution of the acute viremic phase. Chronic carriers show low normal erythrocyte parameters or occasionally mild to moderate anemia. Persistent non-specific hypergammaglobulinemia may indicate low-grade chronic infection.[104,107,108]

Serologic testing for EIA should be performed in all horses with anemia if the etiology is not obvious or if concurrent clinical signs, such as intermittent fever, edema, petechiation, and weight loss, indicate possible EIA infection. Horses usually seroconvert within 14 to 45 days after infection.[109] The most widely accepted diagnostic test is the Coggins' test, an agar gel immunodiffusion procedure that is sensitive and specific for antibodies against the EIA p26 core protein antigens.[104,107,110] Two highly sensitive enzyme-linked immunosorbent assays are available which test for antibodies against p26 core proteins (competitive ELISA) or gp 45 transmembrane glycoproteins (synthetic antigen ELISA).[104,107,110] Both tests are rapid and highly specific for EIA infection, even in chronic carriers. However, confirmation of positive ELISA results by Coggins' test and Western blot may be required due to possible false-positive results of the ELISA tests.[104,107,110]

During febrile periods, serum iron decreases, whereas the total iron-binding capacity does not change significantly.[111] Bone marrow evaluation reveals a normal M:E ratio despite anemia, indicating hyporesponsive bone marrow. The content of stainable iron in the reticuloendothelial cells of the bone marrow (and other organs like the liver) is increased.[104,111]

Necropsy examination Necropsy findings vary with the stage of the disease process. During active disease, splenomegaly, hepatomegaly, lymphadenopathy, hemorrhages, and edema are common findings. Histopathologic findings include lymphoid necrosis and perivascular lymphocytic infiltrates of most organs and widespread hemosiderosis, especially in the liver. Glomerulonephritis may be present.[104,107]

Diagnostic confirmation The diagnosis of EIA is based on a positive Coggins' test or EIA ELISA. Virus isolation is usually not necessary.[110] Differential diagnoses include equine viral arteritis, equine ehrlichiosis, purpura hemorrhagica, and other causes of immune–hemolytic anemia. For chronic forms, other causes for chronic weight loss should be considered.

Therapeutic aims No effective treatment is available to eliminate the infection.

Therapy Clinical recovery can be achieved with rest and supportive treatment.

Prognosis The prognosis is unfavorable. Most horses spontaneously recover from the initial viremic episode but latent infection persists and recrudescence of clinical signs is common. Most horses become inapparent carriers with time and a few progress to a debilitating form of the disease.[104]

Etiology and pathophysiology Equine infectious anemia virus is a non-oncogenic retrovirus that infects and replicates primarily in tissue macrophages and integrates into the host genome.[104,112,113] Transmission of the disease requires a vector allowing blood transfer from an infected to a susceptible horse. Interrupted feeding of large hematophagous insects (*Tabanidae*; horseflies, deerflies, stable flies) is the principal mechanism of disease transmission.[108,114] Iatrogenic transmission via blood transfusion, blood-contaminated instruments, or needles is possible. Transplacental passage, infection of nursing foals through the colostrum or milk, and venereal transmission by asymptomatic stallions can occur.[104,107,115] The incubation period is 1 to 3 weeks, but can be as long as 3 months.[104,110]

Infection causes a strong cellular and humoral immune response, which cannot clear the virus completely from the body but finally leads to a remission of clinical signs and latent infection. Recurrence of the disease is associated with recrudescence of viremia due to production of antigenetically novel virus strains that temporarily escape the host's immune system.[104,107] Treatment with corticosteroids or environmental stress can also elicit viremic and symptomatic episodes. Infection of a naive host leads to acute EIA. The severity of clinical signs then decreases with each viremic

episode and the host mounts an immune response against all common variants of EIAV, leading to the chronic subclinical carrier stage.[104] Viral titers in infected animals vary depending on the stage of the disease, being highest during febrile periods. However, chronic infected subclinical carriers may remain viremic and can be a source of infection of other animals.[104,115]

The manifestations of the disease are associated with the host's immune response rather than being the result of direct viral replication.[104] Thrombocytopenia is one of the earliest and most consistent hematologic abnormalities. Anemia is primarily caused by complement-mediated intravascular and extravascular hemolysis secondary to virus–antibody complex attachment to erythrocytes.[104,108] Furthermore, direct bone marrow suppression and sequestration of iron in the reticuloendothelial system occurs,[111] presumably as a direct viral effect[116] and as a response to inflammation as commonly seen in anemia of inflammatory disease (see below).

Immune-complex-mediated glomerulonephritis is common in EIAV-infected horses, but clinical proteinuria is uncommon.[104]

Epidemiology Equine infectious anemia occurs worldwide with variable prevalence. The potential of chronic inapparent carriers to serve as a source of infectious virus is of epidemiologic importance and emphasizes the need for rigorous disease control measures.

Prevention Equine infectious anemia is a reportable disease. Coggins' test or ELISA are obligatory for many health certificates required for traveling and participation in equestrian sports events. Testing of horses at prepurchase exams or before introduction into a new population of horses is recommended. Tests should be performed after a quarantine of 60 days duration after potential exposure to EIAV. Control measures are usually aimed at elimination of inapparent carriers, although the regulations for Coggin's-positive horses may vary. In certain circumstances keeping affected horses in isolation is permitted. Separation from other horses by 200 m is effective in preventing transmission of the disease because the vectors are unlikely to fly a long distance before completing an interrupted meal. Insect control and strict prevention of iatrogenic transmission is required.[104,107,109,114]

Equine piroplasmosis (babesiosis, theileriosis)

- Equine piroplasmosis is a tick-borne protozoal disease characterized by hemolytic anemia, fever, peripheral edema, and weight loss.
- Development of immunity leads to a chronic carrier state, characterized by chronic anemia and poor performance.
- *Theileria equi* is considered more pathogenic than *Babesia caballi*.
- The diagnosis is based on direct detection of intraerythrocytic parasites or indirect serologic tests (complement fixation test or indirect fluorescent antibody test).
- Treatment is aimed towards resolution of the clinical signs. Infections with *T. equi* are difficult to eliminate with the currently available drugs.
- The worldwide distribution of the disease is related to the presence of the tick vectors.
- Equine piroplasmosis is a reportable disease. Regulatory measures are important for international equestrian sports and horse trading.

Piroplasmosis is a tick-borne disease of horses, caused by the intraerythrocytic protozoa *B. caballi* and *T. equi* (formerly *B. equi*). The disease has important implications in the international equestrian sports and trade of horses.[117–119] Potential tick vectors are present in many disease-free countries and would allow the disease to become endemic once introduced into the native horse population by carrier animals. Equine piroplasmosis is therefore classified as an OIE List B disease.[106] Import regulations of various countries restrict entering of horses with antibodies against *B. caballi* or *T. equi*.

History and presenting complaint Piroplasmosis can occur in acute, subacute, and chronic forms.[120] Clinical cases are more frequently caused by *T. equi*; *B. caballi* seems to be less pathogenic.[117,120] Acute forms usually present with depression, anorexia, fever, and peripheral edema. Subacute cases show similar signs, accompanied by weight loss, and occasionally colic and diarrhea. The fever can be intermittent. In chronic cases, unspecific clinical signs including poor performance, mild inappetence, and weight loss are the major complaints. A detailed traveling history should be obtained for horses with suspicious clinical signs, which are not living in endemic areas. Excessive tick infestation may be reported.

Physical examination The clinical signs are often nonspecific.[117,120] Acute piroplasmosis is characterized by high fever, tachycardia, tachypnea, congestion of mucous membranes, peripheral edema, swelling of the eyelids, icterus, and hemoglobinuria. Subacute disease presents with similar signs. The mucous membranes appear from pale pink to pale yellow or bright yellow. Occasionally, petechiae and ecchymoses are found. Physical examination in chronic cases does often not reveal significant abnormalities. Untreated cases become severely anemic and weak. Infection with *B. caballi* is often not clinically apparent, or causes unspecific clinical signs of chronic inappetence, poor performance, weight loss, and persistent anemia.[117,120] Acute renal failure, colic, enteritis, pneumonia, loss of fertility, and abortion are reported complications of equine piroplasmosis. Occurrence of central nervous signs has also been reported.[117]

Special examination Splenomegaly is usually detected on rectal examination and ultrasonographic evaluation of the abdomen.[120]

Laboratory examination The laboratory findings are generally similar to those found in immune-hemolytic anemia, often associated with thrombocytopenia.[121] Neutropenia and lymphopenia are common in acute infections. Varying degrees of hemoglobinuria are observed.[117]

Direct detection of the parasites during the acute phase of the infection can be achieved by examination of Giemsa-stained blood smears.[117,119,122] The presence of large, paired intraerythrocytic merozoites forming an acute angle is indicative for *B. caballi* (Fig. 44.5A). *T. equi* is typically characterized by four small merozoites arranged in a tetrad ('Maltese cross'; Fig. 44.5 B).[121] In carrier animals and in most cases of *B. caballi* infection, parasitemia is very low and

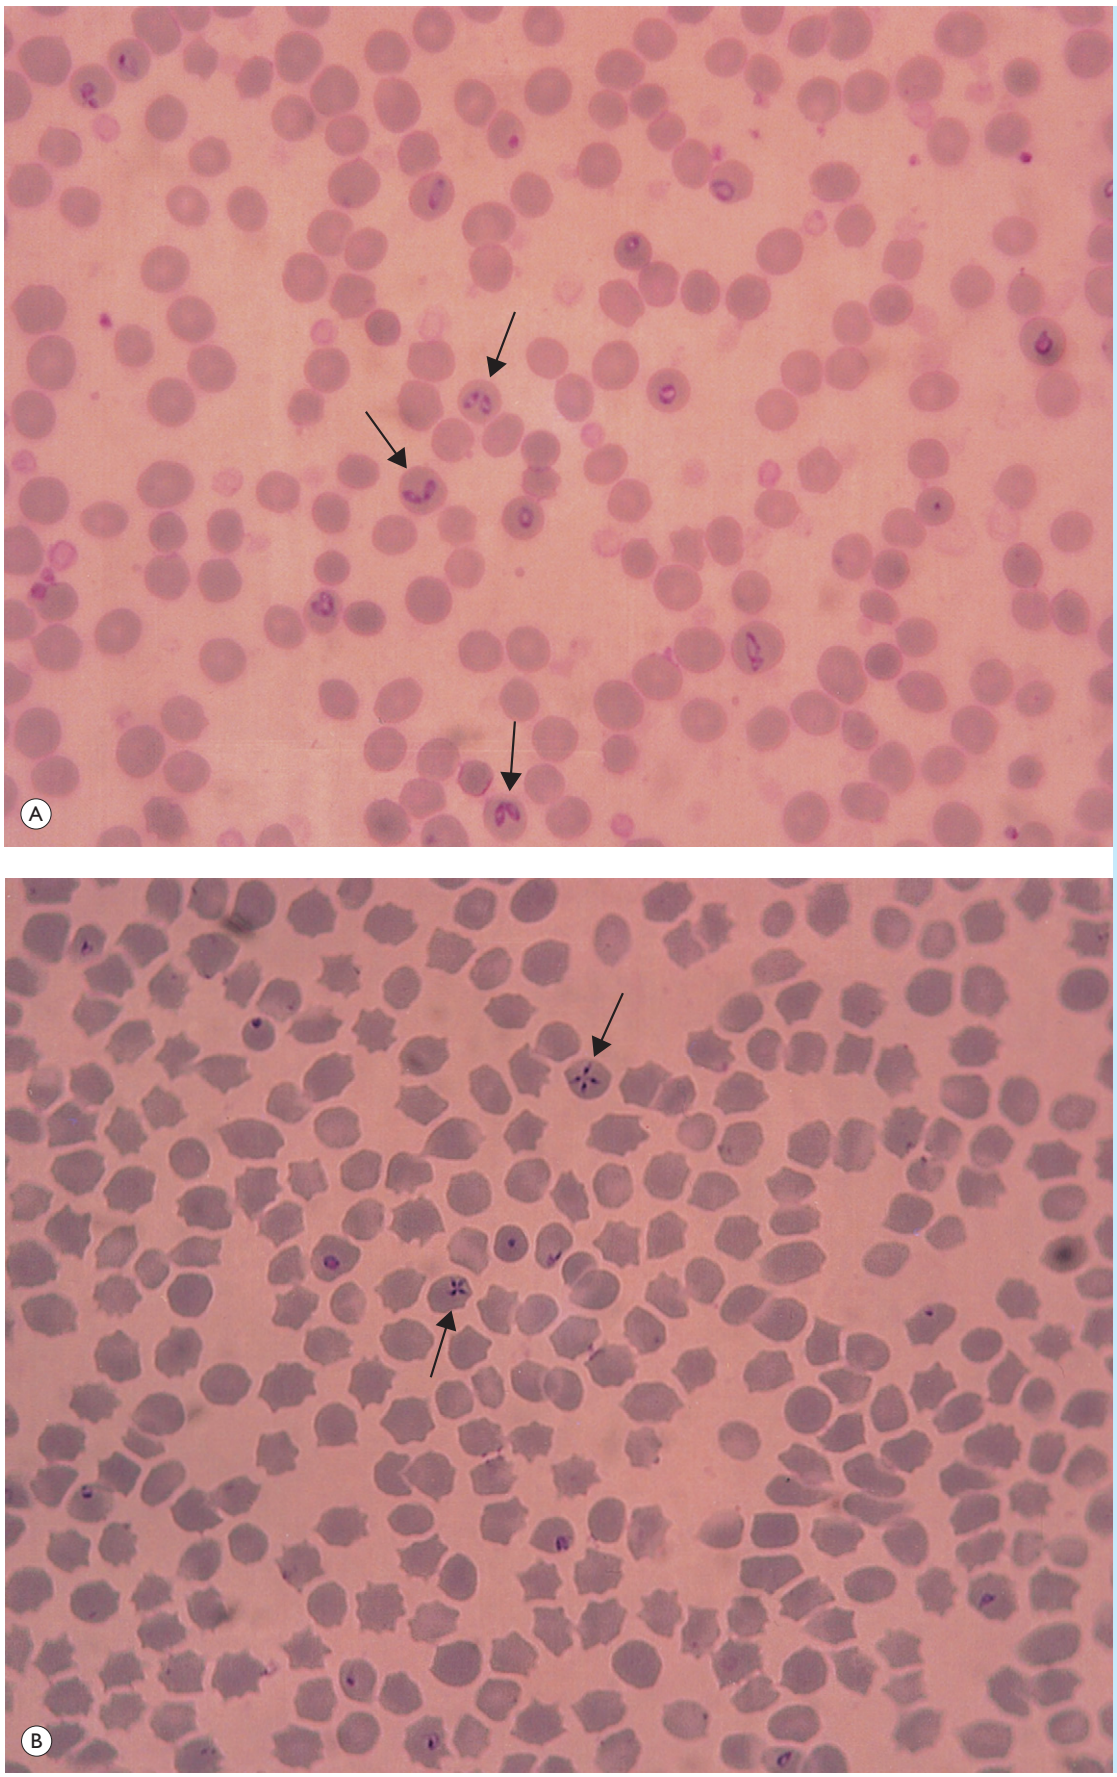

Fig. 44.5
Blood smears of horses with piroplasmosis. (A) *Babesia caballi* is characterized by paired intraerythrocytic merozoites (arrows). (B) *Theileria equi* is characterized by four smaller merozoites forming a 'Maltese cross' (arrows). (Courtesy of Dr Heinz Sager, Institute of Parasitology, University of Berne, Switzerland.)

detection on routine blood smears is usually not possible.[120] A quantitative buffy coat analysis technique using microhematocrit tubes and acridine orange staining (QBC® Malaria) is a simple, rapid, and more sensitive method for detection of blood parasites in all mammal species, but is not specific for piroplasmosis.[122,123] The use of polymerase chain reaction (PCR)[124–126] and in vitro culture[125] have been described for diagnosis of piroplasmosis in horses and, if available, may be useful for detection of carrier animals.[122]

Indirect tests are used for diagnosis of latent or chronic infections. Antibody titers become detectable between 2 and 20 days after infection, depending on the type of assay used. Several serologic tests are available for diagnosis of piroplasmosis in horses.[119,120,122] The complement fixation test (CFT) is frequently used for qualifying horses for international import/export. However, the CFT has technical drawbacks, is characterized by low sensitivity and specificity, and is not able to detect latent infections.[119,122,127–129] Indirect fluorescent antibody test (IFAT) has proven more sensitive and specific and can be used to distinguish between *B. caballi* and *T. equi* infections. Antibody titers remain positive during the latent phase of infection.[119,122,127–129] Western blot and ELISA techniques are considered very sensitive and specific for detection of carrier horses.[119,122,127] Competitive ELISA assays using monoclonal antibodies may be used in the future as screening tests for equine piroplasmosis and may replace CFT and IFAT assays.

Necropsy examination Gross pathological findings include generalized pallor or icterus, subcutaneous and subserosal edema, emaciation, hepato- and splenomegaly, enlarged kidneys, ascites, hydrothorax, pericardial effusion, pulmonary edema, and lymphadenopathy. Histopathological examination reveals pulmonary edema, liver necrosis, renal tubular degeneration, tubular protein and hemoglobin casts, proliferation of reticuloendothelial cells in liver, kidneys, lungs, and lymph nodes.[117]

Diagnostic confirmation The detection of intraerythrocytic parasites or positive direct or indirect tests in an animal with clinical signs of piroplasmosis is diagnostic.

Therapeutic aims The first goal of treatment is resolution of the clinical signs. The second goal is elimination of the parasites from affected horses. *T. equi* is less susceptible to treatment than *B. caballi*. Clinical recovery is usually achieved but infections with *T. equi* are difficult to eliminate with the currently available drugs. Horses recovered from clinical disease usually remain carriers, probably for life.[118–120] Elimination of *B. caballi* infections is rarely recommended in endemic areas.[120]

Therapy Imidocarb is the drug of choice for treatment of piroplasmosis. For *B. caballi*, two doses of 2.2 mg/kg i.m. at 24-h intervals are recommended; *T. equi* may be treated with four doses of 4 mg/kg i.m. at 72-h intervals.[117,120,130] This dose, however, is near toxic levels and may be detrimental to the animal itself. The drug should only be administered intramuscularly. Cholinergic adverse effects can be treated with atropine sulfate. Combined treatment with buparvaquone (4 mg/kg i.v.) and imidocarb (4 mg/kg i.m.) has been suggested for elimination of *T. equi*.[131,132]

Administration of polyionic electrolyte solutions is indicated to prevent or treat acute renal failure due to pigmenturia. Colic, enteritis, and pneumonia should be treated as necessary. Blood transfusions are indicated if signs of tissue hypoxia are present (see the section 'Acute blood loss').

Prognosis Early treatment is effective even without completely eliminating the etiologic agent. Chronic carriers are resistant to new infections.

Etiology and pathophysiology During the life cycle of *B. caballi* and *T. equi* ticks (*Dermacentor, Hyalomma*, and *Rhipicephalus* spp.) serve as vectors for transmission of the disease between host animals;[120,133] the incubation period varies from 5 to 30 days.[117,120,131] Erythrocyte destruction is related to the reproduction of merozoites in the erythrocytes,[133] and is primarily caused by intravascular hemolysis, mediated by antibodies against epitopes of the infectious agent, complexes of erythrocyte membrane and microbial proteins, and exposed erythrocyte membrane epitopes.[121] All mammalian hosts are able to develop immunity to the parasites after infection.[133] Development of an immunity without expression of clinical signs is common in endemic areas.[117,133] Acute infections are followed by a chronic carrier state that leads to persistent anemia and can result in decreased performance in race horses.[133]

Epidemiology Piroplasmosis occurs most commonly in subtropic and tropic regions in South and Central America, Africa, Asia, the Middle East, and Eastern and Southern Europe. It is, however, not strictly confined to these areas. The United States, Canada, Australia, Japan, Germany, England, and Ireland are considered non-endemic areas, although epidemic foci and introduction of the disease by imported horses have been reported.[119,120] The worldwide distribution is related to the presence of tick vectors.[117,120]

The infectious reservoir for *B. caballi* is the tick vectors. The parasites are transmitted transovarially (vertically) and trans-stadially (horizontally) within the tick population; *T. equi* is only transmitted trans-stadially (horizontally) and the reservoir is therefore considered to be the horse population. Unlike horses infected with *B. caballi*, those infected with *T. equi* are likely to remain lifelong carriers, even after treatment and resolution of the clinical signs.[117,118]

Prevention Tick control by regular application of an acaricide is the cornerstone for prevention of equine piroplasmosis. Currently, vaccines for equine piroplasmosis are not available.

Immune-mediated hemolytic anemia

- True autoimmune hemolytic anemia is uncommon in horses. Secondary IMHA has been reported secondary to infections, administration of certain drugs, and neoplasia, or in association with other immunologic diseases.
- Immune-mediated erythrocyte destruction leads to intravascular or extravascular hemolysis.
- The primary disease often predominates the clinical picture.
- Typical laboratory findings are autoagglutination of the blood and the presence of spherocytes. Coombs' test and direct immunofluorescence flow cytometry tests can confirm the diagnosis.

- Therapy consists of elimination of the primary cause, administration of corticosteroids, and supportive treatment.
- The prognosis depends on the underlying disease.

History and presenting complaint Lethargy, depression, weight loss, anorexia, and tachypnea are frequent presenting complaints. A history of recent drug administration or infectious disease may be obtained.

Physical examination Hemolysis can be acute and severe or chronic and insidious.[108] Clinical signs depend on the severity of the anemia, the rate of erythrocyte destruction, and the underlying disease process. Often, the clinical signs of the primary disease predominate the clinical picture. Lethargy, depression, pyrexia, tachycardia, tachypnea, icterus, and hemoglobinuria are found. Pallor of the mucous membranes can occur but is not a consistent finding.[103,108]

Special examination Ultrasonographic examination of abscesses and local swellings (myositis, cellulitis) can be useful to detect clostridial infections (gas and fluid accumulation). Rectal examination, and ultrasonographic examination of abdominal and thoracic cavity should be performed to detect possible neoplasia. Splenomegaly is occasionally found, and is likely caused by splenic hypertrophy or an underlying disease (neoplasia).

Laboratory examination Complete blood count and bone marrow analysis reveal signs for regenerative anemia within days after onset of hemolysis.[30] Serial measurements of hematocrit are helpful to detect ongoing hemolysis or regenerative response. Occasionally, the immune reaction also affects red blood cell precursors in the bone marrow, leading to non-regenerative anemia.[29,30] The presence of spherocytes is highly suggestive for immune-mediated hemolytic anemia.[29] Autoagglutination of red blood cells (Fig. 44.6) is a consistent finding in immune-mediated hemolytic anemia and should be distinguished from normal rouleaux formation (see above).[21,29,30]

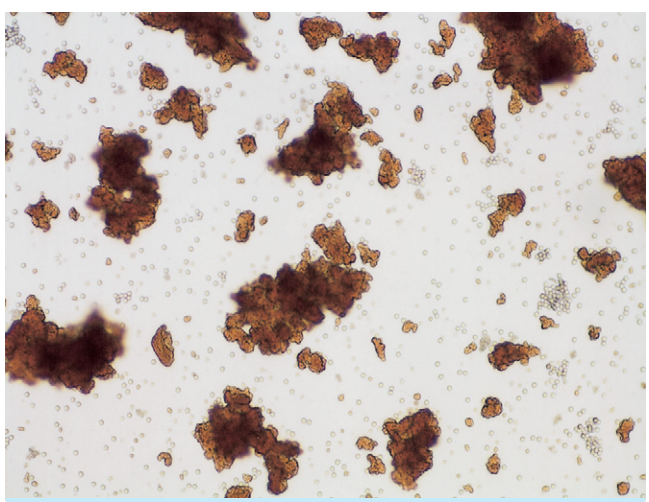

Fig. 44.6
Autoagglutination of erythrocytes in a horse with immune-mediated hemolytic anemia secondary to clostridial myositis.

Moderate neutrophilic leukocytosis is a common feature[134] and, occasionally, immune- mediated hemolytic anemia is associated with thrombocytopenia.[21,135,136] Red discoloration of the plasma after centrifugation indicates hemoglobinemia. The plasma protein concentration is typically normal. Hyperbilirubinemia may be present.[103]

The direct antiglobulin test (Coombs' test) using multivalent, species-specific reagent detects IgM (cold agglutinin) and IgG (warm agglutinin) anti-erythrocyte antibodies as well as complement protein C3 on the erythrocyte surface.[30] Although the specificity of the Coombs' test is very high, its sensitivity is low and a negative test does not rule out immune hemolytic anemia.[29] Previous corticosteroid treatment may lead to false-negative test results.[134] Direct immunofluorescence flow cytometry has recently been described for diagnosis of immune-mediated hemolytic anemia in horses.[137,138] This method allows the detection, differentiation, and quantification of cell-bound IgG-, IgM-, and IgA-antibodies. The sensitivity of the test is thought to be very high, whereas its specificity is somewhat lower than in the Coombs' test, occasionally leading to false-positive results. However, test characteristics have not yet been determined in horses.

Agar gel immunodiffusion for EIA (Coggins') should be submitted in all cases of hemolytic anemia. If the horse is living in or was imported from an area in which piroplasmosis is endemic, blood smears should be evaluated for presence of intraerythrocytic parasites, and appropriate further diagnostic should be performed. Determination of anti-penicillin IgG antibodies may be performed when penicillin-associated hemolytic anemia is suspected.[139–141] Clostridial infection (myositis or cellulitis) can be diagnosed by fine-needle aspirate, cytologic examination, Gram stains, and bacterial culture. Cytologic evaluation of abdominal or pleural fluid is recommended in cases with detectable effusion. Fine-needle aspiration of mass lesions is indicated to diagnose neoplasia.

Necropsy examination Generalized pallor or icterus is present on post-mortem examination. Lesions of primary disease may be found predominantly. Hemosiderosis of liver and kidneys, bone marrow erythroid hyperplasia, and extramedullary hematopoiesis are present.[46]

Diagnostic confirmation Diagnosis of immune-mediated hemolytic anemia is confirmed by ruling out other causes of hemolytic anemia, positive Coombs' test, positive flow cytometry test, and response to treatment with corticosteroids.

Therapeutic aims Treatment of the underlying disease, suppression of the abnormal immune response, and supportive care are the basic prerequisites for successful treatment of immune-mediated hemolytic anemia. Monitoring and support of renal function is important. If signs of tissue hypoxia and ischemia are present, increasing the hemoglobin concentration in the blood should be attempted.

Therapy The treatment depends on the severity and the primary cause of the anemia. Previously administered drugs should be discontinued. If antibiotic treatment is necessary, the class of the antimicrobial agent should be altered. Treatment with isotonic crystalloid solutions is crucial to avoid pigment nephropathy and acute renal failure in cases with severe hemolysis and hemoglobinuria.

Corticosteroids stabilize cell membranes, decrease the antibody production, decrease the affinity of the antibodies to the red blood cells, and decrease the rate of RBC destruction by macrophages of the reticuloendothelial system.[21,29,142] An initial daily dose of 0.05–0.1 mg/kg of dexamethasone i.m. or i.v. usually leads to a clinical and hematological response within 5–6 days. Alternatively, prednisolone can be administered orally at an initial dose of 1–1.5 mg/kg once daily. The dose should then be gradually reduced and continued for the total duration of 3 to 6 weeks, depending on the clinical response. Prior to initiation of corticosteroid treatment, possible infectious causes of immune hemolytic anemia should be precluded. In these cases, corticosteroids should be used with caution, as immune suppression can lead to exacerbation of the disease.[134]

Cytotoxic drugs including cyclophosphamide are recommended for severe therapy-resistant cases.[142] There is one report of treatment of a horse with cyclophosphamide and azathioprine.[46] Other therapies occasionally used in humans and dogs, including splenectomy, administration of intravenous immunoglobulins, and plasmapheresis, have not been described in horses.[29]

Clostridial myositis or cellulitis requires surgical debridement of necrotic tissue, analgesia, fluid therapy, and correction of electrolyte and acid–base disturbances.[143] Although penicillin is commonly recommended as the antimicrobial agent of choice, there is evidence that treatment with oxytetracycline and metronidazole may be more effective in decreasing toxin production and increasing the overall survival rate. [144,145]

If signs of tissue hypoxia and ischemia indicate the need to support the oxygen-carrying capacity of the blood, the use of whole-blood transfusions, packed red cells, or polymerized ultrapurified bovine hemoglobin (PUBH) should be considered (see the section 'Acute blood loss'). Transfusion of blood or erythrocyte concentrates may have limited benefits, as transfused cells are rapidly removed from the circulation and put additional workload on the reticuloendothelial system. Compatible donors often are not available, and cross-matching is usually positive. The absence of cell-surface antigens in PUBH solutions make them a useful agent for the treatment of severe immune-mediated hemolytic anemia, although costs are often prohibitive.[11,146, 147]

Prognosis The response to corticosteroid treatment is usually good in horses.[29] However, recurrence of the anemia after cessation of the treatment is possible, especially when the primary disease process is still present. The prognosis is best for patients with penicillin-associated anemia and primary idiopathic autoimmune hemolytic anemia. The prognosis for patients with neoplastic disease is usually poor.[29,134,148] Repeated monitoring of the hematologic parameters is recommended for 6 to 12 months after cessation of treatment.

Etiology and pathophysiology Immune-mediated hemolytic anemia is caused by antibodies directed against erythrocyte membrane proteins or membrane-bound antigens. Initiating factors are thought to be alterations of the erythrocyte membrane, alterations in immune regulation, or stimulation by other antigens, leading to the production of cross-reacting antibodies.[29,30] Erythrocyte destruction is the result of complement-mediated intravascular hemolysis or, more commonly, phagocytosis of antibody-coated erythrocytes by the macrophages of the reticuloendothelial system in liver and spleen (extravascular hemolysis).[29,30]

Occasionally, autoantibodies are also directed against bone marrow erythroid precursors, thereby interfering with erythropoiesis and leading to acquired pure red cell aplasia.[29,30] In patients in which no demonstrable underlying disease is present, the anemia is referred to as primary idiopathic autoimmune hemolytic anemia.[21,148] More commonly, immune-mediated hemolytic anemia occurs in association with other disease processes (secondary immune-mediated hemolytic anemia). A variety of causes has been described in association with immune-mediated hemolytic anemia in horses.

Immune-mediated hemolytic anemia secondary to clostridial myositis or cellulitis is not uncommon in horses. Autoagglutination can occur without clinically detectable hemolysis. Clostridial myositis or cellulitis is most commonly caused iatrogenically as a result of intramuscular injections of nonantibiotic drugs (flunixin meglumine, ivermectin, antihistamines, B-complex vitamins, prostaglandins, dipyrone, phenylbutazone).[143,149] Although *Clostridium perfringens* alpha toxin has a direct hemolytic effect resulting from massive acute destruction of the red cell membranes,[143,149,150] clinical and laboratory findings (delayed onset hemolysis, autoagglutination) suggest an immune-mediated cause of the anemia.[149] The pathomechanism may be related to bacterial synthesis of neuraminidase and subsequent enzyme-mediated exposure of a membrane-bound antigen (Thomsen–Friedenreich cryptantigen).[143,151] However, the contribution of this mechanism to the hemolytic process is unknown.

Immune-mediated hemolytic anemia is a rare complication after administration of penicillin[139–141,152] and possibly trimethoprim–sulfamethoxazole[153] in horses. Presumably the drugs act as haptens. They bind to erythrocyte membrane proteins and plasma proteins, and induce production of anti-penicillin IgG antibodies. Binding of the antibodies to the erythrocyte-bound penicillin leads predominantly to extravascular hemolysis, and to a lesser extent to complement-mediated intravascular hemolysis.[139,141] In part, the anemia may also result from pooling of red blood cells in the microcirculation or in the spleen, which would explain the rapid rise in hematocrit seen in some horses after cessation of penicillin treatment and initiation of corticosteroid treatment.[140]

Lymphosarcoma and other neoplasms are commonly associated with anemia of chronic disease and blood loss anemia. Occasionally, immune-mediated hemolytic anemia (and thrombocytopenia) may be found.[21,135,154]

Other primary disorders which may be associated with immune-mediated hemolytic anemia are purpura hemorrhagica and systemic lupus erythematosus, inflammatory bowel disease, and chronic bacterial infections or abscesses.[21,155,156] The etiology and pathogenesis of equine infectious anemia and piroplasmosis were described above.

Prevention Administration of drugs that are known to cause immune-mediated hemolytic anemia in an individual horse, and injection of irritating drugs (flunixin meglumine, ivermectin) that could cause clostridial myositis or cellulitis, should be avoided.

Heinz body hemolytic anemia

- Heinz body anemia results from toxic effects of maple leaves, wild onions, phenothiazines, or methylene blue.
- Oxidative damage to erythrocytes leads to hemolytic anemia characterized by the presence of Heinz bodies and eccentrocytes on the blood smear.
- Maple leaf toxicity also leads to methemoglobinemia and brown discoloration of mucous membranes, urine, and blood.
- Prognosis with rapidly developing severe anemia is poor.

History and presenting complaint Clinical signs vary depending on type and amount of toxin, time since exposure, and occurrence of complicating factors like pigment nephrosis and acute renal failure. Horses usually present with weakness, depression, anorexia, exercise intolerance, and signs of hematuria. Colic, ataxia, or acute death may occur.[108,157,158]

Physical examination Tachycardia, tachypnea and icterus are common findings. Brown discoloration of the mucous membranes, blood, and urine indicate methemoglobinuria, commonly found with maple leaf toxicity (Figs 44.7 and 44.8).[108,157]

Laboratory examination Moderate to severe anemia, hyperbilirubinemia, hemoglobinemia, and hemoglobinuria are present. Heinz bodies and eccentrocytes can be detected on blood smears (Fig. 44.9).[108,157] Measured blood methemoglobin concentration is increased in cases with maple leaf toxicity and can exceed 50% of total cellular hemoglobin concentration (normal methemoglobin fraction is less than 2% of total hemoglobin).[108] Serum biochemistry and urinalysis should be performed to monitor liver and kidney function. Blood gas analysis and serum lactate measurements may be used to assess severity and metabolic consequences of the anemia.

Diagnostic confirmation Clinical diagnosis is established based on history, clinical signs, specific laboratory findings, negative Coombs' test, and exclusion of other causes of anemia.

Treatment and prognosis Treatment consists of removal of the source of the toxin, administration of activated charcoal via nasogastric tube to decrease toxin absorption, intravenous fluid therapy to support renal function, and administration of high doses of vitamin C (30 mg/kg i.v. twice daily) as an antioxidant agent.[157,159,160] Whole-blood transfusion may be necessary when the hematocrit is less than 12% or if signs of tissue hypoxia are present (see the section 'Acute blood loss'). The use of a polymerized ultrapurified bovine hemoglobin solution (Oxyglobin®, Biopure Corporation, Cambridge, MA, USA) has been reported in horses for transient support of the oxygen-carrying capacity of the blood, providing a more optimal environment for a subsequent effective whole blood transfusion.[11,146] However, its use in adult horses is often limited by prohibitive costs.

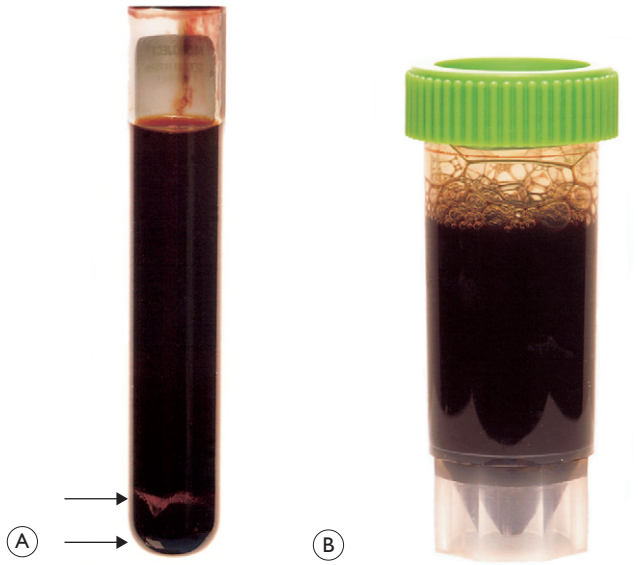

Fig. 44.8
(A) Blood sample of the same horse after complete sedimentation of the erythrocytes (arrows). Severe hemolysis and methemoglobinemia lead to a dark red-brown discoloration of the plasma. (B) Dark brown urine is consistent with hemoglobinuria and methemoglobinuria.

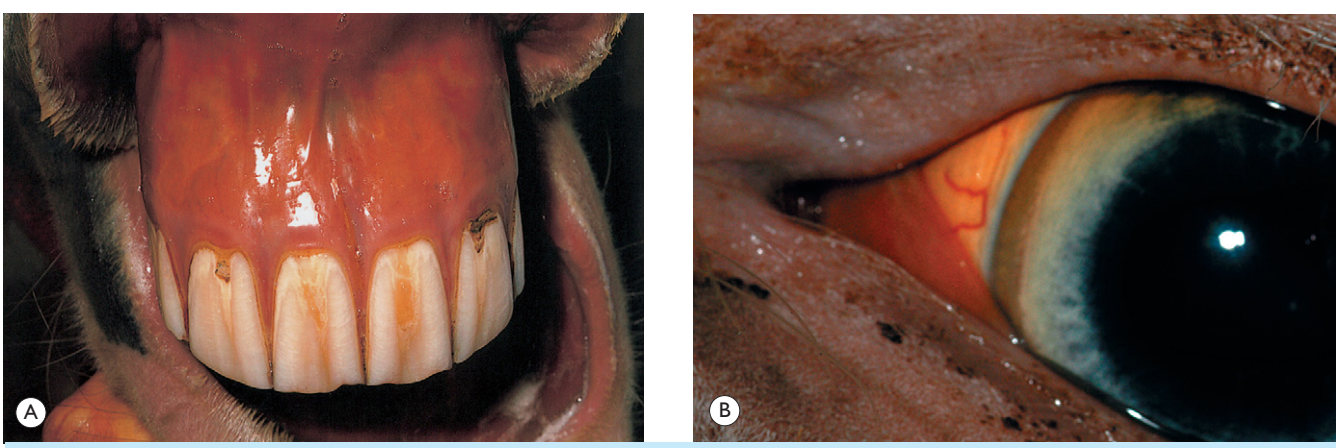

Fig. 44.7
Brown discoloration of mucous membranes (A) and conjunctivae (B) indicate severe methemoglobinemia associated with red maple leaf toxicity. The methemoglobin fraction in this horse was 44.3% of the total hemoglobin.

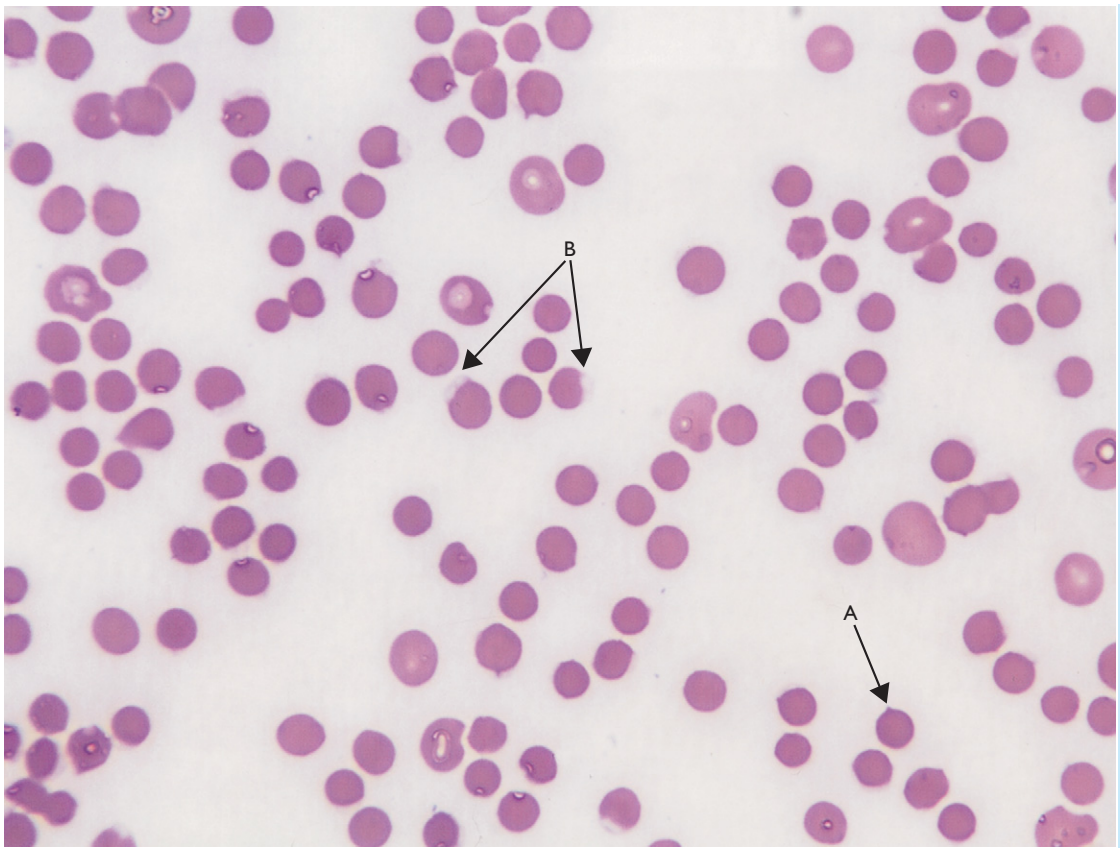

Fig. 44.9 Heinz bodies (A) and eccentrocytes (B) in a blood smear of a horse with hemolytic anemia due to red maple leaf toxicity.

The prognosis depends on the amount of the ingested toxin, occurrence of complicating factors, and the response to treatment. With rapidly progressive severe anemia, the prognosis is poor. The mortality rate with maple leaf toxicity is 60 to 65%.[157]

Etiology and pathophysiology Heinz body hemolytic anemia results from acute oxidative damage to the erythrocytes, caused by ingestion of maple leaves (red maple, *Acer rubrum)* and potentially, sugar maple (*A. saccharum)* and silver maple (*A. saccharinum*), wild onions (*Allium canadense*), or certain drugs including phenothiazines or methylene blue.[108,157,158,161]

Oxidative denaturation and aggregation of hemoglobin results in development of typical Heinz body inclusions, increased osmotic fragility of the erythrocytes, and enhanced cell clearance by mononuclear phagocytes, leading to intravascular and extravascular hemolysis. Maple leaf toxicity is also associated with formation of methemoglobin, which is incapable of carrying oxygen to the tissue.[108,157]

Hypoproliferative anemia

Anemia of inflammatory disease (AID)

- Non-regenerative anemia secondary to inflammatory or chronic disease is the most common type of anemia in horses.
- It is characterized by moderate anemia associated with normal or decreased serum iron concentration and total iron-binding capacity, and normal or increased serum ferritin and bone marrow iron stores.
- The pathogenesis is multifactorial, including sequestration of iron, decreased erythrocyte survival, and decreased bone marrow response to anemia.
- Treatment is directed against the primary disease process.
- The prognosis depends on the underlying problem.

Anemia of inflammatory disease (AID) is a mild to moderate, non-regenerative anemia associated with inflammatory disease, chronic infections, traumatic conditions, and neoplastic disorders.[37] It is also commonly referred to as anemia of chronic disease, although the syndrome may include anemias associated with diseases that are not chronic.[37,162] Anemia of inflammatory disease is considered the most common type of anemia in veterinary medicine, but it is usually a secondary finding of little clinical significance.[37]

History and presenting complaint The presenting complaints usually result from the primary underlying disease. Often, a history of poor performance, chronic weight loss, long-lasting disease processes and infectious conditions may be obtained.

Physical examination Signs of the primary disorder usually predominate the clinical picture. Weight loss and fever are often present. Pale mucous membranes are not consistently found, due to the mild to moderate character of the anemia.

Laboratory examination Laboratory findings include slightly to moderately decreased PCV and erythrocyte counts,

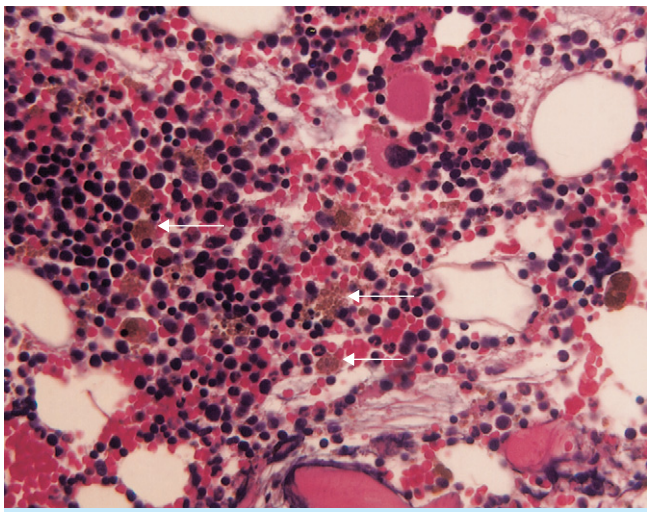

Fig. 44.10
Sternal bone marrow biopsy of a horse with anemia of inflammatory disease. Using conventional staining, increased hemosiderin deposits appear as brown aggregates (arrows). The cellular pattern is normal (hematoxylin–eosin staining).

and a low–normal or decreased MCV. Neutrophilic leukocytosis, monocytosis, and increased plasma fibrinogen and globulin concentrations usually indicate chronic inflammation.[163] Serum iron concentration and TIBC are normal or decreased, whereas serum ferritin and bone marrow stainable iron are normal or increased.[47,162] Bone marrow evaluation reveals increased stainable iron deposits with a nearly normal cellular pattern (Fig. 44.10).[37]

Diagnostic confirmation The presence of chronic inflammatory or neoplastic disease associated with mild to moderate non-regenerative anemia is highly suggestive for AID. Diagnostic confirmation of AID can be achieved by evaluation of the body iron status.[37]

Therapeutic aims Treatment is directed against the primary disease process. The anemia is rarely severe enough to require treatment.

Therapy Supplementation of iron is not useful, as the body is not iron deficient.

Prognosis The prognosis depends on the primary disease. The anemia usually resolves within weeks or months after resolution of the primary disease.

Etiology and pathophysiology The conditions leading to AID are inflammatory diseases, chronic infections, traumatic injuries, or neoplastic disorders. The anemia usually develops slowly to reach a plateau after the first 1 or 2 months of illness, but initial changes in hematocrit and hemoglobin concentration may occur after 3 to 10 days. There is no correlation between the duration of the disease and the severity of the anemia.[37]

The pathogenesis of AID is multifactorial, including sequestration of iron into storage forms in liver and bone marrow, decreased erythrocyte survival, and decreased bone marrow response to anemia.[37,162]

Increased sequestration of iron in macrophages and decreased absorption of iron from the intestinal tract is part of the acute-phase reaction, mediated by inflammatory mediators (interleukin-1, tumor necrosis factor α). This is considered to be part of a non-specific antibacterial immune response, reducing the availability of iron for bacterial growth. Increased erythrocyte destruction may be a major factor in the early stage of AID, presumably due to alterations in the red cell membrane, binding of IgG, and activation of the macrophages leading to a more efficient clearing of senescent and IgG-coated red blood cells from the circulation. Finally, decreased erythropoiesis results from blunted erythropoietin release in response to anemia, diminished bone marrow response to erythropoietin, and limited availability of iron.

Some chronic diseases and organ dysfunctions (chronic renal disease, hepatic disease, endocrine disease, and gastrointestinal disease) are associated with anemia that differs from AID in regards to pathophysiologic mechanism and iron metabolism.[162,163] However, no difference exists regarding treatment and prognosis of this type of anemia.

Iron-deficiency anemia

- Iron-deficiency anemia is rare in adult horses. It usually occurs secondary to chronic blood loss.
- The primary disease may predominate the clinical picture.
- Iron-deficiency anemia is characterized by microcytic non-regenerative anemia with low serum iron and serum ferritin concentrations, low bone marrow iron stores, and normal or increased iron-binding capacity.
- Treatment consists of elimination of the underlying disease process and iron supplementation.
- The prognosis depends on the primary cause of iron deficiency.
- Prevention should focus on potential causes of iron deficiency rather than daily supplementation of iron.

History and presenting complaint Clinical signs vary depending on cause and severity of the anemia and the presence of other concomitant disorders.[47] Poor performance, depression, weakness, and weight loss are common, as are unspecific features of iron-deficiency anemia.[47]

Physical examination Physical examination usually reveals signs of mild to moderate anemia. Pale mucous membranes, diarrhea, hematuria, hematochezia, melena, and epistaxis may be found in affected horses.[47] The primary disease may predominate the clinical picture.

Special examination Gastroscopy, fecal parasite egg counts, fecal occult blood test, urinalysis, and bronchoalveolar lavage may be performed in order to identify the underlying process leading to chronic blood loss and iron deficiency.

Laboratory examination Anemia due to chronic blood loss is initially macrocytic and regenerative. Only after weeks or months, in very late stages of severe iron depletion, does microcytic non-regenerative anemia develop.[47,48] The RDW may be increased because of the presence of microcytes together with normocytic cells. Hypochromasia is rarely apparent in horses with iron-deficiency anemia.[47] Hypoproteinemia is often associated when substantial recent or ongoing blood loss is present.[47]

Evaluation of the body iron status typically reveals low serum iron concentrations and increased TIBC. Serum

Table 44.8 Differentiation between anemia of inflammatory disease and iron-deficiency anemia[37,47,48]

	Iron-deficiency anemia	Anemia of inflammatory disease
Mean corpuscular volume (MCV)	⇓	Normal or ⇓
Red blood cell distribution width (RDW)	Normal or ⇑	Normal
Serum iron	⇓	⇓ or normal
Serum ferritin	⇓	Normal or ⇑
Total iron-binding capacity	Normal or ⇑	⇓ or normal
Bone marrow stainable iron	⇓ or absent	Normal or ⇑

ferritin concentration correlates directly with body iron stores and is usually low in iron-deficiency anemia.[47,48,53,54] Bone marrow evaluation is the most sensitive method for detection of iron deficiency, prior to development of microcytic anemia.[47,48,164] Typically, erythroid hyperplasia and ineffective erythropoiesis with asynchrony and shift to later rubricytes are found. Reduced erythropoiesis is apparent at later stages. Stainable iron in the bone marrow is minimal or absent.

Diagnostic confirmation Primary differential diagnosis in cases with mild to moderate non-regenerative anemia is anemia of inflammatory disease. Diagnostic confirmation of iron-deficiency anemia can be achieved by evaluation of the body iron status (Table 44.8).

Therapeutic aims Treatment should be directed towards elimination of the underlying process which causes the chronic blood loss.

Therapy Besides treatment of the primary disease process, iron supplementation is recommended. Oral supplementation of iron compounds is safe and can be achieved by administration of commercially available hematinics containing ferrous sulfate, copper, and various B-vitamins.[54] Parenteral iron dextran preparations should not be used due to severe tissue irritation (thrombophlebitis, myositis), possible related anaphylaxis, and fatal reactions.[47,54]

Prognosis The prognosis largely depends on the underlying disease causing the iron deficiency. Several months may be required to replenish body iron stores and to normalize hematocrit and red cell indices.

Etiology and pathophysiology Iron-deficiency anemia is rare in adult horses.[17,47,48,55] It usually occurs secondary to chronic blood loss due to gastrointestinal ulcers, parasites, neoplasia, and urinary or pulmonary hemorrhage. Dietary causes are rare. Unless the anemia is severe, clinical signs of iron deficiency are more likely the result of the underlying disease and the impaired function of iron-containing enzymes rather than the reduction of the oxygen-carrying capacity of the blood.[59]

Prevention The administration of hematinics (iron and B-vitamin-containing compounds) to horses is common practice, although efficacy of these treatments to enhance performance has not been proven.[48,54,59,165] Current recommendations suggest that the iron requirements vary between 500 and 1200 mg/day for a 500-kg horse, depending on work intensity.[165] Although exact iron requirements for athletic horses in training are not known, the usual dietary sources are considered adequate to maintain a sufficient supply of iron for hemoglobin synthesis and function of iron-dependent enzymes.[53,54,165,166] Prevention should therefore focus on potentially underlying disease processes rather than iron supplementation.

Other nutritional deficiency anemias Deficiencies of copper, folic acid, vitamin B_{12} (cobalamin), and cobalt can potentially lead to hypoproliferative anemia in humans and animals. However, reports on anemias due to nutritional deficiencies are often based on response to supplementation or treatment rather than demonstration of deficiency of a defined nutrient.[164] The true incidence of this type of anemias is therefore often unknown. Copper, folic acid, and cobalamin are common ingredients of modern horse feed and hematinic preparations, which are used empirically in horses.[54]

Copper Copper, as part of a copper-containing plasma protein (ceruloplasmin), plays an important role for transmembranous iron transport and transfer of iron from ferritin (ferrous form) to transferrin (ferric form). Although not well defined, daily copper requirements are currently estimated to be 131 to 187 mg/day for a 500-kg horse.[69,165] Copper deficiency can lead to impaired iron metabolism and accumulation of iron stores with signs of functional iron deficiency.[47,53] There is evidence of a relationship between developmental orthopedic disease and dietary copper intake in foals.[69,71] However, adult horses are usually not affected by copper deficiency.

Folic acid, vitamin B_{12}, and cobalt Folic acid and vitamin B_{12} (cobalamin) belong to the group of water-soluble vitamins (B vitamins). Interactive reactions of folic acid and vitamin B_{12} are involved in DNA synthesis and amino acid metabolism. These two vitamins are therefore essential for cell division and proliferation, especially in rapidly dividing cells such as the hematopoietic cells and the gastrointestinal endothelium.[77,167]

Requirements for vitamin B_{12} and folic acid are likely to be met by microbial synthesis within the large intestine of horses. Intake of folic acid is further provided by oral dietary intake.[54,71,167–169] Cobalt is essential for vitamin B_{12} synthesis.

Macrocytic or normocytic normochromic non-regenerative anemia caused by folate or vitamin B_{12} deficiency occurs in humans and ruminants. Although cases of poor performance and anemia have occasionally been associated with folate deficiency,[75] it seems to occur rarely in horses.[18,71,164,167] Horses also appear to be unaffected by vitamin B_{12} and cobalt deficiency.[71,168] However, serum folate concentrations in stabled, intensively training Thoroughbred and Standardbred horses are generally lower than in pastured horses,[73–76] and additional dietary folic acid may be indicated for some horses in training.

Administration of sulfadiazine and pyrimethamine to treat equine protozoal myeloencephalitis requires special consideration regarding folate metabolism. Both drugs sequentially limit folate synthesis by inhibition of protozoal enzymes and competition with para-amino benzoic acid, which is a precursor of folic acid.[77] Mammals are less sensi-

tive to these effects but intestinal uptake of folic acid may be inhibited. A rapid and significant reduction of serum folate concentrations occurs after administration of sulfadiazine and pyrimethamine to horses.[73]

Anemia, leukopenia, glossitis, oral ulcerations, and bone marrow hypoplasia have been reported in a horse during long-term treatment with orally administered folic acid, sulfadiazine, and pyrimethamine.[77] Experimental evidence from other species suggests that concomitant oral administration of folic acid and pyrimethamine may result in decline, rather than an increase, in plasma folate concentrations. This paradoxical effect is likely due to competition of the orally administered inactive form with endogenous folates for intestinal absorption and interruption of the enterohepatic circulation of folic acid.[77,170] Monitoring of serum or erythrocyte folate concentrations and hemograms may therefore be indicated in horses treated with sulfadiazine and pyrimethamine. However, against common recommendations, the use of folic acid as a dietary supplement with sulfadiazine/pyrimethamine treatment may be contraindicated.

Pure red cell aplasia secondary to treatment with recombinant human erythropoietin (rhEPO)

- Recombinant human erythropoietin is sometimes used as a supposed performance-enhancing agent.
- This form of doping is dangerous and can lead to severe pure red cell aplasia.
- The proposed underlying pathophysiologic mechanism is the production of anti-rhEPO antibodies that cross-react with endogenous erythropoietin and thereby suppress erythropoiesis.
- Diagnosis is based on exclusion of other causes for hypoproliferative anemia, bone marrow examination, and a history of rhEPO administration.
- The prognosis is guarded.
- Administration of rhEPO to horses is not recommended.

Recombinant human erythropoietin (rhEPO) is commonly used to treat human patients, dogs, and cats with chronic renal failure or other chronic or neoplastic desease.[171,172] Although rhEPO is not routinely used for therapeutic purposes in anemic horses, there seems to be an increasing tendency to administer rhEPO to equine athletes, as a performance-enhancing agent, to increase the total red cell mass and oxygen-carrying capacity of the blood.[173,174] However, this form of doping is dangerous. Similar to dogs, cats, and some people,[171,172,175,176] multiple administrations of rhEPO to horses can cause erythroid hypoplasia and severe non-regenerative anemia.[177,178]

History and presenting complaint Affected horses usually present with a history of poor performance, depression, anorexia, and weight loss.[177] Detailed information about previous administration of rhEPO is sometimes not readily available from trainers or owners.

Physical examination Poor body condition, lethargy, weakness, tachycardia, tachypnea, and pale mucous membranes are found in cases of severe anemia. Cardiac arrhythmia may indicate hypoxic myocardial damage. Earlier in the course of the disease, the anemia may be less profound and the clinical signs mild. Due to the slow development, the chronicity of the anemia, and effective compensating mechanisms (see above), most horses can tolerate even severe anemia.

Laboratory examination Laboratory evaluation usually reveals profound anemia without any signs of regenerative response. The severity of the anemia varies between individual horses and depends on the time since administration of the drug.[178] The PCV decreases continuously and can reach values as low as 5%. White blood cell counts, leukocyte differential, and platelet counts are usually within normal limits. Mild elevations of liver enzyme activities and cardiac troponin I serum concentrations may occur, most likely due to tissue hypoxia secondary to severe anemia.[178] Measurements of serum urea nitrogen, serum creatinine concentration, and urinalysis should be performed to rule out primary kidney disease and chronic renal failure.

Coombs' test and Coggins' test are negative. Evaluation of the serum iron concentration, percentage saturation of transferrin, ferritin concentration, and total iron-binding capacity indicates adequate iron supply and precludes iron-deficiency anemia.[177] Bone marrow evaluation typically reveals generalized hypocellularity with markedly decreased numbers or complete absence of erythroid precursors and increased M:E ratio (Fig. 44.11). The myeloid series appears normal and the number of megakaryocytes seems adequate. There is no evidence for a myelophthisic process. The findings are consistent with erythroid hypoplasia or pure red cell aplasia.[177,178]

Measurements of serum erythropoietin concentrations are of limited value for the diagnosis of rhEPO-associated anemia. Clearance of rhEPO from plasma in horses is rapid,[179,180] which precludes the possibility of detection of rhEPO at the time of onset of clinical signs. Furthermore, measurements of endogenous serum erythropoietin concentrations in affected horses are known to be inconsistent and

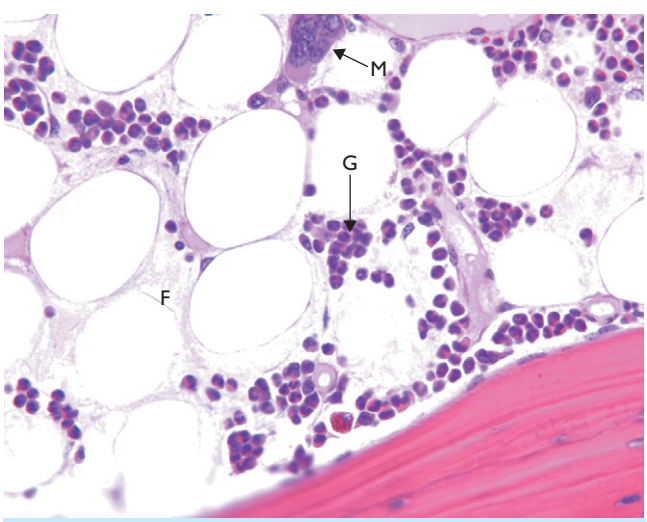

Fig. 44.11
Histologic preparation of a bone marrow biopsy taken from the sternum of a horse with rhEPO-induced pure red cell aplasia (PCV 5%). The bone marrow appears hypocellular. Cells of the granulocytic series (G), megakaryocytes (M), and fat (F), but no cells of the erythroid series are present.

Fig. 44.12
Diaphyseal bone marrow of the tibia in a horse with rhEPO-induced pure red cell aplasia. The yellow fatty appearance of the marrow indicates absence of hematopoietic tissue. Although this would be expected for diaphyseal marrow in normal horses, there should be a hematopoietic response given this horse's severe anemia (PCV 5%).

results vary considerably between different assays, possibly due to interference by anti-EPO antibodies.[178]

Clonogenic assays can be performed to determine whether the serum of affected horses contains substances inhibiting erythroid development. Positive results suggest presence of anti-rhEPO antibodies.[177] However, currently established methods for specific detection of anti-rhEPO antibodies in horses are not routinely available.

Necropsy examination The bone marrow found on necropsy has a markedly pale appearance, due to the lack of erythropoiesis (Fig. 44.12). Histopathology shows generalized hypocellularity with severe erythroid hypoplasia, normal myeloid series, and adequate numbers of megakaryocytes. There is no evidence of myelophthisic disease. Evidence for hypoxic damage of kidneys, liver, myocardium, and other organs may be present.

Diagnostic confirmation Exclusion of other causes for non-regenerative anemia, together with a history of rhEPO administration, strongly suggest rhEPO-associated anemia.

Therapeutic aims The initial goal of treatment is to provide adequate oxygen-carrying capacity to avoid hypoxic organ damage and sudden death. The second therapeutic aim is suppression of the immune response against erythropoietin.

Therapy Administration of rhEPO should be discontinued immediately. Blood transfusions should be performed when the PCV is below 10% or if signs of severe tissue hypoxia are present (see the section 'Acute blood loss'). Experience has shown that even large volumes of blood transfusions are not able to increase the PCV significantly and persistently, although clinical signs may improve.[178]

Dexamethasone or prednisolone have been used to attempt to suppress the hypothesized immune response that is causing the anemia.[77,178] The dose should be adjusted according to clinical response and considering possible adverse effects. The efficacy of corticosteroid treatment is unknown. In addition to corticosteroids, treatment with immunoglobulins, plasmapheresis, cyclophosphamide, and cyclosporine has been described in humans.[172,175]

Prognosis Erythropoietin-induced anemia may be reversible in some cases after cessation of treatment and decline in circulating anti-rhEPO antibodies.[77,171,176] However, the overall prognosis in horses is guarded. Potential recovery may take several months or years,[172,175] and acute death due to chronic hypoxia and organ failure is possible if the anemia remains untreated.

Etiology and pathophysiology The anemia is most likely the result of production of anti-rhEPO antibodies that cross-react with endogenous erythropoietin and inhibit its effect on bone marrow erythroid precursors.[171,172,175,177,178] Twenty to thirty percent of cats and dogs treated with rhEPO develop anti-rhEPO antibodies.[171,176] The susceptibility for rhEPO-induced anemia and the severity of the anemia seems to vary considerably between individual horses.[178]

Development of anemia is probably dose independent but may require repeated exposure to the antigen.[177] Equine erythrocytes have a long half-life and thus the development of the anemia is slow and clinical signs of anemia may occur with a delay of 2 to 6 months after administration of the drug and onset of the adverse reaction.[177,178,181] The clinical signs result directly from a reduced oxygen-carrying capacity of the blood and related compensatory mechanisms.

Prevention Administration of recombinant human erythropoietin to horses should be strictly avoided.

Other causes of hypoproliferative anemia Other very rare types of hypoproliferative anemia in horses are anemia secondary to organ dysfunction, aplastic anemia, myelophthisic disorders, and myelodysplastic syndromes.

Mild to moderate hypoproliferative anemia can occur in association with chronic renal failure, liver disease, gastrointestinal disease, or chronic endocrine disorders, which suppress hematopoiesis independent of alterations in iron metabolism that characterize anemia of inflammatory disease.[163]

Aplastic anemia is characterized by pancytopenia in peripheral blood, bone marrow panhypoplasia with fatty replacement, and the absence of primary disease processes infiltrating the bone marrow or suppressing hematopoiesis.[38,182] Clinical signs include hemorrhagic diathesis due to severe thrombocytopenia, increased susceptibility to infections due to neutropenia, and non-regenerative anemia.[183] The cause usually remains undetermined.[184–186] An association with administration of phenylbutazone has been suspected, but not conclusively proven, in some cases.[187] The underlying pathophysiologic mechanism of aplastic anemia may be immune-mediated in most cases.[182,186] Infectious agents, drugs, and toxins may also be responsible for development of aplastic anemia.[38]

Myelophthisis is characterized by normo- or hypercellular bone marrow and replacement of normal hematopoietic cells by neoplastic cells[188] or proliferating fibroblasts (myelofibrosis).[189]

Myelodysplastic syndromes are a heterogeneous group of disorders characterized by peripheral cytopenias and

normocellular or hypercellular bone marrow with abnormal morphology.[182,190] Refractory, severe anemia is usually accompanied by leukopenia and thrombocytopenia in variable degrees.

Anemia associated with administration of heparin

A distinct type of apparent anemia in horses cannot be categorized in the classical groups of regenerative and non-regenerative anemias. Anticoagulatory treatment with unfractioned heparin (sodium or calcium heparin) has been reported to decrease hematocrit, hemoglobin concentration, and erythrocyte concentration by as much as 50%.[191–194] This adverse effect of heparin is unique to horses. It is associated with erythrocyte agglutination and is thought to occur secondary to sequestration of the red cell agglutinates in the microcirculation, potentially leading to impairment of microvascular blood flow. The effect is reversible and resolves within 3–4 days of discontinuation of heparin therapy. Similar adverse effects are not encountered with use of low-molecular-weight heparin.[195,196]

Red cell hypervolemia in Standardbred Trotters

- Occurs predominantly in well-performing Standardbred Trotters, mainly stallions and geldings, 5–6 years of age.
- Initially good race horses gradually start to deteriorate in performance, after a long, often successful, racing career.
- Horses diagnosed as having red cell hypervolemia generally show no specific findings upon clinical examination.
- Diagnosis is based on history of impaired performance and determination of the total blood and red cell volume.
- Horses with this condition have an increased red cell volume compared to normovolemic horses of corresponding age and sex.
- Affected horses show decreased resting plasma cortisol concentrations and a decreased response to exogenous ACTH, suggesting a chronic stress syndrome.
- During exercise, these horses have higher pulmonary artery pressure and a higher pulmonary vascular resistance than normovolemic trotters.
- The pulmonary hypertension seen in horses with this condition is speculated to lead to a low-grade pulmonary edema and epistaxis.
- Red cell hypervolemic horses exhibit a more marked hypoxemia during exercise compared to normovolemic horses.
- The treatment is aimed towards eliminating stress factors in the environment and by changing the training regime.

Recognition of disease

History and presenting complaint

Red cell hypervolemia, or 'polycythemia' is reported to be a common finding in Standardbred Trotters in Sweden that are presented with a complaint of impaired performance capacity.[14,197,198] The Standardbred population in Sweden consists mainly of French and American Trotters and a mixture of these bloodlines. Red cell hypervolemia has been diagnosed in Standardbred Trotters both with American and French origin. The condition is mainly found in middle-aged (5–7 years) race horses, predominantly in stallions or geldings, that have recently experienced a gradual decline in performance.[199] The decline in performance is reflected in the marked drop in individual performance index, in earnings, and finishing status.[199] Generally, affected horses have initially been very successful on the race tracks in comparison to the contemporary average population. To enable the horse to remain competitive, trainers often train these horses very hard with a lot of high-speed interval training. A common complaint from trainers of affected horses is that such horses perform well during the major part of the race but are unable to increase speed during the final 400–500 m of the race. Many of these horses also have a history of epistaxis in association with intense exercise.[198,200,201] Another frequent observation by the trainers of these horses is a change in behavior of the horse. From previously having shown no remarkable signs of becoming easily excited before exercise, these horses gradually show more and more signs of apparent anxiety in connection with racing or training, the most common signs described being muscle

Table 44.9 Reference values (mean ± SD) for bodyweight (BW, kg), total red cell (CV/BW, mL/kg), total blood (TBV/BW, mL/kg), plasma (PV/BW, mL/kg) volumes relative to BW, and packed cell volume (PCV, L/L) in different age and sex groups in normally performing Standardbred Trotters

Age (years)	Sex	*n*	BW	CV/BW	TBV/BW	PV/BW	PCV
2		30	416 ± 38	52.2 ± 6.8	102.1 ± 7.6	49.9 ± 3.1	0.510 ± 0.035

The relationship between speed at a heart rate of 200 bpm (m/s) and the red cell volume in relation to body weight (mL/kg) in normovolemic (○) and polycythemic (●) horses.

tremor, tachycardia, excessive pulling during the race, sweating, and sometimes loose feces.

Physical examination

Generally, horses diagnosed to have red cell hypervolemia show no specific findings upon physical examination but in some cases this condition is associated with other clinical disorders such as small airway disease.[200,202–204] However, as already mentioned, many of these horses appear to be very nervous upon examination and handling.

Special examination

Hematocrit Previous studies have shown that there is a strong relationship between the red cell volume and total hemoglobin concentration and the aerobic metabolic capacity of horses.[14,16,198] Consequently, the estimation of total blood volume and red cell volume is useful in the evaluation of the exercise capacity in horses as well as evaluation of horses with impaired performance.[14,15,202,203,205] Horses with red cell hypervolemia have a significantly increased red cell volume and higher maximal hematocrit in comparison to normovolemic horses of corresponding age and sex.[14,206] One screening method to determine if a horse suffers from red cell hypervolemia is to measure the maximal hematocrit after exercise. The easiest way to do this is by having the horse exercise at a level that induces a pulse rate that exceeds 200 bpm, which induces a complete emptying of the splenic red cell reservoir.[14,198] This is preferably done on a track using a heart rate meter to assess the heart rate during exercise. The blood sample for measurement of hematocrit should be collected within 1 min of the end of exercise.[207] The measured hematocrit could then be compared to the hematocrit values from horses of the same age and sex. If the horse has a maximal hematocrit above 2 standard deviations of what is expected considering its age and sex, the horse can be suspected to have red cell hypervolemia. If, on the above screening testing, the horse is shown to have a high hematocrit value suggesting red cell hypervolemia then the total red cell volume and total blood volume should be determined to confirm the diagnosis. This is done using the Evans Blue dye dilution technique to measure plasma volume, and determination of the maximal hematocrit after exercise, which then allows calculation of the total blood volume and red cell volume.[14,207]

Red cell volume To standardize the exercise conditions, the exercise test is often done on a treadmill. The horse performs a standardized submaximal incremental exercise test on an inclined (3.6° [6.25%]) treadmill.[14,198] During the standardized submaximal exercise test the heart rate is recorded and mixed-venous blood samples are drawn at the end of each speed step. The blood samples are then analyzed for the concentration of blood lactate. This makes it possible to calculate the individual values for $\dot{V}La_4$ and $\dot{V}_{200}$. Red cell hypervolemic horses have an abnormally high heart rate in relation to their red cell volume during submaximal exercise. [14,198] Despite this, the values for $\dot{V}_{200}$ do not seem to differ between red cell hypervolemic and normovolemic horses during submaximal exercise.[208,209] However, nothing is known about the relationship between pulse rate and red cell volume during intensive exercise to fatigue in red cell hypervolemic horses. Red cell hypervolemic horses also have a tendency to have lower blood lactate concentrations immediately postexercise than normovolemic horses.[205] The clinical impression is also that horses with red cell hypervolemia tend to reach the lactate threshold of 4 mmol/L later during exercise than well-trained normovolemic horses. There is, however, no scientific evidence to support this opinion.

Endoscopy Endoscopy of the respiratory tract within 90 min of performing the submaximal exercise test often reveals blood in the trachea in these horses. Although the prevalence of EIPH after racing is reported to be lower in Standardbred Trotters (23–45%) than in Thoroughbreds (over 90%), there are indications that Standardbred Trotters with red cell hypervolemia have an increased incidence of exercise-induced pulmonary hemorrhage (EIPH) (92%) than normovolemic Standardbred Trotters[198,201,210,211] (Adehed & Funkquist, unpublished data). The reason for this increased incidence of EIPH may be related to stress failure of the capillary endothelial layers.[201,212]

Laboratory examination

Bronchoalveolar lavage often reveals hemosiderophages, which is interpreted as evidence of previous EIPH, but is a common finding in almost all actively racing horses.[213–215] Consequently these horses frequently exhibit hemosiderosis on bronchoalveolar lavage.[201] The clinical impression is also that some horses with red cell hypervolemia have signs of a subclinical bronchiolitis on bronchoalveolar lavage.

Histochemical analysis of muscle biopsies collected from the gluteus medius muscle from horses with red cell hypervolemia reveals that the muscle fiber composition and fiber area do not differ from normovolemic horses.[216,217] However, a higher percentage of type IIB fibers shows a high oxidative capacity on the NADH-stain than in normovolemic horses.[216] A recent study using the immunohistochemical technique has shown that horses with red cell hypervolemia express less of the isoform of myosin heavy-chain MHCIIX in comparison to well-trained normovolemic horses.[218] There are three different isoforms of myosin heavy chains (MHC) MHCI, MHCIIA, MHCIIX, and the oxidative capacity is highest in the type I and lowest in the type IIX fibers. Training has been shown to cause a transformation of IIX to IIA fibers.

Measurement of maximal hematocrit, as well as determination of the total blood volume, are common methods used in clinical practice to diagnose this condition. However, research on red cell hypervolemic horses have shown that they have an altered physiological response to exercise in comparison to normovolemic horses. The methods used in research are often too complicated or too expensive to be used in practice. However, research on horses with this condition has shown that:

- Red cell hypervolemic horses appear to have an adrenocortical malfunction with decreased resting plasma cortisol concentrations and a decreased response to exogenous ACTH.[197]
- During exercise, red cell hypervolemic horses have higher pulmonary artery pressure (PAP) and systemic artery pressure (SAP) than normovolemic Trotters and also a higher pulmonary vascular resistance.[200] There is also an increasing difference in vascular resistance between hypervolemic and normovolemic horses as exercise intensity increases.
- Red cell hypervolemic horses have a more marked hypoxemia during exercise in comparison to normovolemic horses.[202,204] This is mainly a result of an increase in inequality of the ventilation–perfusion distribution ($\dot{V}_A/\dot{Q}$). This has been found in studies using the multiple inert gas elimination technique described by Wagner et al.[219–221] The mismatch in $\dot{V}_A/\dot{Q}$ is likely caused by a mild interstitial pulmonary edema that occurs as a result of an increased fluid transudation secondary to the pulmonary hypertension.[212,222]
- Unpublished data indicate that blood viscosity is higher in red cell hypervolemic horses than in normovolemic horses (P. Funkquist, unpublished data: 6.67 ± 0.37 mPa × s, range 6.27–7.19, at maximal exercise to fatigue).
- Horses with red cell hypervolemia have also been found to have a lower capillary supply in muscle compared to well-trained, normovolemic horses.[209] Moreover, the activities of muscle enzymes such as citrate synthase (CS), lactate dehydrogenase (LDH), or 3-hydroxy acyl CoA dehydrogenase (HAD) in horses with this condition are unaltered in comparison to normovolemic horses.[208,209,216,217]

Necropsy examination

Generally, horses with red cell hypervolemia are not euthanized so little is known regarding specific findings on necropsy.

Diagnostic confirmation

Differential diagnoses to red cell hypervolemia are other clinical disorders that cause an impaired performance capacity in horses that have previously performed well. As red cell hypervolemia can sometimes be secondary to other diseases, such as small airway disease or myocardial disease causing hypoxia, it is important to eliminate these disorders as a cause of the increase in red cell volume. The diagnosis of red cell hypervolemia is confirmed by the finding of abnormally high total blood volume and maximal hematocrit values in a horse without any other clinical findings that could explain the onset of poor performance.

Treatment and prognosis

Therapeutic aims

Occasionally, the red cell hypervolemia is associated with another clinical disorder,[203,223] for instance chronic small airway disease, that could be the primary cause for the development of an increased production of erythrocytes. The therapy is thus directed towards treating the primary disorder. However, many horses diagnosed with red cell hypervolemia have no detectable underlying disease as an explanation for the development of this condition. The pathophysiology behind red cell hypervolemia is incompletely understood but there are indications that these horses could suffer from a chronic stress syndrome.[197] The therapeutic aim is therefore oriented towards diminishing the stress factors for the horse. Excessive training is thought to be an important reason for the development of red cell hypervolemia and consequently an alteration in training regimen is often indicated.

Therapy

Alterations in training regimens Despite some minor differences in training regimens between different trainers, Standardbred Trotters in Sweden are trained in a similar manner. The normal training regimens for a Standardbred Trotter often consist of 2 or 3 days of interval training (6–7 intervals) on a straight or round course for 600–700 m. The last interval is often performed at near to, or maximal speed; the speed is dependent on the age and training status of the horse. Between the days of interval training there are often 1 or 2 days of slow aerobic exercise (driven or ridden), and 2 days of rest in the paddock. Horses with red cell hypervolemia often have a history of very intense training with a lot of interval training at high speed. It is recommended that horses with red cell hypervolemia rest completely from training for a period of 3–6 months, depending on the severity of the condition. However, some trainers choose to continue the training without any resting period as they find it difficult to

get these horses back in condition again. After the initial period of rest, training intensity should be reduced by leaving out the interval training and using races as speed training. An additional recommendation is also to reduce the frequency of racing and to choose races with a less intense competition.

It is also recommended to move these horses from busy large training camps to smaller and quieter stables. All these recommendations are given with the purpose to reduce the stress connected with training and stabling for these horses.

Phlebotomy There is evidence that phlebotomy of horses with red cell hypervolemia decreases both the maximal hematocrit as well as maximal hemoglobin concentration.[201] Phlebotomy also decreases the pulmonary artery blood pressure, blood viscosity, and incidence of pulmonary hemorrhage. The duration of this effect has not been determined. In the study by Funkquist et al[201] the run time to fatigue during submaximal exercise on a treadmill was decreased by phlebotomy. Conversely, clinical experience suggests that phlebotomy could have a positive effect on performance. However, the study by Funkquist and colleagues found that the plasma volume was not restored after phlebotomy. This could be one explanation for the decrease seen in performance after phlebotomy.

Castration The prevalence of red cell hypervolemia is higher in stallions compared to mares. This may be because stallions have been shown to have a larger red cell volume and total blood volume in relation to bodyweight than both mares and geldings, probably due to the erythropoietic effect of testosterone.[14] Thus one therapeutic method that has been used in stallions in order to decrease the erythrocyte production is castration. However, no studies regarding the effect of castration on the red cell volume support castration as a treatment for horses with this condition.

Prognosis

Although a slight improvement can be seen after a longer period of rest and alterations in training regimes, there are indications that horses with red cell hypervolemia seldom reach their previous racing capacity.[199] Thus it is common for red cell hypervolemia to denote the end of a successful racing career.

Prevention

As the pathophysiology of red cell hypervolemia is unclear, it is difficult to give recommendations for prevention of this condition. Given that these horses often have a history of a long period of intensive training before the development of the condition, and show signs of chronic physical and environmental stress, it is likely that they have reached their genetic limit of performance. The prevention of excessive training could be a factor of importance in trying to prevent the condition from occurring. However, as there is a great genetic variability in the exercise capacity of individual horses, it is difficult to determine when the training is overly intense. Further studies are needed to find different markers for this.

Etiology and pathophysiology

The exact cause of the development of red cell hypervolemia is still unclear. The prolonged and excessive training is, however, thought to be an important factor for the development of this condition. Red cell hypervolemia is likely a result of a decreased peripheral oxygen utilization, either depending on a peripheral circulatory insufficiency and tissue hypoxia during intensive exercise or a decreased oxygen uptake by the muscle cell.[14,197] The former has similarities to a condition called vasoregulatory asthenia, which is seen in man after excessive physical training.[224] The decreased uptake of oxygen could be a result of a reduced diffusion of oxygen to mitochondria. The hypoxia is thought to cause a compensatory increase in plasma erythropoietin that results in an absolute secondary erythrocytosis. The mobilization of red blood cells from the spleen during exercise has been reported to contribute to the exercise-induced hypoxemia seen in normal horses during exercise.[202] In horses with red cell hypervolemia this hypoxia is likely exaggerated because of an increase in blood viscosity, a higher pulmonary vascular resistance and an inequality in ventilation–perfusion distribution. Little is known about the plasma erythropoietin concentrations in horses with red cell hypervolemia and further studies are needed to establish if horses with this condition show alterations in the concentrations of plasma erythropoietin in comparison to normovolemic horses.

CHAPTER 45

Immunological responses to exercise and training

David W. Horohov

It is a common belief that habitual exercise provides an individual with enhanced protection from disease. A review of the scientific literature, however, reveals seemingly paradoxic reports on the effect of exercise on the immune system.[1–3] More than 30 years of research on this topic has made it clear that the effects of exercise on the immune system are complex and dependent upon multiple factors, including: (i) the immune function or characteristic being analyzed; (ii) the intensity and duration of exercise; and (iii) the timing of the measurement of immune function in relation to the exercise bout.[1,2,4] The underlying mechanisms whereby exercise alters immune responses are likewise multifactorial and likely include both neuroendocrine[5–7] and metabolic factors.[8–10] Although the clinical consequences of the exercise-induced immune changes have not formally been identified, there is evidence that high-intensity exercise in humans can lead to an overall impairment of the cellular immune system, resulting in low concentrations of lymphocytes, suppressed natural immunity, suppressed lymphocyte proliferation, suppressed levels of secretory IgA in saliva, and an increased incidence of upper respiratory tract infections.[8,11–16] By contrast, a regular routine of moderate exercise seems to improve immunological function and increase disease resistance, particularly in the elderly.[4,17]

The majority of the studies concerning the immunologic responses to exercise and training have focused on humans and laboratory animals. Although the horse provides an excellent opportunity for exercise-based studies, there is a limited amount of information available concerning the effect of exercise on the equine immune system.[18] Most of this review will therefore emphasize those results obtained from human and rodent exercise studies. When possible, specific information regarding equine exercise studies will also be included.

Immune responses

Most investigations on the effect of exercise on immune function have focused on the innate immune response in both horse and man.[1,18,19] This initial response to pathogens plays a central role in disease resistance and the development of subsequent adaptive or specific immune responses. The innate immune response includes both cellular and humoral components, although most studies on the effect of exercise on this response have focused on the cellular components, namely neutrophils, macrophages, and natural killer (NK) cells.[18,19] The essential characteristic of the innate immune response is that it does not exhibit specificity for the invading organism. Thus the induction of an innate immune response does not require prior exposure to the invading organism, nor is it augmented by repeated exposure to the same organism. The innate immune response plays an important role in prompting the adaptive immune response as well as providing valuable time for specific adaptive responses to develop.

The adaptive immune response is likewise mediated by both humoral and cellular components. The humoral response consists of antigen-specific antibodies produced by B cells and plasma cells. The cellular response is composed of effector T cells such as cytotoxic T-lymphocytes (CTLs) that exhibit both antigen specificity and the phenomena of immunological memory. The regulation of the adaptive immune response is mediated by T helper (Th) cells that produce various cytokines, small hormone-like proteins that control the growth, differentiation, and activation state of various cells of the immune system.[20] Together, these responses provide the functional capacity to completely protect an animal against a particular pathogen.

Functionality of the innate immune response is assessed in vitro by measuring the phagocytic or oxidative metabolic activity of macrophages and neutrophils[21–24] and the cytotoxic activity of NK cells.[25–28] The adaptive immune response is assessed in vitro by the ability of lymphocytes to proliferate[4,29–31] or produce cytokines in response to various mitogens and specific antigens;[4,30,32] and in vivo by measuring antibody responses.[30,33–35]

Exercise intensity and immune function

An acute exercise bout or test is the most frequently used method for exercise immunology studies.[3,36,37] Even with this approach the overall response depends on many factors, including the intensity, duration, and mode of exercise; plasma concentrations of hormones and cytokines; physiologic changes in the body including temperature, blood flow, and hydration status; and the overall fitness of the subject.[36] In general, acute exercise bouts of moderate duration (< 60 min) and intensity (< 60% $\dot{V}O_{2max}$) are associated with fewer perturbations to the immune system than prolonged, high-intensity sessions in humans[36,38,39] and horses (Table 45.1).[23,24,40] Conditioning of elite human athletes may or may not alter exercise-induced changes in immune function, and may be sport dependent.[41,42] Studies of unconditioned horses have shown decreased immune responses after a single[43,44] and multiple bouts of intensive exercise.[30] Other studies involving conditioned horses found decreased lymphoproliferative responses following treadmill exercise[45] or racing[29] and impaired neutrophil function after endurance riding.[46,47] Long-term exercise training of low intensity appears to improve some measures of human immune function,[48] whereas overtraining is associated with decrements in some immune measures (granulocyte oxidative burst, NK cell activity, lymphocyte proliferation, the production of cytokines in response to mitogens, nasal and salivary immunoglobulin A levels) and increases in others (granulocyte and monocyte phagocytosis, and inflammatory cytokine production).[8,13–16] Interestingly, overtraining in humans is associated with a decrease in maximum exercise-induced adrenocorticotropin hormone (ACTH) and, to a lesser degree, cortisol and free plasma catecholamines.[49] No similar alterations in stress hormone production have been seen in overtrained horses,[50,51] although the possibility of immunological alterations in overtrained horses has not been addressed.[18]

Table 45.1 Summary of exercise intensity effects on immune functions[18]

Immune function	Moderate exercise	Intense exercise
LAK/NK lysis	↑	↓
Lymphoproliferation	↓	↓
Neutrophil function	↓	↓
Macrophage function	↓	↓
Proinflammatory cytokines	↑	↑
Antibody levels	↕	↓

The stress response

The physiologic and immunologic consequences of intensive exercise parallel the effect of other physical and psychological stressors.[52–54] It should be noted that exercise stress is not a single homogeneous stressor. Rather, it is actually a culmination of several different stressors, including physiologic, environmental, social, and psychological stressors.[53–55] Stress has been defined, in general, as an abnormal or extreme adjustment in the physiology of the animal to cope with adverse effects of its environment or management.[56,57] Initial theories attempting to identify a common non-specific stress response pathway (e.g. Hans Seyles' General Adaptation syndrome) have been discounted and instead four separate pathways have been identified: the hypothalamic–pituitary–adrenal (HPA) axis, the autonomic nervous system, extra-adrenal pathways, and extra-neuronal production of cytokine mediators (Fig. 45.1).[58] Although products of each of the pathways appear to be involved in stress-induced immunomodulation, the HPA axis and its production of cortisol and catecholamines has been the most intensively studied stress pathway in terms of exercise-induced immune modulation (Fig. 45.2).[54,59]

Cortisol represents the chronic response to stress whereas catecholamines represent the acute stress response.[60,61] Cortisol, the primary biologically relevant corticosteroid of humans and horses, is a cholesterol derivative produced by the adrenal cortex under the direction of ACTH produced by the pituitary.[62] Production of ACTH is regulated by corticotropin-releasing factor (CRF), which is produced by the hypothalamus.[63] Cortisol production in humans and horses has an ACTH-dependent circadian rhythm with peak levels in the early morning and a nadir in the evening.[64–66] This rhythm can be disrupted by physical and psychological stress.[65,66] Intensive exercise is likewise associated with an increase in plasma cortisol in both man and horse.[54,67,68] Therefore it is tempting to

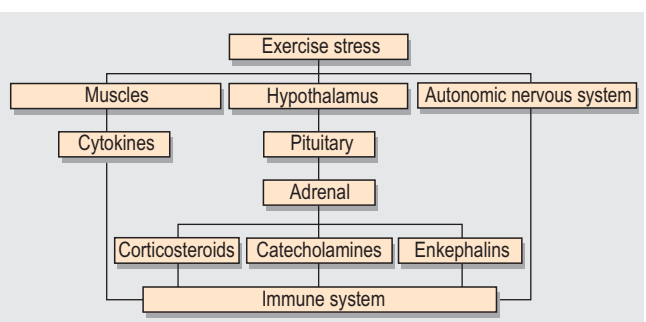

Fig. 45.1
Exercise effects on the immune system. Exercise can affect the immune response either directly via the production of various cytokines by muscle cells or via hormone produced via the hypothalamus–pituitary–adrenal axis.

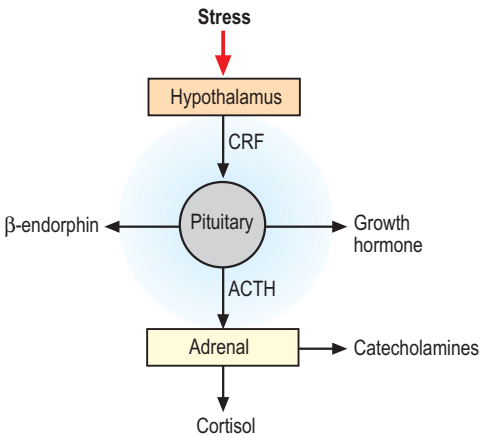

Fig. 45.2
Hypothalamus–pituitary–adrenal (HPA) axis. The perception of the stressor signals corticotropic-releasing factor (CRF) production by the hypothalamus, which causes the pituitary to produce adrenocorticotrophic hormone (ACTH) and β-endorphin. ACTH stimulates cortisol production by the adrenal glands, which also produce catecholamines.

ascribe exercise-induced changes in immune function to increases in plasma cortisol, because corticosteroids are known to be potent anti-inflammatory agents and to have dramatic effects on immune cell function (see below).[69]

Catecholamine production by the nervous system is another important component of the stress response.[59,70] Catecholamines, such as epinephrine (adrenaline) and norepinephrine (noradrenaline), are derivatives of tyrosine produced by sympathetic nerve endings and the adrenal medulla.[71] They mediate a multitude of physiologic changes that broadly encompass the 'fight or flight' response to stressors.[57,72] Catecholamines exert their effects within minutes of their induction and are considered to represent the active response to stress.[73] Catecholamines mediate their effect through the interaction with adrenergic receptors found on the surface of various cells, including lymphocytes.[74–76] A number of immunomodulatory effects of catecholamines has been described (see below).

It has been suggested that stress-induced impairment of either innate or specific immune responses opens a 'window of susceptibility' to infectious agents.[77] This is likely due to subtler changes in immune function rather than complete immune suppression.[78–85] These subtle changes in lymphocyte function could account for aberrant responses to vaccination seen in stressed individuals[86,87] and the increased incidence of upper respiratory tract infections in human athletes.[88–91] Although the precise mechanism responsible for the increase in disease remains uncertain, a number of in vitro correlates have been identified.

Exercise-induced leukocytosis

One of the most consistent effects of exercise on the immune system is the leukocytosis seen after strenuous exercise in humans,[21,92–95] as well as horses.[96–98] As with the other effects of exercise on immune function, the magnitude of the leukocytosis increases as the intensity and duration of exercise increases.[94] The leukocytosis observed following acute intense exercise is biphasic in nature, characterized by an initial increase in lymphocyte numbers followed by an increase in neutrophil and monocyte numbers.[93,95,99] Lymphocyte numbers have been shown to return to resting levels in as short as 1 h after exercise, whereas neutrophils are slower in returning to resting values and, considering the fact that lymphocyte numbers decline rapidly, are responsible for the increased neutrophil to lymphocyte ratio reported in most studies.[95,96] Lymphocyte numbers have been shown to drop below baseline values in human and equine subjects during the recovery phase following intense exercise creating a lymphopenia,[61,100] and this effect has been attributed to post-exercise production of cortisol.[77]

In addition to the increase in lymphocyte numbers in response to exercise, it has been shown that exercise has an effect on lymphocyte subpopulations. The majority of the work has concentrated on the changes in circulating numbers of $CD4^+$ and $CD8^+$ T-lymphocytes.[39,101–105] Most Th cells are $CD4^+$ while CTLs are $CD8^+$. In one study with a limited number of horses, $CD4^+$ T cell numbers were shown to decline following intense exercise, with no change in $CD8^+$ numbers.[18] In related studies using human subjects, $CD4^+$ and $CD8^+$ T cell numbers have been shown to increase, decrease, or remain stable following exercise.[39,103–105] In general, these results indicate that exercise-induced lymphocyte subset reduction is transient and dependent upon exercise intensity and duration with high-intensity exercise tending to decrease the number of $CD4^+$ T cells.[12,39,103]

The number of circulating NK cells, identified by the presence of the CD16 cell-surface antigen, has been shown to increase following exercise in humans.[12,28,39,106–108] The effect of exercise on NK cells in the horse is unknown, because equine NK cells are difficult to identify. Several markers that selectively bind to the equine NK cell have been identified and may provide the answer to this and many other questions regarding equine NK cells.[109,110] Equine lymphokine-activated killer (LAK) cell activity, which appears to be distinct from NK cell activity,[111,112] has been shown to increase following exercise,[113] although the circulating numbers of these cells remain stable following exercise.[27]

There are three likely mechanisms to explain the exercise-induced leukocytosis. The first mechanism involves hemoconcentration resulting from shifts in fluid balance with the overall effect of decreasing the extracellular fluid compartment.[102,114,115] The increase in the packed cell volume and total protein concentration due to intense exercise are partially due to this mechanism as well.[116,117] The second mechanism involves catecholamine levels, which have been shown to rise in response to exercise and are known to mobilize leukocytes from the marginal pool.[95] The third mechanism that may play a role in the leukocytosis of exercise involves the mobilization of granulocytes from the marrow pool caused by exercise-induced increases in cortisol

concentration.[102,118–120] It is believed that this latter mechanism is responsible for the previously mentioned biphasic nature of exercise-induced leukocytosis.[77,93,95,99,120,121]

Exercise and leukocyte function

Single bouts of moderate to intensive exercise are associated with an initial increase in NK or LAK cell function in humans[26,28,107,122] and horses[27] but severe exercise is followed by depression of NK function.[122] Single bouts of moderate to intensive exercise transiently impair neutrophil antimicrobial functions in both horse and man.[21,98] High-intensity exercise on a treadmill has been associated with a general reduction in neutrophil function in both species.[44,123] Endurance racing is likewise associated with negative changes in neutrophil function in both man and horse.[46,47] Similar effects of intensive exercise on bronchoalveolar macrophage function are also seen in horses,[23,24] although in mice there appears to be an enhancement of macrophage function following an exercise challenge.[22] As such, these studies indicate that equine innate immune functions, like those of humans, can be adversely affected by intensive exercise.

There are relatively few reports of exercise-induced changes in antigen-specific lymphoproliferation as the majority of the work on exercise-induced changes in lymphocyte function has concentrated on the mitogen-specific response. In general, intense exercise leads to decreased lymphoproliferation to both mitogens and antigens.[11,12,124] The magnitude of this effect has been shown to increase with increases in exercise intensity and duration.[36,38,39] In one study in horses, there was no change in the lymphoproliferative response to the various mitogens.[24] In contrast, other studies have shown that unconditioned horses exhibit decreased lymphoproliferative responses to both mitogens and equine influenza virus in response to a single bout[43,44] and multiple bouts of intensive exercise.[30] Studies involving conditioned horses found decreased lymphoproliferative responses to mitogens in response to treadmill-based exercise challenge[45] and racing.[29] While positive training effects have been observed on human basal immune responses,[4,17] exercise-conditioned horses do not appear to have a similar increase in their basal immune responses (Table 45.2).

More recently it has been suggested that strenuous exercise might also alter patterns of cytokine gene expression, though the absolute effect varied.[32,33,125] Production of the proinflammatory cytokines interleukin (IL)-1, IL-6, IL-8, IL-12, granulocyte/macrophage-colony stimulating factor (GM-CSF), and tumor necrosis factor (TNF)-α is enhanced by intensive exercise,[126–128] suggesting that exercise is a form of limited inflammatory response.[129] IL-6 is thought to play a central role in this process as it is produced in large quantities in response to exercise and locally in skeletal muscle in response to exercise.[130] From these results, it has thus been proposed that skeletal muscle damage during physical exercise results in an inflammatory response.[131,132] It has recently been reported that multiple bouts of high-intensity exercise may be more potent inducers of this inflammatory response.[133,134] Although the overall significance of these results remains controversial,[135] it is becoming increasingly apparent that exercise is associated with a proinflammatory cytokine response. Whereas these cytokines themselves have immunoregulatory functions, their production may also have a role in post-exercise immune suppression.[136,137] The theory is that the counter-regulation of the initial inflammatory immune response involves the production of cortisol, prostaglandins, and IL-10 (an anti-inflammatory cytokine), all of which contribute to the post-exercise immune suppression.[130,137] This mechanism is also consistent with reports that exercise may enhance Th2 immune responses at the expense of Th1 responses.[32] IL-10 and corticosteroids suppresses Th1 responses and favor Th2 development.[137] Intensive exercise-induced inhibition of Th1 cytokine production also occurs in horses,[30] although the role of IL-10 in this process is unknown. Clearly the effect of exercise on cytokine production in the horse needs further work.

The effects of exercise on humoral immunity are conflicting at best. Prolonged periods of intense training lead to an impairment of mucosal immunoglobulin levels in humans.[2,138–140] Exercise appears to have little effect on immunoglobulin concentrations or antibody production in horses.[30,98] Actively exercising horses and humans produce similar levels of antibodies following vaccination as unexercised controls,[34,141] however, cell-mediated immunity following vaccination may be impaired.[30,142,143] The possibility of altered patterns of immunoglobulin isotype production in response to exercise has not been addressed, although such alterations have been described in other stress models.[86,87] Additional work needs to be done to elucidate the effect of exercise on immunoglobulin levels and isotype production in both horse and man.

Table 45.2 Basal immune responses of trained and untrained horses[43]

Immune response	Untrained horses	Trained horses
Mitogen proliferation	68 266 ± 2082 cpm	68 066 ± 5428 cpm
Influenza proliferation	7358 ± 426 cpm	8480 ± 1494 cpm
LAK cytotoxicity	16.2 ± 1.8 lytic units	12.8 ± 3.1 lytic units

LAK, lymphokine-activated killer.

Mechanisms of exercise-induced changes in immune function

The mechanisms responsible for changes in immune function are unknown, although much of the data seem to implicate a

central role for cortisol and/or catecholamines. Exercise has been shown to significantly increase the plasma concentration of cortisol and catecholamines and the magnitude of this response is directly related to the intensity and duration of exercise.[54,77] Hormonal responses of the horse to exercise have been shown to mimic the response of humans and other mammals in which both cortisol and catecholamine levels have been shown to significantly increase in response to high-intensity exercise.[68,100,144–146] Again, the general consensus is that cortisol mediates the later changes following exercise while the early or immediate effects of exercise are due to the catecholamines (Fig. 45.3).

Production of cortisol, the primary secretory glucocorticoid, in the horse has been well studied but the actual physiological significance of the changes that occur following exercise are far from being understood. Plasma cortisol in the horse has a half-life of 70–100 min and has been shown to peak 20–30 min after the cessation of exercise.[145] It has been determined that plasma cortisol levels do not increase due to exercise until the work load reaches the 60% maximum oxygen uptake ($\dot{V}O_{2max}$).[30,147–149] The increase in plasma cortisol concentration is the result of a change in the balance between the combined increased secretion of cortisol and increased clearance rate in response to exercise, with the secretion rate showing the greater increase.[67] Exercise training is associated with an adaptation of the HPA axis leading to decreased pituitary sensitivity to corticosteroids and increased plasma cortisol levels.[150,151] Exercise-induced alterations in glucocorticoid receptor expression and signaling in lymphocytes have also been reported in human athletes,[152,153] and this can lead to decreased sensitivity of corticosteroid suppression of immune function.[154] No similar information is available for the horse.

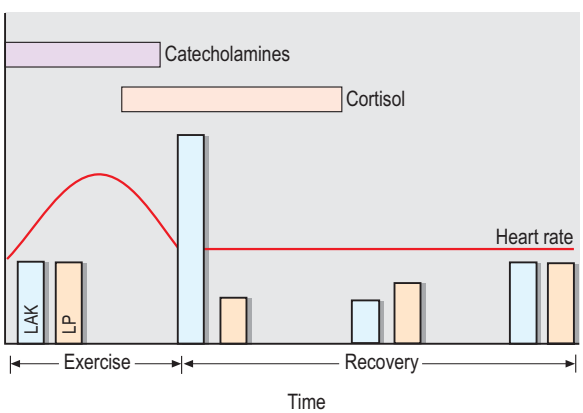

Fig. 45.3
Equine exercise–immunology model. Exercise is associated with the early production of catecholamines and an increase in heart rate. Cortisol production occurs later and is intensity dependent. Lymphokine-activated killer (LAK) cell activity and the lymphoproliferative (LP) response to mitogens are at a baseline level prior to exercise. Upon completion of exercise, LAK activity increases with a concomitant decrease in the LP response. Later in the recovery period, both LAK and LP responses are suppressed, although eventually they will return to baseline levels. The magnitude and duration of the effect on LAK and LP is also intensity dependent.

Because corticosteroids are known to be potent anti-inflammatory agents and to have dramatic effects on immune cell function,[69] it is tempting to attribute exercise-induced changes in immune function to increases in plasma cortisol. Thus corticosteroids inhibit synthesis of various cytokines such as IL-1, IL-2, IL-3, IL-6, interferon gamma (IFN-γ), GM-CSF, and TNF-α.[69,155,156] Likewise, the production or release of lymphotoxin, monocyte chemotactic factors, vasoactive amines, prostaglandins, and plasminogen activator are diminished in the presence of corticosteroids.[69,155,156] Indirect corticosteroid effects on in vitro lymphoid cell function have likewise been reported, presumably resulting from altered regulation of cytokine production and activity and/or antigen-presenting cell function.[157] Thus a variety of research has demonstrated corticosteroid-related decreases in mitogen responses, LAK cell activity, CTL function, NK cell-mediated cytotoxicity, and lymphocyte proliferative responses to specific antigens.[54,158–160] Although the magnitude of the cellular response to glucocorticoid depends upon the hormone level to which it is exposed, the relationship between corticosteroids and the immune system is complex and may be obscured by factors such as steroid preparation and species sensitivity to corticosteroids.[161] Studies that demonstrate corticosteroid-associated immune suppression in vitro often utilize synthetic preparations and/or non-physiologic concentrations of the steroid. Synthetic hormones such as dexamethasone or prednisolone have a longer half-life in circulation, bind less strongly to cortisol-binding globulin, and have a higher affinity for the corticosteroid receptor and are thus more potent than cortisol.[162,163] Pharmacologic concentrations of cortisol that are immunosuppressive are not relevant to the in vivo situation.[163] Finally, it should be noted that most studies on the effects of corticosteroids have been performed on corticosteroid-sensitive species such as rats and mice.[164] In these animals, relatively small amounts of corticosteroids have dramatic suppressive effects on immune function, including thymic involution and lymphoid cell death.[164] In corticosteroid-resistant species such as the horse, immune suppression by corticosteroids may be absent or else require even higher doses and prolonged exposure to corticosteroids for expression.[165] It is important to keep these caveats in mind when considering the role that cortisol may play in exercise-induced immune modulation. To address some of these issues we have tested equine peripheral blood mononuclear cells in vitro for the effect of cortisol on lymphoproliferative and LAK cell function (Fig. 45.4). Significant effects were only observed at the highest (10^{-6} M) concentrations. Likewise, injection of a single bolus of cortisol at physiologic concentrations failed to alter immune cell function, although hematologic responses were observed (Table 45.3). Together, these results indicate that cortisol alone may not account for exercise-induced changes in immune cell function in the horse.

Catecholamines have also been shown to significantly increase in response to exercise in the horse.[146,166] Epinephrine (adrenaline) and norepinephrine (noradrenaline) are the major secretory catecholamines and have similar

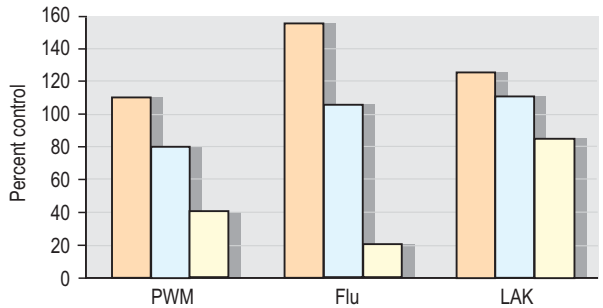

Fig. 45.4
The effect of cortisol on equine proliferation and lymphokine-activated killer (LAK) cell activity. Peripheral blood mononuclear cells were incubated with increasing concentrations of cortisol (10^{-10}, 10^{-8}, and 10^{-6} M, orange, blue and yellow bars, respectively) and either equine influenza virus antigens (Flu) or pokeweed mitogen (PWM) and the proliferative response determined by ^{3}H-thymidine incorporation on days 5 and 3, respectively. Cortisol was added to equine LAK cell cultures at the same doses and cytotoxic activity assayed as previously described (see Table 45.3). Data are presented as the average ± SE of the percentage of the response of cultures not receiving any cortisol.

functions including enhancement of cardiac contraction, blood flow to the heart and skeletal muscle, blood glucose, lipolysis, and oxygen consumption.[57,72] The plasma half-life of both epinephrine (adrenaline) and norepinephrine (noradrenaline) is less than 30 s in the horse.[166] As is the case for cortisol, catecholamine secretion has been shown to increase as the intensity of exercise increases.[166–168]

Catecholamines exert some of their effects on immune responses indirectly by causing the redistribution of the blood cells leading to leukocytosis, lymphocytosis, neutrophilia, decreases in the CD4:CD8 ratio, and increases in NK cell numbers.[25,75,95,169] Catecholamines also directly influence antigen-specific antibody responses, mitogen-stimulated lymphocyte blastogenesis, and natural cytotoxicity.[170–172]

Table 45.3 Hematologic results from an intravenous injection of cortisol or vehicle[43]

	Cortisol			Vehicle		
	–60	+20	+120	–60	+20	+120
WBC	8.4	7.7*	8.5	10.9	11.0	11.2
Neuts	5.1	4.9*	6.0	6.8	6.6	6.7
Lymphs	2.8	2.5	2.0*	3.0	3.2	2.8
N/L	1.8	2.0	3.0*	2.3	2.1	2.4
LAK	62.3	53.2	108.9	52.9	58.2	58.5
PWM	35.3	35.0	33.4	28.4	31.5	35.7
Flu	4.3	1.9	3.6	3.4	2.3	4.1

Flu, proliferative response to influenza virus (× 10^3 net cpm); LAK, lymphokine-activated killer – cell activity as lytic units per 10^6 cells; Neuts, neutrophils; lymphs, lymphocytes × 10^3/μL; N/L, neutrophil/lymphocyte; PWM, proliferative response to pokeweed mitogen (× 10^3 net cpm); WBC, white blood cells.
* Significantly different from – 60 timepoint ($P < 0.01$, RMANOVA).

In addition to the effects of cortisol and catecholamines on the immune system, several other mediators have been implicated as having a potential role in the changes seen following exercise. These include β-endorphin, growth hormone, prolactin, and enkephalin.[126,149,173,174] Among these, β-endorphin has been the most extensively studied in terms of its effect on immune cell function. β-Endorphin release has been shown to increase following intense exercise requiring intensity in excess of 60% $\dot{V}O_{2max}$.[149,173,174] β-Endorphin has been shown to be generally immunosuppressive.[54,126]

Exercise and infectious disease

The central question remains, does exercise lead to increased susceptibility of horses to bacterial and viral infections? Although the physiologic and immunologic consequences of intensive exercise parallel the effect of other physical and psychological stressors,[53,54] do these changes in immunologic function measured in vitro correlate with increased susceptibility to disease in vivo? Epidemiologic surveys have confirmed an increased incidence of upper respiratory tract infection symptoms in human athletes following participation in high-intensity events, such as marathon races,[89–91] although the precise mechanism responsible for this increase remains uncertain.[175–177]

The marked susceptibility of race horses to respiratory infections is widely recognized.[178–180] The reasons for this remain unknown, although they are likely to include the immune status of the susceptible population as well as exposure to infected individuals.[181,182] Interestingly, a recent history of vaccination is not necessarily associated with a reduction in disease risk.[182] The possibility of training or racing schedules affecting the incidence of disease has not been widely considered.[181] In a recent study using a treadmill-based exercise protocol it was shown that vaccinated ponies subjected to repeated bouts of high-intensity exercise were susceptible to influenza virus infection, whereas non-exercised controls were protected.[30] This increased susceptibility was associated with alterations in the in vitro cell-mediated immune response to the virus.[30] Could a similar exercise (stress)-induced alteration in immune function account for influenza infections in vaccinated race horses? Do exercise-induced alterations in neutrophil function likewise leave endurance and race horses susceptible to bacterial infections? Although there is little information currently available to support these concerns, the experience from human sports medicine does suggest that there could be a similar 'window of vulnerability' in our equine athletes.

Assuming that there is an association between exercise-induced immune suppression and increased incidence of respiratory disease in the horse, what can be done? Some attempts have been made through chemical or nutritional means (e.g. indometacin, glutamine, vitamin C, and carbohydrate supplementation) to attenuate immune changes after intensive exercise,[9,183,184] although no consistent relationship

between nutritional interventions, exercise immunology, and upper respiratory tract infection risk has yet been established.[183] Increased carbohydrate ingestion was associated with an attenuated cortisol, growth hormone, and epinephrine (adrenaline) response and fewer perturbations in immune function.[9] Whereas dietary manipulation has been widely recognized as a means to meet the energetic needs of the equine athlete,[185,186] the possible effect of diet on immunocompetency in the exercising horse has not yet been addressed.

Conclusions

Our understanding of the effect of exercise on the immune system is improving, although a number of issues remain unresolved, including the in vivo significance of some of the in vitro findings. Further work defining the mechanisms and long-term consequences of exercise-induced immune modulation is needed before specific changes in current training or vaccination programs can be contemplated. Nevertheless, evidence from the human literature indicates that such efforts could prove useful in protecting the health and welfare of the equine athlete.

CHAPTER 46

Effects of exercise on gastrointestinal function

Mireia Lorenzo-Figueras and Alfred M. Merritt

Background

Based upon the design of its gastrointestinal tract (GIT) alone, the horse would be an unlikely animal for humans to choose as their athletic alter ego. The very large cecum and folded large colon, normally filled with ingesta, must certainly not be the easiest structures to move around. Likewise, the anatomic arrangement and complexity of function of these fermentation vats could, theoretically at least, set the system up for any number of exercise-induced abnormalities. When left to their own devices in the wild, herbivores, whether they be the forestomach fermenters or the hind-gut fermenters which include the equidae, spend the large majority of their day quietly grazing or resting.[1] Instances of movement faster than a walk are usually brief and in response to attack by a predator or a rival.

'Domesticated' horses, on the other hand, are often subject to many situations that result in a greater percentage of their level of daily activity being much more vigorous than just walking and standing around grazing. While hard data concerning the effect of any form of exertion on the equine GIT, whether it be direct or indirect, are scarce, we have some results showing that even the anticipation of an upcoming training session on a treadmill, such as turning on the treadmill motor, will evoke an increase in intra-abdominal pressure, reflecting tensing of the abdominal muscles.[2] One outstanding effect this pressure increase, and that associated with subsequent trotting or galloping, has on the stomach, for example, will be discussed later in this chapter. The point is that the intra-abdominal pressure response could have far-reaching effects on abdominal viscera, and that the character of the response could vary depending upon the type and duration of the exertion. Galloping may have a different effect than trotting, while trotting may have a different effect than pacing. Jumping may have entirely unique consequences. Effects could include distortion and/or displacement of viscera, redirection of blood flow, and release of various regulatory peptides.

A study of human subjects that were 'encouraged to perform at near-maximal effort' indicated that runners have more complaints of gastro-esophageal reflux (GERD) than do cyclists.[3] Could this be because, in the bent over position in which they ride, cyclists create less abdominal muscle press than do runners? Or is it because, as one report has suggested, the physical displacement of the abdominal viscera associated with the 'pounding of the pavement' results in an irritation that produces symptoms – the so-called 'cecal slap syndrome'?[4] Or, could it be a question of experimental methodology, since two subsequent studies found that subjects asked to perform at up to 90% $\dot{V}o_{2\,max}$ on a stationary bicycle experienced GERD that was exercise intensity dependent?[5,6] That is, type, duration and intensity of exercise all need to be considered from the standpoint of potentially differential effects on the gut.

Finally, considering all of the things humans ask horses to do in the form of exertion, are some forms more stressful than others? In general, existent data indicate a direct relationship between plasma adrenocorticotrophin (ACTH) and cortisol concentrations and intensity and duration of exercise, respectively, in horses.[7] But in one study, for instance, galloping caused no significant increase in pituitary venous blood corticotrophin-releasing hormone (CRH), although ACTH concentration did increase significantly.[8] These issues must also be factored in with respect to the potential impact on the GIT. This chapter considers the potential effects of exercise on: (i) digestion; (ii) absorption; (iii) secretion; (iv) motility; (v) maintenance of mucosal barrier integrity, and (vi) liver-specific functions. These functions are directly influenced by blood flow status, and activity within the enteric nervous system (ENS), which may be strictly intrinsic or may be modified by input from the central nervous system (CNS). With respect to

horses, some special species-relevant aspects of these functions deserve note, and will be explained further below.

Digestion

Some fermentation of soluble carbohydrate occurs within the stomach, with the production of lactic and volatile fatty acids. Whether and to what extent these products are absorbed across the gastric wall and into the bloodstream is not known, though a large proportion should be in the non-ionized, diffusable form, given the acidic environment. Pancreatic secretion, on the other hand, while being large in volume, is very low in amylase and protease activity. The usual complement of small intestinal (brush border) disaccharide enzymes is present. However, small intestinal proteolytic enzymes have not been measured in horses. From a comparative perspective, the one thing that makes horses unique with respect to other domestic species is the degree of cecal and colonic digestion of dietary fiber; up to 35% of the animal's daily caloric needs may be derived from the volatile fatty acids (VFAs) produced from the fermentation of dietary fiber.[9]

Absorption

As indicated above, one of the most unique aspects of equine gut function is the fermentation of carbohydrates at both ends of the tract. While we still know little about where and how the products of gastric fermentation are absorbed, we do know that absorption of VFAs produced in the cecum and colon requires mucosal Na^+/H^+ exchange. A mole of water follows each mole of VFA to be absorbed. It follows that disruption of any of the mechanisms involved in support of normal mucosal function, because of an exercise-related event for example, could have major consequences on water and electrolyte balance, and nutrition. In addition, under conditions where the cecum and colon are presented with a large amount of fermentable carbohydrate over a short period of time, the production rate of the VFAs may initially outstrip absorption and, through the osmotic gradient created, pull water from plasma into the colonic lumen.

Secretion

Gastric acid secretion occurs in the horse even under fasting conditions.[10] The important role played by acid in gastric squamous mucosal ulcerogenesis has been demonstrated, especially as related to the high incidence of this form of gastric ulcer disease in horses under intensive training conditions.[2,11–13] This association probably provides one of the clearest representations to date of how exertion can affect the equine GIT (see below). As mentioned above, from a comparative perspective, pancreatic secretion in horses is very high in daily volume – estimated at 50–60 L/day – but is relatively low in bicarbonate and amylase and protease enzyme concentration.[14] At least when the stomach is empty, large volumes of small intestinal contents, made up primarily of pancreatic juice, periodically reflux into the stomach, providing some buffering of the acid present.[15] The effect of exercise, if any, on this process still needs to be investigated. Finally, the horse undoubtedly possesses all the intestinal secretory mechanisms that have been described in other species, but to what degree needs to be defined. What must be remembered is that, in contrast to humans and animals with relatively simple colons, a hypersecretion of strictly small intestinal origin in the horse would not manifest as diarrhea because of the ability, from a water balance perspective, of the ceco-colon to compensate for that malfunction.[16] Thus, diarrhea in adult horses is indicative of a large bowel dysfunction, which could include hypersecretion at this level.

Motility

As an extension of the human experience, horse trainers often try to schedule the training sessions for a time when they think the horse has a relatively empty stomach. Humans in general do not feel that they can perform maximally on a 'full stomach.' It has been shown that pedaling exercise slows gastric emptying rate in humans, though more runners than cyclists complain of GI problems.[17] The effects of exercise on gastric motility and emptying function in horses are not known and require study, as they may have important implications regarding squamous mucosal ulcerogenesis. As in other species, the proximal stomach relaxes in response to active ingestion (receptive relaxation), and the degree of this relaxation is directly related to the amount of feed ingested.[18] A more sustained, but less profound, postingestion proximal relaxation (accommodation) then occurs, along with peristaltic-like contractions that begin in the middle of the gastric body and traverse through the antrum and promote emptying of gastric contents into the duodenum. The presence of those contents within the duodenum will, in turn, have modulatory effects on the rate of gastric emptying, the degree of which will depend upon their specific composition.[19] This complex regulatory process could be affected by exertion. As indicated earlier, intragastric fermentation of ingested soluble carbohydrates occurs to a considerable degree in horses, and this implies gas production as a result. It follows that this gas must also be moved aborally into the duodenum, since horses do not normally eructate. Likewise, the large amount of gas that is generated from hindgut fermentation must be moved aborally, along with the contents, to be expelled via the anus. Thus, any condition that could adversely reduce the delivery of gas and/or contents, such as an exercise-induced dysmotility, could result in notable abdominal discomfort and/or diarrhea.

Maintenance of mucosal barrier integrity

Normal gut function is dependent upon a reasonably intact barrier between luminal contents and the submucosa.[20–22] Maintenance of barrier integrity is dependent upon numerous factors that include blood flow, mucosal cell turnover rate, and immunologic tolerance to luminal antigens. Methods for experimentally evaluating the 'leakiness' of GI mucosa are discussed below. From the few in vivo and in vitro studies done to date, it appears that horses probably will not differ fundamentally from other species with respect to regional mucosal barrier characteristics, though this needs much more investigation.[23–28]

Liver specific functions

Irrespective of species, normal liver function is critical to good health, and this is highly dependent upon adequate blood supply from both arterial and portal venous sources. Blood supply is emphasized here because it is probably the aspect of liver function most prone to modification by exercise. From a species-specific perspective, it should also be kept in mind that certain detoxifying and conjugative functions of the equine liver might be prone to modulation by fasting and fever, as is the case for endogenously generated bilirubin.[29]

Available methodologies to document the effects of exercise on the equine gastrointestinal system

Methods that have been used in horses

Transit markers

Gastrointestinal transit time can be measured by the use of indigestible, non-absorbable markers. The rate of passage is normally expressed as mean retention time (amount of marker excreted at a certain time after administration of the marker), cumulative excretion, or percentage recovery rate.

Comparison of rate of digesta passage during rest and light to moderate exercise has been evaluated in horses and donkeys. Some of the markers used in these studies were cobalt-EDTA, for liquid phase, chromium-mordanted fiber, for solid phase, and ruthenium-phenanthroline and ytterbium chloride, for particulates passage.[30–32] Non-absorbable markers, such as phenol red in man[17,33,34] and horse,[35] and polyethylene glycol in dog,[36] have been used to measure the effect of different levels of exercise on gastric emptying (GE) of liquid meals. After ingestion of a labeled meal, gastric contents are aspirated through a nasogastric tube or recovered by drainage through a gastric cannula. The amount of marker remaining in the stomach after exercise will depend on the rate of GE of the labeled meal. However, repeated nasogastric intubation per se may affect gastric emptying rate.

Apparent digestibility of diet

Changes in efficiency of dietary fiber utilization in response to exercise may reflect changes in the passage rate of digesta, the activity or population of microbes within the gut, or mucosal integrity.[37] Apparent digestibility is calculated as the

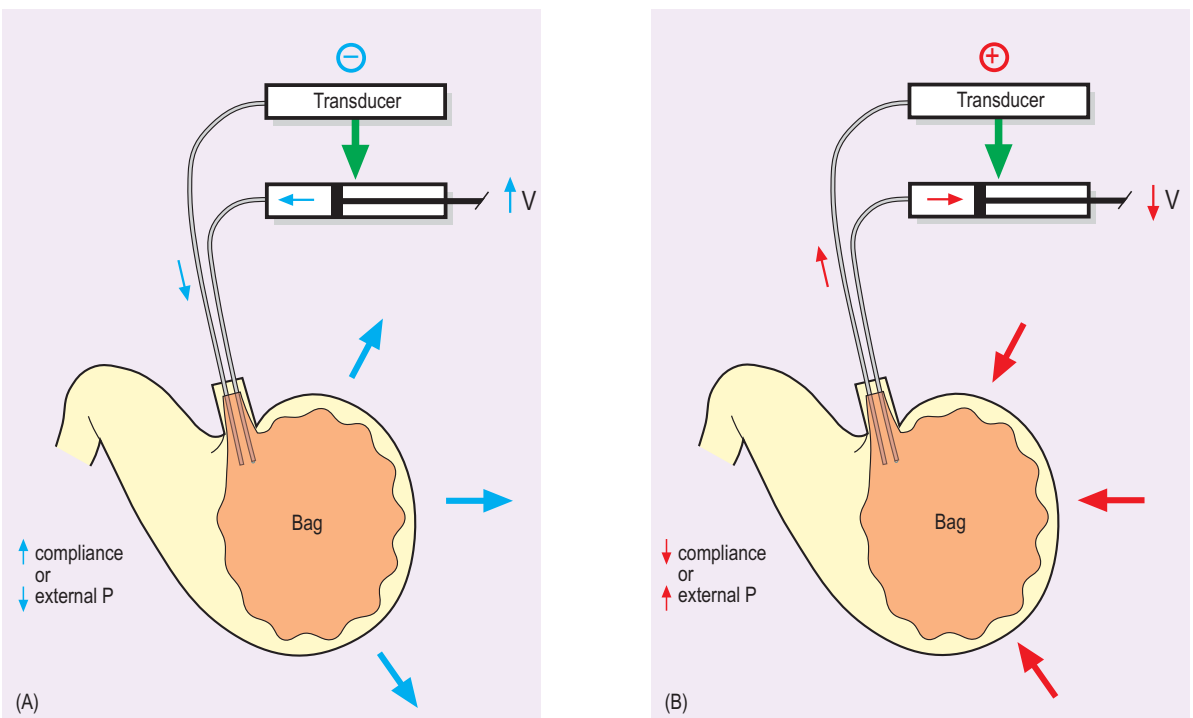

Fig. 46.1
Motility of the stomach can be indirectly measured by an electronic barostat. The barostat maintains a constant pressure (P) within an intra-gastric bag. When the stomach relaxes or the gastric wall becomes more compliant, the system injects air into the bag (panel A). Conversely, when the stomach contracts or the gastric wall becomes less compliant, air is aspirated from the bag (panel B). Changes in bag volume can also reflect changes in pressure exerted extraluminally upon the stomach. The same method could be applied to study motility at any site of the intestine.

difference between specific components of the diet and those found in feces, expressed as percent utilization. The effect of exercise on diet digestibility has been studied in horses.[30–32]

Barostat

The electronic barostat has been extensively used to document gastrointestinal motility in many species, including horses.[2,38–40] Unlike other methods, this system is more useful for recording changes in smooth muscle tone than active, phasic contractions. The principle of the barostat is to maintain a constant pressure within a plastic bag of infinite compliance, positioned within the lumen of the segment to be studied. When the internal pressure of the organ increases for any reason (e.g. contraction, increased mural tone), the barostat aspirates air from the bag to maintain the intrabag pressure constant. Conversely, when the internal pressure decreases, air is injected into the bag. Therefore, as the bag follows the movement of the visceral walls, changes in bag volume are an indirect measurement of changes in tone of the organ (Fig. 46.1).[41]

In other instances, changes in bag volume reflect changes in external pressure exerted over the organ containing the bag. As we mentioned earlier, we observed such changes in the proximal stomach of horses under a training session[2] and related them to increased intra-abdominal pressure caused by tensing of the abdominal muscles during exercise. Interestingly, we also observed in some horses relaxation of the proximal stomach soon after exercise (unpublished data). What effect this might have on gastric emptying, for instance, could provide some useful information concerning optimal timing of feeding with respect to a given exercise schedule.

Blood flow measurement

Adequate local perfusion is necessary for normal gut tissue activity, which requires oxygen and nutrients supplied by peripheral blood. Exercise leads to blood flow diversion from the GIT to the working skeletal muscles and the skin.[42] Decreased perfusion or ischemic damage may result in impairment of normal function of the gastrointestinal tissues, including mechanisms of mucosal protection, membrane secretory and absorptive functions, and motility.

The effect of short-term exercise on blood flow of abdominal organs has been measured in the horse, using radionuclide-labeled microspheres.[43] Once injected into the general circulation, the distribution of microspheres is proportional to the blood flow during its first transit through the circulation.[44,45] Consequent quantification of radioactivity within tissue preparations from horses that have been exercised indicates the level of regional blood flow to those tissues.

Additionally, hepatic blood flow can be quantified by intravenous infusion of a marker, such as, bromsulfalein (BSP). As BSP is highly extracted by the liver, hepatic clearance of BSP is mainly dependent on liver blood flow. Decreases in blood clearance of BSP have been attributed to exercise-induced splanchnic vasoconstriction, leading to decreased portal vein blood flow.[46]

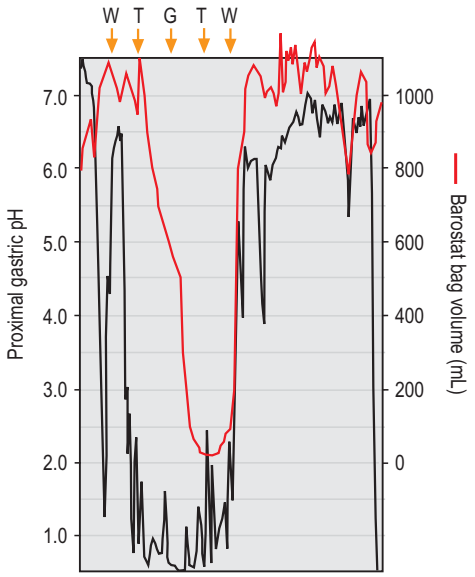

Fig. 46.2
Composite of continuous pH and intragastric barostat bag volume monitoring in two different horses respectively during exercise. In red: changes in intragastric pressure were indirectly measured by changes in volume of a bag placed within the proximal stomach, with its internal pressure constantly controlled at 6 mmHg by an electronic barostat. The decrease in volume indicates increased pressure > 6 mmHg on the bag. In black: intragastric pH was measured by a self-referencing pH electrode positioned 2 cm below the entrance of the stomach. Both patterns are characteristic responses to exercise. W, walk; T, trot; G, gallop.

Continuous pH monitoring

Continuous pH monitoring of the GIT luminal contents with a self-referencing pH electrode may be useful for tracking the effects of exercise on digestive function. The stomach and distal small colon are accessible without special preparation; other parts of the tract would need to be surgically cannulated. Continuous recording of pH changes within the proximal portion of the stomach has suggested that exposure of the squamous mucosa to hydrochloric acid is increased during exercise (Fig. 46.2).[2] There are no data in the literature that describe pH changes within the small colon in response to exercise. Such data have the potential to provide information about the effect of exercise on mucosal secretion, net electrolyte flux and fermentation activity within the large intestine.

Measurement of GI regulatory peptides and steroids

Modification of gastrointestinal regulatory peptides and steroids in response to exercise may either result in, or reflect changes in, gastrointestinal function. Some of these substances have been measured in horses under different exercise regimens, varying in type, intensity, and duration.

Exercise stimulates adrenal secretion and activity of the sympathetic autonomic nervous system. This stimulation is

reflected in increased plasma levels of ACTH, catecholamines, cortisol, and β-endorphins,[7,47–49] which are used as indices of physical stress. As the horse's fitness improves, these hormonal responses to exercise diminish.[50] Variations in plasma cortisol are more sensitive to duration of exercise, whereas ACTH and catecholamine levels are more closely correlated with exercise intensity.[7,51] The effect of variations of stress hormone levels upon equine gastrointestinal function is still unknown. In other species, cortisol can have a deleterious effect on mucosal immune function and epithelial permeability,[52] whereas catecholamines have the potential to delay gastric emptying, prolong transit time,[53,54] and decrease perfusion of the gastric mucosa.[55]

Gastrin is a major regulatory peptide of acid secretion, the plasma concentration of which was increased after prolonged exercise in the horse in one study,[56] but not in another.[57] In a third study, gastrin concentration did not increase after short, sprint exercise, but was higher postprandially in trained horses compared to non-trained horses.[58] Plasma concentrations of inhibitors of gastric acid secretion, such as somatostatin in man[59] and vasoactive intestinal polypeptide (VIP) in man[60] and horse,[56] may increase with exercise. Additionally, somatostatin may favor colonic electrolyte transport and inhibit nutrient absorption.[61]

Potential exercise-induced changes in fluid absorption and secretion within the gut may reflect changes in expression of some regulatory hormones, and vice versa. Exercise increases plasma levels of secretagogs, such as VIP and glucagon, in the horse,[56] and secretin, gastric inhibitory polypeptide, and prostaglandins in man.[59,62,63] On the other hand, atrial natriuretic peptide and aldosterone, which favor sodium absorption, also increase during prolonged exercise in horses.[48, 64]

Agents such as motilin,[65] neuropeptide Y[66] and prostaglandins[63] can affect motility and are released during endurance-type exercise in man. The effect of exercise on GI motility can, therefore, be indirectly studied by measuring endogenous expression of hormones that control intestinal motility.

Finally, alterations of hormone levels may result from a decrease in GIT blood flow, leading to decreased hepatic and renal clearance.[42] VIP[56] and arginine vasopressin[8] in horses, and endothelin-1[67] and angiotensin II[68] in other species, are released during exercise and act as vasoconstrictors. The resulting decrease in blood flow may affect function and regulation of the GIT.

Methods that could potentially be useful in horses, based upon experience in other species

Gastric motility and emptying

In contrast to the phenol red technique mentioned above, barium *contrast radiography*[69] and *scintigraphy*[70] have the advantage of non-invasiveness, and have been previously applied to equine studies. An additional advantage of the latter technique is the differentiation between solid- and liquid-phase emptying.

Breath tests employing stable isotopically labeled tracers are potentially very useful, since they are non-invasive, non-radioactive, and easy to perform (Fig. 46.3). As it empties the stomach, the ^{13}C-enriched marker is readily absorbed in the proximal intestine and metabolized to CO_2. Thus, breath $^{13}CO_2$ enrichment reflects the rate of GE of the labeled meal. The effect of exercise on GE of carbohydrate meals marked with ^{13}C acetate has been studied in humans.[71,72] The ^{13}C-octanoate breath test has been validated in the horse[73] and its use in exertional studies is promising.

Imaging of the stomach by ultrasound has shown that strenuous exercise disrupts gastric motility in man, although the examination was done right after, rather than during, the active exertion.[74] Another available technique in humans is electrogastrography (EGG), which consists of measuring

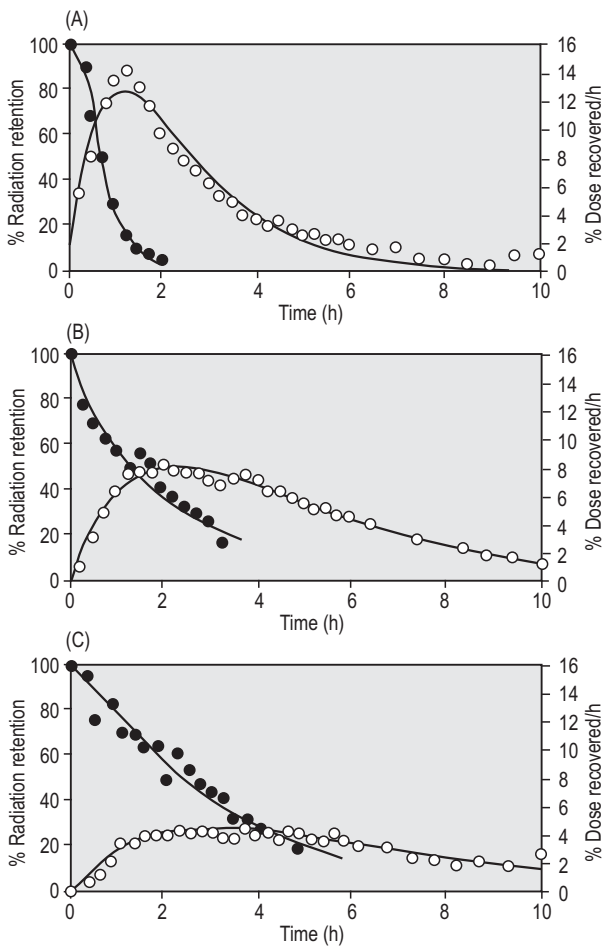

Fig. 46.3
Results of simultaneous ^{13}C-octanoic acid breath test and gastric radioscintigraphy in three typical cases. (A) Rapid gastric emptying rate ($T_{1/2}$ = 0.73 h). (B) Normal gastric emptying curve ($T_{1/2}$ = 1.34 h). (C) Slow gastric emptying pattern ($T_{1/2}$ = 2.62 h). Scintigraphic data (•) on the left y-axis and breath test data (○) on the right y-axis are plotted against time. The continuous lines represent a modeled fit. (Reproduced with kind permission from Sutton et al.[73])

gastric myoelectrical activity by electrodes positioned on the surface of the epigastrium.[75] Although both techniques as applied to the stomach are unsuitable in the horse for anatomic reasons, they could be potentially used to measure cecal motility percutaneously – also known as electrocecography[76] – during the recovery period after exercise.

Gastric secretion

Collection of gastric contents from cannulated dogs has allowed constant measurement of acid and pepsin during exercise.[36] This method could be useful in determining changes in acid secretion and other gastric components in cannulated horses. It would require that the animal be fasted, however.

Gastric ischemia

Air tonometry measures changes in luminal intragastric P_{CO_2} and seems to be a more reliable indicator of gastric ischemia than measuring splanchnic blood flow. Detection of ischemia is based on the difference between arterial P_{CO_2} and intragastric P_{CO_2}, which better reflects mucosal balance between needed and supplied levels of O_2.[77] It would be interesting to apply this technique to the horse.

Intestinal transit and motility

Mouth-to-cecum transit time can be measured by the *H_2 breath test* during exercise.[78,79] For this test, lactulose, a non-absorbable disaccharide, is added to the meal. Breath H_2 starts rising when lactulose reaches the cecum and is degraded by bacterial fermentation. Though fermenting bacteria are also present in the equine stomach and small intestine, the cecum and the large colon are the primary sites of microbial fermentation.[80] However, not all horses exhale excess hydrogen after ingestion of lactulose, so this technique may not be reliable.[81] Lactose, another disaccharide, has been used as a marker for H_2 breath test,[81] since adult horses appeared to be lactose intolerant.[82] Yet the presence of brush border lactase in the small intestine of adult horses has been recently reported,[83] and also excludes the usefulness of this sugar to measure oro–cecal transit time. The *lactose-^{13}C ureide breath test* (LUBT) is another method under investigation in horses. The labeled lactose ureide reaches the large intestine intact, where it is hydrolyzed by bacteria, producing ^{13}C-labeled CO_2. In contrast to the H_2 breath test, LUBT seems to be a repeatable and more reliable method.[84]

Motor activity of the intestinal tract can be studied by several invasive techniques. For example, *electrodes* implanted on the serosa of the gut can detect surface potentials or voltages generated by the gastrointestinal muscle. These electrodes measure two different patterns of electrical potentials: slow waves, which reflect basal electric rhythm, and action potentials, which correlate with contractions. By implantation of bipolar electrodes in dogs, slow wave patterns and the migrating motor complex (MMC) of the proximal jejunum have been studied in relation to exercise of different intensities.[85] This technique has certainly been successfully applied to horses,[86] but not, as yet, to evaluate the effects of exercise.

Strain gauge transducers have also been secured onto the serosa of the GI segment to be studied; they measure mechanical instead of myoelectrical activity. They detect unidirectional, isometric muscle contractions and monitor the stress/tension applied by these muscle contractions on them. Colonic MMCs have been evaluated during long-distance exercise in dogs using this method.[87] As with the serosally applied electrodes, this technique has been used successfully in horses,[88,89] but never in association with exercise.

Manometers and transducers are used to measure changes in intraluminal pressure, which are interpreted as contractions that generate them. This technique has been used to study changes in the small intestinal MMC in dogs during exercise.[36] Unlike the methods mentioned above, this technique does not need surgical implantation so long as the GIT section of interest is accessible by either mouth or anus.

Mucosal permeability and absorption

Intestinal permeability can be assessed non-invasively in vivo by *orally administered markers.* These markers are cleared unaltered by renal excretion, wherein their concentrations in urine can be quantified over a specified postfeeding time period to determine the amount absorbed. Appearance, or not, of these markers in the urine will depend on the integrity of the intestinal mucosa,[90] since they are not absorbed through the intact mucosa.

Polyethylene glycol (PEG) polymers of different molecular weights have been widely used for assessment of permeability. This marker is also used to determine net water absorption, which is calculated directly by changes in PEG concentration within the gut contents.[91] PEGs of high molecular weights have also been used as markers of gastrointestinal transit time in the horse.[92] PEG is not, however, an ideal marker for these kinds of studies, since its purported size can be somewhat variable, and too large a dose can induce an osmotic hypersecretion.[93]

Sugars are also commonly used as probes to evaluate intestinal integrity. Disaccharides, such as lactulose, and monosaccharides, such as L-rhamnose, D-xylose, 3-*O*-methyl-D-glucose and mannitol are used to assess both transcellular and paracellular transport capacity across the intestinal mucosa. Their natural transport across the epithelium may be impaired by cellular damage, whereas necrosis may facilitate their passive movement into the bloodstream due to compromise of the mucosal barrier. Sugars have been used in humans to study the effect of running and cycling on intestinal transport.[94,95] Agents such as these are preferable over PEG because of their uniformity of respective size, making them better discriminators at specific sites of GIT permeability. However, results of these tests should be regarded with caution when they are applied to the horse, since sugar absorption may be highly variable among individuals.[81] This variability most probably originates from regional variations in the GIT microbial population among horses, particularly in the stomach.[80]

Finally, isotopic tracers like ^{51}Cr-labeled ethylenediaminetetra-acetic acid (^{51}Cr-EDTA) and ^{99m}Tc-diethylenetriamino-

penta-acetate (^{99m}Tc-DTPA) can be added to drinks and used to measure unidirectional flux, from the intestinal lumen to the vascular compartment. Although the activity of these tracers in blood is readily measured, their radioactive character is a clear disadvantage[90] largely limiting application to a laboratory setting.

Exercise and gastrointestinal function: what is known in other species that is pertinent to horses

Gastric motility and emptying

Different GI symptoms occur in as many as 30–50% of human participants in endurance events.[96] Lower GI symptoms, which include diarrhea, rectal incontinence, urge to defecate, rectal bleeding, and abdominal cramps, are more common than upper GI symptoms, such as gastroesophageal reflux, nausea, vomiting, and stomach pain. A direct effect of exercise on GI motility has been hypothesized to explain many of these disorders. Because of this high prevalence and the severity of some of the symptoms, many experiments have focused on the study of GI motor function and transit. In the horse, exercise does not seem to directly result in signs of GI disturbance, but this observation should not exclude the possibility of GI alterations in response to the high demand imposed on the horse's body. Dehydration, musculoskeletal or metabolic disorders may mask mild GI tract dysfunction during long, intense exercise.

During moderate exercise (less than 75% $\dot{V}O_{2max}$), gastric emptying in man occurs at a rate similar or slightly greater than that during rest.[97] However, more intense exercise appears to inhibit gastric emptying.[17,97] In equine events where oral supplementation with electrolyte and carbohydrate solutions may be important to compensate a deficit of water, electrolytes, and carbohydrates, the rate of gastric emptying may limit the availability of administered fluids.[98] Solutions with higher carbohydrate concentration seem to delay gastric emptying in humans,[34] though increasingly larger volumes leave the stomach at faster rates.[33,99] Pyloric closure and reduced antral contractions, observed by ultrasound after exercise, may be in part responsible for the delay in GE in humans.[74] In horses, solid meals ingested before exercise may be retained within the stomach for prolonged periods, favoring their bacterial fermentation, with production of volatile fatty acids and lactic acid, which may be deleterious to the squamous gastric mucosa.[100] By contrast, GE of fluid does not seem to be affected by exercise. Sosa et al[35] reported that GE of a single dose of isotonic fluid administered after intense exercise (70% $\dot{V}O_{2\,max}$) in the horse did not differ from rest, which suggests that GE is not a limitation for rehydration. However, as discussed by the authors of this study, the results were highly variable, suggesting high measurement error due to the technique.[35]

Intestinal motility and transit

In humans, inactivity has often been considered a cause of constipation; conversely, physical activity seems to promote colonic transit. Soffer et al found that bicycle exercise could convert the motor-fed pattern of the small intestine into a migrating motor complex (MMC), and that this effect was intensity related, although there was no effect on oro–cecal transit time.[79] By contrast, Moses et al observed that moderate and intense treadmill exercise delayed small intestinal transit in humans.[101,102] In a study performed in fed dogs, moderate treadmill exercise decreased jejunal myoelectric activity only when exercise was prolonged beyond 30 minutes, and this inhibitory effect continued during recovery.[85] Furthermore, prolonged exercise induced MMCs characteristic of the interdigestive motor pattern in the jejunum of fed dogs,[85] whereas it can interrupt MMCs in the stomach and duodenum of fasted dogs.[36] Therefore, exercise can alter motor activity, which may explain some of the GI symptoms associated with exercise in humans.

Increased stool frequency and diarrhea induced by strenuous exercise in humans has been attributed to accelerated colonic transit time, or alternatively, to changes in absorption/secretion by the intestinal epithelium.[96] Acute graded bicycle exercise decreases colonic phasic motor activity in an intensity-dependent way. This may facilitate transit by offering less resistance to colonic flow. After the end of exercise, propagated activity is increased, and this also may enhance colonic propulsion.[103] In fasted dogs, exercise decreases the frequency of colonic MMCs, and stimulates non-migrating colonic contractile activity within 3 hours after ingestion of a meal. Exercise also stimulates defecation, giant migrating contractions and mass movements in the colon, in both fasted and postprandial states.[87]

Current knowledge regarding exercise-induced changes in GI motility in the horse is meager. Pearson and Merritt studied the effect of a 14-km walk in donkeys, and neither GI transit nor the digestibility of hay was affected.[30] On the other hand, Pagan et al showed that 8 km of trotting and galloping by a group of Thoroughbreds resulted in a small, but significant decrease in dry matter digestibility, whereas transit rates of both a forage diet and a forage/grain diet were increased at 24 hours after the exercise.[32] Finally, Orton et al studied the effect of 12-km daily trotting in yearling horses. Exercise increased apparent digestibility of dry matter, and increased the transit rate of particulates, but decreased the transit rate of the fluid phase (Fig. 46.4).[31]

As mentioned, release of catecholamines and β-endorphins into the bloodstream, and stimulation of the sympathetic nervous system occur in the horse and in other species in response to exercise. This effect correlates with intensity of exercise and diminishes with continued training.[47–50] Each of the components of this stress response affects gastrointestinal

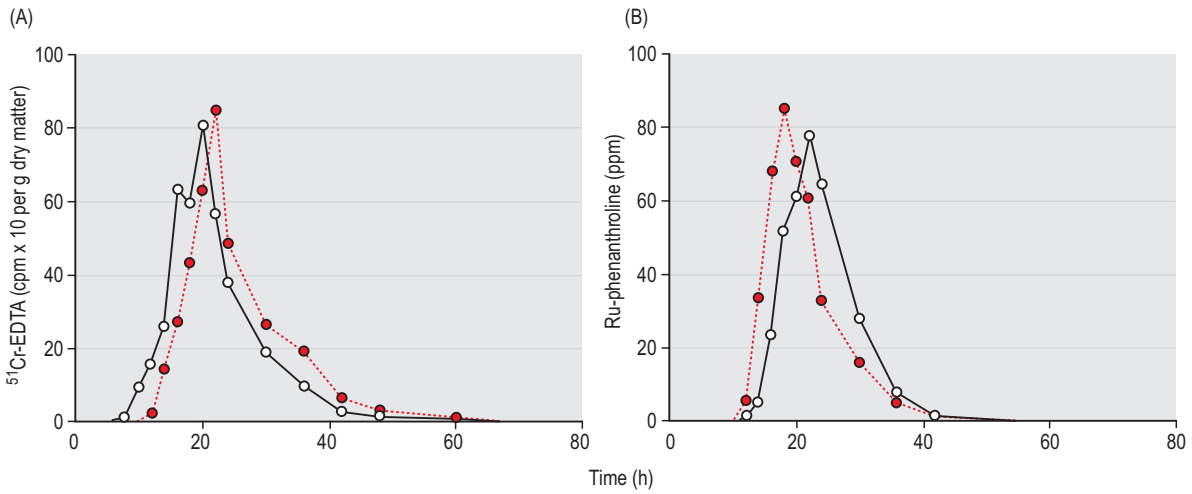

Fig. 46.4
Effect of exercise on rate of passage of fluid (A) and particulate (B) digesta.
(A) Concentration of ^{51}Cr-EDTA in the feces of exercised (broken red line) and non-exercised (solid black line) yearling horses. Four animals per group. (B) Concentration of ruthenium (Ru)-phenanthroline in the feces of exercised (broken red line) and non-exercised (solid black line) yearling horses. Four animals per group. Exercise: 12 km trotting at 12 km/h. Transit of the fluid phase marker (A) was delayed in exercised horses, whereas transit of the particulate phase marker (B) was accelerated. These results are supported by Pagan et al,[32] who observed that fecal excretion of the particulate marker ytterbium was accelerated in Thoroughbreds trotted and galloped for 8 km/day. (Reproduced with kind permission from Orton et al.[31])

motor function. Inhibition of gastric emptying and stimulation of colonic motor function are the characteristic pattern in response to different stressors. Central CRH seems to be a main component in the induction of this stress-related motor response. In some studies, CRH modulation of autonomic nervous system activity was found to be independent of activation of pituitary–adrenal hormone release.[104] Alexander et al measured plasma concentrations of CRH and ACTH in the horse during and after acute intense exercise; ACTH was elevated, whereas CRH concentrations were not different from resting values.[8] However, as suggested above, central rather than peripherally circulating CRH may be responsible for the GI motor changes[104] and could be involved in the exercise-induced changes in GI transit documented in horses.[31,32]

Gastrointestinal blood supply

Reduced splanchnic blood flow during high-intensity exercise may also play a role in slowing the rate of gastric emptying. Manohar et al reported a significant reduction in splanchnic blood flow during moderate exercise in the horse (Fig. 46.5).[43] Likewise, acute exercise decreased the clearance of BSP from the blood in an intensity-dependent manner in horses as a result of decreased splanchnic blood flow (Fig. 46.6).[46] Splanchnic vasoconstriction in the horse may be induced by epinephrine (adrenaline) and norepinephrine (noradrenaline),[7] or by release of hormones such as arginine vasopressin,[8] and VIP.[56] Endothelin, another potent vasoconstrictor released by endothelial cells, increases with exercise in humans[105] and horses.[106] Its effect should be further investi-

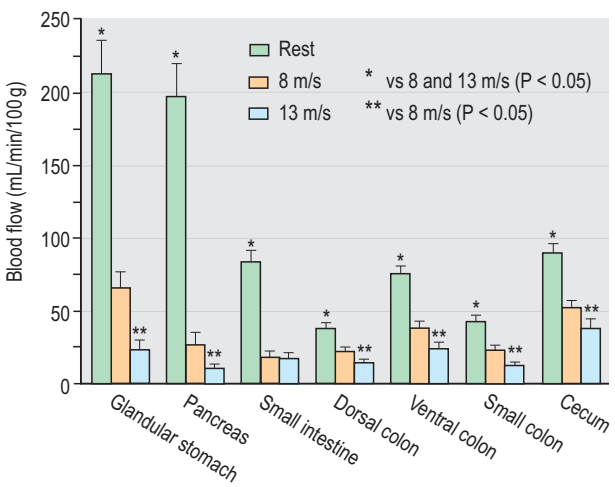

Fig. 46.5
Blood flow to pancreas and various gastrointestinal tract tissues in standing (rest) and exercised horses (n = 9 horses). (Reproduced with kind permission from Manohar et al.[43])

gated in horses, especially in view of a recent study that demonstrated a significant association between plasma endothelin-like immunoreactivity and pathogenesis of certain GIT disorders.[107]

Reduced blood flow during exercise also disrupts intestinal absorption. Carrier-mediated glucose uptake decreased with intense cycling in humans.[108] This decrease in absorptive capacity may be a consequence of impaired blood flow and insufficient energetic supply for glucose active transport, which relies on ATPase activity, and could: (i) prevent adequate plasma volume restitution, or; (ii) increase osmotic pressure within the

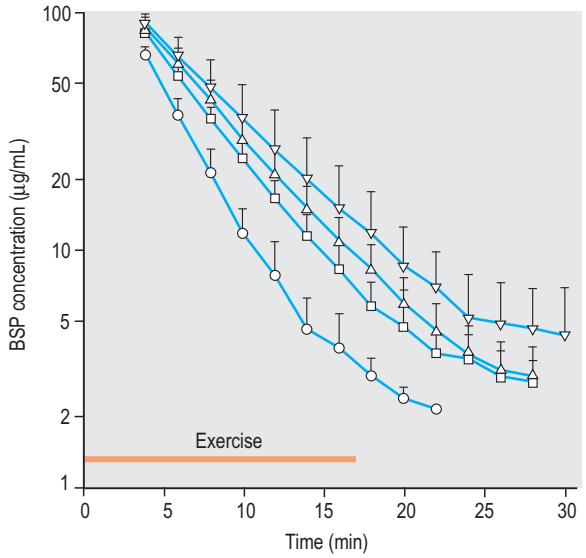

Fig. 46.6

(Reproduced with kind permission from Dyke et al.[46])

gut, which could result in diarrhea or loose stools.[42,109] On the other hand, 1 hour of exercise on a treadmill at 71% $\dot{V}O_{2max}$ did not affect glucose, D-xylose, water, sodium, chloride and bicarbonate intestinal uptake in humans.[110] In the horse, impaired glucose absorption could lead to its accumulation within the intestinal lumen, creating an osmotic load and/or an increase in the substrate available for bacterial digestion within the large intestine. However, it is unlikely that this would have any significant detrimental effects on the animal.

Mechanical factors

Mechanical bouncing of the body during exercise or compression of the viscera by abdominal muscles may also affect GI motility, since GI symptoms in humans occur more frequently during running than cycling events. Some cases of postrunning volvulus have been reported in humans.[109] Although light exercise has often been used as a way to facilitate passage of gas and promote transit in the large intestine of sick horses, strenuous exercise may promote excessive visceral movement. This, especially if combined with GIT dysmotility, could potentially promote intestinal displacement. The amount of colonic filling could have an influence on this bouncing effect.

Increased concentrations of prostaglandins and VIP, released by rubbing of the intestinal mucosa and distension,[109] may shift intestinal absorption into secretion. Upregulated expression of these agents in the horse, especially within the distal large intestine, could theoretically result in diarrhea.

Mucosal barrier integrity

Fecal occult blood has been documented repeatedly in endurance athletes, but its etiology is still unknown. However, the stomach is the most frequent site of running-associated hemorrhage in humans, possibly due to ischemic damage or trauma from the diaphragm.[96] Bleeding may reflect pronounced tissue damage. Inadequate perfusion to the intestinal epithelium can compromise the protective barrier function. Compromised barrier function might also facilitate bacterial and endotoxin translocation and initiate a local immune response. Subsequent production and release of inflammatory mediators would exacerbate this whole process. Reduced mesenteric blood flow may also generate O_2 free radicals,[111] which can also contribute to tissue damage. For example, running by some human subjects at 80% $\dot{V}O_{2max}$ increased small intestinal permeability of lactulose compared with rest and running at 40 and 60% $\dot{V}O_{2max}$. Since lactulose crosses the epithelium only paracellularly, its increased transport is a strong indication of breakdown of the small intestinal barrier.[112] To date, no studies have been done to investigate the effect of exercise on the integrity of the mucosal barrier in horses.

Clinical implications of exercise-associated changes in gastrointestinal function

As has already been alluded to, the anatomically and physiologically complex ceco-colon of horses could, in particular, predispose them to GIT disturbances during athletic training and competition. Undoubtedly a major confounding factor in this consideration is the feeding program, especially abrupt changes in diet composition or feeding routine. In fact, with respect to incidence of colic, the majority of the recent epidemiologic studies more strongly indicate change in feeding program than type or duration of athletic activity as a high risk factor.[113–117] Concerning the effect of exercise, Cohen et al[114] reported that primary use of the horse was not significantly associated with colic, although they then remarked that horses with colic were significantly more likely than control horses to have had a change in activity level during the 2-week period prior to examination. Likewise, Tinker et al[116] found that horses used for eventing or training had a significantly higher incidence rate of colic when compared to mature horses that were sedentary. This is not to say that the origin of the problem in all these cases was large intestinal (there was no information on site in the report) but, because of that organ's complexity, it must be considered as a highly likely origin nonetheless.

Anatomic considerations

From an anatomic standpoint, the fact that a large section of mid-colon floats freely within the abdominal cavity makes it

prone to various forms of displacement that can result in serious colic. Whether any of these conditions may result from, for example, a combination of physical characteristics of the contents therein (e.g. collected sand; the gas : ingesta ratio) and type of exercise the horse is asked to perform remains to be established.

Physiologic considerations

From a physiologic standpoint, at least three areas deserve attention in future research on the effects of exercise on GIT function in horses. The first concerns factors that determine daily net water movement across the gut mucosa, between lumen and plasma. It is a common practice to withhold food hours before an event to decrease gut fill, and consequently, bodyweight. However, eating before or during a competition may have beneficial effects, as observed in human endurance athletes.[118] Ingestion of food may attenuate the reduction in blood flow induced by moderate to severe exercise.[119] Accordingly, blood flow to the digestive tract during exercise seems to be higher in fed than fasted ponies.[119] Fed horses may start with elevated blood flow of the GI tract, so that the impact of exercise on blood distribution is not so marked. Ingestion of food is accompanied by saliva production, and gastric and pancreatic secretion.

Forage stimulates more water ingestion and digestive secretions than concentrate meals.[120] Factors which determine daily net water flux across ceco-colonic mucosa are complex and are characterized by regional compartmentalization.[121] Such factors include timing and composition of ingested food which impact directly on fermentative activity, water and electrolyte status of the horse, and efficacy of gastrointestinal motility. For instance, Clarke et al have shown that during early postprandial stages of a large meal of balanced ration pellets, the VFA production from its fermentation within the colons may outstrip the subsequent VFA absorption, resulting in a large flux of water into the colonic lumen from the plasma space.[122] This can deplete plasma volume to a point where renin–angiotensin and aldosterone are released to promote plasma water conservation, the degree of which may be great enough to result in significant rebound dehydration of distal colonic contents (Fig. 46.7).[123] Combine a strenuous training session on top of this, and you have the makings of a serious impaction. By contrast, when that same meal was split into small volumes and given over 12 hours, mass movement of plasma water into the colons did not occur.[122]

Second, the effect of exercise on increasing GI mucosal permeability in humans has been discussed earlier in the chapter. So far, no untoward effects from this have been documented in people, and this would certainly appear to be the same for horses, should it occur. However, it is safe to assume that there is, at any given time, a much greater load of endotoxin within the equine ceco-colonic lumen than in that of humans.[124] Detrimental effects of endotoxemia in horse are well recognized and include leukopenia, hypotension, intestinal dysmotility and hypersecretion, and laminitis.[124,125] Clearly, if athletic activities consistently caused signs indicative of endotoxemia in a large number of horses, the beast would not be used for the many things humans ask of it. However, it would still be important to know if exercise,

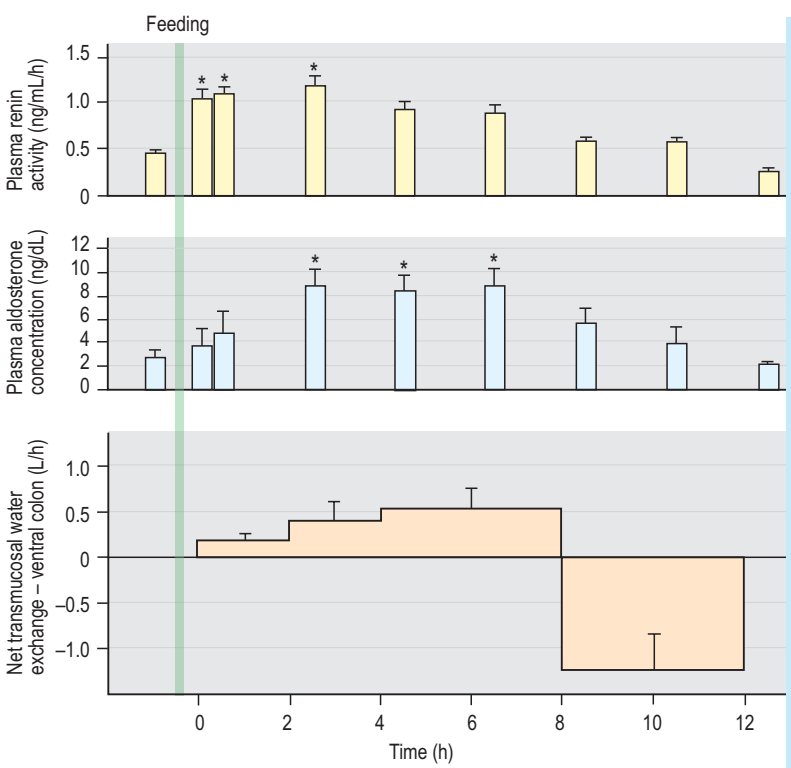

Fig. 46.7
Postprandial activation of the renin–angiotensin–aldosterone system superimposed on net fluid transport in pony ventral colon. Rapid accumulation of bacterially produced volatile fatty acids within the colon after ingestion of a single large meal results in net flux of water from the plasma compartment into the colonic lumen. In response to this plasma volume depletion, renin–angiotensin and aldosterone are released to promote water absorption from the luminal compartment back into the vascular system. Addition of strenuous exercise during this period could exacerbate dehydration of colonic contents, and therefore, increase the risk of colonic impaction. [*Significantly ($P < 0.05$) greater than preceding value.] (Reproduced with kind permission from White.[123])

especially if strenuous, does cause a degree of endotoxemia that could be clinically important.[126] This suggestion is further supported by the observation that physical stress enhances colonic epithelial permeability in rats via peripheral release of CRH.[127] Accordingly, Baker et al[128] reported in 1988 that a group of racing-fit horses had significantly higher serum anti-lipopolysaccharide antibody concentrations than a similar group of horses that were not trained, suggesting that increased intestinal permeability could have occurred as a result of their repeated exertion. More studies following up on this important observation need to be done.

Third, the transient defecation of non-formed, sometimes quite watery feces from some horses when they are subjected to a training session or race environment is a well-recognized phenomenon. It is usually of little consequence to the horse, but can be very bothersome to owners and trainers, especially when it occurs during a public display. Commonly, it is attributed to 'nerves,' which could be one reasonable explanation. Nonetheless, this is an exercise-related event and it would be interesting to know its functional basis because it might be controllable. Probably the first place to look would be the small colon, where final desiccation of colonic contents takes place resulting in the formation of the fecal balls. This process involves a coordinated interaction between mechanisms that control motility and net transmucosal water flux; this is undoubtedly closely monitored by the enteric nervous system, much of which we still need to learn about with respect to equine small colon function. What we do know is that at least some of the water absorption is determined by a Na^+/K^+-ATPase pump, the functional status of which is under the control of aldosterone.[25] It seems unlikely, however, that the transient, exercise-related loose feces problem would be due to a downregulation of this system. More likely possibilities would be either a small colon dysmotility that allows more rapid passage of contents through the organ, the upregulation of a secretagog such as CRH, VIP, or some combination thereof.[56,104,126,127]

CHAPTER 47

Oral and dental disease

Jack Easley

Introduction

Today's performance horse is involved in a wide variety of disciplines. In most disciplines, horses carry bridle and bit for guidance and control. If a horse is to respond correctly to subtle pressures placed on the bit by rider or driver, it must have sound dentition and a healthy oral cavity.

Sound dentition is of such importance that every performance horse pre-purchase examination should begin at the head and include an evaluation of the mouth and temporomandibular joints. Oral and dental problems can lead to bad habits and vices, such as resisting the bridle, being sensitive around the poll, and head shaking. Serious problems can compromise and even end a horse's performance career.

Many serious problems can be prevented with annual oral examinations which lead to early detection and correction of dental problems. Treatment varies from simple procedures with immediate positive results to prolonged and expensive procedures that might not be successful. Horses used for breeding should be selected for sound dentition. The inherited or congenital nature of some oral and dental conditions should exclude some horses from being retired to a breeding status.

Over 100 years ago, Merillat in his thesis on horse dentition accurately summarized the importance of teeth in the management of the performance horse.

> In drivers, runners and saddle horses, sharp teeth are of greatest sources of annoyance. The expert reinsmen will properly recognize their presence by the horses's behavior in harness. Lugging, side reining, ptyalism and tenderness about the seat of the bit are manifestations of pain from the bridle. The aim in dressing the teeth of a horse should be to simply blunt the enamel points along the course of the arcades and to round up the first superior and inferior molars as smooth as ivory.[1]

Bits and bridles

For more than 5000 years, the bit and reins have been used to transmit cues from the rider or driver to the horse. Bits are grouped under two basic types – snaffle and curb.[2,3]

Snaffle bits have only one cheek ring that connects to the bridle, and reins, and the mouthpiece can be either jointed or solid. Curb bits are leverage bits that provide a mechanical advantage to the rider. They have two sets of bit rings with the upper ring attaching to the bridle and the lower rings to the reins. A curb chain or strap goes under the horse's chin. The ratio between the length of shank from upper ring to the mouth piece and down to the lower ring and reins determines the mechanical leverage that is employed. Depending on the bit type used, a pull on the reins can put pressure on the tongue, hard palate, bars, lips, chin groove, bridge of the nose, or poll. Hackamores, cavesanes, bosals and nosebands place pressure on the cheeks (Fig. 47.1).

Dental anatomy

The equine species has unique tools to detect, prehend, masticate and initiate the digestion of grass during frequent grazing. These unique tools include molarized hypsodont cheek teeth, facial bone construction, tactile and prehensile lips, muscles of mastication, tongue, hard palate, olfactory organs, taste buds, salivary glands and ducts, blood, lymphatics and nerves that support them.

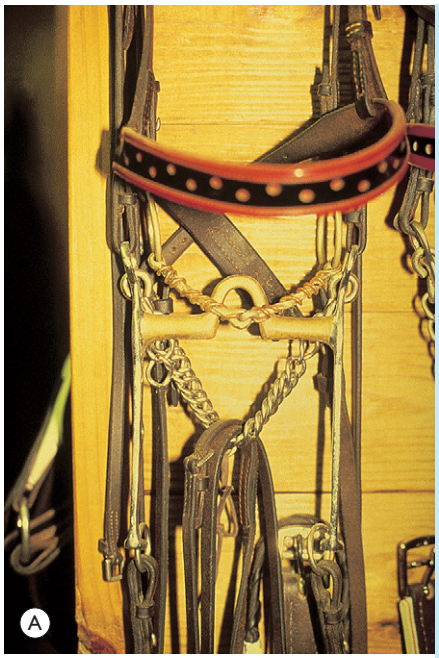

Fig. 47.1
(A) A double bridle. The mouthpiece of the snaffle bit or Bridoon is broken or hinged in the middle and wrapped with a strand of copper wire. The mouthpiece of the curb bit or Weymouth has a medium port to give the tongue some relief. The reins are hanging in the curb chain. (B) Show horse working in a double bridle. The upper set of reins is attached to the snaffle or Bridoon bit and is used to turn the horse. The lower set of reins attaches to the leverage bit or Weymouth and is used to set the horse's head position.

The horse is anesognathic, meaning the bottom jaw is more narrow than the upper. The molar tables are sloped at a 10–15 degree angle from dorsal lingual to buccal ventral. As the horse chews, the jaw moves in a rotating motion from side to side with limited rostral-caudal excursion. The extent of lateral excursion of the mandible during normal mastication is affected by the feed being consumed. A horse on pasture or being fed hay has a full or wide area of mandibular excursion while horses eating pellets or concentrates have a limited amount. Horses on pellets or limited long-stemmed roughage are apt to have incomplete wear of the molar surface, which predisposes the arcades to sharp enamel edges, vaulted ceiling of occlusion, and/or shear mouth.[4]

The mature mouth of a horse contains three upper and three lower incisors and six upper and six lower cheek teeth on each side of the mouth. The rostral three cheek teeth are premolars and the caudal three are molars. Premolars have deciduous and permanent sets while molars come in at an older age and only one set is present. The premolars and molars of the upper jaw are broad and square and contain two infundibula. The lower cheek teeth retain a more narrow, rectangular shape. Equine males normally have two upper and two lower canine or bridle teeth, while mares generally do not.

The Modified Triadon three-digit system of dental nomenclature has been used to designate equine teeth. The first digit designates the quadrant and arch location and whether the teeth are deciduous or permanent. For adult teeth, the quadrants are numbered from 1 to 4 in a clockwise direction, beginning at the right maxillary quadrant. For the deciduous teeth, these quadrants are numbered 5 through 8. The teeth in each quadrant are numbered from the central incisor (01) to the last molar (11). For example, the upper right permanent second premolar would be designated as 106.

A hypsodont tooth has a long anatomic crown and a relatively short root. Much of the crown is held in reserve in the alveolar bone with the root. The root apices complete their development in early middle age (normally 6–9 years). Once fully formed, the tooth no longer grows in length, but continues to erupt as occlusal wear takes place, usually at the rate of 2–3 mm per year. The reserve crown length is 80–90 mm in an unworn first molar tooth.[5–7]

Oral examination

All horses should have their oral cavity examined every 6–12 months, with proper dental maintenance performed as needed. The examination findings should be recorded as part of an effort to formulate an appropriate treatment protocol and to monitor progress after treatment (Fig. 47.2).

Clinical signs that a horse is suffering from dental problems include abnormal head carriage, taking a long time to eat, dysphagia, dribbling feed, quidding forage, eating hay before grain, and being reluctant to drink cold water because of dental pain.[8]

Proper mechanical digestion of feed allows better carbohydrate absorption in the small intestine and improved fiber fermentation in the cecum and large colon. If the horse is masticating properly examination of the horse's manure should not reveal whole grain or stem particles longer than 5 mm. Chronic colic or choke can result from improper mastication of feed due to dental problems.

A horse's overall condition should be evaluated in light of its use and dietary intake as part of a dental examination. Temperament should also be noted. Breed, body type and head conformation should be considered in evaluating the masticatory system. Horses with small heads have more of an angle in the curve of the mandibular ramus (curvature of Spee) and are predisposed to dental crowding and ramps on the lower dental arcade.[9]

Age is a factor, with different conditions arising at various stages of development and maturity. Use, especially if the

horse is worked in bridle and bit, should be given consideration. Additionally, stable surroundings should be carefully observed for evidence of vices, such as cribbing or poor eating habits.

The head should be observed from both sides and the front for symmetry, protuberances, or swellings. Epiphora should be noted as well as any nasal discharge. Neurologic evaluation should be considered if any cranial nerve deficit is detected. External palpation of the head should be performed.

Fig. 47.3
Complete oral examination requires the use of a full mouth dental speculum and good light source. The oral cavity should be inspected both visually and with a digit to detect both dental and soft tissue abnormalities.

The frontal and maxillary sinuses should be percussed with the mouth open. The width between the mandibular rami should be noted as this is possibly correlated with room for the bit. The sides of the head lateral to the upper dental arcades are palpated, beginning at the orbit and moving forward to the first cheek tooth at the level of the nasal notch. Any protuberance, depression, asymmetry or evidence of pain should be noted. The commissures of the lips should be observed and palpated for evidence of trauma from sharp teeth or improperly fitting bits.

The oral examination should begin with rinsing the mouth, taking note of volume, consistency and odor of material flushed. A loose-fitting halter is necessary to properly evaluate the oral cavity. After observing the incisors for approximate age, they should be evaluated for symmetry and evenness of wear. The diastema or interdental space should be observed for canine teeth or remnants as well as bar enlargements, blind wolf teeth, unerupted canines, or thickening of the palate. The tongue should be observed for lesions from bits, sharp teeth, or tongue ties. The upper rostral arcades should be thoroughly palpated for detection of wolf teeth, hooks, and/or sharp buccal cusps.

Range of motion of the mandible is evaluated by holding the head stationary with one hand while sliding the mandible from side to side with the other. Resistance or abnormal incisor separation during this maneuver should be noted.

To complete the oral examination, a full mouth speculum should be applied and the mouth examined digitally and visually with a flashlight or headlamp (Fig. 47.3). An endo-

(E) Cheek trauma from a snaffle bit being pulled against sharp enamel points on the buccal edges of the upper dental arcade.

scope or buccal retractor and mirror may aid in a more detailed examination.

If areas of impacted or trapped feed are present, they should be removed with the examiner's digit or a dental pick and the mouth rinsed completely. Horses with sharp buccal points on the upper dental arcades resist the full mouth speculum and floating the upper arcades early in the examination may be beneficial.

Diagnostic radiology is a valuable aid. Good-quality films can be obtained with portable X-ray machines and rare earth intensifying screens without a grid. Indications for head radiology are any suspicions of dental infection, facial swelling, deformity, neoplasm, trauma or fracture, maleruption of teeth, or oral pain of unknown origin. Radiographs should be taken before and after dental extraction.

Oral injuries

Injuries to the lips, tongue and buccal mucosal can be caused by sharp enamel points or rough use of the bit. Tongue damage can be performance limiting (Fig. 47.4). A tongue can protrude from the mouth secondary to hypoglossal nerve paresis, hyoid bone injuries, a drooping lower lip, or missing canine or incisor teeth. Tongue lacerations can be repaired if the blood supply to the rostral portion of the injury is adequate. The rostral aspect of the tongue can be amputated up to the frenulum without compromising function.[10]

Injuries to the bars are most often bit induced. Acute bar injuries cause swelling and pain. Bar lacerations or fracture are common. More chronic cases develop scar formation or exostosis in the interdental space. Some injuries lead to bone sequestrum formation with a draining tract.[11–13]

Bar injuries may be diagnosed by careful palpation and radiography. Conservative treatment of bar injuries may consist of bit changes. Cases that do not respond to conservative therapy might require surgical correction.[14]

Dental floating

The main purpose of molar floating or leveling is to remove sharp enamel points from the buccal aspect of the upper and lingual aspect of the lower cheek teeth. Floating might also entail removing minor hooks or ramps from the rostral or caudal aspect of the arcades or leveling minor elevations on the occlusal surface of the arcades.

Float blades made of carbide chips or solid tungsten carbide make the work of floating more efficient. The outward curve of the upper arcade makes the central buccal area involving PM3 through M2 the easiest to reach with the float. To reach the rostral aspect of upper PM2 (106 and 206) and the caudal aspect of lower M3 (111 and 211) requires an offset or angled head on the rasps. In most cases, floating the lower arcade to remove the lingual enamel points can be done with a flat, long-handled rasp.

The mouth speculum or a dental wedge can make floating easier if the horse closes its mouth on the float. In horses with slightly ramped back teeth due to a greater curvature of Spee, a mouth speculum and a slightly curved or swivel head float might be needed to reach the table of the last two or three molars.[15]

For correction of rostral and caudal hooks, solid carbide blades and power burrs might be necessary. In performance horses, a seat for the bit is made by rounding the first upper and lower cheek teeth and lowering of the buccal cusps from

Fig. 47.5

upper PM2 to PM3 (106, 206 to 107, 207). The dental contouring requires an offset head float or an S-shaped rasp. Floating and other corrective measures may require the physical restraint of dental halter and/or sedation.

Wolf teeth (rudimentary first premolars)

Wolf teeth (105 and 205) can cause difficulties if sharp or displaced (Fig. 47.5). They can cause buccal mucosa pain when pressure is applied to the bit. If erupted, their presence causes a problem in creating a bit seat on the rostral edge of PM2 (106 and 206) (Fig. 47.6). Clinical experience indicates the incidence of upper wolf teeth is at least 80% in horses 1–3 years of age. They usually erupt between 6 and 18 months of age and, typically, are positioned just rostral to the first cheek tooth. Lower wolf teeth (305 and 405) are occasionally positioned rostral to the first cheek tooth in the mandible. Unlike incisors and cheek teeth, wolf teeth (and canine teeth) are brachyodont or short crowned, with no reserve crown. As a result, they do not continue to erupt throughout the horse's life. Unerupted or blind wolf teeth can be as troublesome as those visible on dental examination.

Commonly, wolf teeth are removed from horses between $1^1/_2$ and 3 years of age before a bit is introduced. Tools used for wolf tooth extraction include a cylinder- or Burgess-type wolf tooth elevator set, a dental root elevator, and a pair of small dental extraction forceps (Fig. 47.7).

The first objective in extraction is to cut the gingival attachment to the crown of the tooth. This is best achieved by placing a cylinder-type punch extractor over the crown. A dental root elevator is then introduced deep into the alveolus to loosen the tooth from its periodontal and alveolar attachment. Once freed, the tooth can be elevated from the dental socket either by the root elevator or with the use of extraction forceps. The process should not be attempted by using the first cheek tooth as a fulcrum, as this increases the risk of fracturing the wolf tooth root. Care should be taken to avoid damaging the soft tissues of the mouth during extraction. Misguided use of instruments can easily lacerate the palatine artery which runs the length of the hard palate immediately axial to each upper arcade.

The procedure for extraction of blind or unerupted wolf teeth is similar to that for erupted teeth. Evaluation of the size and position of the unerupted teeth may be aided with radiography. Proper restraint during the procedure includes chemical sedation and assistance from a trained handler.

Canine teeth

Canine teeth (104, 204, 304, and 404) are present in most male horses over $4^1/_2$ years of age. They normally cause few problems. The upper canine is located in the juncture of the incisive and maxillary bones with the lower canine positioned just rostral. Some mares have small rudimentary canines that generally do not cause problems unless they become loose or accumulate tartar. Long or sharp canines in a stallion or gelding can interfere with bitting.

In older horses, the crown enamel can become worn and pitted, allowing tartar accumulation and gingivitis. By polishing or grinding down the canines, these problems can be avoided. Care should be taken not to shorten the canines to such an extent that the pulp is exposed or the tongue is allowed to protrude from the mouth (Fig. 47.8). Erupting canine teeth in the 4- to 6-year-old horse can cause subgingival pain and bit irritation which often is manifested by head-shaking or other bad habits. The mucosa should be removed

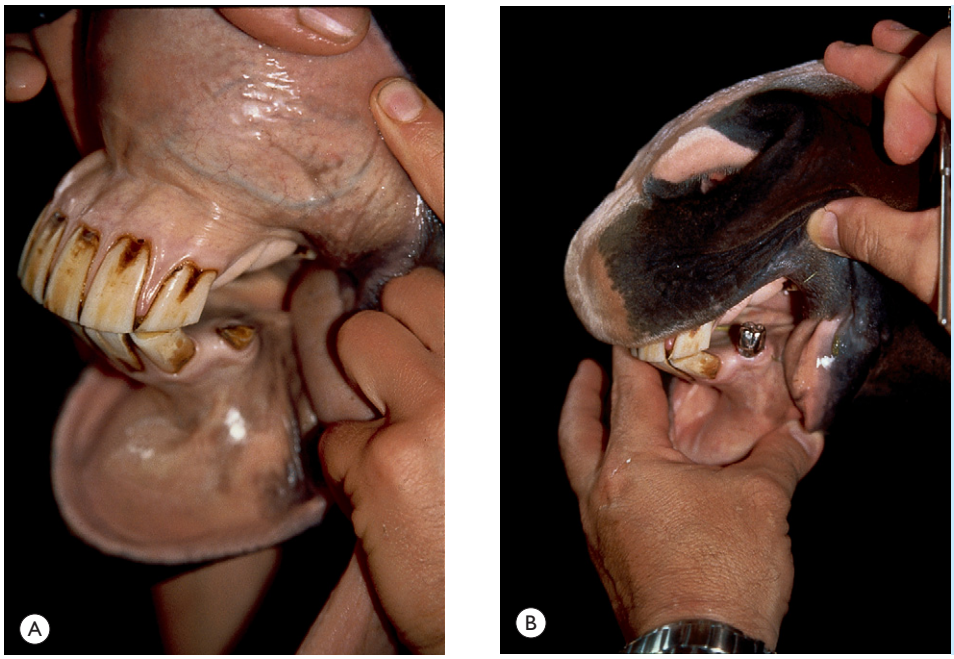

Fig. 47.8

over canines if gingival eruption cysts are present (Fig. 47.9). This problem was reported by Percivall over 100 years ago:

> I was requested to give my opinion concerning a horse, then in his fifth year, who had fed so sparingly for the last fortnight, and so rapidly declined in condition in consequence, that his owner, a veterinary surgeon, was under no light apprehensions about his life. He had himself examined his mouth without having discovered any defect or disease, though another veterinary surgeon was of the opinion that the difficulty or inability manifested in mastication, and the consequent cudding, arose from the preternatural bluntness of the surfaces of the molar teeth, which were, in consequence, filed but without beneficial result. It was after this that I saw the horse, and I confess that I was, at my first examination, quite as much at a loss to offer any satisfactory interpretation as others had been. While meditating, however, after my inspection, on the apparently extraordinary nature of the case, it struck me that I had not seen the tusks. I went back into the stable and discovered two little tumors, red and hard, in the situation of the inferior tusks, which, when pressed, gave the animal insufferable pain. I instantly took out my pocket knife and made crucial incisions through them both, down to the coming teeth, from which moment the horse recovered his appetite and, by degrees, his wonted condition.[16]

Fig. 47.9
(A) Upper canine tooth eruption cyst on a 7-year-old Saddlebred gelding. The horse exhibited head tossing behavior when driven in a snaffle bit and overcheck. (B) The eruption cyst was opened and the mucosa removed from over the erupting canine tooth. The horse responded well to this treatment.

Fig. 47.10
Deciduous tooth caps and cap fragments can be a source of oral discomfort for 2–4-year-old horses. These cap fragments have large root slivers that can be broken off below the gum and cause chronic gingivitis.

Caps (deciduous teeth)

The premolars and incisors should be closely evaluated when examining the dentition of horses of 2–4 years of age as these teeth are shedding their deciduous caps. The caps normally are shed in sets of four; one cap from each arcade. Generally, the shedding time is as follows: $2^1/_2$ years for the first set (506, 606, 706, 806); 3 years for the deciduous 07s, and $3^1/_2$ to 4 years for the deciduous 08s. Irregular shedding, if not corrected, can lead to severe problems in the development of the permanent arcade. Clinical signs that indicate retained or loose caps include feed being impacted under the caps, excessive salivation, oral malodor, tilt of the head, dribbling feed, tongue lolling, and ill response to the bit.

To detect problem caps, one should palpate along the lingual surface of the premolars and cheek for pain. If a cap is present, an indentation at the gingival line will demarcate between the deciduous premolar cap and the erupting permanent tooth. Ideally, one will feel and visualize the demarcation midway between the gingiva and the occlusal surface of the cap. If this indentation is below the gum, removal of the upper cap could result in exposing the premature permanent premolar with an underdeveloped infundibulum.

To remove caps, an extraction forceps is clamped firmly on the base of the cap and gently rocked lingually. Care should be taken not to place the forceps below the level of the gingiva as the palatine vessels along the upper arcade could be disrupted upon clamping, resulting in potentially severe hemorrhage. Rolling the cap toward the lingual surface will reduce breakage of the buccal roots (slivers) of the cap (Fig. 47.10).

Abnormal dental wear patterns

The most common abnormal dental wear pattern is formation of rostral upper overgrowths (hooks) on PM2 (106 and 206). A hook can begin as a ramp or a small enamel point or beak, depending on the degree of rostral protuberance of the upper molar arcade. The most severe form of this condition is seen in parrot mouth horses with a malocclusion of the incisors and molar arcades. The more common presentation is a horse with normal incisor occlusion and a small malalignment of the cheek tooth arcades.

Horses that eat forage from an elevated hay rack or those that chew with their heads elevated have a predisposition to rostral upper PM2 hook formation. These hooks form because when the head is held in an elevated position, the lower jaw is slightly retracted caudal on the upper jaw, bring-

Fig. 47.11
(A) Rostral upper premolar hooks usually become longer and broader at the base over time. (B) Enlarging cheek teeth hooks can place caudal pressure on the lower jaw causing an incisor overjet.

ing the rostral order of the upper arcade out of occlusion with the lower, preventing normal wear. A sharp rostral hook or beak can cause cheek pain if the horse wears a snaffle bit.

As the rostral hook becomes longer and broader at its base, it begins to put caudal pressure on the lower jaw when the horse closes its mouth. This caudal retraction of the lower jaw brings the distal molars further out of occlusion, contributing to ramp and hook formation in the back of the mouth as well. The caudal pressure on the mandible or lower jaw also places abnormal stress on the temporomandibular joints. In addition, the caudal jaw position leads to malocclusion of all cheek teeth and can contribute to abnormal wear. These exhibit as abnormal transverse ridges and enamel points, cupping out of some upper cheek teeth, and wave formation on the occlusal surfaces. Abnormal wear patterns can be subtle in the early stages, but become progressively worse during the life of the horse (Fig. 47.11).

Clinical signs of a horse with a hook problem include not flexing at the poll, head throwing when asked to work in collection, shortening of the stride, soreness in the neck and back muscles, opening of the mouth when asked to collect, bouncing of the head during collection, and inefficient eating.

Many horses with hooks function well in activities where head carriage is not important, such as hunting and trail riding. In activities where head carriage is important for balance and collection, such as dressage, hook problems can be career ending if not properly diagnosed and treated. The most successful therapy is routine reduction of abnormal wear patterns as they develop.

A physical examination should be used to confirm a diagnosis of soreness due to dental hooks. Soreness at the insertion of the masseter muscles just below the temporomandibular joint is often evident. Horses with a severe problem can develop temporomandibular degenerative joint disease, exhibited as crepitation on joint palpation, reluctance to open the mouth or move the jaw to the side.[17]

Open-mouth radiographs can document the presence of dental hooks, but radiology has not been rewarding in evaluation of the temporomandibular joint. Other imaging modalities, such as nuclear scintigraphy, magnetic resonance imaging, and computed tomography, have been used to evaluate the temporomandibular joints, along with thermography.[18] Arthrocentesis and synovial fluid analysis can help with the diagnosis of temporomandibular degenerative joint disease and also aid in giving a prognosis and formulating a therapy plan.[19,20]

Oral examination with the aid of a full-mouth speculum and good light source will allow the evaluation of the dental arcades. Careful palpation is necessary to avoid confusing the normal upward curvature of the mandibular third molar in short-headed horses with an actual hook. Examination should include checking for other abnormal cheek teeth wear patterns.

Therapy should consist of hook removal and balancing the dental arcades. After hook reduction and dental equilibration, it is important to evaluate lateral excursion and cheek teeth contact. Often, horses that have had hooks and caudal jaw retraction for a prolonged period, also have some malalignment and subsequent abnormal wear of the incisor arcades. The incisors often need crown reductions and alignment to bring the cheek teeth into proper occlusal contact.[21]

Hand floating is a common method for reducing hooks. A long-handled, straight-head float set to cut on the pull is required for reducing caudal hooks. Rostral hooks are best reduced using an offset float or an angled float.

Two other tools are the sliding percussion chisel and molar cutters, but both should be used with caution. Chisels do not cut, but fracture the tooth crown. Excessive or incorrectly positioned force may shatter the tooth or repel it. Molar cutters should be reserved for older horses, as those under 9 years of age have less secondary dentition and structurally weaker teeth. Fracture of the tooth or extraction is a potential complication of this method, as is removal of too much hook and exposure of the pulp cavity.

Three types of power tools which increase precision and reduce effort are available. They are reciprocating, rotary burr and disk-type, and can be electric or air powered. The horse must be well restrained and sedated when power tools are used.

Incisor overgrowth might become evident after hook correction as caudal pressure on the mandible is released and the incisors once again come in full occlusal contact. Overgrown incisors, when returned to full occlusal contact, may take the cheek teeth completely out of occlusion. When lateral jaw excursion is attempted, no contact between the cheek teeth arcades is evident. Incisor length should be reduced as necessary to return cheek teeth to occlusion during lateral excursion and normal mastication.

The immediate relief of caudal pressure on the mandible changes the jaw position and acutely shifts the mechanical forces placed on the temporomandibular joint, muscles of mastication, and dental arcades. This can lead to mild inflammation and short-term soreness after treatment.

Inflammation can be treated symptomatically with nonsteroidal anti-inflammatory drugs. Some horses with residual temporomandibular joint pain after dental correction show quick relief of clinical signs with intra-articular therapy. Oral supplements, such as hyaluronic acid, methylsulfonylmethane (MSM), glucosamine, and chondroitin, have been shown to be of some value. Additionally, physical therapy and/or acupuncture can be of benefit.

CHAPTER 48

Gastrointestinal diseases of performance horses

Guy D. Lester

Equine gastric ulcer syndrome

- Spontaneous erosion or ulceration of the gastric mucosa represents the most important gastrointestinal disease of the athletic horse, both in terms of prevalence and economic impact. The latter is influenced not only by reduced earnings due to diminished performance, but also by the high costs associated with therapeutic and prophylactic medication.
- The pathophysiologic basis of gastric squamous ulceration in horses is multifactorial.
- The history and clinical signs of gastric ulceration in adult horses are often vague and not specific.
- The most effective treatment strategies are those that reduce gastric acidity. These include administration of antacids, H_2 receptor antagonists, or proton pump blockers.

Gastric anatomy

The horse is a hindgut fermenter with an extensive and complex cecum and large colon, but has a simple stomach similar in shape to that of domestic carnivores and omnivores. The nonglandular, squamous mucosal lining of the distal esophagus spreads through the cardia and covers the proximal half of the stomach. The margo plicatus defines the lower border of the squamous mucosa with the glandular mucosa. The glandular mucosa covers the remainder of the stomach through the antrum and down to the pylorus. Histologically the glandular mucosa is divided into three areas: the cardiac, fundic and pyloric regions. The cardiac gland region is a narrow strip of mucosa that lies immediately beneath the margo plicatus. The natural bend to the stomach permits further anatomic classification into greater and lesser curvatures.

Recognition of the disease

Equine gastric ulcer syndrome (EGUS) is not a single disease entity, but rather a term that embraces a group of distinct disorders that can affect horses of all ages.[1] These disorders include not only primary gastric disorders, but also related diseases of the distal esophagus and proximal duodenum. Many of these diseases share aspects of pathology, but likely differ widely in terms of primary pathophysiology.

1. *Neonatal gastric ulceration*. As the name indicates this syndrome is usually limited to diseased or otherwise highly stressed newborn foals. Ulceration and occasional perforation frequently, but not exclusively, occur in the cardiac gland region of the stomach. This syndrome is often clinically silent due to the coexistence of severe primary diseases such as systemic sepsis or peripartum asphyxia syndromes. The first signs may not be apparent until fatal perforation has occurred. Attenuated mucosal protection through reduced blood flow is a likely key component of the pathophysiology of neonatal gastric ulceration.
2. *Gastroduodenal ulcer disease (GDUD)*. This form of EGUS occurs primarily in suckling foals and in its most severe form involves the proximal duodenum, pylorus, stomach, and distal esophagus.[2,3] It is highly likely that the initial lesion in affected foals is a diffuse duodenitis. This initially results in a functional delay to gastric emptying with secondary gastric and esophageal irritation, probably due to prolonged exposure of susceptible mucosa to acidic luminal contents. During the healing process strictures may form in the duodenum and/or pylorus which result in a mechanical obstruction to emptying, again leading to gastric distension and secondary gastric and esophageal erosion. Of all of the forms of EGUS this syndrome is the one most likely to have a precipitating infectious

component. This is further supported by the observation that cases frequently occur in clusters and are often preceded by episodes of diarrhea. Acid suppression is a key component in the management of GDUD when delayed gastric emptying (either functional or mechanical) is present, but does not have a role in prophylaxis.

3. *Glandular ulceration*. Experimental induction of glandular ulceration is easily achieved using repeated high doses of non-steroidal anti-inflammatory drugs, such as phenylbutazone.[4] Lesions in the glandular mucosa also occur spontaneously in both athletic and non-athletic horses and often coexist with squamous mucosal lesions. They are usually seen in response to some form of stress, such as training or concurrent diseases. Glandular lesions are often associated with the most overt clinical signs of EGUS, such as postprandial abdominal pain and inappetence.
4. *Squamous mucosal ulceration*. Most discussion of ulcer disease in performance horses refers to erosion or ulceration of the squamous mucosa, the most common form of EGUS in this type of horse. The regions adjacent to the margo plicatus are most frequently diseased and are usually more prominent on the lesser curvature between the cardia and the margo plicatus.[5]

This discussion focuses on the glandular and squamous ulceration syndromes of performance horses. Readers are directed to other more general equine medicine texts for further information on neonatal cardiac gland disease and GDUD.

Clinical signs

In sharp contrast to young foals with GDUD, the history and clinical signs of gastric ulceration in adult horses are often vague and not specific. Only since the release of the 3-m endoscope has an association between signs and disease evolved. This has however been complicated by the frequent disparity between clinical signs and disease severity. It is not uncommon to observe horses with severe endoscopic lesions with no reported abnormal clinical signs. Conversely, there are horses with typical signs that have minimal changes on gastroscopy.

Probably the most common and consistent findings associated with gastric squamous ulceration are related to consumption of feed. Affected animals will typically take a longer than expected time to consume a concentrate feed and owners or trainers often report problems in achieving or maintaining body condition. More overt signs may include colic, particularly after eating. Anecdotally, horses with moderate signs of pain due to gastric ulceration commonly have glandular lesions, often around the pylorus, with or without squamous disease. This reinforces the importance of a complete endoscopic examination in animals presenting with colic in the absence of other abnormal findings.

Other reported signs consistent with ulcer disease include a rough hair coat, aggressive or nervous attitude, intermittent diarrhea, and poor performance. It is the latter sign that is most difficult to directly ascribe to gastric disease, but trainers will often report improved performance when horses are placed on antiulcer therapy.

Diagnosis

Endoscopy of the stomach is the most accurate method for establishing a diagnosis of gastric ulcer disease. This is best achieved using a 2.5- to 3-m flexible endoscope in the standing, sedated horse. The duration of fasting prior to endoscopy varies with the type of examination required. Examination of the antrum, pylorus and duodenum usually necessitates an overnight fast of 12–16 hours and withdrawal of water 1–2 hours prior to the procedure. The fasting period can be shortened to 6–8 hours if the examination is limited to the squamous mucosa. Adding air to the stomach will make the procedure easier to perform, but care should be taken not to overdistend the stomach particularly in foals and young horses. A suction system aids not only in evacuation of air at the completion of the procedure, but also to remove any excess fluid in the antrum.

A 2.5-m endoscope may not permit complete examination of the margo plicatus in large horses. This may be problematic as squamous ulceration tends to be more severe at the lesser curvature due to the greater exposure of this region to acidic fluid. The gastric squamous mucosa is scored using a simplified system that ranges from 0 to 3.[1] Examples are included in Fig. 48.1. Lesions are graded as follows: Grade 0, intact mucosal epithelium with or without reddening or hyperkeratosis; Grade 1, single or multiple small ulcers; Grade 2, single or multiple large ulcers; and Grade 3, extensive ulceration with coalescing of ulcerated areas. A modified system was recently published to categorize lesions of the squamous mucosa, glandular body of the stomach, antrum, pylorus, and duodenum.[6] The authors used the following 0–4 scoring system: Grade 0, intact epithelium with no apparent mucosal changes; Grade 1, mucosal reddening or squamous hyperkeratosis; Grade 2, small single or multifocal lesions; Grade 3, large single or multifocal lesions or extensive superficial lesions; and Grade 4, extensive lesions with apparent deep ulceration.

In other species, elevations in the serum concentration of pepsinogen have been observed in association with ulcerative diseases of the stomach and duodenum. Pepsinogen is converted to pepsin by autocatalytic activation under acidic conditions. Although equine pepsinogen has been isolated and appropriate assays developed, no such association has been published to date in adult horses.[7,8] Serum levels in foals with confirmed or suspected gastric or duodenal ulcers were significantly greater than serum pepsinogen levels in apparently healthy age-matched foals.[9]

Indirect methods of diagnosis include recognition based on clinical signs, although the vague nature of these signs can be problematic, and through response to treatment. Given the expense of treatment and the difficulty in evaluating improvement associated with therapy it is often more economical to perform gastroscopy.

Treatment

As discussed below, the pathophysiologic basis of gastric ulceration is likely multifactorial. Despite the apparent complexity of the disease the role of gastric acidity appears to be

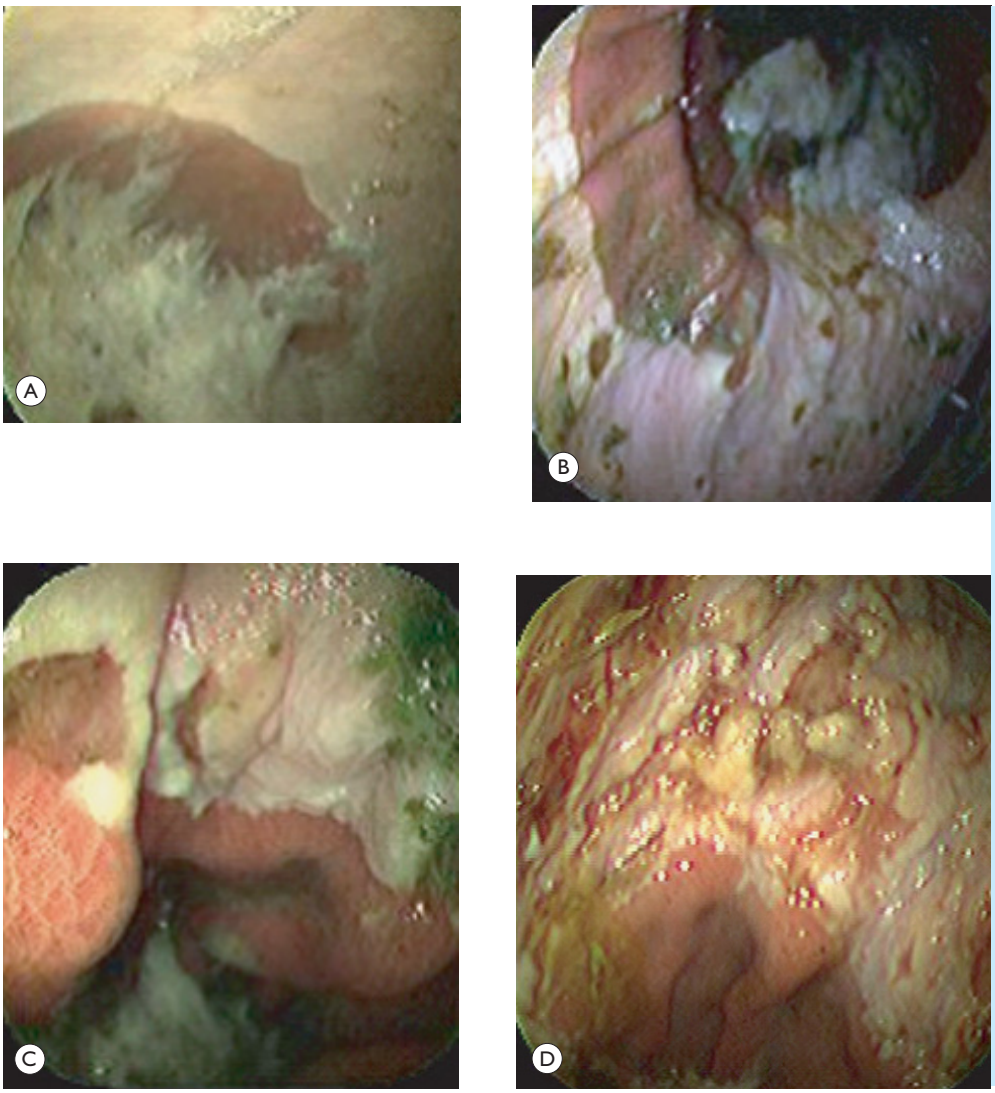

Fig. 48.1
Gastric ulcer scoring system.(A) Grade 0: Intact mucosal epithelium with or without reddening or hyperkeratosis. (B) Grade 1: Single or multiple small ulcers. (C) Grade 2: Single or multiple large ulcers. (D) Grade 3: Extensive ulceration with coalescing of ulcerated areas.

pivotal. Consequently, the most effective treatment strategies are those that reduce gastric acidity. These include administration of antacids, H_2 receptor antagonists, or proton pump blockers.

Antacids are most commonly used to provide temporary symptomatic relief from ulcer disease. They are used in relatively large volumes (240–360 mL) to improve appetite, feed consumption, and athletic performance in affected horses. Unfortunately, the effect of antacids is short-lived necessitating frequent treatment (q 2–6 hours) if ulcer healing is required. The oral administration of 30 g of aluminum hydroxide and 15 g of magnesium hydroxide resulted in a mean hourly gastric pH ≥ 4.0 for at least 120 minutes in one study.[10] A cautionary note: antacids reduce the bioavailability of many concurrently administered oral medications.

Histamine type-2 receptor antagonists have been widely used in equine practice to successfully treat and prevent gastric ulceration.[11,12] These drugs block histamine binding to receptors on the parietal cell. The duration of action is dependent on plasma levels, but is generally between 2 and 8 hours. Bioavailability of H_2 receptor antagonists is relatively poor and variable between animals; approximately 27% for ranitidine in adult horses[13] and between 7 and 22% for cimetidine.[14] The recommended oral dose for ranitidine is 6.6 mg/kg q 8 hours in the adult horse. Response data derived from healthy neonatal foals indicates that a dosing interval of 12 hours may be adequate in that age group.[15] The reported recommended dose of oral cimetidine in the literature is highly variable. Most veterinarians are using a total daily dose of 60–100 mg/kg divided and administered three to four times daily. Famotidine has been evaluated in adult horses, but further studies are required in order to characterize an optimal dose rate for acid control.[16] A dose of 2 mg/kg bodyweight was effective at significantly elevating the intragastric pH.

Proton pump blockers are effective at increasing intragastric pH and healing gastric ulcers in adult horses.[17–22] These drugs irreversibly bind parietal cell H^+-K^+-ATPase, the 'proton pump' responsible for H^+ secretion. Omeprazole is the most commonly prescribed proton pump blocking agent in

horses. The drug is well absorbed and at recommended doses will suppress acid production for approximately 24 hours. The recommended therapeutic dose rate of commercial omeprazole paste (GastroGard (USA) and GastroShield (Australia), Merial, Ltd) is 4 mg/kg bodyweight once daily. A dose of 1 mg/kg bodyweight daily has been recommended for the human preparation of omeprazole, a 20-mg capsule of enteric-coated granules.[23] Omeprazole paste has been shown to not only heal squamous mucosal ulcers, but also to maintain healing in Thoroughbred race horses maintained in active training.[19]

The effect of H_2 receptor antagonists and proton pump blockers on gastrin levels requires further investigation in horses. The secretion of gastrin is inhibited by gastric acid, therefore treatments that reduce acid secretory responses increase gastrin release and increase enterochromaffin-like (ECL) cell numbers. The prolonged usage of acid-suppressing drugs has been linked to the development of ECL cell tumors, although direct causal data are lacking.[24] Of more practical concern is the possibility of rebound hypersecretion of acid after withdrawal of acid-suppressing therapy.

Additional strategies involved in antiulcer therapy include coating of the ulcer with an acid-resistant compound and simulating or supplementing protective prostaglandins. The use of sucralfate – a polysulfated sugar (sucrose octasulfate) combined with aluminum hydroxide – in horses is controversial.[25,26] Anecdotal evidence suggests that sucralfate can be an important adjunct in the management of glandular ulcers. Sucralfate has a number of potentially beneficial properties, including binding to exposed gastric mucosa, stimulating mucus production and local prostaglandin synthesis, and improving mucosal blood flow. An effective dose rate has not been determined; commonly quoted dose rates range between 10 and 20 mg/kg bodyweight given orally every 6–8 hours. Additional problems associated with sucralfate administration include interference with the absorption of other drugs (e.g. certain antibiotics and H_2 receptor antagonists) and the requirement for an acid medium for maximum efficacy. As a result of the latter problem, most clinicians dose the drug 60 minutes prior to the administration of acid-suppressing agents.

Prostaglandin replacement therapy is often considered in animals undergoing prolonged therapy with non-steroidal anti-inflammatory agents and in those experiencing high levels of physiologic stress. Direct replacement with a PGE_2 analog, such as misoprostol, is costly and has been associated with undesirable gastrointestinal side effects (diarrhea and colic). Reported dose rates range between 1.5 and 2.5 μg/kg bodyweight every 8 hours. An indirect method of supplementing PGE_2 centers on feeding linoleic acid in the form of corn oil. Supplementation at a rate of 20 mL/100 kg bodyweight significantly increased PGE levels in the gastric fluid of cannulated ponies (AM Merritt, personal communication).

Etiology and pathophysiology

The pathophysiologic basis of squamous ulceration is likely multifactorial. A simplistic approach is to conclude that erosions or ulcers occur when there is an imbalance between ulcerogenic factors, such as the presence of hydrochloric acid, pepsin, or bile salts, and mucosal defense mechanisms. The glandular mucosa requires an extensive defense system because it is constantly exposed to acidic luminal contents. Prostaglandins, particularly PGE_2, play a key role in glandular mucosal defense through a number of mechanisms, including promotion of effective mucosal blood flow, increased mucus and bicarbonate secretion, supporting epithelial cell restitution, and by reducing acid output. The importance of homeostatic prostaglandins is clearly demonstrated through the experimental induction of glandular ulcers using NSAIDs.

The stomach is covered by a continuous layer of viscoelastic mucus.[27,28] This layer acts as the primary physical barrier to luminal contents. The gastric mucus covering the glandular stomach is actually made up of overlapping layers of mucin secreted by highly specialized cells of the glandular mucosa. Luminal acid, bradykinin and PGE_2 all increase the thickness of the mucus layer.[27] Within the mucus barrier is a pH gradient that varies from around 1.0 at the luminal surface to 7.0 pH units at the mucosal junction. Active mucosal secretion and entrapment of bicarbonate (HCO_3^-) within the mucus barrier is the primary factor responsible for the gradient. Bicarbonate secretion is enhanced during acid secretion through a process referred to as the 'alkaline tide'.[28] Briefly, within the parietal cell 1 mole of HCO_3^- is produced for each mole of H^+. The HCO_3^- is transported across the basolateral surface of the parietal cell in exchange for Cl^-. The HCO_3^- is subsequently transported via the local vascular supply to the epithelial cells where it is excreted. Acidic luminal contents provide the primary stimulus for bicarbonate secretion.[27] Sympathetic stimulation, mediated primarily through α_2-adrenoreceptors, is inhibitory to gastric and duodenal bicarbonate secretion.[28] This may be an important mechanism whereby stress can lead to reduced mucosal defense and ulceration.

Acid secretion

The horse stomach is similar to that of most other mammals in that it is capable of secreting large volumes of 0.16 N hydrochloric acid.[29] The acid is produced by gastric parietal cells located in the oxyntic glands of the glandular mucosa. The mucus layer that prevents the luminal contents from coming into direct contact with the epithelial surface does not impede the transport of acid or pepsin from the crypts into the gastric lumen.[28] The secreted hydrogen ions travel through small channels within the mucus gel created by hydrostatic pressure with the glands.

Acid secretion is regulated both centrally and peripherally, but it is the latter that has been the primary focus for pharmacologic control. The key local stimuli of acid secretion are acetylcholine, histamine, and gastrin. Acetylcholine release from postganglionic fibers at the level of the fundic mucosa directly binds to muscarinic receptors of the M_3 subtype.[30] Equally or more importantly acetylcholine also stimulates local ECL cells to release histamine, which subsequently bind

with histamine type 2 (H_2) receptors on the parietal cell, causing acid release.[29] Acetylcholine can also indirectly stimulate ECL cells through augmentation of gastrin release from G-cells. It does this by directly acting on G-cells and also by inhibiting the release of somatostatin from D-cells.[29]

ECL cells are small cells that lie subepithelially, and are therefore not directly exposed to luminal contents. The cells contain numerous cytoplasmic vesicles and function to synthesize, store and release histamine. Histamine release from ECL cells is stimulated by gastrin, acetylcholine, and β-adrenergic agonists. Release is inhibited by somatostatin and by histamine itself, through an autocrine feedback mechanism. Gastrin is a long-recognized acid secretagog and acts directly on the ECL cells by binding to the cholecystokinin B subtype (CCK_B) receptor to cause histamine release. Gastrin also has a hypertrophic and hyperplastic effect on ECL cells, as well as a key role in regulating the relative proportions of different gastric epithelial cell types, including stimulation of parietal cell differentiation.[31] In contrast to ECL cells, the gastrin-producing G-cells do have direct contact with gastric contents. A number of factors are known to regulate gastrin release, acting at either the luminal or basolateral surfaces of the G-cell. These include acetylcholine, gastrin-releasing peptide, somatostatin, and the chemical effects of luminal contents. The known luminal stimuli of gastrin release include amino acids (particularly aromatic amino acids), dietary amines, and calcium.[31] Gastrin is also released in response to sham feeding, oropharyngeal stimulation, and gastric distension. The pH of gastric contents has an important effect on gastrin, such that release is inhibited when the luminal pH is less than 3. This probably occurs indirectly through the paracrine release of somatostatin and provides an important feedback mechanism for parietal cells. Gastrin is considered to be a true peptide hormone in that it travels to target tissues via the blood. The hormone can therefore be measured in peripheral blood. The application of kits used to measure human gastrin in horses has been questioned as antisera raised against human gastrin binds poorly to equine gastrin.[32,33] Consistent with data derived from other species, serum gastrin levels in horses were increased after meal feeding.[34,35] The magnitude of the postprandial increase was also greater in treadmill-conditioned animals. These factors could provide a basis for the increased prevalence of squamous ulcers in Thoroughbreds in race training. Gastric distension in response to abdominal disease in horses also resulted in a significant increase in serum gastrin levels.[36]

Somatostatin is released from enteric fibers as well as fundic and antral D-cells. Somatostatin has a variety of functions in the stomach, one of which is inhibition of gastrin release from G-cells. Administration of the somatostatin analog, octreotide, at doses between 0.1 and 5 μg/kg bodyweight to healthy ponies resulted in a significant increase in intragastric pH that was sustained for between 2.4 and 5.4 hours.[37]

On the cellular level acid secretion from the parietal cell involves an elevation of intracellular calcium and cAMP, followed by activation of protein kinase cascades, which in turn trigger the translocation and insertion of the proton pump enzyme, H^+-K^+-ATPase, into the apical membrane of the cell.[38] After insertion the apical membrane opens up potassium and chloride ion conductance pathways. The H^+-K^+-ATPase enzyme catalyzes the electroneutral exchange of intracellular protons for extracellular potassium ions, thereby generating the proton gradient associated with HCl secretion.[38]

The parietal cell has a number of probable receptors, including those for histamine (H_2 receptor), acetylcholine (M_3 receptor), gastrin (CCK-B receptor), somatostatin, prostaglandins, and epidermal growth factor.[29,38] The latter three are thought to be inhibitory to the parietal cell.

Enterogastric reflux

Evidence exists to support a role of enterogastric reflux in gastric homeostasis. Visual inspection of the pylorus during routine gastroscopy in fasted horses frequently reveals entry of bile-colored fluid from the duodenum into the antrum. Bile salt concentrations obtained from the stomach of fasted horses with gastric cannulas averaged 0.23–0.44 mmol/L with some samples approaching 1.0 mmol/L.[39] Other investigators have measured intragastric concentrations of bile acids up to 2–3 mmol/L (AM Merritt, personal communication). Concentrations in fed animals are lower, usually less than 0.2 mmol/L.[39]

The importance of enterogastric reflux in the pathogenesis of squamous ulcer disease is not clear. Bile salts, such as taurodeoxycholate, have been incriminated in the pathophysiology of gastro-esophageal reflux disease (GERD) in people.[40] Several groups have demonstrated a harmful effect of bile acids on squamous mucosa in the presence of a low pH.[39–42] At a pH below their p*K*a bile acids are mostly non-ionized and insoluble, permitting mucosal uptake and damage. At a low pH (1.7 pH units) high concentrations of taurocholate (2.5 mmol) failed to cause additional damage to equine squamous mucosa above that induced by acid alone.[43] At a neutral intragastric pH bile acids are predominately ionized and remain in the gastric lumen. In vitro experiments have confirmed that bile acids at a neutral pH have no deleterious effect on the bioelectric properties of equine gastric squamous mucosa.[39,43]

Alternatively, the frequent refluxing of duodenal contents into the stomach may provide protection against mucosal ulceration or erosion by acting as a buffer. The continuous measurement of intragastric pH from healthy horses often reveals periodic and sudden elevations in pH. These pH shifts often occur at 15- to 30-minute intervals and are seen in both fed and fasted states. It is likely that these increases reflect enterogastric reflux of bicarbonate-rich fluid, rather than any abrupt cessation to local acid production.

Epidemiology

There is little doubt that the importance of gastric squamous ulceration has increased with the advent of 2.5-m and 3-m flexible videoendoscopes. These endoscopes have given us a

clear understanding of the prevalence of ulceration across a variety of horse types and activities. A number of important, albeit unexpected, observations have been made with respect to the prevalence of equine gastric squamous ulceration. For example, squamous ulceration occurs commonly (up to 50%) in young suckling foals in the absence of clinical signs and heals spontaneously without medication.[2]

Squamous mucosal ulceration has also been frequently reported in adult horses but the prevalence is dependent on a range of factors that include activity type and level, feed intake, management (diet, housing), and the presence of clinical signs compatible with ulcer disease.[5,6] Reported rates of disease frequently range between 50 and 90%, with horses in race training carrying the greatest risk of squamous mucosal ulcer disease (80–90%).[5,6,44] In this group the severity of disease usually increases as the intensity of training increases. By contrast, horses that are pastured and have limited controlled exercise are usually free of squamous ulcers.

The prevalence of gastric glandular ulceration is also greater in exercising horses, but the frequency of lesions is usually less than that reported in the squamous mucosa. In a retrospective study of 162 horses squamous ulceration was observed in 58% of animals.[6] By contrast, erosions and ulcers in the body of the glandular region were seen in only 8% of animals. Interestingly, antral and pyloric lesions were again noted in 58% of horses, but the authors could not find any association between sites with respect to either the presence or severity of lesions.

Role of feed and diet composition

The association between race training and gastric squamous ulceration has frequently led to speculation that diet may be a critical factor in the development of ulcer disease. Animals in race condition commonly receive high caloric diets, rich in concentrates and low in roughage.[5] Potentially ulcerogenic short chain volatile fatty acids (VFAs) are produced in the stomach from fermentable carbohydrates through the action of resident bacteria.[45] In the acidic conditions of the equine stomach these VFAs often exist in non-ionized forms and consequently are likely to penetrate and damage squamous epithelial cells.[46] The addition of the short chain fatty acid, acetate, to the mucosal side of isolated porcine gastric squamous epithelium in the presence of a low pH, resulted in reduced tissue electrical resistance consistent with damage to the mucosa.[41]

In a study using similar methodology on harvested equine gastric squamous mucosa the authors concluded that butyric, propionic, and valeric acid, but not acetic acid, were identified as potential ulcerogenic VFAs in that species.[47] This finding prompted the same group of investigators to examine the effect of diet on gastric squamous epithelium ulceration using healthy mixed breed horses with surgically implanted gastric cannulas.[46] The two diets contrasted in the experiment were a grass hay (bromegrass) diet and a combination of legume hay (alfalfa) and grain. In an unanticipated outcome, the number and severity of squamous ulcers were greater in horses that received the grass hay only diet. This was associated with a lower postprandial intragastric pH, and lower concentrations of acetic, propionic, valeric and isovaleric acid, and higher concentrations of butyric acid in animals that received the bromegrass hay. The authors suggested that the high calcium and/or protein content of the alfalfa and grain diet could have provided a protective buffer to the gastric contents. Alternatively, the transient postprandial increase in butyric acid with the grass hay diet may have been injurious to the squamous mucosa, particularly in light of the group's in vivo finding and documentation of a falling postprandial intragastric pH. These results further support the contention that gastric acidity may be a critical factor in the development of gastric ulceration.

Feeding frequency has an important impact on gastric squamous ulceration. Murray and Eichorn demonstrated that squamous ulceration could be induced in normal adult horses by alternating 24-hour periods of feed deprivation and ad libitum access to hay over an 8-day period.[11] Changes occurred rapidly and were usually apparent within 24–48 hours of cumulative feed deprivation. Feed deprivation results in increased gastric acidity.[48] The median intragastric pH during a 24-hour period with ad libitum access to grass hay was 3.1 pH units. Feed deprivation in the same group of healthy horses was associated with a lower median intragastric pH of 1.6. The common conclusion of these studies is that gastric acidity is the primary mechanism responsible for squamous ulcer disease.

The feed deprivation model for induction of squamous ulcer disease does not appear to result in glandular lesions.[6] This is not an unexpected finding in that the glandular mucosa is better suited to acid resistance, through a variety of mechanisms including secretion and maintenance of mucus-bicarbonate layer and mucosal blood flow.

Exercise

The prevalence data support a strong link between exercise and gastric ulceration. Using a barostat system, investigators recently measured the change in gastric volume in response to feeding and exercise.[49,50] Gastric volume was abruptly and significantly reduced during treadmill exercise in healthy horses. The authors concurrently measured intra-abdominal pressure and concluded that exercise-induced increases in intra-abdominal pressure were likely responsible for the observed reduction in gastric volume. The decrease in volume resulted in greater exposure of the squamous mucosa to the acidic contents of the ventral or dependent area of the gastric lumen.[49] The significance of these findings with respect to ulcer development is yet to be fully elucidated, particularly as the duration of exercise is often limited to minutes each day.

A further consideration is the effect of exercise on antroduodenal motility and gastric emptying. Data derived from human athletes indicated that exercise can delay gastric emptying.[51] Similar data are not available from horses, but it would not be unreasonable to assume that upper gastrointestinal tract motility was attenuated in exercising horses.

Stress

Diminished mucosal defenses associated with physiologic stress are thought to play an important role in the development of glandular lesions in humans. Similar mechanisms are likely responsible for glandular lesions in sick adult horses and newborn foals. It is highly unlikely that physiologic stress has a direct negative effect on squamous mucosa. By contrast, the role of psychologic stress in EGUS is not clear. Several studies have reported a higher prevalence of ulceration in horses that appeared to be more anxious or nervous, though differences were not great.[44,52] It has been hypothesized that horses of a nervous disposition may have reduced gastric volume in response to persistent tension of their abdominal muscles. This presumptive elevation in intra-abdominal pressure may force acidic contents into the dorsal region of the stomach (see above).

Housing

Simply relocating horses from pasture to a stall environment can induce gastric squamous ulcer disease.[11] Lesions are apparent within 7 days of the change. This occurs despite allowing free and continual access to grass hay. There could be a number of factors responsible for the increased incidence after confinement, including changes in diet and exercise, and induction of psychologic stress.

Right dorsal colitis

- An ulcerative syndrome of right dorsal colitis (RDC) that is associated with non-steroidal anti-inflammatory drug use, most commonly phenylbutazone.
- The clinical signs of RDC are variable depending on the duration and severity of the underlying colonic lesion, but include colic, weight loss, poor hair coat, diarrhea, reduced feed intake, and dependent edema.
- Both surgical and medical treatments have been utilized in the management of RDC. Surgery is usually performed on horses with narrowing of the right dorsal colon and correction involves surgical bypass or resection of affected tissue. Conservative medical management includes dietary control, medications, and avoidance of NSAIDs.

Recognition of the disease

Clinical signs

The clinical signs of RDC are variable depending on the duration and severity of the underlying colonic lesion. Commonly reported clinical signs include colic, weight loss, poor hair coat, diarrhea, reduced feed intake, and dependent edema. Signs of abdominal pain are often mild, but recurrent. The exception is horses where colonic stricture has occurred as a chronic response to persistent inflammation.[53] These horses often present with moderate and persistent pain due to impaction of proximal colonic segments and require surgical exploration or euthanasia. The diarrhea is highly variable in terms of volume and consistency, but is often of normal volume and soft, but formed consistency. The edema is due to hypoproteinemia secondary to loss across the inflamed and ulcerated colonic mucosa. The edema is most prominent in dependent regions including the ventrum, prepuce, distal limbs, and muzzle. In most horses with RDC dependent edema is absent or mild.

It is not uncommon for persistently affected animals to have flare ups of clinical signs. During these episodes horses may be febrile and colicky with diarrhea. The fever is likely due to the absorption of luminal toxins across the compromised mucosa.

Diagnosis

The diagnosis of right dorsal colitis is most commonly based on clinical signs, laboratory data, and a history of non-steroidal anti-inflammatory usage. Hypoproteinemia, specifically hypoalbuminemia, is the most characteristic laboratory finding in horses with RDC. Peripheral leukocyte changes are variable, and total white cell counts may be decreased, normal, or elevated. The count reflects the stage and severity of colitis at the time of sampling, and frequently, during acute exacerbations of the disease, there may be endotoxemia with resultant leukopenia with neutropenia, left shifting, and toxic neutrophil changes. As the disease progresses the total white cell count is commonly in the upper normal range or is mildly increased. Mild hyperfibrinogenemia is a common feature of RDC.[53] There may be a range of other biochemical and electrolyte abnormalities, but none is specific for RDC. Commonly reported derangements include hypocalcemia, hypophosphatemia, hyperbilirubinemia, and azotemia. Many abnormalities are attributable to a combination of mild dehydration and reduced feed intake.

Ultrasound may be a useful diagnostic aid although sensitivity and to a lesser extent specificity data are lacking. The colon on the right side of the abdomen may appear thickened with a distinctive hypoechoic line caused by edema formation. In some cases ultrasound is also used to assess disease progression and response to therapy. Recently, the use of ^{99m}Tc-HMPAO-labeled white blood cells in establishment of a diagnosis of RDC was described.[54] The authors reported linear uptake of radiolabeled white cells in the right craniioventral abdomen at 20 hours postinjection in two horses with RDC. The technique is clearly limited to referral practices with access to appropriate nuclear medicine facilities.

Treatment

A range of surgical and medical methods have been utilized in the management of RDC.[53,55–57] Surgery is usually performed on horses with narrowing of the right dorsal colon and correction involves surgical bypass or resection of affected tissue. Many cases have been successfully managed

conservatively, through a combination of dietary control, medications, and avoidance of NSAIDs.

Dietary management of RDC is aimed at minimizing the mechanical load on the colon.[55,57] This is achieved primarily by reducing the volume of long-stem roughage. Successful management often involves feeding of a complete pelleted ration, that is, a processed feed that contains both concentrates and fiber (roughage). If such a feed is not available or is not readily eaten then roughage is best provided in the form of frequent but brief access to pasture. Supplemented concentrates should be offered as frequent, small feeds. Psyllium mucilloid (30–100 g daily) has been fed to horses with RDC to aid in mucosal healing. The theoretic basis of psyllium supplementation is as a prebiotic, to promote the numbers of healthy bacteria that may facilitate mucosal healing, and to alter the concentration of luminal short chain acids to favor a ratio of acids that accelerate mucosal healing.[55,58] Feeding of psyllium is usually recommended for a minimum of 12 weeks after the diagnosis has been established.

The addition of linoleic acid, usually in the form of corn oil, to the diet of affected animals has been commonly advocated as a preventative strategy against gastric glandular ulceration in animals maintained on high doses of NSAIDs. Linoleic acid is a precursor of eicosanoids, such as PGE_2, and therefore may promote mucosal defensive mechanisms and aid in healing. An additional benefit of oil is the provision of calories, absorbed predominately in the small intestine.

Drug therapy in the management of RDC is controversial. Metronidazole has been used in many cases based on data derived from other species where certain intestinal obligate anaerobic bacteria, such as *Bacteroides vulgatus*, perpetuated the development of colitis.[59] Metronidazole also has anti-inflammatory effects and protects against the uncoupling of mitochondrial oxidative phosphorylation caused by NSAIDs.[60]

Sucralfate has been used in the management of RDC despite very little supportive data. Justification for use in colonic disease is based on limited cost, oral administration, an apparent absence of side effects, and limited efficacy data derived from humans.

There are a number of other drugs that have theoretical use in the management of RDC in horses, based on efficacy in the management of inflammatory bowel disease (IBD) in humans.[61] Pentoxifylline and thalidomide have anti-tumor necrosis factor alpha (TNF-α) effects that are of benefit, given the pivotal role of TNF-α in IBD. It is not known whether this cytokine plays a role in perpetuating the inflammation in RDC.

The avoidance of NSAIDs is often highly problematic in horses with RDC. This is particularly true for those with intermittent abdominal pain associated with the disease. If necessary, attending veterinarians should aim to minimize dosing and maximize interval times between doses. Preference is usually given to flunixin over phenylbutazone, but all drugs of this type should ideally be avoided. The other common circumstance of continued use involves persistent skeletal problems. Phenylbutazone is particularly attractive to horse owners because it is cheap, easy to administer, and effective. The development of RDC appears to be an idiosyncratic response to phenylbutazone in many horses, and as such, even infrequently administered small doses of the drug may be detrimental.

It has also been recommended to reduce physical and physiological 'stress' in animals to facilitate healing.[57] It is particularly important to ensure that rehabilitating animals are not exposed to episodes of dehydration. This means avoidance of forced exercise and unnecessary transportation.

A positive response to treatment can be gauged by an improvement in clinical signs, normalization of circulating protein concentrations, and a reduction in bowel wall thickness on ultrasound. Improvement is gradual, usually over 4–8 weeks, and it may take months to normalize many of these parameters. Animals are at risk of relapse, particularly in response to dietary changes and/or administration of NSAIDs.

Pathophysiology

The pathophysiologic basis of RDC remains to be fully elucidated. The adverse effects of NSAIDs on the gastrointestinal tract are however well described across a wide range of species.[62] Most of these are ascribed to the suppression of protective endogenous prostanoids, particularly PGE_2, and result in mucosal erosion or ulceration. Excessive doses of NSAIDs reliably produce gastric glandular ulceration in normal horses, but member drugs do so with differing potencies.[63,64] The variability between drugs with respect to adverse side effects is likely due to their relative inhibition of cyclooxygenase I or cyclooxygenase II isoenzymes.[65] Ulcerative lesions involving the right dorsal colon have also been induced experimentally in normal horses by giving 6 g of phenylbutazone daily for 5 days in the face of reduced access to water.[56] The susceptibility of the right dorsal colon over other regions of the colon has been the focus of much discussion. An inflammatory disease of the colon has also been described in humans associated with the administration of NSAIDs.[66]

Both phenylbutazone and indometacin influence in vitro ion transport in tissues collected from the right dorsal colon.[67] The primary effect is likely mediated by prostaglandins as changes were reversed when PGE_2 was added to the bathing media. There was a strong association between prostaglandin supplementation and chloride and bicarbonate secretion. The authors reported that the major histologic lesion induced by phenylbutazone was consistent with the induction of apoptosis.[67]

Salmonella species have been isolated from the feces of animals with RDC, raising the possibility of a direct causal relationship. Given that the recovery of *Salmonella* is uncommon in horses with suspected RDC, and that the organism is often shed by small numbers of healthy animals, this association remains doubtful.[57]

Epidemiology

The ulcerative syndrome of right dorsal colitis (RDC) is associated with non-steroidal anti-inflammatory drug use, most com-

monly phenylbutazone. Most cases are reported to occur after prolonged or excessive courses of the drug, but some have occurred in horses that have received appropriate doses of phenylbutazone for as little as 3–5 days.[55,56] Although uncommon, RDC has been reported after the administration of other anti-inflammatory drugs, such as flunixin meglumine.

Cecal emptying defect

- Cecal emptying defect (CED) is a primary motility disease involving the cecum or ileocecocolic region.
- The pathophysiology of CED is not known, but the syndrome may best mimic postoperative ileus in humans, which is considered a large intestinal disorder.
- Clinical signs are often subtle unless cecal perforation has occurred.
- Management of CED includes fluid therapy in combination with lubricants or laxatives, such as mineral oil or magnesium sulfate, and careful use of anti-inflammatory drugs.

Recognition of the disease

Clinical signs

Clinical signs are often subtle unless cecal perforation has occurred. In horses with CED after anesthesia evident signs are usually apparent 3–5 days after the procedure; early signs include depression and a reduction in both feed intake and fecal output. Ineffective emptying results in overfilling of the cecum with moist contents, which is manifest by signs of mild to moderate colic. Cecal distension with digesta can be palpated rectally in horses with advanced cecal dysfunction. If recognized late or untreated the cecum may rupture resulting in fatal peritonitis.

Treatment

Fluid therapy is an important component in the management of CED, usually in combination with lubricants or laxatives, such as mineral oil or magnesium sulfate, and with careful use of anti-inflammatory drugs. Horses with primary cecal impaction or impaction secondary to an emptying defect frequently require surgery in order to prevent fatal rupture. The surgical management of these cases is controversial and may include typhlotomy alone, typhlotomy with a bypass procedure such as ileocolic or jejunocolic anastomosis, or a bypass without typhlotomy.[68] Most horses that undergo simple typhlotomy have an uneventful recovery,[69] although a small number will reimpact and require a second laparotomy. The use of prokinetics in the prevention and treatment of CED is also controversial. Intravenously administered erythromycin lactobionate (1.0 mg/kg i.v.) hastens cecal emptying in normal animals and induces colonic MMC-like activity across the colon.[70] Administration is often associated with defecation and abdominal discomfort. The drug may be helpful at preventing cecal impaction in horses after anesthesia, though its effectiveness on cecal motility in the immediate postoperative period may be reduced.[71] High doses, constant infusion or prolonged use of erythromycin induces receptor downregulation and inhibition of activity. Erythromycin can induce diarrhea in adults therefore dosing over many days should be avoided. Other drugs that may be useful include bethanechol, lidocaine (lignocaine), or yohimbine, although efficacy data are lacking.[72]

Pathophysiology

The pathophysiology of CED is not known, but the syndrome may best mimic postoperative ileus in humans, which is considered a large intestinal disorder. An important difference in horses is that laparotomy is a rare predisposing factor, and most cases occur in horses undergoing routine extra-abdominal surgical procedures. General anesthesia itself is a potent inhibitor of gastrointestinal motility in horses, but these effects are short-lived and reversible within hours of anesthetic withdrawal.[73] The return of normal motility in horses after experimental ileus was most delayed in the cecum, suggesting that this may be a common site of ileus in horses.[71] A link between routine postoperative medications, such as phenylbutazone and aminoglycoside antibiotics, has been suspected but not established. An inhibitory effect of NSAIDs on large colon contractility has been demonstrated using in vitro techniques.[74] Primary sympathetic overstimulation could be involved as many of the affected animals are young, male horses, or animals with painful diseases. The development of small intestinal postoperative ileus but not cecal emptying dysfunction, is influenced by the duration of surgery.[75,76]

Epidemiology

Cecal emptying defect (CED) is a primary motility disease involving the cecum or ileocecocolic region.[76–78] The syndrome occurs sporadically, but anecdotally appears to be more prevalent in young athletic horses. Most cases are reported after general anesthesia and extra-abdominal surgery, particularly orthopedic and upper airway procedures. Others occur spontaneously, often in animals with painful primary conditions such as uveitis or septic tenosynovitis.

Stress-associated diarrhea

Diarrhea occurs commonly in certain animals when placed under stressful conditions. These include transportation, placement into a foreign environment, exposure to unknown animals, or associated with moderate to heavy exercise. The intermittent nature of the diarrhea, coupled with an absence of abnormal clinical findings, likely reflect a physiologic rather than pathologic basis. In any animal exposure to hostile condi-

tions initiates a stress response that comprises alterations in behavior, autonomic function, and the secretion of multiple hormones.[79] The latter includes increased secretion of epinephrine (adrenaline) and norepinephrine (noradrenaline), the release of corticotropin-releasing factor (CRF) and vasopressin, and the secretion of adrenocorticotrophin (ACTH).

Corticotropin-releasing factor is the neurohormonal factor of greatest interest with respect to stress-induced alterations in colonic motility. The central release of CRF acts in the brain to inhibit gastric emptying; while CRF-induced modulation of parasympathetic outflow stimulates colonic motility and fecal excretion in response to psychologic stress.[80] Hypersecretion of CRF may contribute to stress-related exacerbation of irritable bowel syndrome in man.[80] Similar neurohormonal responses to stress have not been reported in horses, although exercise in conditioned horses was not associated with significant increases in CRF levels collected from pituitary venous blood.[81]

Treatment is rarely indicated in horses with stress-associated diarrhea as the volume of diarrhea rarely results in clinical dehydration. Novel treatments for irritable bowel syndrome in humans include tachykinin receptor antagonists, 5-HT_3 receptor antagonists, and 5-HT_4 agonists, but none of these agents has been evaluated clinically in horses.

CHAPTER 49

Veterinary aspects of racing and training Thoroughbred race horses

Christopher B. O'Sullivan and Jonathan M. Lumsden

Providing optimal veterinary services to Thoroughbred race horses requires an understanding of both the veterinary aspects of their care, and the dynamics and economics of the racing industry. This chapter provides a demographic overview of Thoroughbred racing and in particular wastage. Commonly encountered diseases are discussed with an emphasis on the veterinary management and disease prophylaxis during both training and racing.

Demographics and wastage

Thoroughbred racing evolved in England over 200 years ago and now exists in over 50 countries.[1] A comparison of the size of Thoroughbred industries between some of the major racing countries based on foal crop, number of races and starters, prize money and betting turnover is illustrated in Table 49.1. The figures in this table under-represent the number of Thoroughbred race horses since they do not include horses involved in National Hunt and point-to-point racing. Similarly, this chapter will concentrate on the veterinary management aspects of Thoroughbred horses racing on the flat.

All facets of the Thoroughbred racing industry rely heavily on veterinary input which extends from pre-conception to the end of a horse's athletic career. Termination of a racing career may result from veterinary advice pertaining to injury or disease, or be based on economic grounds and an assessment of athletic ability. Horses are typically retired to stud if they have accomplished a superior racing career that they are unlikely to better, or have genetic potential that would offset their future potential race earnings. Alternatively, other horses are routed to other athletic endeavors if they are functionally sound.

Horses have their first opportunity to race as 2-year-olds and their competitive longevity is the result of a multitude of veterinary and specific industry-based factors. Generally the majority of the racing population is made up of horses aged 2 to 5 years of age. Sex distribution of the racing population commences with relatively equal proportions of males and females as yearlings and 2-year-olds.[2,3] In subsequent racing years there is an attrition of females to breeding so that horses older than 4 years of age are typically gelded males (Figs 49.1, 49.2).[2–4]

Age at first race start depends on athletic conformation, degree of maturity, genetics, aspirations and expectations of the owner and trainer, as well as race programming and prize money structure of the specific country. Attempts to judge musculoskeletal maturity and suitability for racing based on objective means such as physeal closure have been generally unsuccessful.[5]

The actual time of first race start is then dependent on the response to training, health, and soundness. Interestingly, in a study examining factors affecting early career wastage there was no correlation between sex and foaling date and time of first race start.[3] While concerns over racing 2-year-old horses exist, two studies found that horses who raced first as 2-year-olds had greater numbers of career starts and raced longer than did horses that commenced racing at an older age.[2,3] This may in part be due to injury or disease that prevented these older horses competing as 2-year-olds and which may have persisted further into their career.

Wastage refers to all losses occurring at any stage in the breeding, growth, training and racing of a race horse. Wastage includes all losses in breeding, deaths at any stage, lost training days, unraced horses and retirement. Considerable wastage occurs in the Thoroughbred racing industry as a whole from the time that the mare is covered to the commencement of racing by the progeny. A UK-based

Table 49.1 A comparison of some key industry figures for international Thoroughbred flat racing among major racing countries, for the year 2000

Country	Foal crop	Number of races	Number of horses started	Average prize money $(US)	Yearly national betting turnover (US$ millions)
USA	33 360	55 486	64 443	16 201	2029
Australia	18 481	21 561	31 251	7756	699
Japan	838	25 500	29 282	34 532	4926
Great Britain	5194	4394	7685	16 445	1069
France	4180	4250	7330	15 716	795

Argentina	6582	7825	10 974	4696	46
Brazil	3391	5851	7788	2430	21
Canada	2570	5386	6557	12 421	67
New Zealand	4958	2647	5077	5054	44
Italy	1905	5110	6636	9202	334

Source: International Statistical Survey of Horse Racing and 2000 statistics, compiled by the Société d'Encouragement and presented at the 34th International Conference of Racing Authorities, Paris, France, 8 October 2001. In some cases national betting turnover includes harness racing. Total betting turnover in South Africa not available. Additional data can be found at http://home.jockeyclub.com/factbook/worldwide.html.

wastage study calculated 72.8% of mares each year fail to have progeny that will go on to race between 2 and 4 years of age.[6] In this study, the 1975 foal crop was followed and of those named and eligible for training only 50.6% raced as 2-, 3-, or 4-year-olds, this result is confounded by horses reserved for National Hunt racing that did not race on the flat.[6] Similar prospective studies of 353 and 553 yearlings sold at auctions in Australia revealed that approximately 50% of these horses raced as 2-year-olds and that 75 to 80% of horses had raced by their 6-year-old seasons.[2,3]

Lameness, followed by respiratory disease, is the major cause of wastage for Thoroughbreds in race training, manifesting as lost or affected training days.[3,6–9] A UK wastage study found that 53% of horses showed lameness at some stage during a season and in 20% of cases the lameness was sufficient to prevent racing after injury.[6] A subsequent study identified lameness (67.6%) and respiratory disorders (20.5%) as the most common cause of lost training days.[7] Similarly a USA-based study looking at 95 horses over an 81-day period reported musculoskeletal injuries altering training or racing schedules in 35–55% of horses and preventing training or racing for a period of time in 26–46% of horses.[10] A recent Australian wastage study of 2- and 3-year-old horses found that of lost or modified training days, 56% were due to lameness and 16% due to respiratory disease.[11] Similar findings have recently been reported from New Zealand, identifying musculoskeletal (82%) and respiratory diseases (11%) as the major cause of involuntary time out of training.[9]

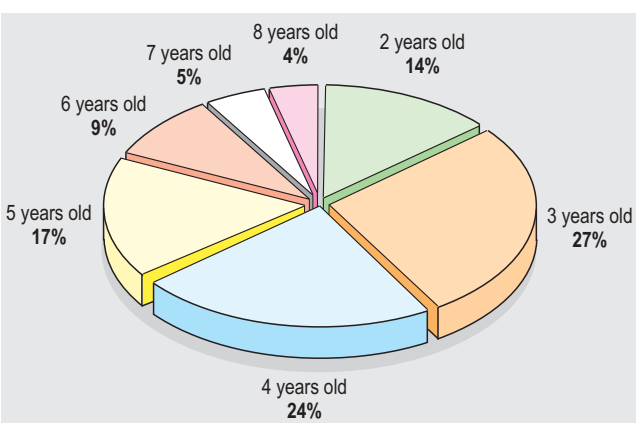

Fig. 49.1
Age distribution of Thoroughbred race horses in Australia over a 6-year period (1992/1993–1997/1998). (Source of data: VRC racing services.)

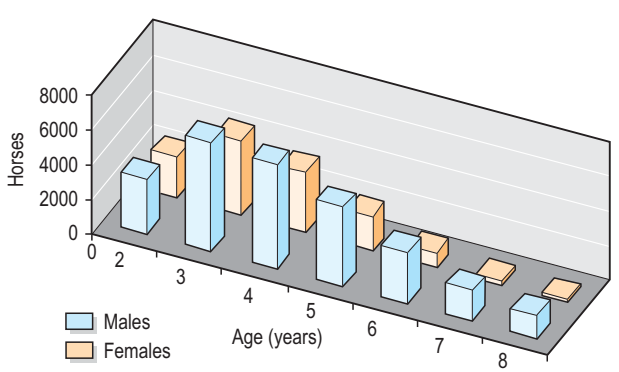

Fig. 49.2
Average age and sex distribution for horses racing in Australia over a 6-year period (1992/1993–1997/1998). (Source of data: VRC racing services.)

A further reason horses may not race or race less than the average number of times is a 'lack of athletic ability'.[2,6]

Breakdowns, fatal musculoskeletal injuries and sudden death during racing and training have been a focus of many recent studies, most aimed at identifying risk factors in an attempt to minimize these injuries.[12–23] Regional differences exist with regard to risk factors, prevalence and types of injuries between countries, states, regions and even individual tracks.[13–17] The rate of breakdown injuries during racing differs between countries with rates of 2.2/1000, 2.9/1000 and 21/1000 starters in the USA, Australia and Japan, respectively.[12,15,18] These differences are difficult to interpret since they may in part be due to potential errors inherent with epidemiologic studies and different definitions of a breakdown.[16,19] Approximate risk of fatal or catastrophic musculoskeletal injury is 0.6/1000 starters in Australia and 1.4–1.7/1000 starters in the USA, while in the UK there are 0.8 deaths/1000 starters.[15,19–22] The reasons for differences in rates between countries are multifactorial, but dirt tracks have been implicated as one factor contributing to a higher incidence of injury.[22,23]

Catastrophic life-threatening injuries appear more likely to occur when racing whereas non-fatal injuries are more common in training, which may be a function of speed.[16,18] Breakdown injuries more commonly involve a forelimb than hindlimbs; common sites of injury include fetlock and suspensory ligament, carpus, humerus, pelvis, tibia and superficial flexor tendon.[13,18,19,21] There is evidence that pre-existing lesions predispose to catastrophic injuries, highlighting the value of early identification of such lesions in preventing injury.[17,18,24–26]

A multitude of risk factors contributing to breakdown injuries has been identified including track characteristics,[15,23,27] weather and season,[23] race distance, starting postion and race quality.[19,28] Individual horse characteristics identified include racing frequency, training intensity, age at first start, duration of career, number of life time starts and the hoof or shoeing characteristics.[14,15,23,29,30] Causes of sudden death other than fatal musculoskeletal injuries that have been described include ruptured aorta, myocarditis, valvular insufficiency, sclerosis of the coronary arteries, severe pulmonary hemorrhage and disseminated massive hemorrhage.[31]

Provision of services

A working relationship between the veterinarian and trainer is paramount to providing optimal services to a stable. Excellent communication is essential, as is an appreciation of the trainer's perspective and recognition of the non-veterinary factors such as owner expectations and aims, economics and the trainer's previous personal experience. The veterinarian should also have knowledge of normal training techniques and schedules, which often differ between trainers. Veterinary services should be preventive as well as problem oriented and applied at both the individual horse and whole stable level. The level and extent of services provided on an ambulatory basis will be dictated by the ability to access a hospital center or referral clinic.

The veterinarian–farrier relationship is important because of the prevalence and significance of hoof-related problems. Ideally management and prevention of hoof-related lameness should be a joint approach as opposed to demarcating and allocating 'foot' and 'non-foot' cases. Adequate diagnostics and an understanding of the principles involved in the application of physical and alternative therapies allows the veterinarian to appropriately prescribe and substantiate or refute their use.

Establishment of a complete and reliable recording system of disease, lameness and treatment is essential. Accurate recording of administered medications is important where withdrawal times prior to racing must be considered. The system must be easily accessible, efficient and permanent. Ensuring accurate identification of horses prior to treatment or procedures is paramount in a stable environment, particularly where there are large numbers of horses and staff involved. Similarly, clear instructions and great care should be taken when dispensing and administering medications that may be regulated by racing authorities.

The importance of a thorough clinical examination cannot be overstated. It is often easy to neglect the basics in the busy stable environment. A thorough relevant history and systematic clinical examination are the foundation of any accurate and efficient diagnosis, treatment and prognosis. Horses are often presented for a particular complaint but on closer inspection reveal multiple related and unrelated problems. It is also important to judge what can and cannot be done efficiently, adequately and practically at the racetrack/stable and what is better performed in the clinic setting.

Acquisition of race horses involves selection of yearlings, 2-year-olds and tried (older) horses. Economics and method of purchase by public auction or private treaty, will determine the extent of veterinary prepurchase examination. Limiting comments to lesions and conformational faults only, and their likely effects on future athletic soundness, appears the most appropriate advice from a veterinary perspective.

General disease and injury management concepts

Prophylactic measures

Ligament, tendon and joint injuries may occur during breaking and pre-training and reports of swelling or lameness during this period warrant investigation. Subclinical conditions such as osteochondrosis may manifest during preliminary training and early identification may allow treatment with minimal impact on a horse's racing career.

Prophylactic measures to prevent and minimize problems are implemented as part of good stable management. Such measures include routine selection of horses for lameness and clinical examinations, vaccination and parasite

prophylaxis programs. Feeding and training regimens are typically established by the trainers. Sound reasoning coupled with subtle diplomacy is required to obtain trainer compliance with regard to feed and work schedule related changes.

The veterinarian has an important role in advising trainers on the value of instructing stable hands and setting up reliable recording systems that ensure staff observe and report on their horses as they go about caring for and riding them. Feedback from stable staff is important at all levels including observations such as fecal amount and consistency, feed consumption, water intake, signs of colic, coughing or evidence of stable vices, all of which can be detected by educated grooms maintaining stalls. Regular assessment of bodyweights can be used as a monitor of fitness, disease or 'training off'. Recording rectal temperatures of horses with reduced feed intake, subdued demeanor or any other clinical signs of disease should be ingrained as an automatic process.

Daily tacking up can identify a variety of subtle changes including changes in gait as horses are walked out of stall, acquired swellings, skin conditions, nasal discharge and change in response to saddling or bitting. Riders, trainers and clockers can monitor for lameness and more subtle gait changes such as 'hanging on a rein', 'feeling rough' or repeatedly changing strides. Likewise other observations such as respiratory noise, altered breathing pattern or performance and poor recovery after exercise may all facilitate early identification of problems.

Routinue 'trot-up' examinations are an efficient management tool for early detection of musculoskeletal disease and may consist of regular daily, weekly, pre-race or post-race evaluations. Ideally an environment is created where if there is any question as to what effect continued exercise will have on a horse, the trainer will be prompted to have the horse examined. Continuity and regular assessment of individual horses facilitates more specific treatment decisions and detection of subtle changes in gait or lameness. Such monitoring creates a rewarding environment for assessment of therapy, since race performance alone is not always an accurate determinant of therapeutic success.

General management of disease

Early detection and accurate diagnosis of disease coupled with appropriate therapy, rest periods and rehabilitation are all essential to maximize racing longevity. The goal of treatment should be a rapid return to soundness and functionality, without compromising long-term soundness and earning potential. The economic cost of unnecessary or incorrect therapy may be significant. Training alterations require additional considerations, including the impact on the animal's other body systems, particularly the musculoskeletal and cardiorespiratory systems. Furthermore, veterinarians should habitually establish appropriate 'informed consent' of trainers and owners because every treatment has a complication rate that may range from a mild injection site reaction to life-threatening colitis, sepsis or anaphalaxis. In this light, the veterinarian must also consider the risk of musculoskeletal injury with continued racing and training and importantly the associated risk to riders.

Medication of horses in training should include considerations of potential side effects as well as optimizing administration times in conjunction with training programs. There is often a compromise required between appropriate medication, required optimal rest and lost fitness. The final decision should be that of the trainer/owner, while the role of the veterinarian is to provide information regarding a disease and then provide a range of options for management allowing the trainer to weigh up the cost benefits of therapy and modification of their training. Regulatory concerns and drug withdrawal times warrant careful consideration, particularly the use of oral preparations or 'in feed' drugs where stall contamination represents a particular concern.

Specific disease and injury management

The purpose of this section is to provide some general approaches to managing commonly encountered injuries and diseases of Thoroughbreds in race training. While different strategies are employed to address different pathology some conceptual similarities exist with regard to the management of injured or diseased race horses, particularly with respect to the effect of alterations in training.

Musculoskeletal diseases

Dorsal third metacarpal disease, carpal and fetlock joint disease and tendon or ligamentous injuries are the most common musculoskeletal problems leading to wastage.[6,11,22] Routine, diligent observation of subtle changes in symmetry and meticulous palpation combined with use of hoof testers and flexion tests aids early identification of the most likely site of lameness. Where possible, targeted diagnostic anesthesia and imaging is used, which is both economical and time saving. Quality imaging modalities including radiography, ultrasonography and scintigraphy, are essential for accurate diagnosis, treatment and prognostication.

The presence of a secondary lameness is common and may go undetected without appropriate diagnostic anesthesia. Bilateral disease is commonly identified, particularly with carpal and fetlock injuries, tibial stress fractures and sites of osteochondrosis.[32–37] Lameness examinations can be aided in the fractious patient with a small dose of sedation.[38] Jogging in a circle or figure-8 can also be useful for assessment of mild lameness and may help differentiate among sites of lesions causing lameness.

Exercise modification

Musculoskeletal diseases often require modifications to the training program, dictated by the disease or injury and the horse's level of fitness. Changing the typical training formula is achieved by alteration of distance and/or speed. Terminology differs geographically in describing the approximate speeds at which horses train and race, and understanding local terminology allows assessment of the current workload and appropriate suggestions with regard to modifications. Speed and distance may be expressed in furlongs (220 yards or approximately 201 meters) (Table 49.2).

Trainers may have a variety of track surfaces available for training horses and advice with respect to training surface should be formulated based on knowledge of the local track characteristics, current track conditions and their contributions to injury risk. Traditionally turf has been associated with a lower risk of musculoskeletal injury than dirt although confounding factors, primarily geographic, may contribute to this apparent lower risk.[15,23,39] Some specific injuries appear to have an association with particular track surfaces. There is an apparent increase in the incidence of proximal suspensory desmitis in horses working on woodchip compared with turf tracks, and an increased incidence of subsolar inflammation and bruising is noted in horses performing high-intensity exercise on sand tracks (PE Sykes, 2002, personal communication). The incidence of dorsal third metacarpal disease is higher in horses training on dirt than on wood fiber tracks.[40]

Track condition or rating has been reported to influence the risk of injury.[15,41,42] However, several large epidemiologic studies have found no association between track condition and injury rate.[19,23] The mechanical characteristics of a track are determined in part by its structure with moisture content being the major variable influenced by weather and track maintenence.[27,41,43,44] Injury risk is higher on turf tracks when the surface moisture content is low, resulting in a harder track and faster race times.[15,18] Dirt tracks on the other hand have been associated with injuries under a variety of conditions typically when moisture content is either too low or high or surface is of inadequate depth or composition.[16,27,42] Unleveled track surfaces and areas where track is compacted such as 'crossings' for horse and vehicular access and areas around starting chutes have been associated with increased risk of injury.[27,45] An inadequate banking or camber on turns may also contribute to injuries and alterations to track camber and surfaces have shown benefits in reducing injury rates in Thoroughbred and Standardbred racing.[46–48] Therefore consideration to track characteristics should be given, especially with advice regarding horses working at high speed or rehabilitating from injury.

Hill or incline work, either under saddle or on an inclined treadmill, allows work rate to increase while limiting speed.[49,50] Inclines modify the activity and loads on various muscles,[51] probably increasing the overall load on the hindlimbs that may be beneficial if attempting to strengthen the hind quarters, or being contraindicated in horses with hindlimb injuries. Walking in waist deep water in a pool or on a submerged treadmill provides greater work to the advancing limb and may benefit attempts to improve extensor and particularly quadricep strength.

Direction around turns (clockwise versus anticlockwise) influences limb loading patterns, with the lead limb subject to a greater load than the contralateral limb, and this additional loading may predispose the lead limb to injury.[19,52] Typically in a counter-clockwise racing direction the horse preferentially leads with the left forelimb on the turn, and for clockwise racing the right forelimb, with most horses changing to the opposite lead at some stage during the straight.[53] Many injuries appear to have 'lead' or inside limb predilections depending on the direction of racing such as dorsal third metacarpal disease,[54,55] superficial digital flexor tendinitis,[42]

Table 49.2 Common terminology and speeds associated with Thoroughbred flat work

Common terms	Approximation to race speeds	Speed	Time per furlong
Trotting work (UK, Australia), jogging (USA)		Approximately 4 m/s	
Slow work 'canter' '1/2 pace' (UK, Australia) 'gallop' (USA)	~50% race speed	Approx 8–12 m/s	18 second furlong (11 m/s)
3/4 Pace work 'even time' (Australia, UK) 'breezing', 'licking' (USA) Primarily aerobic	~75% race speed	Approx 13 m/s (2 minute miles)	15 second furlong
Come or sprint home, gallop (Australia) Home, finish or sprint Some anerobic contribution	90–100% of race speed	16–18 m/s	11–13 second furlong
Top race speeds		18 m/s	11 second furlong or better

and antebrachiocarpal joint injuries, particularly the distal radius and proximal intermediate carpal bone.[53] 'Outside' limb injuries are commonly associated with the medial middle carpal joint.[53] Common musculoskeletal injuries associated with limb predilections may be minimized or prevented by training in both directions on turns. If introduced early in a training program it allows development of balance in both directions and minimizes repetitive loading of specified predilection sites.

Walking exercise can be provided by hand walking, mechanical walkers, or treadmills. Often overlooked, walking is useful in horses that are temporarily out of work and beneficial in horses susceptible to 'tying up' or with chronic joint complaints. Walking after high-intensity exercise improves recovery.[56] 'Ponying' is useful for horses that do not settle at slow speeds or horses with back complaints, particularly wither or girth rubs. Some musculoskeletal back problems may be exacerbated if the horse has a tendency to track sideways.[57]

Swimming is a primarily aerobic exercise medium useful in reducing the effects of weight-bearing work and has been suggested to decrease the rate of musculoskeletal disease (Fig. 49.3).[58] While allowing non-weight-bearing joint motion, swimming does not stimulate appropriate bone responses or maintain joint ligament tone.[59] Potential complications of pools include infection of pre-existing wounds, interference injuries (higher risk in circular pools), exercise-induced pulmonary hemorrhage, colic and rarely drowning. Swimming increases muscle activity in some selected muscle groups and therefore may be contraindicated in the presence of primary muscle injuries.[60]

The effect of complete cessation of exercise on a horse's level of cardiovascular fitness often depends on the horse's stage of training. Horses early in their training phase appear to lose significant amounts of aerobic fitness within 2 weeks, whereas horses more advanced in training are slower to detrain, losing fitness over 4–6 weeks.[61–63]

Bandages and bandaging

Support bandaging can be useful to minimize swelling and edema associated with acute pathology or intermittent limb edema. The role of athletic support bandages in preventing injury and their effect on performance is unknown; studies in healthy human athletes indicate they can be performance impairing.[64] Cohesive single layer bandages (Coban, Vetwrap, Equisport) have been shown in vitro to reduce hyperflexion of the fetlock, and increase absorbed energy.[65,66] Equisport (3M Corporation, St Paul, MN) and Elastikon (Johnson and Johnson Inc, New Brunswick, NJ) bandages provided superior energy absorbing capacity when compared with Ace (Beckton, Dickson and Company, Rutherford, NJ), Vetwrap (3M Corporation, St Paul, MN) or Coban (3M Corporation, St Paul, MN).[67] Improperly applied bandages may contribute to pathology and any bandaging may be contraindicated due to effects on heat dissipation.[68,69] Work boots or padded bandages can be used to limit and reduce the severity of interference injuries.

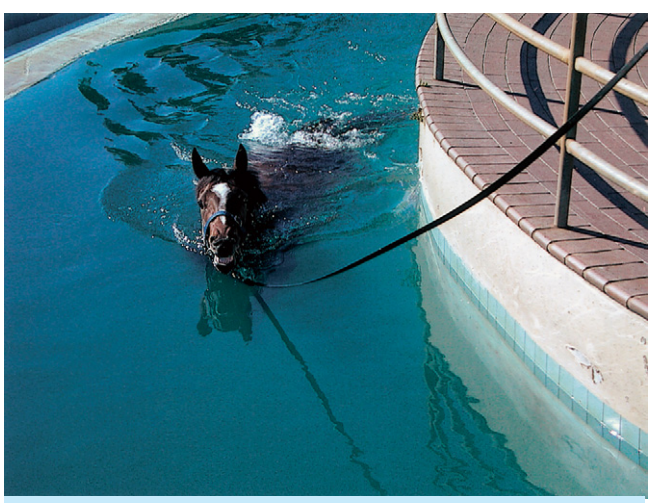

Fig. 49.3
A Thoroughbred race horse swimming in a circular pool.

Cold therapy

Cold therapy provides anti-inflammatory, analgesic effects and reduces cellular metabolic demands and should be considered in any acute or chronic injury.[70] Rapid icing of acute injuries is followed by intermittent icing for approximately 48–72 hours until inflammation is resolved; chronic injuries benefit from icing after every bout of high-intensity exercise.[50] Ice water slurries in large rubber boots are easy to apply, have the ability to include the carpus, and cool the limb more efficiently compared with commercial cold packs, reaching stable tissue temperatures in 10 minutes (Fig. 49.4).[71] Excessive icing can cause dermatitis and ice burns. Limiting 'icing' times to 30 minutes and applying multiple applications with durations of at least 20 minutes out of the ice seems to minimize this complication.

Joint diseases and injuries

Medical management of joint injuries and disease

Early and aggressive anti-inflammatory therapy is indicated with all joint injuries provided the diagnostic process is not compromised. Once the level of joint compromise is determined appropriate specific treatment can be pursued. Joint inflammation can be controlled with systemic non-steroidal anti-inflammatories (NSAIDs) at recommended doses for 24–48 hours, combined with cold therapy and bandaging. Cessation of high-intensity exercise and the substitution of walking is indicated while the joint is acutely inflamed. Trotting and swimming can be used to maintain activity until the horse is able to return to its previous level of work intensity. Rapid resolution of synovitis and capsulitis is beneficial in avoiding capsular edema and capsular fibrosis that may lead to reduced range of joint motion.[72,73] Passive joint flexion may aid in maintaining range of joint motion.

Intra-articular medications (as discussed in Chapter 23) are likely to be most efficacious if used in a planned manner with consideration given to the horse's training and racing schedules. Maximal anti-inflammatory effect is likely to be gained by early treatment followed by cessation of high-intensity exercise. Joints that are chronically affected should

Fig. 49.5
Intra-articular medication being administered via a dorsal approach to the left forelimb fetlock joint.

be treated after exercise on a day of planned high-intensity fast work, allowing at least 3–5 days or longer of modified low-impact activity prior to racing. Medicating chronically inflamed joints prior to prolonged layoffs may be beneficial in assisting the resolution of synovitis and capsulitis. Aseptic technique during intra-articular injections is essential and excessive ice therapy or the use of liniments or blisters should be avoided because the resultant dermatitis may compromise a suitable injection site (Fig. 49.5).

Intermittent anti-inflammatory therapy can be used in combination with long-term administration of disease modifying osteoarthritic agents such as polysulfated glycosaminoglycans (PSGAGs), pentosan polysulfate, glucosamine and chondroitin sulfate. Although definitive evidence with regard to their cost benefits, ideal dosing and efficacy is still lacking, subjective evaluation indicates that continual short interval (5–7 days intramuscular and daily oral agents) dosing is optimal for Thoroughbreds with osteoarthritis while in training.

Surgical management of joint injury and disease

The primary aim of surgery is to return the joint to non-painful function and limit the formation and progression of osteoarthritis. Surgery is occasionally indicated in order to salvage an animal for breeding or retirement. Before deciding if surgery is indicated, careful consideration must be given to the prognosis, expected rehabilitation time and economics. In many cases surgery assists the diagnostic process and may more accurately determine the prognosis and post-surgical management. Horses occasionally perform successfully with intra-articular lesions that may be addressed surgically, and weighing up the long-term benefits of surgery against the potential short-term economic losses can be difficult, particularly during the high earning stages of horses' careers. A good working relationship with a surgeon experienced in treating joint disease in Thoroughbred race horses will facilitate the decision-making process. Importantly only horses not at risk of breakdown should continue to train and should be monitored for evidence of progression.

Osteoarthritis

Early osteoarthritis can be managed with medical therapy and rest when indicated. The progression of osteoarthritis is often difficult to predict accurately. Despite this, initial and subsequent joint radiography provides valuable assessment of disease progression, in conjunction with regular lameness examinations and assessment of response to therapy. Complete rest for long periods in older horses with osteoarthritis can often be contraindicated with regard to racing longevity, since retraining often places demands on the arthritic joints that they cannot accommodate. Alternatively, maintaining such horses in lower-intensity modified training regimens which include swimming, longer intervals between high speed work combined with intermittent anti-inflammatory therapy, physical therapy and continual use of disease-modifying osteoarthritis agents may assist in prolonging their racing longevity. Advancing osteoarthritis requires continual monitoring, particularly for evidence of subchondral bone injury that may propagate to complete fracture. Eventually a stage is reached where the level of osteoarthritis becomes incompatible with safe and economic training and racing, and in these cases clinical findings combined with appropriate diagnostics support advice for retirement.

Bone-related injuries and diseases

Non-adaptive exercise-induced bone remodeling and incomplete stress fractures are reported in a variety of bones

including the third metacarpal bone, tibia, humerus, pelvis, sacrum, lumbar vertebrae and scapula. These manifestations of bone fatigue have been postulated in some instances as precursors to complete spontaneous fractures.[24,32,36,74–79] Similarly, osteochondral fractures have been proposed to be associated with cyclic loading and bone adaptation responses.[80]

Training modifications

Training protocols appear to directly influence bone-related injuries and disease. Changes in training intensity induce bone adaptation via altered forces and fatigue damage, with initial bone weakening due to increased bone porosity.[81] The decreased mineral content is thought to impact significantly on bone strength around 3 weeks after an alteration in training,[82,83] and it may take up to 3–4 months or longer to replace the lost bone, during which time the bone is weaker.[82–84] It is the bone adaptation process itself that appears the more important component of bone weakening, rather than the fatigue damage.[85] Two-year-old horses appear to be at greatest risk of adaptive bone pathology as their skeleton models and remodels in response to race training. The lowest bone mineral density in these horses occurs at 2–3 months after entering race training.[84,86] Significant decreases in bone mineral content detrimental to bone strength occur during periods of inactivity,[87] and are likely to result from a decrease in bone strains leading to extensive bone remodeling and increased porosity.[81] A greater risk of bone fatigue related injuries has been associated with return to work after periods of inactivity or lay-up.[79,88]

Since horses training at slow speeds adapt their bones to that particular speed, the introduction of higher speed pace work ('breezing') results in altered loads and bending forces requiring a further bone adaptation response, making bone susceptible to fatigue injury during this adaptation period.[81,89] A study examining gait and speed as risk factors for fatigue injury of the third metacarpal bone in 2-year-old Thoroughbred race horses recommended training modifications to reduce the incidence of 'bucked shins' consisting of reducing the extent of the low-speed long-distance work and increasing the frequency of the short-interval high-speed work.[90] Therefore, allocating less training time to long-distance slow exercise and the introduction of earlier more frequent short-distance fast exercise affords bone more time to adapt to race speeds.[79] Problems that may be encountered include the inability to control young poorly educated horses, and the uninvestigated effects of this training protocol on other structures, particularly tendons and ligaments. The most appropriate training regimens to obtain optimal remodeling and modeling responses of bone that will best accommodate forces associated with racing and training are yet to be determined.[91]

Dorsal metacarpal disease

Dorsal metacarpal disease manifesting as 'bucked or sore shins' is one of the most common causes of lost training days in 2-year-old Thoroughbreds; one survey reported it as affecting 70% of Thoroughbreds, with increased risk of third metacarpal stress fracture within 6–12 months.[81,92,93] Deciding if affected horses can continue training will depend on the severity of the condition as determined by regular palpation of shins, lameness examination and radiographic evaluation. Early identification of disease through palpation and detection of subtle lameness allows early treatment and the majority of horses to remain in training. Treatment should include immediate modifications to the training program and aggressive anti-inflammatory therapy. Monitoring the horse's gait during exercise and the level of pain on palpation of shins are useful in assessing the response to therapy. Swimming can be used to augment fitness, with the track regimen consisting of trotting and shorter distances of pace work regularly (for example 1–2 furlongs every other day). Horses with more advanced dorsal metacarpal disease have marked pain, plus evidence of swelling or cortical lucency identified radiographically, and should be removed from training on economic grounds for at least 6 weeks. They should be returned to training with suitable modifications to the training regimen as discussed above for horses with adaptive bone pathology.

Third metacarpal dorsal cortical stress fractures

Conservative management typically requires a minimum of 7 months' rest with a variable degree of success in achieving healing.[94,95] Surgery offers an advantage and the combination of osteostixis and screw fixation is reported to be more reliable than osteostixis alone, with healing and screw removal at 2 months after surgery, followed by resumption of training within 1 month of screw removal.[54,55]

Stress fractures at other sites

Stress fractures may be seen at a variety of sites (third metacarpal bone, tibia, humerus, pelvis, sacrum, lumbar vertebrae and scapula) and periods of reported rest for these fractures vary; there is no clear consensus on an appropriate duration of stress fracture rehabilitation.[96] Provided the stress fracture is not at risk of propagation to a complete fracture, general recommendations include: stall rest with hand walking (the horse should be offered approximately 10 minutes hand walking twice daily, doubling weekly) until the horse is sound at the trot in a straight line. The horse should be evaluated for lameness after 2–4 weeks, first at the walk and if appropriate at the trot. Once sound at the trot, access to a small yard (20 feet square) for a further month is followed by a month of pasture release prior to return to training. A more rapid rehabilitation plan can be instituted under direct veterinary supervision with gradual introduction to low level trot work after the month of stall rest and walking. However, such a program requires regular lameness and radiographic evaluation to monitor healing and possibly follow-up scintigraphic evaluation. This protocol can minimize time of maximal exercise restriction but return to high-speed training should be delayed for at least 3 months from time of stress

fracture diagnosis. Stress reactions and non-adaptive exercise-induced bone remodeling can also be managed with a similar approach.

Sclerotic subchondral bone lesions

Subchondral bone sclerosis and associated osteoarthritis occurs primarily in the carpus associated with the third carpal bone and the fetlock joint in the palmar/plantar metacarpal/metatarsal condyles and proximal sesamoid bones.[74,78,97] The pathogenesis of these injuries is poorly understood but involves disease of both the articular cartilage and subchondral bone.[80,97] Subchondral epiphyseal bone changes have been identified as potential precursors to some slab fractures of third carpal bone and condylar fractures of the cannon bone.[74,78,98]

The diagnosis and management of subchondral bone diseases is problematic and both joint and bone disease issues should be addressed. Often radiographic findings are equivocal and in these cases scintigraphy can be a useful aid in diagnosis. Determining the degree of subchondral bone injury and collapse on radiographs alone can be difficult; computed tomography and magnetic resonance imaging (MRI) are likely to enhance identification and management of subchondral bone diseases. Typically if subchondral bone damage is evident, prolonged periods of rest are usually required and surgery may be indicated, particularly if disease is involving the carpus. Many advanced subchondral bone injuries carry a guarded prognosis for future athletic performance, due to lameness.

Breakdown injury

Major breakdown injuries in racing Thoroughbreds include severe bone and ligament injuries involving the fetlock (traumatic disruption of suspensory apparatus, condylar fractures and proximal phalanx fractures) and carpus (distal or proximal row slab fractures with unstable or collapsed carpus) as well as major fractures of the humerus, tibia and pelvis. Appropriate assessment and use of coaptation for transport of major musculoskeletal injuries has been well described elsewhere and is important knowledge for any racetrack veterinarian.[99] Appropriate first-aid measures prevent further osseous and cartilage injury, maintain skin cover and prevent further damage to blood supply that may ultimately determine the ability to salvage the animal. Removal of these patients from the racetrack environment allows appropriate diagnostics, communications and decision-making to take place.

Tendon- and ligament-related injuries and diseases

The combination of training and aging may have a progressive detrimental effect on tendon strength. Micro-trauma due to accumulated submaximal strains results in alterations in tendon structure that decrease its ability to cope with cyclic strains and may ultimately result in injury.[100,101] There may be an 'optimal window' during growth and training for the development of tendon extracellular matrix that would best prepare the tendon for cyclic damage associated with race training. This timing and activity level is yet to be determined and excessive exercise at a young age may result in damage.[102] Prevention and early detection of lesions may become reality with further research into marker molecules that could allow identification of subclinical tendinitis.[103]

Tendon injuries

Superficial digital flexor tendon (SDFT) injuries are a substantial cause of wastage with a reported incidence in racing Thoroughbreds of 8–43%, and are more prevalent in horses older than 2 years of age.[22,42,104–108] Astute observations of changes in flexor tendon profile, careful palpation and ultrasonography are the essential tools for the identification, assessment of severity, prognostication and monitoring of healing in tendon injuries.[104,105,109–111]

Clinically apparent swelling, heat and pain on palpation indicate the need for careful ultrasonographic evaluation. Re-evaluation of a tendon at 1–3 weeks after injury may provide a more accurate indication of lesion severity and is particularly important when a lesion is suspected but not well defined on the initial examination.[104,105,109,110] Peritendinous inflammation ('bandage bow') is typified by apparent tendon swelling with less intense pain on palpation when compared with tendinitis. Ultrasound conformation of the diagnosis is required and treatment consists of aggressive anti-inflammatory therapy and cessation of pace work until all inflammation has resolved.[111,112] Slow resolution of inflammation or residual thickening should prompt follow-up ultrasonographic examination.

Ultrasonographic monitoring of healing allows alterations to be made in the rehabilitation program and examinations are advised prior to any major increase in the level of exercise intensity.[110,113,114] Clinical reassessment during rehabilitation is also important and changes should prompt ultrasonography. Blisters are not advised since they affect both the clinical and ultrasonographic assessment of a tendon and have no documented benefits.[107,115] The prognosis for SDFT injuries in the Thoroughbred is reported to range from 20 to 60% of horses returning to successful racing and up to 80% sustaining a reinjury.[105,116–119] Continuing to train with a mild lesion in a Thoroughbred race horse results in progression to a more severe lesion. This is seldom economically or clinically successful and carries the risk of a catastrophic breakdown.

Controlled exercise rehabilitation programs may improve results, with 71% of horses treated with a graded exercise program racing at least once compared with 25% of horses subjected to pasture rest alone.[120] The decision to embark on a rehabilitiation program should take economics into consideration, particularly the costs and benefits.[110,113] Regardless of the level of rehabilitation undertaken, initial management involves cessation of training and aggressive anti-inflammatory therapy. The value of additional medical management procedures including intralesional or

peritendinous sodium hyaluronate, polysulfated glycosaminoglycans and beta-aminoproprionitrile furmarate has not been well defined.[106,107] Surgical intervention has been suggested to improve prognosis with tendon splitting in the acute phase often combined with superior check ligament desmotomy.[121,122] Superior check ligament desmotomy has a reported prognosis of 68–88% for returning horses to racing, with 52–56% racing at least five times after surgery.[108,123,124] These results are similar to reports of conservative therapy alone.[108,118] Furthermore, superior check desmotomy may increase the risk of suspensory ligament injury.[108] Regardless of additional therapies the total time required prior to reintroduction to race training is 8–12 months; a worse prognosis is documented for horses rested for less than 6 months.[105,110,113]

Injuries of the suspensory ligament and its insertions

Training appears to have a strengthening effect on the suspensory apparatus with untrained horses more likely to experience ligament failure at smaller loads, whereas trained horses fail at greater loads with fracture of the proximal sesamoid bones.[125] The diagnostic approach is similar to that for tendon lesions although prognostication based on a lesion's ultrasonographic appearance is more difficult. Inferior ultrasonographic image quality compared with that obtained when imaging superficial digital flexor tendons and the presence of muscle fibers complicates both diagnosis and assessment of healing, particularly in the high suspensory area.[110,126] The prognosis for return to racing after suspensory desmitis has been reported to be relatively poor.[127]

Suspensory branch desmitis and sesamoiditis

Suspensory branch desmitis appears most prevalent in younger horses and particularly 2-year-olds early in their career.[128–131] Desmitis of the suspensory branches may manifest with concurrent sesamoiditis, sesamoid fractures or splint bone lesions.[128,131] Sesamoiditis on the other hand is often identified prior to training and a range of severity exists and may progress with training.[129] Management of sesamoiditis is difficult and can be frustrating as recurrence with resumption of higher intensity exercise is common. Initial therapy consists of local application of cold therapy, pressure bandaging and administration of systemic anti-inflammatory agents. Long-term rest up to 6 months is important to allow bone maturity and prevent fracture. Despite the benefits of long-term rest the radiographic appearance of the lesions seldom makes an appreciable improvement. The long-term effect on the horse's career is not clear. However, it appears that the severity and presence of additional pathology such as enthesiophytes impact on both racing longevity and earning potential.[132,133]

Suspensory branch and body

Horses developing small lesions of the suspensory branch early in training often only require 4–6 months of rest and have a fair to good prognosis. In contrast, lesions in older horses, more advanced lesions, or those slow to resolve ultrasonographically, have only a poor to fair prognosis and require prolonged periods of rest up to 12 months. A higher incidence of recurrence is seen in these horses, the desmitis behaving similarly to that described in show and dressage horses.[134] Rehabilitation is the same as for tendons, with a graded exercise program and ultrasonographic monitoring of healing combined with attention to foot balance, particularly avoiding excessive heel length. There are anecdotal reports of horses with mild lesions remaining in training and racing, particularly if speed work is limited to race starts only. However, there is a risk of progressive damage or complete failure.[134]

Lesions of the suspensory body are dealt with using similar methods as discussed for tendon injuries. The presence of concurrent splint bone lesions should be ruled out. Typically, management and the prognosis for return to racing is determined by the lesion severity and assessment of the healing response. At least 8–12 months is usually necessary prior to returning to training.

Proximal suspensory and its attachment

Lameness associated with the proximal suspensory ligament and its attachment is relatively common in Thoroughbred race horses.[135] Diagnosis can be difficult because of the variety of ligament or bone lesions seen separately or together, with a wide range of clinical severity.[136] In addition, the intimate association of the carpometacarpal joint and proximal suspensory ligament limits the specificity of diagnostic anesthesia to identify lameness arising from the proximal suspensory area and the carpometacarpal and middle carpal joints.[131,134,137] Clinical differentiation of high suspensory pain and third carpal bone disease can be difficult.[134]

Horses identified with primary ligament lesions are managed similarly to tendon injuries. Those with primary bone damage may have non-adaptive bone remodeling 'stress reaction', longitudinal or avulsion fracture of the palmar cortex of the third metacarpal.[138–140] Management of bone injuries has been discussed and typically at least 3–6 months is required depending on the specific lesion.

Nuclear scintigraphy may be particularly useful in assessing the relative contribution of bone and ligament pathology causing lameness. Mild lameness of short duration often responds to medical management. A combination of NSAIDs, infiltration of the proximal suspensory area with a corticosteroid, correction of dorsopalmar foot balance and modifications to training mimicking that advised for horses with bone remodeling problems, have provided success in treating approximately half these cases. Horses are limited to a low-intensity workload until the lameness has resolved, typically within a 5-day period. Persistent lameness indicates the need for further diagnostics. Extracorporeal shock wave therapy may be useful for treatment of proximal suspensory ligament injury as well as having potential for treatment of other tendon, ligament or insertional injuries.[141,142]

Foot-related injuries and shoeing

The foot is a common site of lameness and poor foot conformation is a common Thoroughbred trait, particularly underrun heels and long toes that may predispose to injury.[3,6,30,143,144] Foot balance in the dorsopalmar or plantar plane appears important. Excessive heel length or wedging and the resultant high hoof angles preferentially load the suspensory ligament and SDFT predisposing these structures to injury.[145–148] Suspensory apparatus failure has been associated with underrun heels (difference in toe and heel angles) and low toe angles have been associated with an increased risk of catastrophic injury. Decreasing the difference between toe and heel angle and increasing the toe angle alone may reduce injury risk.[29,149,150] Toe grabs have been associated with an increased incidence of injury.[30,150]

Overreach injuries are typically high impact, with deep tissue damage usually greater than is initially apparent. Rarely do they initially cause a significant lameness unless there is major tissue trauma. These injuries can become a site of lamina detachment and if overlooked result in pocketing of dirt and subsequent infection, manifesting as lameness 3–7 days after the initial injury (Fig. 49.6). Prevention of this sequela requires excision of the separated tissue back to lamina attachment combined with bandaging while avoiding sand and dirt from gaining entry to the lamina–wall interface. Repetitively injured horses can be managed with 'bell boots' and shoeing changes.

Corns are a common cause of lameness and appear to be more commonly associated with flat sole, low heel and long toe conformations increasing weight bearing in the caudal aspect of the foot.[151] Addressing foot balance combined with light paring of sole over the bruising and application of a seated-out heart-bar shoe combined with 2–3 days of low-intensity exercise are generally adequate to resolve lameness. In some cases it may be necessary to 'float' the affected heel off the shoe. Hoof treatments are initially aimed at reducing inflammation through magnesium sulfate foot soaking and poulticing coupled with anti-inflammatory agents. These modifications combined with low-impact work including walk, trot, swimming are undertaken until there is resolution of inflammation and lameness. Use of heart-bar or egg-bar shoes and correction of foot balance by removal of excess toe provides more support for the caudal third of the foot. Time is necessary for dissipation of interstitial fluid and re-cornification of the bruised solar tissue. Once the pain is resolved, hardening of the new sole can be achieved by applying diluted iodine solution (2%) or formalin (10%).

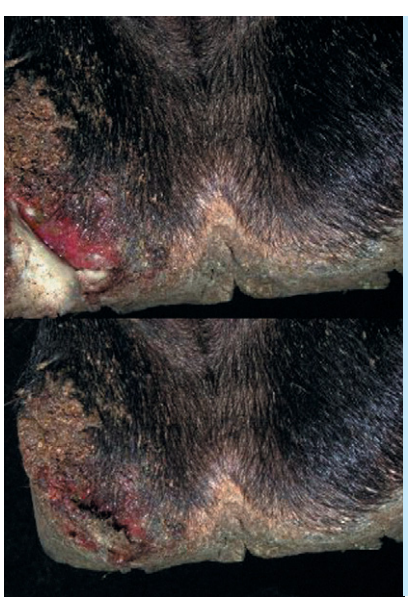

Fig. 49.6 Overreach injury to the lateral heel of a left forelimb above. The picture below demonstrates the lamina detachment that can be present with these injuries.

Quarter cracks are manifestations of shear forces within the hoof wall and laminae. Some cases may be associated with hoof imbalance and excessive wall length in the affected quarter.[152] Cracks may be identified prior to lameness, providing an opportunity to prevent crack propagation and lameness by corrective trimming/shoeing and modified exercise regimens. Depending on size, stability and the extent of propagation many smaller stable cracks can be debrided and patched. This combined with rasping of the quarter, attention to foot balance and application of a bar shoe all assist in stabilizing the crack.[153] Unfortunately many cracks in Thoroughbreds involve the heel or caudal aspect of the quarter and are not readily amenable to repair. These caudal cracks, and cracks with coronary band involvement often require stripping of the hoof wall to allow regrowth of stable horn tissue.

Pedal osteitis, pedal bone 'rim' fractures, sole bruises and other injuries secondary to solar concussion are often accentuated by exercise on sand tracks. Management includes sole pads, wide web seated-out shoes and egg-bar shoes. Discrete sole lesions can be covered temporarily with a small welded plate to protect the area, while still allowing access of topical treatment.

High nails or 'nail presses' can be overlooked during lameness examinations. Nail and/or hematoma pressure may result in persistent lameness without evidence of infection. Evaluation of clinch heights and sequential application of hoof testers to each nail will facilitate their identification. If identified before the onset of infection, the nail can be removed and iodine solution flushed down the nail hole to disinfect and facilitate drying. If infected, soaking the foot in Epsom salts, poulticing and debridement are indicated.

Interference injuries

Interference injuries can result from one or a combination of factors including conformation, shoeing, soundness and immaturity (Fig. 49.7). Identifying the cause of the interference is necessary in order to develop a plan aimed at resolving the problem. The presence of neurologic disease should be ruled out. If necessary, identification of the source of interference can be determined by applying chalk to the affected area to identify the limb and area causing the interference. Resolution requires ideal foot balance and in younger horses time is needed to learn and achieve balance on the straight before high-speed work around turns is introduced. Protective bandaging and bell boots minimize trauma while

Fig. 49.7
Multiple interference injuries on the medial aspect of this Thoroughbred's left hock. This type of interference is commonly referred to as 'hock hitting' or 'speedy cutting'.

attempts are made to resolve a problem. Lighter shoes, partial shoes ('tips') and 'safing' (rounding) of edges resolve many problems.

'Going down on bumpers' or 'running down behind' describes excoriation typically of the plantar fetlock in the hindlimbs and occasionally in the forelimbs (Fig. 49.8). This can be multifactorial and may be associated with fatigue, shoeing, or compensation for lameness. At times this may be severe and result in the removal of full thickness skin cover. If no lameness problems are identified and if the problem continues with a temporary decreased intensity of training, the application of extended heel- or egg-bar shoes and correction of dorsoplantar foot balance can assist resolution. Recurrently injured horses often require taping of the fetlocks with protective padding such as orthopedic felt or other padding. All interference injuries should be treated as contaminated wounds with potential for infection.

Fig. 49.8
An example of 'running down behind' or 'going down on the bumpers' chronic excoriation seen here on the plantar aspect of the right hind fetlock in this Thoroughbred race horse. Note also the slightly wedge heeled shoe that has been applied in an attempt to reduce the ongoing trauma to the area.

Muscle-related injuries and disease

Recurrent exertional rhabdomyolysis (RER)

Most commonly seen in 2-year-old fillies RER is reported to affect approximately 5% of racing Thoroughbreds.[154,155] The quantitative correlation between muscle enzymes and severity of clinical signs is poor and elevation of muscle enzymes after exercise does not always indicate clinical rhabdomyolysis; conversely, clinically affected horses may have delayed peaks and more prolonged elevations of enzyme activity in serum.[154,156] Horses exhibiting elevated muscle enzymes and minimal clinical signs warrant further investigation and management changes, since the effect on ultimate performance is unknown.[156] Serial monitoring of muscle enzymes is a reasonable tool to determine responses to management changes and therapy. Cases responding poorly warrant further diagnostic evaluation.[156]

Management issues that can be manipulated include diet, exercise schedules and potential stressors.[157,158] Minimizing stressors by maintaining a regular daily work schedule and quieter stall location remote from major traffic areas in the stable are recommended. Benefit can be gained from different exercise prior to track work, including extensive walking, swimming or 'ponying'. Tranquilization can also assist, with low doses of acepromazine (5–10 mg intramuscularly 60 min prior to work) effective in some cases. Reduction of the amounts of digestible carbohydrate in the diet can be achieved by reduction of the quantity of grain or substitution of a less digestible carbohydrate source replacing oats with corn,[159] while adding fat to maintain dietary calories.[157] Dietary change may be more important in modulating the degree of nervousness and excitability rather than playing a direct role in the pathogenesis of the disease.[158] While the use of progestagens is often advocated, no association in elevation of muscle enzymes was seen in fillies associated with their estrous cycle, controlling estrus behavior may still act to minimize stress levels in some individuals.[154] Electrolyte, and vitamin E and selenium supplementation may also be of benefit.[156]

Avoiding 'days off' and substituting different forms of exercise on days that horses are not worked, combined with reduction or complete removal of grain from the diet on these rest days is indicated. A slow introduction of high-intensity work coupled with a gradual increase in carbohydrates which follows increased workloads limits subclinical elevations in muscle enzymes. Cases responding poorly to other management changes may respond to administration of muscle relaxants such as methocarbamol, dantrolene and phenytoin.[156,160] Use of oral branch chain amino acid preparations prior to exercise has been reported anecdotally to reduce the magnitude of muscle enzyme elevations.

Treatment of acute cases includes immediate cessation of exercise and administration of polyionic fluids (either intravenous or oral depending on severity) to achieve rehydration and promote diuresis, combined with administration of NSAIDs (flunixin meglumine or phenylbutazone). Acepromazine appears efficacious in calming these horses and may facilitate resolution of RER. Occasionally extremely

uncomfortable horses may require α-2 sedatives and opiates for analgesia.

Muscle strains and tears

Primary muscle injuries are difficult to verify as a source of lameness and usually require exclusion of skeletal lesions. Swelling, asymmetry and pain on deep palpation may be apparent in some cases. Measurement of muscle enzymes is of limited value as elevated enzyme levels are generally not a consistent finding with isolated muscle tears. Lameness is typically the most obvious at the walk and swing phase of the trot. Muscles commonly identified include semimembranosus, semitendinosus and brachiocephalicus. Accompanying bone lesions may be present and are seen most commonly at the tuber ischii with tears of the semimembranosus and semitendinosus. Muscle tears generally require a rest period of 2–3 weeks to resolve if no bony involvement is present,[157] but brachiocephalicus tears require 3–6 weeks of rest.

Back and wither injuries

Withers are a common site of injury due to saddle rubs or falls. These are susceptible to rubbing, hematoma formation and infection. They are best managed by avoiding saddle contact until completely healed and exercise may continue with use of military saddles or swimming and 'ponying'. Padding in most cases is inadequate due to the propensity to rub.

Diagnosis of back injuries and related pain is often difficult. Typically pain is muscular in origin and may be associated with an underlying lameness. The presence of bony pathology such as vertebral stress fractures and overriding spinous processes may be demonstrated with radiology or nuclear scintigraphy.[161,162] Treatment is directed at identifying the underlying cause coupled with temporary cessation of pace work, anti-inflammatories and local therapy.[163]

Infections of the musculoskeletal system

High-intensity exercise, close horse-to-horse and horse-to-handler interaction, confined surroundings and veterinary intervention contribute to Thoroughbred race horses commonly experiencing a variety of musculoskeletal infections. Cellulitis is common and generally seen in the lower limb. Occasionally idiopathic peri-articular tarsal infections are seen.[164] Traumatic injury leading to osseous infection is common. Although rare, clinicians should be observant for signs of septic arthritis given the frequency of intra-articular therapy and the repercussions of this complication. There are rare reports of idiopathic synovial infections of horses in training[165] (Sykes and Lumsden, unpublished data).

Successful treatment is facilitated by rapid identification and institution of appropriate antimicrobial therapy, adequate wound therapy, clean bandaging and avoiding areas of contamination, such as sand rolls, water activities, and the hands of the stable staff. Antibiotic selection should take into consideration the high concentrations of horses interacting in a common environ coupled with intense human contact and frequent use of antimicrobials. It is likely that individual racetrack environments will establish predominant pathogens with specific sensitivities akin to a hospital environment.

Respiratory diseases

Lower respiratory disease

Respiratory disease is a major cause of wastage for horses in race training, and lower respiratory diseases in particular appear to contribute most significantly.[166–169] An appropriate diagnostic workup consisting of a clinical examination and use of clinical pathology (hematology, transtracheal aspirate (TTA) and bronchoalveolar lavage (BAL)), endoscopy, ultrasonography and radiography, when indicated to allow appropriate management and prognostication.[170]

Coughing horses and inflammatory airway disease (IAD)

Horses suffering from IAD typically present as otherwise apparently healthy young horses usually 2 or 3 years old that have been in the stable environment for a couple of weeks or longer and present primarily for 'coughing'.[166–168,171–173] The presence of a nasal discharge may be variable. Endoscopic evaluation typically reveals a mucopurulent tracheal exudate containing elevated numbers of neutrophils. Excessive coughing is stimulated by laryngotracheal palpation, auscultation with the aid of a rebreathing bag or passing an endoscope into trachea.[166–168,171–173]

Historically, viral respiratory infections have been implicated as the major cause of lower respiratory disease in young race horses.[174,175] Recent studies suggest that a variety of pathogens including bacteria, mycoplasma and non-infectious agents contribute to IAD.[176–180] The role that bacteria isolated from transtracheal aspirates play in this syndrome is unclear. Their quantity, location (whether extra- or intracellular) and species (*Streptococcus*, *Pasteurella* and *Bordetella* spp.) have all been considered as characteristic of IAD.[173] The role of antibiotics in treating IAD has yet to be established.

The environment appears to be an important component of IAD, triggering allergic or non-allergic airway inflammation.[171,181,182] Air quality improvements can be made by minimizing feed dust with low dust or wet feeds, soaking hay and feeding on the ground. Housing changes including improving ventilation by use of yards or pens and reviewing choice of bedding avoiding straw and dusty beddings in favor of wood shavings or clean sand.[183] Minimizing noxious gases by regular stall cleaning and minimizing dust production by avoiding sweeping and mechanical 'blowers' in favor of hosing also improve air quality. Quarantine of cases may reduce risks if an infectious cause is suspected because of the sudden onset of multiple cases.

Pharmacologic therapy for IAD includes systemic or inhaled mucolytics, bronchodilators and corticosteroids. The presence of mast cells in BAL fluid may indicate the presence of immune-mediated airway disease. In such cases use of a short course of systemic corticosteroids and an inhaled mast cell stabilizer (sodium cromoglycolate) may be indicated.[182,184,185]

Exercise-induced pulmonary hemorrhage (EIPH)

Exercise-induced pulmonary hemorrhage (EIPH) is thought to occur due to high transmural alveolar capillary pressures,[186,187] and numerous factors may contribute to the severity of hemorrhage including exercise intensity, distance, age, upper respiratory obstruction, heterogeneous ventilation, hemorrheological factors, small airway disease and lower airway inflammation.[188–193]

The reported prevalence of EIPH depends on the criteria used, with epistaxis occurring in approximately 1–2% of race starters.[188,194] After high-intensity exercise (30–90 min) there is endoscopic evidence of EIPH in approximately 75% of horses.[188,189] Bronchoalveolar lavage (BAL) is a more sensitive means of documenting EIPH and has demonstrated its presence in nearly all racing Thoroughbreds. Furthermore, BAL may better correlate with severity and chronicity.[195]

Identification and appropriate treatment of IAD combined with the use of bronchodilators and furosemide (frusemide) prior to exercise are still the popular mainstays of EIPH therapy. Furosemide is administered to the majority of Thoroughbred race horses prior to racing in the USA and Canada, although efficacy in reducing EIPH has not been definitively demonstrated.[196,197] Even in jurisdictions where furosemide is not allowed on race day it can be incorporated in the training program and used prior to high-intensity training. The furosemide dosage (150–250 mg) is typically given intravenously or intramuscularly 2–4 hours prior to work.[197–199] One study suggested administration 30 minutes prior to exercise was superior to administration 240 minutes prior to exercise.[200]

The association with the high work intensity makes training modifications difficult; slower longer duration work may decrease severity of EIPH, since the disease has been documented with greater incidence in racing distances less than a mile.[193] Blood in the airway incites an inflammatory response and complete erythrophagocytosis takes up to 2 weeks.[201,202] Management should be aimed at minimizing high-intensity exercise during the inflammatory period, and treating airway inflammation. Response to therapy can be assessed with a follow-up BAL. Recently investigation of the FLAIR nasal strip (CNS Inc, Minneapolis, MN) has shown potential benefits in upper airway mechanics and a reduction of EIPH. However, controversy and conflicting results exist with its use.[203–206]

Upper respiratory diseases

Upper respiratory diseases commonly manifest as poor performance, and in most cases are associated with abnormal upper respiratory noise. Upper airway abnormalities have a prevalence of approximately 10% in racing populations.[207,208]

Detailed investigation of an upper respiratory abnormality should include a thorough accurate history aimed at characterizing the noise and determining if there is an effect on performance. Track visits or the use of 'sound spectrum analysis' assist noise characterization.[209] Diligent and systematic clinical examination is indicated particularly with respect to palpation of the larynx, nasal septum, jugular veins and assessment of facial symmetry, previous surgical scars and airflow from each nostril. Resting upper airway endoscopic examination should document nasal passages, nasopharynx, trachea and guttural pouches as well as dynamic function by induced swallowing response and nasal occlusion. Further diagnostics such as high-speed treadmill endoscopy, radiography and oropharyngeal examination may be indicated.

Left laryngeal hemiplegia (LLHP)

Once diagnosed the prognosis and suitability for surgery should be determined. Potential diagnostic oversights include previous surgery, arytenoid chondritis, fourth branchial arch defects, or the presence of another upper airway problem in conjunction with the LLHP. Presence of these abnormalities will negatively impact on the surgical prognosis. The level of arytenoid function should be determined and horses with grade III/IV hemiparesis, or those likely to be suffering from an additional upper respiratory problem, warrant endoscopic examination at high speed on a treadmill.[210,211] If arytenoid abduction at maximal exercise is judged better than would be obtained with surgery, continued training and racing with regular monitoring may be indicated; surgery may be required if there is progressive loss of function. This assessment is important since horses with grade III/IV movements may be less successful candidates for a laryngoplasty.[211] Prior to embarking on surgery, an assessment of the horse's athletic ability and evaluation of other performance-limiting conditions may be better assessed by continued training and racing over 5–6 furlongs if the degree of airway compromise permits. Prognosis for laryngoplasty has been reported over a wide range from 48% to 85% for successful outcome with horses able to return to training within 2 months.[212,213] Complications of surgery, such as coughing and aspiration, can be managed by dampening feed at ground level, avoiding feeding prior to work and long-term treatment with mucolytics, antibiotics and mucociliary transport mechanism stimulants.

Neuromuscular pedicle grafting has been reported to provide a similar prognosis. However, it appears best applied to horses identified with hemiparesis and younger than 2 years old due to the prolonged rehabilitation time (6–12 months). Laryngoplasty can be performed after neuromuscular pedicle grafting if reinnervation is unsuccessful.[214,215] Other management options include short-distance racing with the expected decrease in performance – these horses are usually only competitive over less than 6 furlongs. Furthermore, permanent tracheostomy or

temporary tracheotomy are both alternatives if sanctioned by racing authorities.

Intermittent dorsal displacement of the soft palate (IDDSP)

Diagnosis is based on a combination of appropriate history and endoscopic examination, subjective judgment of laryngopalatal instability and/or presence of soft palate ulceration.[216] Evidence of epiglottic flaccidity, dysfunction or hypoplasia may warrant further diagnostics including radiography and treadmill endoscopy. Ensuring IDDSP is a repeatable phenomenon is essential before embarking on exhaustive diagnostics and management changes.

Medical management may include continued training as the condition may resolve with increased fitness and weight loss, or rider and gear changes. Inexperienced riders can often encourage the likelihood of displacement by taking too heavy a hold on the reins. Gear changes including tongue ties and figure-8 nosebands used individually or combined can be effective. Medical management of upper airway inflammation (pharyngitis) may be beneficial when neuritis of the pharyngeal branch of the vagus nerve accompanies upper airway inflammation.[217] Anti-inflammatory therapy, both systemic and local pharyngeal spray, may benefit these horses.[218,219]

Immature horses should be given time to mature, as many resolve their tendency for IDDSP. When medical management fails surgery is indicated and a variety of procedures have been described.[216] The combined sternothyrohyoideus myectomy, tenectomy and staphylectomy appears to have gained most support as a surgical procedure. The procedure requires only a short time out of training, approximately 14 days with reintroduction back to fast work after approximately 3–4 weeks.[216] Epiglottic augmentation may assist horses with an apparently hypoplastic epiglottis in which the above surgery is unsuccessful; this procedure does require approximately 2–3 months out of training.[220] The prognosis for resolution of IDDSP is similar regardless of type of therapy pursued, with approximately 60% of horses improving.[216]

Arytenoid chondritis

Small mucosal lesions noted on the axial surface of arytenoids in the absence of arytenoid thickening are encountered infrequently and generally heal without complication. However, rarely these mucosal lesions have been seen to progress to chondropathy in yearlings (Kelly and Lumsden, unpublished data, 2001). Therefore, endoscopic monitoring of arytenoid mucosal lesions appears appropriate, and if indicated medical management consisting of cessation of high-intensity training, parenteral and topical antibiotics and anti-inflammatory agents.

Arytenoid chondropathy identified in the acute stages with only mild cartilage thickening may be managed with cessation of training and medical therapy. Periarytenoid inflammation with minimal cartilage involvement may be arrested medically and may allow continued training if mucosa is intact and abductor function and airway are judged as adequate. Cases with minimal cartilaginous distortion, granulation tissue on the axial surface and complete arytenoid cartilage abduction capability may be managed with a combination of medical therapy, surgical debridement of granulation tissue and draining tract and short-term rest.[221,222] Horses failing to respond to the above approaches or those with moderate to severe cartilage thickening are candidates for partial arytenoidectomy. This procedure is associated with a longer convelescence (3–4 months) and the reported success rate for horses returning to racing following partial arytenoidectomy is approximately 60%.[223] Despite this, a drop in class is anticipated, which may be minimized in horses racing over shorter distances and where residual cricoarytenoideus dorsalis muscle function exists.

Other upper respiratory problems

Other regularly recognized upper respiratory problems that can be managed with minimal lost training time and while the horse remains in the stable include uncomplicated epiglottic entrapment and subepiglottic cysts. Problems that often require 2–4 weeks out of training for surgery include alar fold flutter, axial deviation of aryepiglottic folds and atheromas. Pharyngeal collapse, fourth branchial arch defects, septal abnormalities and advanced sinus cysts limiting airflow carry a poor prognosis even with appropriate surgery if indicated.

Gastrointestinal diseases

Parasite prophylaxis programs are best coordinated with the spelling facilities. Mouth cuts in the commissures are often encountered and may be overlooked in a horse 'hanging' on a rein. Management involves ruling out a musculoskeletal problem and minimization of the trauma by using topical medical therapies, changing to a thicker or rubber bit, using cheekers or ponying without a bit until healed.

Gastric ulceration

Gastric ulceration in Thoroughbred race horses is reported to affect between 66 and 93% of the population, increasing to 80–100% for horses in advanced training or racing.[224–227] The disease most commonly manifests in racing Thoroughbreds as a decrease in feed intake, and conformation of ulceration is achieved via endoscopy. However, a poor correlation exists between clinical signs and the severity of ulceration.[228] Risk factors include the stable environment, periods of no feed intake and administration of NSAIDs and corticosteroids.[225,226,229,230]

Feed management in horses with gastric ulceration should focus on regular feeding with multiple daily meals and constant access to hay in order to avoid any prolonged periods that horses are not eating.[229] Pharmacologic anti-ulcer therapy (H2 blockers or proton pump inhibitors) in most

cases improve appetite within 1–2 weeks of commencing therapy. Failure to improve may indicate need for further investigation and management changes. Because the prevalence of ulceration is high in the racing Thoroughbred population and the severity of ulcers in our experience does not seem well correlated with clinical signs, a therapeutic trial may be indicated if gastric endoscopy is not available. Horses that respond to therapy should be maintained on therapy while in training. An oral formulation of ranitidine (L Begg, unpublished data, 2002) has been shown to be effective at healing ulcers while horses remain in training. Similarly other reports suggest only omeprazole is effective in achieving healing of ulcers while in training.[231]

Colic

Typically the incidence of colic is low in racing populations. Swimming activity is noted occasionally to cause colic in some individual horses; in this capacity it is typically seen within 2 hours of a swimming episode. The etiology of swimming-associated colic is undetermined but is typically associated with gaseous distension of the large bowel, which usually responds to medical therapy. Individuals that seem predisposed to recurrent bouts require swimming to be removed from their training schedule.

Diarrhea

Severe enterocolitis needs to be recognized and treated immediately with aggressive medical therapy. Prophylaxis involves avoiding unnecessary use of antimicrobials. Use of specific antimicrobial agents appears to be associated with an increased frequency of enterocolitis. Inclusion of metronidazole in therapy may be indicated if diarrhea is associated with antimicrobial use. Concerns of potential salmonellosis warrant some form of isolation of these cases.

Cardiovascular diseases

Cardiovascular diseases, with the exception of atrial fibrillation, are relatively rare in race horses. However, functional and anatomic cardiac abnormalities should not be overlooked as potential causes of poor performance.

Veins (septic and non-septic thrombophlebitis)

Typically associated with intravenous injections, thrombophlebitis can be very debilitating to a Thoroughbred race horse. Once a vein is inflamed it should be avoided as a site of venepuncture until inflammation is completely resolved. Cessation of high-intensity activity combined with hot packing and antimicrobials may hasten resolution. Progressive sepsis or thrombosis of both veins can become career threatening. The risks of thrombophlebitis may be decreased by use of a disposable 1.5 inch 18-gauge catheter instead of a needle for administration of all agents that may incite an inflammatory response if delivered perivascularly.

Cardiac abnormalities

The most common indication for investigation of cardiac function in racing Thoroughbreds is poor or decreased performance. The most commonly identified pathologic arrhythmia is atrial fibrillation.[232] Atrial fibrillation is typically associated with a marked reduction in high-speed performance and may be noted after a race or strenuous exercise. Atrial fibrillation may be paroxysmal, resolving within 24–48 hours of its identification after exercise, and diagnosis may be difficult if the arrhythmia resolves before it is documented.[233,234] Cases with persistent atrial fibrillation require treatment to achieve conversion; the presence of a preexisting cardiac lesion as a contributing factor should be ruled out as this will negatively impact long-term athletic prognosis.[232,234,235]

Heart murmurs have been documented in a large portion of the population of racing Thoroughbreds. One study identified murmurs in 81% of 846 Thoroughbred race horses and no association was found between racing performance and murmurs.[236] Investigation of cardiovascular function via Doppler echocardiography may be indicated if a murmur not typical of a functional systolic murmur is identified or in horses with poor performance not attributable to the respiratory or musculoskeletal systems. Documentation of apparently pathologic murmurs in young untrained horses warrants documentation and monitoring over time, since mitral and tricuspid regurgitant murmurs have been demonstrated to progress with training.[237]

CHAPTER 50

Veterinary aspects of racing and training Standardbred race horses

Kenneth W. Hinchcliff and Michael Hamlin

The breed and racing

Standardbred

Origins of the breed

The Standardbred racehorse, sometimes referred to as the American Trotter, originated in the USA and Canada in the early 1800s, with the breed society being formed in 1871.[1] Standardbred horses all trace their male lineage to Messenger, a Thoroughbred foaled in England in 1780 and exported to the USA, and to his four sons: George Wilkes, Dictator, Happy Medium, and Electioneer.[2] However, although mainly derived from Thoroughbred stock, Morgan and Hackneys also contributed to the Standardbred gene pool.[1] The Standardbred name derived from the requirement that, in order to be entered into the register of the new breed, Trotters had to complete a mile in a prescribed (standard) time.

Standardbreds are divided into two groups based on gait while racing, although a small number (~ 2%) use both gaits at some stage in their racing career.[3] There is a strong influence of gait on breeding in that most horses race at the gait used by their sire. Approximately 20% of offspring sired by Trotters register as pacers, whereas only 1% of offspring sired by pacers are registered as Trotters.[4] The extent of the genetic difference between Standardbred Trotters and pacers is as great or greater than that seen between some distinct horse breeds.[4]

Subsequent to its development in North America, Standardbreds and harness racing were exported to many countries. The Standardbred (American Trotter) is the origin of the Danish Trotter, Romanian Trotter, Swedish Standardbred Trotter, and the Russian Trotter.[1] The Coldblooded Trotter of parts of Scandinavia is not related to the Standardbred, being derived from the Dole Horse.[5] Trotters in Scandinavia derived approximately 94% of their genetic make-up from North American Standardbreds, with the remainder coming from French horses.[6] Presently, at least 24 countries, including countries in Scandinavia, Europe, and Australasia, have active organizations that promote Standardbred racing. The centers of Standardbred racing are the Midwest and East Coast of the USA, eastern Canada, Scandinavia, Australia, and New Zealand.

Although the Standardbred was derived from Thoroughbreds and in many respects resembles that breed, there are readily apparent differences. Stardardbreds are often not as tall as are Thoroughbreds, being 15 to 16 hands at the withers, are more heavily muscled and tend to be longer in the body. A prominent aspect of many Standardbreds is the presence of a Roman nose and large head. The predominant colors are bay, brown, and black, although gray horses do occur. Regional variations in the breed occur, with Finland having its own variation of the Standardbred.

Genetic aspects of performance

The population of Standardbred race horses has been subjected to strong selection pressure based on racing performance for most of the duration of the breed. The relative consistency of the type of racing, including use of the 1 mile (1640 m) race, has facilitated this selection. A consequence of this strong selection pressure, and other factors such as improved training methods, equipment and racing facilities, has been a progressive reduction in racetimes.[6] The decrease in race time has been well documented for Swedish Trotters (Fig. 50.1).[6] The reduction is exponential and appears to be approaching an asymptote, which is predicted to occur in 2015.[6]

Whereas it is well recognized that many non-genetic factors influence racing ability and, in particular, the speed over any one race, the ability to detect effects of selective breeding relies on identifying methods to compare horses to a common standard. The concept of the 'race pace' has

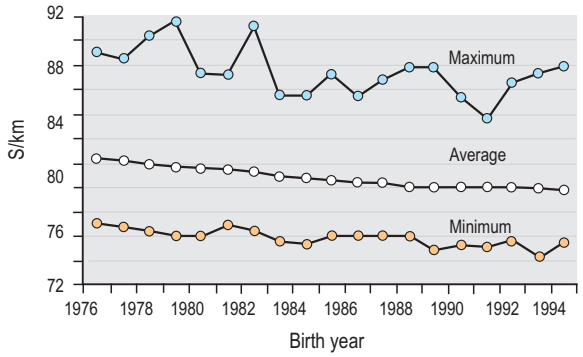

Fig. 50.1
Racing times of Swedish Standardbred trotters demonstrating progressive reduction in race time over an 18-year period. (Reproduced with permission from Arnason.[6])

therefore evolved. The 'pace' of a race is the speed of the winning horses. Performance of non-winning horses is then standardized by linear regression to this 'pace', thereby removing the influence of environmental factors.[7] Using this and similar approaches, heritability of speed was 0.31 ± 0.3 for pacers and 0.16 ± 0.09 for Trotters.[7] Heritability of speed was lower for 3 years than for 2-year-olds (0.25 ± 0.03 versus 0.44 ± 0.07, respectively) and may be due to culling.[7] Similarly, the heritability of earnings, average time and best time for Trotters was 0.20, 0.32, and 0.25, respectively.[8] The heritability of best time for a pacer was 0.23.[8]

Gait and racing

Gait

Standardbreds are raced both under saddle and pulling a light cart (sulky) upon which the driver sits. Racing under saddle is uncommon and mainly of novelty value. Almost all Standardbred racing involves the horse pulling a cart (sometimes referred to as a racebike or 'bike').

Standardbreds race using either of two gaits – trotting or pacing (Fig. 50.2). While within the one racing jurisdiction horses can use either gait, pacers always compete against pacers and Trotters always compete against Trotters. Pacing is the faster gait, with pacers completing 1 mile approximately 3.5 s faster than Trotters.[9]

Trotters move with a diagonal gait such that the left front and right rear legs are advanced simultaneously, as are then the right front and left rear. Trotters are either line-gaited or passing-gaited. Line-gaited Trotters move their ipsilateral limbs in the same sagittal plane whereas passing-gaited Trotters move their limbs in different sagittal planes. The limbs of passing-gaited horses pass each other during the gait whereas those of the line-gaited horse come together (Fig. 50.3). Pacers move in a lateral gait with the legs on one side of their body advancing simultaneously such that the left front and rear, and then the right front and rear, are advanced at the same time (see Fig. 50.2).

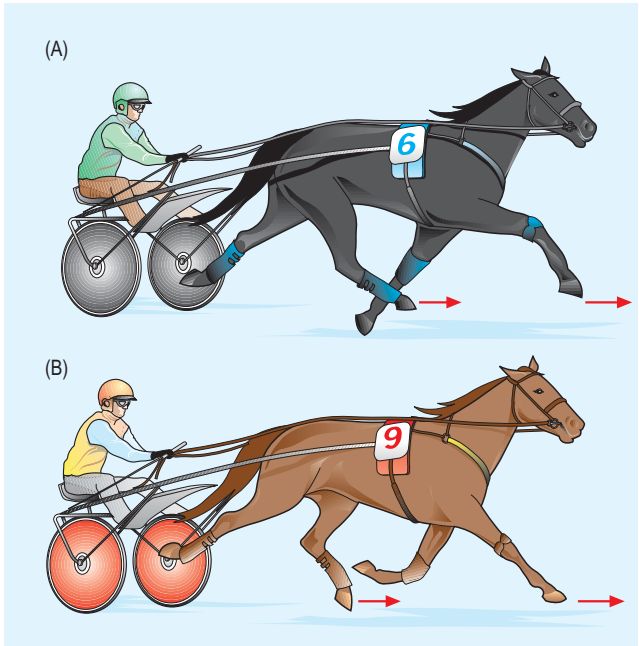

Fig. 50.2
(A) A horse pacing. (B) A horse trotting. Reproduced with permission of the United States Trotting Association.

Gait abnormalities – interference

Aspects of lameness in Standardbreds are discussed in detail later in this chapter. However, the gait of both Trotters and pacers predisposes them to problems arising from interference. Interference is the term used to describe a horse hitting one leg with the hoof of another leg, or, in the case of elbow interference, the same leg.

Interference in Trotters involves the hoof of the forelimb on one side striking parts of the ipsilateral hindlimb (Fig. 50.4). Scalping, speedy-cutting, shin-hitting, and hock

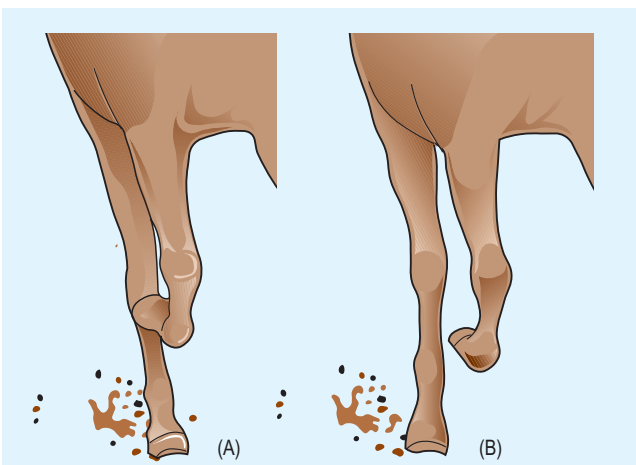

Fig. 50.3
Drawing of leg positions of a line-gaited (A) and passing-gaited (B) Trotter. (Redrawn with permission from Sylvester.[35])

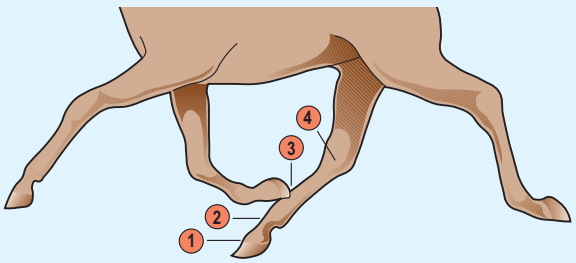

Fig. 50.4
Sites of interference in a trotting horse: (1) scalping, (2) speedy-cutting, (3) shin-hitting (as illustrated), and (4) hock hitting. (Redrawn with permission from Haughton.[36])

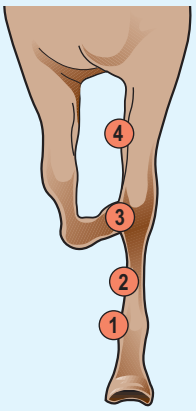

Fig. 50.7
Interference, in which the foot of one forelimb strikes the opposite forelimb, occurs at several levels: (1) the fetlock, (2) the medial metacarpus, (3) the medial carpus, and (4) the medial antebrachium. (Redrawn with permission from Haughton.[36])

hitting can all occur. Injuries are usually mild but can be sufficiently painful for the horse to be hesitant in trotting or pacing, or to not want to race at top speed. Interference in Trotters can result in the horse stumbling and breaking gait. Among pacers, interference is between the forelimb and contralateral hindlimb and is termed 'crossfiring' (Fig. 50.5). Striking of the sole of the forefoot by the ipsilateral hind foot is referred to as 'forging' (Fig. 50.6). Injuries to the fetlock, metacarpus, carpus, and medial antebrachium occur when the contralateral hoof hits one of these areas (Fig. 50.7). Interference can be minimized by changes in shoeing, including the use of weighted shoes, and equipment. Injuries resulting from interference can be minimized by application of protective boots and bandages (see below).

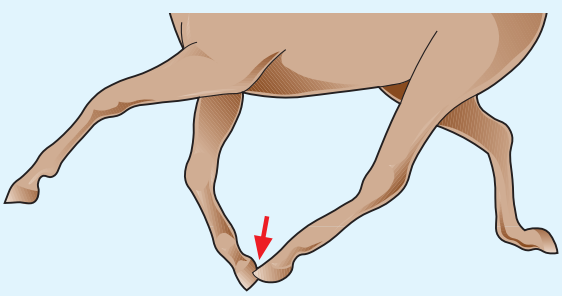

Fig. 50.5
Crossfiring, in which one hind foot hits the contralateral forefoot, occurs in pacers. (Redrawn with permission from Haughton.[36])

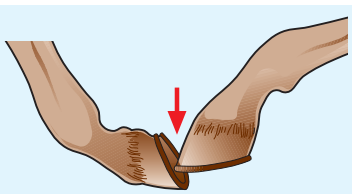

Fig. 50.6
Forging, in which the hind foot hits the ipsilateral forefoot, occurs in Trotters. (Redrawn with permission from Haughton.[36])

Equipment

Standardbreds wear a wide range of equipment when training and racing. The equipment is used to assist the horses maintain the desired gait, attach the horse to the sulky or cart, and permit the driver to maintain control and direct the horse.[10] Pacers are aided in maintaining their gait by light hobbles (Fig. 50.8), which they wear whenever they race, whereas Trotters only occasionally wear trotting hobbles. The hobbles are usually made of light plastic and have a length of 50–60 inches (112–135 cm), which is adjusted depending on the size of the horse and the length of the track. Shorter hobbles are used on smaller (e.g. half mile) than on larger (e.g. 1 mile) tracks.[11] Horses are more likely to 'break' if the hobble is too long, whereas a hobble that is too short limits performance.[11]

The harness consists of a girth, backstrap and crupper, pads, and breast collar. The shafts of the sulky or cart are connected to the harness. The tail is placed through the crupper, which is attached to the backstrap. The backstrap prevents the harness from sliding forward on the horse. The breast collar prevents the harness from slipping back.

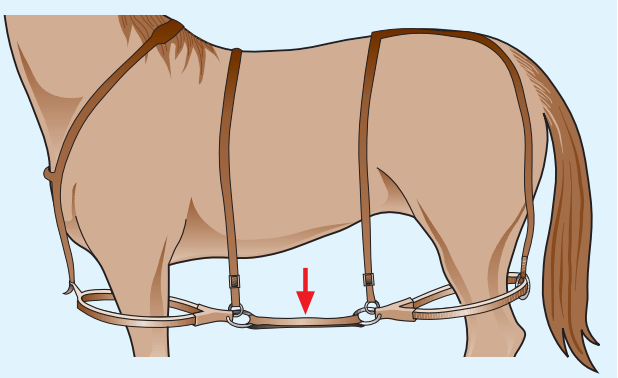

Fig. 50.8
Hobbles used to assist pacers in maintaining their gait while racing and training. (Redrawn with permission from Haughton.[36])

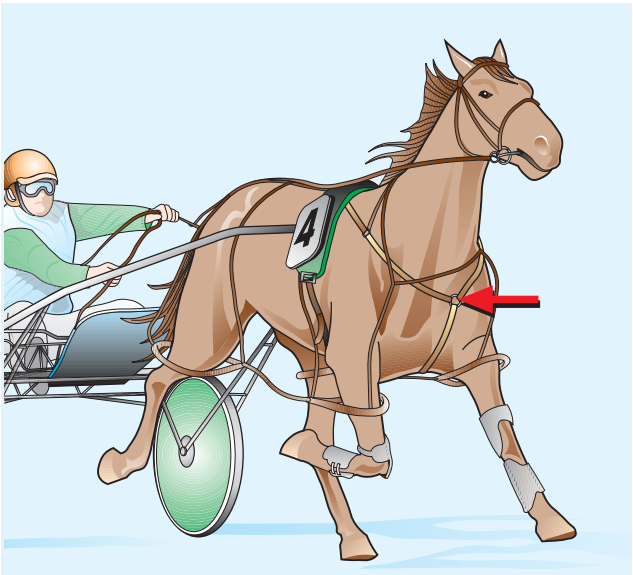

Fig. 50.9
Buxton martingale (arrow) used in place of a chest strap to maintain the correct position of the harness. (Redrawn with permission from Haughton.[36])

The breast strap is occasionally replaced with a Buxton martingale (Fig. 50.9).

Martingales, which usually run from the girth to the halter, are used to keep the horse's head in position and in particular to prevent it throwing or tossing its head. There are several different designs of martingale (Fig. 50.10).

Horses also wear any one of a variety of bridles (which might include 'blinders') designed to limit the visual field (Fig. 50.11). Bridles are selected based on the horse's temperament and handling characteristics. Bits, which are used to direct the horse and to maintain its head position, vary widely in design (Fig. 50.12). Check bits are used with a check rein to prevent the horse excessively flexing its neck and 'choking down'. The check rein is attached to the check bit over the nose and then runs up between the ears before attaching to the girth strap over the horse's back.

Horses can wear a variety of boots to protect against the effects of interference (Fig. 50.13). Boots that cover the dorsal metatarsus and fetlock protect against interference in these areas. Other variations on this boot include an attachment that protects the speedy-cut area of the dorsal pastern. Yet other boots extend proximally to protect the hock. A shorter boot protects just the distal metatarsus and fetlock. Bell boots and scalpers provide protection for the proximal hoof and coronary band.

Racing statistics

Standardbreds are bred with the intention of having them race, although not all foals born and registered eventually race. There were 11 332 registered Standardbreds in North America (the USA and Canada) in 2002.[12] These horses started 39 600 times at 288 tracks for a total purse of $US 500 724 338.[12] This compares with 17 637 registered horses in 1986 starting 57 021 times at 464 tracks for $US 387 474 745.[12] In Australia in 2001 there were 13 552 horses that had 14 471 starts in 15 558 races for a total stakemoney of $71 500 000.[13] Sweden, which permits only Trotters to race, has 31 harness tracks at which approximately 10 000 races are held with 110 000 starters each year.[14] The total prize money annually is 700 000 000 crowns.[14]

Most Standardbreds are eligible to first race as 2- or 3-year-olds. Although information regarding age at first start is

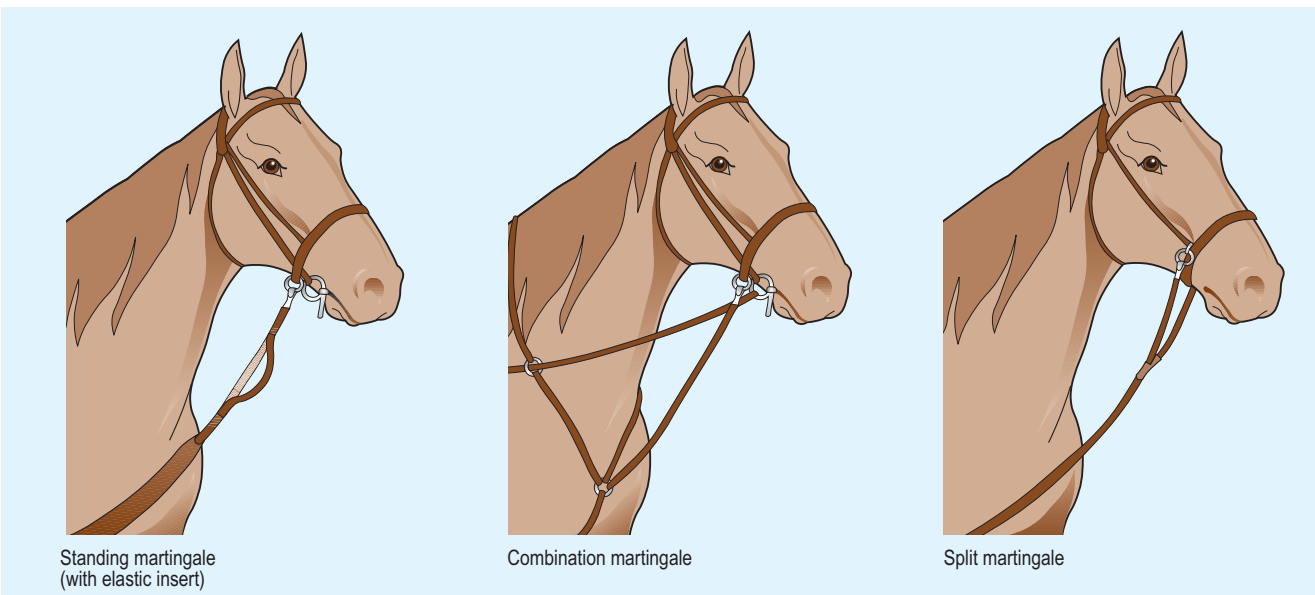

Fig. 50.10
Martingales used on harness horses. (Redrawn with permission from Haughton.[36])

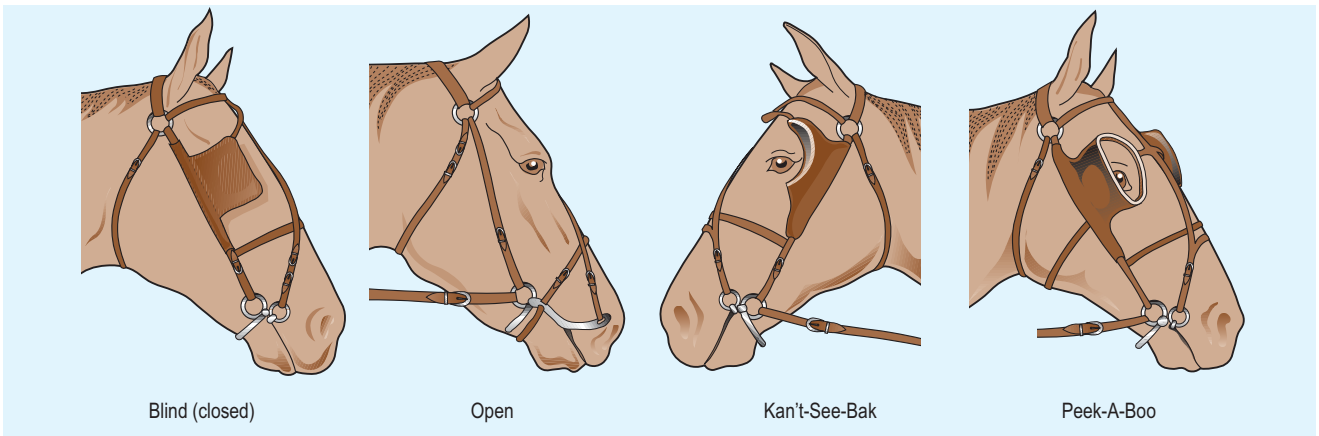

Fig. 50.11
Bridles used on Standardbred race horses. (Redrawn with permission from Haughton.[36])

not available for all regions in which Standardbreds race, in Canada the average age at the time of the first race for horses born in 1972 was 3.4 ± 0.5 years,[3] although the age at which horses first race has likely decreased since that time. For foals born in 1972 in Canada, 67% eventually raced, with approximately 17% having their first race as 2-year-olds, 48% as 3-year-olds, and 22% as 4-year-olds.[3] This is similar to the situation with Dutch trotters.[15] Horses that first raced as 2-year-olds had longer racing careers than horses first raced as 3-year-olds (5.1 versus 4.4 years).[3] Horses older at the time of their first race had progressively shorter racing careers. The racing life ranged from < 1 to 10 years, with an average of 4.1 ± 0.1 years. There is no difference in racing life span of trotters and pacers.[3]

There are important differences among sexes in the proportion of horses that race – 78% of male (colt and stallion), 88% of geldings, and 54% of fillies born in 1972 raced at some time.[3] The smaller proportion of fillies that eventually race is likely related to their tractability in early training, and opportunities for breeding when health and management problems related to training or racing are encountered.

Among Standardbreds born in Canada in 1972, 80% won at least one race during their career.[9] The number of starts during the horses career ranged from 1 to 347, with the 95% confidence interval for number of starts being 21 to 70 races. Thirty percent of horses had fewer than 20 starts and 29% raced more than 100 times.[9] The average horse had its best racing performance (fastest race) 2.55 years after its first race at a mean age of 5.27 years.[9]

Training the Standardbred

General principles

Most human sporting performances are governed by three general factors: technique, physiological fitness, and mental toughness. Standardbred race horses are no different, they require all three factors, but in particular physiological fitness and physical training, although a smooth economical pacing or trotting gait and a tough mental attitude to training and racing will also help. Consequently, one of the major elements to a successful Standardbred race horse is the trainer's ability to enhance physical fitness.

Training can be explained as a systematic and controlled application of a stimulus (stress) above that normally encountered by the animal, which forces the body to reorganize itself and thereby adapt. These overloading stimuli are normally given in a slowly progressive manner to enable the gradual adaptation of the animal to the training stress. In the case of race horses, the aim is to give the appropriate amount of training stimulus to realize the horse's full racing potential.

A major consideration when training horses is the energy requirements needed during the actual racing event. Standardbred race horses generally race over distances of 1600–3200 m (1–2 miles), which usually takes approximately 2:00–4:20 minutes to complete. Although there is some disagreement over the exact proportion of energy supplied by the aerobic and anaerobic pathways, it is generally considered that Standardbred race horses gain the majority of their energy during a race from the aerobic pathway (~60–90%) while the anaerobic pathways contribute a smaller but still important proportion (10–30%).[16] For that reason, training the Standardbred should focus on stressing both the aerobic and anaerobic energy pathways, as both respond to training,[17] however the majority of work should be aerobic in nature.

Training programs

Traditional training programs

Traditionally training programs for Standardbreds have incorporated three or four basic phases:

- *Phase 1. The Initial or Foundation Phase*: The aim of this phase of training is to develop aerobic fitness and decrease bodyweight, strengthen the muscles and joints, improve

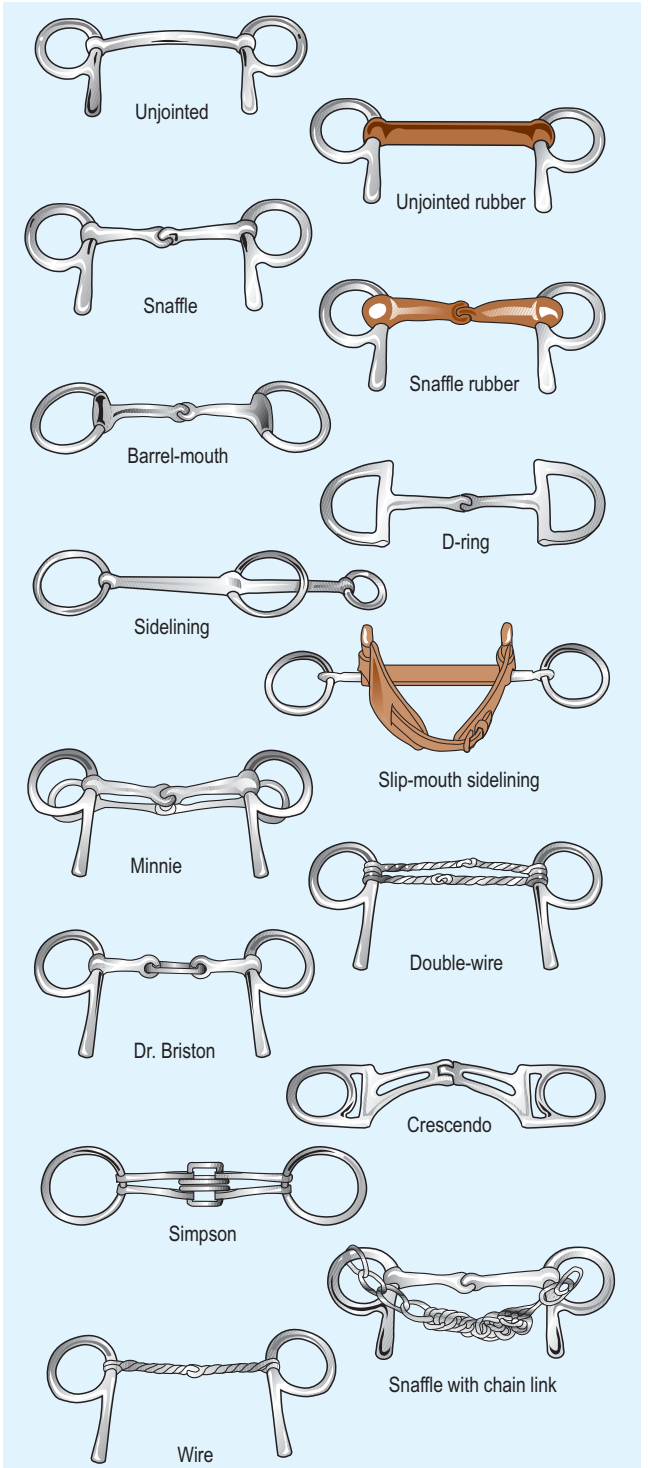

Fig. 50.12
Bits used in Standardbred race horses. (Redrawn with permission from Haughton.[36])

joint mobility and establish good training habits. Training during this phase usually consists of low-intensity moderate-duration exercise. For the Standardbred this usually incorporates slow jogging.

- *Phase 2. Preparation Phase*: This phase is usually separated into a number of subphases but overall the trainer is trying to increase the efficiency of the energy system(s) predominant in the event – namely the aerobic system. The trainer is also attempting to develop and maximize the components of fitness required by the Standardbred during racing, which includes strength, speed, power and flexibility. Training during this phase is usually characterized by alternate days of low-intensity jogging and higher-intensity gallop, pace, or trotting work.
- *Phase 3. Competition or Racing Phase*: The aim of this phase of training is to maintain rather than improve appropriate energy systems and fitness components required by the Standardbred during racing. Training during this phase is characterized by similar training to the final preparation phase, however, it will often involve a reduction in the high-intensity exercise, especially if competing regularly.
- *Phase 4. Rest or Lay-off Phase*: During this phase of training the horse is spelled, usually in a paddock, and given complete rest from any training. To decrease expenses during this phase the horse is normally transported back to the owners. This phase allows the horse to recover both physically and mentally from the racing season.

Standardbreds in Australiasia typically race over distances ranging from 1600 to 3200 m whereas Standardbreds in North America tend to race over the shorter distances of 1600–2200 m. Although current practices of New Zealand trainers, and an example of a more scientific approach from an Australian trainer have been published recently, similar training information from American trainers is difficult to find.[18,19] Sherman & Hopkins (1995)[18] investigated the training practices used by New Zealand's top 100 trainers of Standardbred maiden pacers and revealed that most trainers tend to give their horses very similar types of training. They reported that most New Zealand trainers separated their training into three preparation phases and a racing phase. The initial preparation phase is similar to the foundation phase described above and consisted mainly of jogging the horses at a steady pace (see Table 50.1) for 5–6 weeks with one rest day per week. The middle preparation phase followed and signaled the start of fast work. Fast work normally involved the horses being harnessed-up into their hobbles and pulling the racing cart. The final preparation phase, which lasted about 4 weeks, then followed. In the racing or competition phase, the majority of New Zealand trainers continued a similar pattern of training, however, about one-third of the trainers incorporated one or more 'strong' workouts (galloping rather than pacing in the cart).

Sherman and Hopkins[18] found that the intensity of the fast work increased during training but, interestingly, the intensity of the jog work remained unchanged throughout training. The speed at which horses were jogged remained at about 19 km/h whether they were in the initial preparation phase or the racing phase of training. The intensity of jog work described in the training program by Lovel[19] was almost the same as that described by Sherman and Hopkins.[18] However, the horses in Lovell's program started

The means for 26 trainers (mid-preparation phase) or 94 trainers (all other phases). Workout intensities are percentages of qualifying pace, which was calculated from the average qualifying time for a maiden pacer over 2400 m, which was 3:18 min:s.

with much less jog work, which was quickly increased to be approximately the same as that described by Sherman and Hopkins by week 5 of the program (Table 50.2). Both training programs introduced fast work at about the same time (week 5) and typically trained the horses with alternating fast and slow days. Lovell's program is slightly more scientific in that the work intensities are calculated from a standard fitness test, which he suggests should be carried out every 2

Table 50.2 Suggested training for a mature Standardbred that has raced before but has been turned out for a prolonged rest[19]

V_{HRmax} is an exercise test that uses four bouts of 1000 m at increasingly higher speeds to calculate the velocity at which the horse's heart rate reaches maximum. Overall the horse covers 4000 m during this exercise test, at an average speed of 37.5 km/h. Intensity is given as a percentage of the velocity reached at heart rate maximum during the V_{HRmax} test. Prior to all fast work sessions and exercise tests, horses should be given a warm-up consisting of a jog for 3000 m at a speed of 19 km/h.

weeks or so. Basically, the test uses heart-rate measurements during a series of 1000 m trials at specific speeds to calculate the velocity at which the horse's heart rate reaches maximum. As the horse becomes fitter the speed at which it can travel at maximum heart rate increases, thereby allowing the adequate planning of appropriate training intensities. However, most trainers do not have access to heart-rate monitors and therefore plan their training intensity around distance and time.

As the two training programs demonstrate, there is an increase in intensity of fast work approaching the final preparation and racing phases and a slight reduction in fast work volume. The higher training intensities during these phases are designed to stress the horses in a way that is similar to the actual race. Neither training program actually asks the horses to complete time trials or to train at race pace for any length of time.

Interval and tapered training programs

A relatively new type of training that attempts to improve performance by introducing training that is close to or even above race pace is interval training. Interval training for the race horse has been discussed by Tom Ivers in his book *The Fit Racehorse*.[20] In his book, Ivers outlines the general concept and proposed benefits of interval training and gives examples of structured interval training sessions.

Interval training involves bouts of exercise alternated with periods of relief (or rest) and has been shown to be an effective way to train the appropriate energy systems in human and equine athletes.[21,22] Interval training decreases fatigue and allows for a greater amount of high-intensity work to be performed than if work was carried out in one continuous stretch. For example, suppose you exercised your horse continuously as hard as you could for 3 min, then on another occasion suppose you ran the horse intermittently, exercising the horse just as hard as you did continuously, but for only 30 s at a time with 2 min of rest between each run. If you repeat this six times you would have completed the same amount of work but the degree of fatigue following the intermittent or interval exercise would be considerably less. After the continuous exercise the horse would be extremely fatigued and tired compared with the horse after the interval training session. Essentially, with interval training the recov-

Table 50.3 Sample interval training programme for Standardbred horses[23]

Aim: Able to pace 1600 m in 1:57 (1000-m track).
Required base: At least 400 km in previous 84 days.
Frequency: Every 4 days.
Rest-period criteria: Heart rate 110 or less within 5 min of completing the interval.
Interval criteria: If time greater than 1.5 s outside scheduled time, session halted. Only proceed to next step if all criteria for previous level have been met.

Training level	Distance (m)	Repetitions (number of heats)	Work interval time (min:s)	Rest interval time (min:s)
1	600	2	0:56	5:00
2	800	2	1:15	5:00
3	1000	2	1:35	5:00
4	600	3	0:53	5:00
5	800	3	1:10	5:00
6	1000	3	1:28	5:00
7	1200	2	1:45	5:00
8	600	4	0:50	5:00
9	800	4	1:07	5:00
10	1000	4	1:25	5:00
11	1200	3	1:42	5:00
12	800	4	1:05	5:00
13	1000	4	1:23	5:00
14	1200	3	1:40	5:00
15	800	4	1:03	5:00
16	1000	4	1:20	5:00
17	1200	3	1:38	5:00
18	800	3	1:00	5:00
19	600	4	0:44	5:00
20	1000	2	1:18	5:00
21	800	2	0:58	5:00
22	600	3	0:42	5:00
23	1000	1	1:15	5:00
24	800	2	0:57	5:00
25	600	2	0:41	5:00

ery period allows for replenishment of stored energy in the muscles, removal of lactic acid, and recovery from the exercise bout. Therefore the horse is less fatigued when it starts its next bout of exercise, and the quality of training is better than if the horse completed the exercise continuously.

Normally, in training for middle- to long-distance events, the exercise intensity is set around the anaerobic threshold to improve aerobic capacity without producing too much lactic acid and consequently fatigue. However, trainers should also think about training at intensities over the anaerobic threshold to help train the anaerobic energy system that is also required during a race. Shorter, very-high-intensity sprint intervals might also help at improving speed.

When constructing an interval training program the following terms are used:

- *Work interval*: the length of time the horse is exercising (sometimes expressed as the distance covered, e.g. 1000 m).
- *Rest or Relief interval*: the time between work intervals in a set. The relief interval can consist of light activity such as walking or mild to moderate exercise such as jogging.
- *Repetition*: the number of work intervals per set.
- *Sets*: A group of work and relief intervals.

An example of an interval training program can be seen in Table 50.3. In this program the recovery time has been set randomly at 5 min, during which time the horse walks. As can be seen from the table, the trainer who developed this program considers that the interval training should occur only every 4 days.[23] Most interval training programs allow more days between interval exercise bouts to allow for full recovery from the much higher stresses involved. Horses would normally be given slow work between the interval training days. Because of the high stresses involved, interval training is not recommended until a sound fitness base has been established.

Some trainers prefer to use heart-rate measurements when programming exercise intensity for interval training, rather than strict performance times that can be influenced by track and weather conditions. If using the heart-rate monitor the aim at the start of interval training would be to get the horses' heart rate up to about 180–200 bpm (approximately anaerobic threshold). With a gradual increase in fitness this target can be progressively increased to a heart rate of about 200 bpm or more. In most cases, however, trainers will use the heart-rate monitor to judge the recovery ability of the horses. A target of about 110–120 bpm after 5 min recovery indicates that the horse has recovered sufficiently to continue with the next bout of exercise. If the heart rate exceeds what is expected or takes much longer to recover than normal, it might be an indication that the previous exercise bout was too stressful and further work bouts should be abandoned. Unexpected high heart rates during training and recovery have also been suggested to be an early warning sign of physiological stress, possibly indicating low-grade lameness or musculoskeletal injury.[24,25]

Whereas the proposed benefits of interval training include the intense metabolic demands it produces, as well as the specific neuromuscular and fiber-type activation that is needed during a race, disadvantages include the time-consuming nature of the training compared to conventional training, and an increased risk of injury. In a recent study, interval training was used in an attempt to increase time trial performance in a number of Standardbred race horses over a prolonged period of time.[26] Horses were given a series of 2-weekly taper training programs. The taper is a training technique used in human athletes to optimize performance

Table 50.4 Two-week training cycles for the conventional and taper groups. Numbers in parentheses are training pace as a percentage of pace over the last 1200 m of the most recent 2400 m time trial[26]

Day	Conventional training	Taper 1	Taper 2	Taper 3
1	Rest	Jog 50 min (40%)	Fast 2400 m (89%)	Fast 3000 m (92%)
2	Jog 40 min (40%)	Fast 3000 m (90%)	Jog 50 min (50%)	Jog 50 min (50%)
3	Fast 2400 m (86%)	Jog 50 min (40%)	Fast 2400 m (89%)	Fast 3000 m (92%)
4	Jog 40 min (40%)	Fast 3000 m (90%)	Jog 50 min (60%)	Jog 50 min (50%)
5	Fast 2400 m (86%)	Jog 50 min (40%)	Fast 2400 m (89%)	Fast 3800 m (90%)
6	Jog 40 min (40%)	Fast 3800 m (90%)	Jog 50 min (60%)	Jog 40 min (50%)
7	Fast 3200 m (86%)	Jog 40 min (40%)	5 × 800 m intervals (100%)	Fast 1800 m (94%)
8	Jog 40 min (40%)	Rest	4 × 800 m intervals (100%)	Jog 30 min (50%)
9	Rest	Fast 1800 m (95%)	3 × 800 m intervals (100%)	Fast 1200 m (100%)
10	Fast 2400 m (86%)	Jog 30 min (40%)	2 × 800 m intervals (100%)	Jog 20 min (50%)
11	Jog 40 min (40%)	Fast 1200 m (100%)	1 × 800 m intervals (100%)	Fast 1200 m (100%)
12	Fast 2400 m (86%)	Jog 20 min (40%)	Walk	Walk
13	Jog 40 min (40%)	Walk	Walk	Walk
14	Time trial	Time trial	Time trial	Time trial

All fast work was completed with the horses harnessed up into their hobbles. Horses were only introduced to the above training programs after 8 weeks of foundation training. As an example of intensity the jog at 40% time trial pace was approximately 19 km/h. The relief period between interval repetitions was set at 5 min, during which the horses walked.

by allowing adequate recovery from hard training prior to competition. During the second week of one of the taper programs (see taper 2 in Table 50.4) the researchers used a series of progressively shorter intervals to reduce duration but maintain adequate training intensity. They found a significant improvement in the horse's speed during the taper programs (particularly taper 1), compared to the conventional training, however, there was also an increase in the number of injuries reported in the taper group using the interval training. Also note that the high-intensity interval training days during taper 2 were not separated by recovery or rest days, possibly leading to inadequate recovery, which might have caused the injury problems.

The main objective of any training program is to enhance performance while keeping the animal free from injury and disease. During training, stress in the form of exercise initiates changes within the horse's structural and biochemical make-up. These exercise-induced changes cause adaptation and improved performance if sufficient recovery is allowed. On the other hand, excessive stress due to inappropriate training or insufficient recovery produces maladaptation and poor performance.

Overtraining

A recent study on Standardbred maiden pacers found some useful indicators of overtraining, which might help trainers detect and possibly prevent overtraining.[27] One of the major indicators of overtraining was a drop in bodyweight. The body condition of the horses declined and they lost weight. In addition, heart rate during exercise was elevated in the overtrained horses. In other words, the horses had to work harder to maintain speed during pace work. The increased stress was highlighted further when blood tests after exercise revealed a significant increase in lactate levels. Blood lactate is a normal byproduct from the breakdown of sugar by muscle cells, so an increase during overtraining suggests more muscular work was required by the overtrained horses to maintain speed.

During conventional training, horses are usually able to consume an appropriate amount of food to fuel the energy requirements needed. Horses that become overtrained might lack sufficient carbohydrates to meet the demands of their excessive training. Possible reasons include an inadequate diet, decreased hunger drive, or a problem within the muscle cells themselves. As a result, there is a depletion of carbohydrate stores and weight loss. Ordinarily, when the body's stores of carbohydrates decrease below normal, more can be formed by the breakdown of protein and fat, which requires the hormone cortisol. During overtraining, however, something goes wrong with the hormonal control system, resulting in a decreased magnitude of the cortisol response to exercise. Consequently, a further reduction in the availability of fuel to the working muscle cells can occur, resulting in force loss and poor performance.

Signs of overtraining

Signs of overtraining include:

- Slower split times
- Unexplained drop in form
- A decrease in bodyweight ≥ 6 kg
- Horse might leave feed
- Decreased enthusiasm to train
- Horse might become moody and lethargic
- Increased heart rate during exercise and possibly slower recovery heart rate
- An increase in blood lactate concentration between 8 and 16% after pace and fast work.

Treatment and prevention

The recommended treatment for overtraining is usually a dramatic reduction in the volume, intensity or frequency of workouts or an increase in the time between workouts. Fast workouts should be dropped and only light jogging continued. If the horse doesn't show improvement within 2–3 weeks it should be spelled in the paddock and brought back up again after a few months rest.

The best treatment of all, however, is prevention. The challenge for trainers is to detect the subtle changes in the horse's response and attitude to training that might indicate too much training. After all, unlike a human athlete the horse cannot tell you about problems that arise during training. Training logs with details of training volume, intensity, and recovery should be kept, with regular changes in bodyweight, food intake and behavior noted. Of course, a major difficulty in measuring bodyweight is access to appropriate scales, however, regular weighing remains a cheap and easy way to monitor the effects of exercise training. Regular performance tests can also be helpful, for example timing horses over set distances. As both the sprinting and staying ability of the horse is affected by overtraining, these performance tests should include a measurement of all-out speed and overall speed. If the horse takes longer to complete the test and seems tired, this might be an indication that more recovery is required. If time and equipment allow, a measurement of heart rate and blood lactate during and after exercise would also be useful. Above all, trainers need to be able to judge when the results of the training program are being threatened by too much exercise.

Veterinary problems of Standardbreds

Respiratory abnormalities

Whereas gait and respiration are linked in a 1:1 fashion in cantering or galloping horses, respiration is not linked to gait in pacing or trotting horses.[28] However, abnormalities of the respiratory tract are an important cause of poor performance

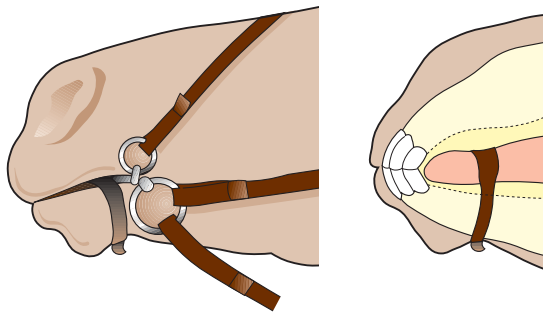

Fig. 50.14
Tongue-tie used to prevent horses from 'choking down' during racing. The tongue-tie should not interfere with the driving bit or overcheck bit. (Redrawn with permission from Haughton.[36])

or reduced racing frequency in Standardbreds. Standardbreds are afflicted with respiratory tract disease in the same way as other race horses, although their gait and associated tack makes problems such as dorsal displacement of the soft palate more problematic.

Upper airway abnormalities

Standardbreds in racing or training can develop a range of upper airway abnormalities including left laryngeal hemiplegia, dorsal displacement of the soft palate, and arytenoid chondritis. The characteristics of these diseases do not differ in any substantive way from those of other athletic horses, as discussed in Chapter 27. Dorsal displacement of the soft palate is a well-recognized syndrome in racing Standardbreds. Its apparent high prevalence in this breed is perhaps related to their tendency to 'choke down' or excessively ventroflex the head during exercise. Treatments for intermittent dorsal displacement of the soft palate include application of a tongue-tie (Fig. 50.14), use of overcheck rein and bit, and surgical manipulation of the pharynx and associated musculature.

Exercise-induced pulmonary hemorrhage (EIPH) occurs in Standardbreds, as in other athletic horses that compete at high speed. The prevalence of EIPH in Standardbred race horses is assumed to be lower than in Thoroughbred race horses, with 26–34% of horses reported to have blood in the trachea after racing.[29,30] However, these studies were based on a single examination and one[29] reported as positive only those horses with blood covering more than one-half of the tracheobronchial tree. When examined after each of three races, 87% of Standardbred race horses have evidence of EIPH on at least one occasion,[31] suggesting that EIPH is as common in Standardbred race horses as it is in Thoroughbred race horses. Management of EIPH is discussed in Chapter 29.

Musculoskeletal disorders (adapted from Ref 32 with permission)

The racetrack practitioner caring for Standardbred horses frequently deals with problems and lameness requiring prompt diagnostic and therapeutic aid, which in most cases must be compatible with the season racing activity and current drug use regulations.[32]

Recognition of lameness

Lameness is the most important cause of poor racing performance in Standardbreds.[33,34] Lameness severity can range from moderate to severe, being visible at a walk or trot in hand, to subtle or mild lameness seen only at speed or while racing. A 1- to 2-s increase in the time for a mile, generally reflected in a slower last quarter-mile time, accompanies many lameness problems but might be confused with other problems such as respiratory abnormalities or recurrent exertional rhabdomyolysis. Bilateral lameness can cause a reduction in race performance without other localizing signs. Lameness is a major cause of horses making breaks (breaking stride) at high speed, although shoeing (particularly in trotters) and equipment considerations are also important contributing factors.

Horses on a line (the driver pulls harder on one line to keep a horse from bearing in or out) generally have ipsilateral lameness problems, although occasionally horses with medial foot or carpal lameness can be on the contralateral line. If on a line at all, horses with hindlimb lameness are usually on the ipsilateral line. For instance, those with left hind lameness are usually on the left line. Horses on a shaft (rear of horse closer to one shaft) generally have contralateral hindlimb lameness. Occasionally, a horse with forelimb lameness (and 'hard on the line') will be on the opposite shaft (horse with right front lameness will be on left shaft). This is usually because the driver is pulling the horse hard enough with the right line to cause it to bend its hind end to the left. These horses are often affected with lameness in more than one limb. Horses with forelimb lameness are generally worse on turns, although foot soreness and splints worsen as the mile progresses. Horses with hock lameness might be worse going into a turn or when coming out of a turn, whereas those with metatarsophalangeal joint (MTPJ) lameness will be worse around turns. Horses with left hind lameness might be able to trot or pace the turns, but those lame in the right hind will be worse in turns. Pacers with hindlimb lameness and a history of being worse when on the pace than when on the trot are usually affected with stifle lameness. Track size varies in Standardbred racing and horses that are lame in the turns are usually worse on smaller tracks. However, racing is generally slower on smaller tracks allowing lame horses, particularly those with soft-tissue injuries to compete successfully.

Breed and gait differences

There is considerable difference regarding lameness distribution and prognosis in Standardbreds as compared with Thoroughbred race horses. Gait difference between the breeds undoubtedly plays a role. The trot and pace are two-beat gaits, and there is more equal distribution of load (and lameness) between the forelimbs and hindlimbs. Fewer rota-

tional forces in certain joints of Standardbreds such as the carpus can reduce overload injury when compared with Thoroughbreds. Diseases such as suspensory disruption, catastrophic or incomplete fractures of the humerus, tibia, ilium, and third metacarpal/metatarsal, and bucked shins are much less common in Standardbreds. In general, Standardbreds have a better prognosis than Thoroughbreds for soft-tissue injuries such as suspensory desmitis and superficial digital flexor tendinitis. There appear to be differences in prognosis within the breed and, in general, prognosis in trotters is worse than in pacers. Lameness in pacers can be difficult to see, particularly in the forelimb. Pacers can usually tolerate lameness better than trotters with the exception of some hindlimb problems such as stifle lameness.

Because many Standardbred lamenesses are subtle, there is no substitute for evaluation of these horses at the track when jogging or training. It can be useful to sit behind the horse, particularly when evaluating subtle hindlimb lameness. Treadmill examination is useful in providing a consistent surface and speed for lameness evaluation but does not simulate turning or pulling weight. Unfortunately, lameness examinations cannot always be performed under ideal situations, and horses are commonly evaluated at a walk and trot in hand. Standardbreds evaluated at slow speed might not exhibit the same lameness as they do at high speed. Problems such as splints and foot soreness might surface only after training or racing, and examination at rest might be nondiagnostic. Care must be taken not to overinterpret subtle hindlimb lameness at a trot in hand. However, careful lameness examination can be useful, even in horses with subtle problems.

Lameness of the forelimb is slightly more common than that of the hindlimb, but there is a near equal distribution between hindlimb and forelimb lameness. Articular and periarticular injuries account for the majority of lameness seen in Standardbreds, whereas long-bone abnormalities are less common. The carpus is the most common articular injury and is likely the most common source of lameness overall. The MTPJ is very important in hindlimb lameness, in fact nearly equal to that of the hock, and has been underemphasized.

Forelimb lameness

Front limb lameness in the racing Standardbred can range from readily apparent lameness to subtle disturbances of gait. There are conditions in which the acute lameness requires immediate radiographic examination to rule out frequent injuries, including sagittal fractures of the proximal PI, proximal sesamoid fractures, pedal bone fractures, and, less frequently, injuries of the proximal metacarpal region. However, more commonly the complaint is a subtle to mild lameness, which can be complicated by problems affecting the hind limb. In such cases the clinician must investigate the horse's history, including the gait, shoeing, recent performance, previous lameness, when the horse becomes lame (after the race, the next day), factors that exacerbate the lameness (e.g. training clockwise or counterclockwise, on turns or on the straight, at the beginning or at the end of the race), wrong postures (horse on a line, on a shaft), and efficacy of previous treatments.

Foot The first step in diagnosis of lameness is a careful examination of the horse's conformation, especially foot conformation (club foot, toed-in, toed-out, hoof wall angle, lateral–medial balance, asymmetrical feet) and the presence of joint effusion, which is easily appreciated when affecting the fetlock and midcarpal joints. Joint distension is less obvious in the dorsal compartment of the coffin joint. The metacarpal region is frequently a site of visible abnormalities; enlargement of the body or branches of the suspensory ligament, bowed tendon, and constriction of the palmar annular ligament represent common findings.

Palpation detects areas of abnormal warmth and pain and allows evaluation of joint angles. The feet may have asymmetric warmth, increased digital pulse, and different responses to hoof testing. When possible, feet are first tested without removing the shoes, and ideally the horse should be kept shod until any examination of gait is completed. Lateral and medial quarters, lateral and medial middle sole, and lateral and medial toe are tested. Compressing the frog rarely brings useful information and squeezing the quarters might cause pain unrelated to primary lameness. The medial quarter is usually more sensitive and this finding must not be overinterpreted. Hoof or foot pain is a common occurrence, although it is often subtle.

Shoeing represents a source of useful information and should be discussed with the trainer to better understand the gait characteristics. For horses with a flat sole, overzealous padding can add to, rather than relieve, pressure on the sole. Wide-web shoes with leather or rubber padding are useful in cases of pain originating from the distal interphalangeal (DIP) joint. Bar shoes are now less commonly used and may exacerbate coffin and fetlock joint problems, by limiting the natural slipping of the landing foot.

Corrective shoeing provides a solution for problems located in the hoof. This pain must be distinguished from problems related to osteoarthritis (OA) of the DIP joint. In this case, flexion of the distal limb frequently elicits pain. The final diagnosis of OA of the DIP is the result of different investigations including history (the horse frequently gets worse at the end of the race and is on a line), conformation (foot smaller than the contralateral club foot), palpation (some pain may be elicited by deep palpation of the dorsal joint capsule, the dorsal wall and/or heels are warmer), diagnostic analgesia (being aware that this problem is not always resolved by intra-articular anesthesia and that the latter may abolish pain originating from the navicular area and from the sole), and exclusion of other sites of pain in the distal limb, especially the fetlock.

Pastern and fetlock The radiographic examination may reveal a prominent osteophyte on the distal aspect of the middle phalanx associated with a variable degree of remodeling of the proximal aspect of the distal phalanx. OA of the DIP joint is frequently bilateral.

The metacarpophalangeal joint is frequently involved in front limb lameness. Survey radiographs may detect dorsoproximal fragmentation of the proximal phalanx and osteochondrosis of the proximal sagittal ridge on the dorsodistal metacarpus. These lesions are frequently diagnosed in yearlings and treated by arthroscopic surgery.

Acute synovitis of the metacarpophalangeal joint is observed in young horses when the training is intensified, especially on hard tracks. The horse appears moderately lame and sensitive to deep palpation of the dorsal joint capsule and to flexion test. Intra-articular anesthesia is usually diagnostic. In older horses, chronic thickening of the dorsal synovial pad (villonodular synovitis) is suspected when the latero-medial radiographic view shows flattening or osteolysis of the proximal aspect of the dorsal sagittal ridge and contrast radiography evidences a filling defect corresponding to the soft tissue mass. Ultrasonography may be used to measure the thickness of the synovial pad.

The palmar aspect of the front limb fetlocks in Standardbreds is characterized by problems affecting the proximal sesamoid bones and adjacent soft tissues. Sesamoiditis in young horses has the typical radiographic feature of radiolucent lines in the palmar abaxial aspect of the bone. Scintigraphic findings are indicative of increased bone metabolism, but radiographic changes are seen in only 50% of Standardbreds with increased radioisotope uptake. In older horses, the radiographic changes include radiolucent lines in the proximal one-half of the bone, irregular palmar/abaxial radiographic outline, enthesophytes, and mineralization of the intersesamoidean ligament. When affecting the base of the sesamoid bone, the presence of enthesophytes is more properly considered distal sesamoidean desmitis.

Desmitis and tendinitis The insertion of the suspensory branch on the proximal sesamoid bone becomes irregular and ultrasonography provides the most accurate diagnostic tool. Suspensory branch desmitis is frequently associated with sesamoiditis. It may be caused by lateral-to-medial hoof imbalance, training over uneven track surfaces, strains, and fractures of the splint bone(s). Acute desmitis may be associated with metacarpophalangeal joint effusion. Ultrasonography is performed to assess the degree of ligament damage with enlargement and loss of definition of the margins of the branch, focal hypoechoic areas, diffuse loss of echogenicity, and hyperechoic foci in horses with chronic desmitis being the most frequent findings. The corresponding splint bone may deviate abaxially, and radiographic monitoring may allow early diagnosis of secondary distal splint bone fracture.

Desmitis of the proximal insertion of the suspensory ligament is commonly diagnosed and carries a better prognosis than desmitis affecting the body or branches of the ligament. When the proximal aspect of the suspensory ligament is affected, the clinician must differentiate pain originating from the carpal joint and perform a local block (subcarpal block, axially to the origin of the splint bones, or direct infiltration over the proximal suspensory ligament). In cases of positive block, ultrasonography is used to assess damage to the suspensory ligament and bone remodeling of the palmar proximal metacarpus; a dorsopalmar radiographic view is used to assess the presence of palmar sclerosis of the third metacarpal (MCIII) in chronic cases.

Superficial digital flexor tendinitis represents a frequent indication for ultrasonographic examination of the distal limb of Standardbred race horses. Most of the lesions are located in the middle and distal third of the tendon. A core lesion located in the palmarolateral border of the tendon characterizes over 30% of the lesions. Central core lesions are uncommon. Chronic recurrent lesions have the typical pattern of diffuse tendinitis. When the lesion affects the distal aspect of the tendon, the digital tendon sheath may be distended, and the typical notch of palmar annular ligament constriction is visible in the palmar outline.

Carpus With the exception of foals and yearlings, lesions are rarely located on the proximal front limb of Standardbreds, and nearly invariably lesions affecting the elbow and shoulder regions are the result of direct trauma.

The midcarpal joint represents a predilection site of lameness in race horses, especially young Standardbreds and Thoroughbreds. Typically, horses affected by midcarpal joint pain tend to trot with a wide-based gait, abducting the affected leg or legs in an attempt to minimize carpal flexion. Visual inspection reveals various degrees of joint effusion, especially on the dorsomedial aspect of the carpus. Palpation may elicit pain over the dorsal aspect of the carpus. The flexion test is positive and intra-articular analgesia abolishes the lameness in the majority of horses. A negative result from intra-articular analgesia does not necessarily exclude pain in this joint because subchondral bone damage under a relatively normal cartilage may cause pain that is difficult to abolish with intra-articular analgesia.

Radiographic examination includes six basic views and a variable number of extra views: dorsopalmar (DP), flexed lateral–medial (LM), dorsolateral to palmaromedial oblique (DLPMO), dorsomedial to plamarolateral oblique (DMPLO), and 33° and 55° skyline views (dorsoproximal–palmarodistal skyline). The latter two views must be of excellent quality because it has been shown that a large number of injuries (especially affecting the third carpal bone) can be diagnosed only on the skyline view.

Treatment depends on the type and degree of injury. Young racing horses without radiographically visible abnormalities (a more sensitive diagnostic tool is represented by scintigraphy, which may reveal increased radionuclide uptake in the early phase of the disease) are best rested and treated with non-steroidal anti-inflammatory drugs, especially polysulfated glycosaminoglycans. Training modulation allows in most of the cases time for bone remodeling and prevents the progress of bone injuries.

When chip fractures are diagnosed, arthroscopic surgery represents the best option and carries a fair to good prognosis. In cases of third carpal bone slab fractures, internal fixation via arthroscopy is the preferred technique and offers good results.

More subtle cases, characterized by mild radiographic changes, may be good candidates for diagnostic arthroscopy. Irregular areas of radiolucency on the radial fossa of the third carpal bone and loss of density on the dorsal distal medial aspect of the radial carpal bone are suggestive of more serious injuries and may be indicative of incomplete fractures. Arthroscopic curettage of the main lesion, frequently associated with curettage of the corresponding 'kissing' lesion on the opposite articular surface, carries a better prognosis than conservative management in selected cases.

Arthroscopic findings in horses with lameness located in the midcarpal joint but no radiographic findings include sinking and discoloration of articular cartilage, loss of articular cartilage in focal areas of the third and radial carpal bone, and rupture of the medial palmar intercarpal ligament. The devitalized cartilage is debrided and the underlying bone may be foraged using micropick technique, which augments cartilage repair. Rupture of the medial palmar intercarpal ligament is less common, and the treatment involves arthroscopic trimming and 4 to 6 weeks rest followed by 4 to 6 weeks of walking exercise. The same postoperative protocol is used for routine arthroscopic surgery, whereas internal fixation of C3 slab fractures is followed by 8 weeks of rest, radiographic control, and 4 weeks of walking exercise. There is usually no need for removal of the screw.

Hindlimb lameness

Careful palpation of all anatomic structures, including static flexion and extension of all joints, should be performed. Frequently overlooked sites of inflammation (in both the forelimb and hindlimb) include the dorsal aspect of the proximal phalanx (P-I, [incomplete midsagittal or dorsal frontal fractures]), proximal sesamoid bones (sesamoiditis, fractures, avulsion injury associated with the suspensory attachment), and carpus and proximal aspect of third metacarpal (MCIII) (avulsion or longitudinal fractures of MCIII, proximal suspensory desmitis, dorsomedial articular fracture, incomplete C-3 chip fractures), proximal plantar third metatarsal (MTIII) region (proximal and midbody suspensory desmitis, pain along medial and lateral splint bones associated with hock lameness), and the MTPJ. In the hindlimb, it is easy to overlook subtle swelling of the suspensory origin and body, because these portions of the ligament are buried beneath the second and fourth metatarsal bones. Hoof tester examination should be performed in all horses because foot soreness is common. Foot soreness is less common in the hindlimb than in the forelimb, but does occur, as do OA of the DIP joint and navicular disease or fracture (rare). Secondary back, gluteal, and trochanteric pain are common and treatment of these areas is often recommended along with therapy of concomitant hindlimb lameness. Back pain in Standardbreds is usually the result of muscle pain, rather than impingement or overriding of dorsal spinous processes. Scintigraphic evaluation has failed to identify a single Standardbred race horse with increased radioisotope uptake involving the dorsal spinous processes, whereas this scintigraphic abnormality is common in horses that are ridden.

Intra-articular and perineural analgesia is important in the diagnosis of Standardbred hindlimb lameness and many times is most reliably done at the track where horses can be moved and evaluated at speed. Care must be taken when incomplete fractures are suspected, particularly of the first phalanx (P-I) because comminution can occur. When performing the plantar digital block, the clinician must keep in mind that pain associated with proximal P-I can be abolished. In these horses, the clinician inadvertently diagnoses a problem in the foot, when in reality the true source of pain is a midsagittal fracture of P-I. Because of the large number of Standardbreds with MTPJ lameness, basisesamoid or abaxial sesamoid nerve blocks are not useful. With these blocks, proximal diffusion of anesthetic occurs so frequently that misdiagnosis is common. I usually perform a plantar digital block, followed by a dorsal ring block, to desensitize the dorsal aspect of the foot. A low plantar perineural block is then performed. This technique is more successful in abolishing subchondral bone pain in the MTPJ than is the intra-articular technique, but all four nerves must be blocked (medial and lateral plantar nerve and medial and lateral plantar metatarsal nerves). Horses with incomplete fractures of MTIII, P-I, or the proximal sesamoid bones or those with non-adaptive remodeling may fail to respond or only partially improve with intra-articular analgesia but become completely sound with the low plantar block. A selective lateral plantar metatarsal block can be performed to identify those horses with stress reaction or non-adaptive remodeling of the distal aspect of MTIII. High plantar analgesia is often overlooked but is critical in the diagnosis of proximal suspensory desmitis or other avulsion injury associated with MTIII. Although all three compartments of the stifle joint should be independently blocked in horses suspected of lameness in this region, the medial femorotibial joint is most frequently affected.

Diagnostic imaging The importance of well-positioned and exposed radiographs cannot be overemphasized. Radiographic views that are extremely important in the Standardbred include:

- Foot: horizontal oblique views to evaluate the subchondral bone of the distal phalanx (P-III) for radiolucent areas or incomplete fractures.
- Tarsus: dorsomedial plantarolateral oblique view (shows most common sites for radiographic changes associated with osteochondritis dissecans, distal tarsitis, and T3 and MTIII fractures).
- MTPJ: down-angled oblique views to open up the space between P-I and the sesamoids; follow-up and down-angled DP views to rule out midsagittal P-I fractures.
- Stifle: caudocranial view to evaluate femorotibial joint space (particularly medial) and condylar lesions.

Ultrasonographic examination of soft tissues in the metatarsal region is important, particularly of the proximal suspensory region. A frequently overlooked region is the proximal plantar metatarsus. Bone scintigraphy is important in the identification of abnormal subchondral bone uptake, particularly of the foot, carpus, tarsus, and MTPJ. Standardbreds appear to be predisposed to abnormal impact loading or stress (non-adaptive) remodeling of subchondral bone.

Stifle lameness has been overemphasized. Specific hindlimb lameness is described as follows.

The hind digits The hind foot is much less commonly the cause of lameness than is the front foot but is still the source of pain in many Standardbreds. Foot abscessation, quarter cracks, hoof avulsion, distal interphalangeal osteoarthritis, P-III fractures, and chronic 'foot soreness' from poor shoeing and balance occur. P-III fractures most commonly involve the

left hind lateral and right hind medial wings of P-III, but this distribution is not as clear cut as in the forelimb. It is critical to separate pain originating from the foot from that of the MTPJ and results of diagnostic analgesia need to be interpreted carefully. Anesthetic diffusion occurs when the posterior digital block is performed, and it is relatively common to desensitize structures in the pastern and MTPJ using this block. The most common diagnoses in horses in which inadvertent analgesia of the MTPJ occurs using posterior digital anesthesia is midsagittal fracture of the proximal phalanx.

Interference is a common problem in trotters. trotters that hike behind and have what appears to be unilateral hindlimb lameness can be lame in the ipsilateral forelimb. Foot or carpal lameness can cause shortening of the ipsilateral forelimb, causing interference and what appears to be ipsilateral hindlimb lameness. Superficial skin soreness or frank osteitis can result from interference, and trotters frequently 'make breaks' as the result of the problem. Corrective shoeing and the elimination of the primary source of pain are important.

Metatarsophalangeal joint Lameness of the MTPJ region has been substantially underestimated in the past. The MTPJ is an extremely important source of hindlimb lameness and, in fact, many horses suspected of having tarsal or stifle pain will 'block out' with low plantar or intra-articular analgesia, if the techniques are routinely performed. One of the most common lameness conditions of the Standardbred race horse is subchondral bone pain of the distal, plantarolateral aspect of MTIII. This is a form of stress or non-adaptive remodeling of MTIII, an early form of OA, which is characterized by lameness most consistently abolished by low-plantar (or selective lateral plantar metatarsal) analgesia. Horses tend to have a 'stabby' hindlimb gait, will likely be on the contralateral shaft, be worse in the turns, and are often misdiagnosed as having tarsal pain. Intra-articular medication is usually ineffective and obvious signs of OA such as effusion, a positive response to flexion, or other abnormalities found on palpation are usually absent. Radiographs are initially negative or equivocal, and the diagnosis is made with scintigraphy. Bone phase scintigraphic images reveal focal radiopharmaceutical uptake of distal, plantarolateral aspect of MTIII. A continuum of stress-related subchondral bone changes results in non-adaptive remodeling, sclerosis, and later areas of necrotic subchondral bone. In older horses, radiographic evidence of subchondral bone injury is seen, but in 2- and early 3-year-olds, radiographic examination may be negative. Because this lesion is a result of a continuum of stress-related subchondral bone damage, management includes a reduction in stress. Modification in exercise intensity, corrective shoeing, swimming physiotherapy, and shock wave therapy have been used, but long-term rest may be best. Intra-articular medication, including corticosteroids, is not effective early in the disease process, presumably because pain originates from subchondral bone, and overlying cartilage damage is minimal. Later, when cartilage damage worsens and subchondral bone collapse occurs (radiolucent changes develop radiographically), injections decrease inflammation and lameness.

A common problem in Standardbreds is plantar process fragmentation of the proximal phalanx. Articular fragments, most commonly involving the medial aspect (can be biaxial and bilateral), can cause high-speed lameness and perhaps contribute to the development of OA in older horses. Currently, I recommend these fragments be removed arthroscopically, preferably before the horse enters training. Large, abaxial, non-articular fragments can also cause lameness, but conventional surgical techniques are necessary for removal.

Fractures involving the MTPJ are more common in pacers than in trotters, with the exception of fractures of the proximal sesamoid bones. Midsagittal P-I fractures are more common in the hindlimb than in the forelimb and can be difficult to diagnose. Pain from this fracture is often thought to originate from the foot because posterior digital analgesia abolishes lameness in some horses. Surgical fixation is recommended in horses with long or displaced fractures, but conservative management is successful in horses with short, midsagittal fractures. Dorsal frontal fractures of P-I occur in pacers and in trotters, are more common in the RH, can be bilateral, and heal with conservative management. Fractures of MTIII condyles occur but are less common than in Thoroughbreds and are unusual in the trotter. Medial condylar fractures tend to spiral proximally, and horses are at risk for catastrophic injury either before surgical fixation or during anesthetic recovery. Lateral apical sesamoid fractures occur commonly. Lateral sesamoiditis causes lameness in 2-year-olds trained in 2:15 to 2:18 for the mile, and prognosis is poor if substantial radiolucency exits.

Metatarsal region The most common and important condition of the metatarsal region is suspensory desmitis. This is often a career limiting or ending injury, particularly in the trotter. Proximal suspensory desmitis, avulsion fracture, or stress reaction/enthesopathy occur but can be difficult to diagnose, and high plantar analgesia is a must to differentiate pain from this areas from that of the MTPJ or tarsus.

Tarsus Distal tarsitis remains the most common lameness of the tarsus. The disease involves OA of the DIT and TMT joints, but there is a significant periarticular soft-tissue component, likely caused by sliding or shear forces, and radiographs are often negative. Osteochondritis dissecans of the tarsocrural joint is the most common surgical condition of the tarsus, is likely hereditary in the breed, and causes effusion and high-speed lameness. Surgical removal of fragments is recommended in horses with clinical signs or those sold at public auction. Tarsocrural arthropathy, an insidious disease resulting in eventual severe lameness and widespread cartilage damage, is seen in older horses. Curb, a common soft-tissue lameness, is frequently tendinitis of the superficial digital flexor tendon rather than long plantar desmitis. Third and central tarsal bone slab fractures, enthesopathy at the attachment of the collateral ligament on the distal aspect of the calcaneus, occur occasionally.

Stifle Stifle lameness has been overemphasized but is still important. The most common condition is OA of the medial femorotibial joint. This condition is difficult to diagnose radiographically because early on, the only sign is narrowing of the joint space seen on the caudocranial view. Effusion of the

medial femorotibial joint is usually present but may be a subtle clinical finding. Intra-articular injections and corrective shoeing (aluminum shoe with a toe grab) usually help. Trotters appear able to race more successfully than do pacers with this problem. Osteochondritis dissecans and osseous cyst-like lesions occur and cause lameness.

CHAPTER 51

Veterinary aspects of competing and training three-day event and dressage horses

Jonathan H. Foreman

Definitions and background

Dressage is a test of obedience, balance, and suppleness. 'The object of Dressage is the harmonious development of the physique and ability of the horse. As a result it makes the horse calm, supple, loose and flexible but also confident, attentive and keen, thus achieving perfect understanding with his rider.'[1] The goal is that the horse 'gives the impression of doing of his own accord what is required of him. Confident and attentive, he submits generously to the control of his rider, remaining absolutely straight in any movement on a straight line and bending accordingly when moving on curved lines.'[1] Examples of horses performing dressage movements on the straight and curved lines are illustrated in Figs 51.1 and 51.2, respectively.

Basic gaits at the lower dressage levels are walk, trot, and canter. The international standard requires that:

> His walk is regular, free and unconstrained. His trot is free, supple, regular, sustained and active. His canter is united, light and cadenced. His quarters are never inactive or sluggish. He responds to the slightest indication of the rider and thereby gives life and spirit to all the rest of his body.[1]

The basic gaits progress to more difficult movements at the upper levels such as extended trot or canter (Fig. 51.1), counter canter, passage, pirouette, and piaffe. Each horse and rider pair performs the same test in any given class or competition. One to five judges score each movement of the test and a composite score is calculated to determine the order of the final places. Movements are judged on 'freedom and regularity of the paces; the harmony, lightness and ease of movements; the lightness of the forehand and the engagement of the hind quarters, originating in a lively impulsion; the acceptance of the bridle, with submissiveness throughout and without any tenseness or resistance.'[1]

Internationally the sport is known as the Concours de Dressage International (CDI).[1] International dressage competitions are ranked by the Fédération Equestre Internationale (FEI) as increasing in difficulty from one (CDI*) through three-star (CDI***). The abbreviation CDIO designates an Official (Officiel) CDI to which national federations are invited to send selected representative teams and individuals, such as for the

Fig. 51.1
The 7-year-old American Thoroughbred gelding Might Tango, ridden by two-time World Champion Bruce Davidson, performing an extended canter during the Dressage Test at the 1978 World Three-Day Event Championships in Lexington, Kentucky. Note the hyperextension of the fetlocks (left fore and right hind) diagonal to the lead canter limb (right fore).

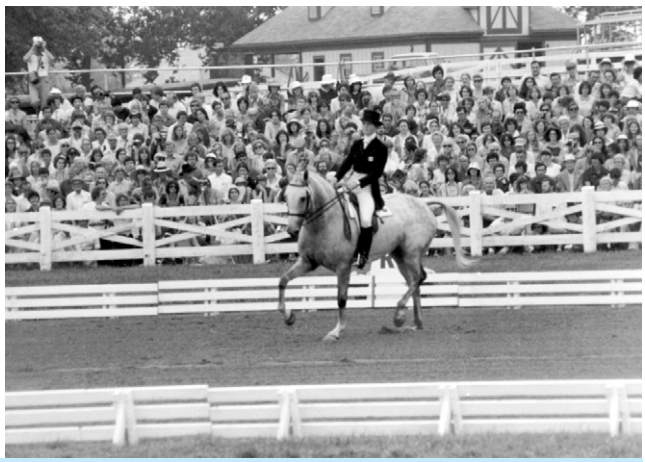

Fig. 51.2
The 14-year-old Canadian Thoroughbred mare Sumatra, ridden by team gold medallist Juliet Bishop, performing a trot circle during the Dressage Test at the 1978 World Three-Day Event Championships in Lexington, Kentucky. Note the degree of lateral bending (lateral back flexion) and impulsion necessary to trot correctly in a curving line, a movement which is required repeatedly in most dressage tests.

Fig. 51.3
The 13-year-old Thoroughbred Village Gossip, ridden by Charlie Micklem, jumping the airy Cirencester Rails over a ditch during the Cross-Country Test of the 1981 Badminton Three-Day Event. The height, spread, and lack of prominent ground lines illustrate the courage and scope required of horses jumping cross-country obstacles at the upper levels of three-day events.

Olympic Summer Games or World Equestrian Games.[2] Levels of increasing difficulty of FEI dressage competition include Prix St Georges, Intermediate I, Intermediate II, Grand Prix, and Grand Prix Special.[1,3] Freestyle is also an FEI-sanctioned competition held at either the Intermediate or Grand Prix level. Competitions sanctioned by USA Equestrian, the national equestrian federation of the USA, are progressively ranked as Training, First Level, Second Level, Third Level, Fourth Level, and Fifth Level (equivalent to international competition).[3]

Event horses are required to perform three sports in one: dressage, cross-country, and showjumping.[4] Events take place over one to three days. Complete three-day events (3DE) involve three tests on consecutive days: the Dressage Test on the first day (Figs 51.1, 51.2), the Cross-Country Test (previously termed the Speed-and-Endurance Test) on the second day (Figs 51.3, 51.4), and the Jumping Test on the third day. The cross-country portion of three-day events involves four phases. Phase A is a trotting warm-up for Phase B, the Steeplechase, in which the horse gallops over brush fences at much faster paces (Table 51.1). Phase C is designed as a cool down phase after Steeplechase. Phases A and C are known collectively as Roads and Tracks. After Phase C there is a mandatory veterinary inspection for 10–15 minutes (Phase X) to determine that the horse is sound and fit to continue (Fig. 51.5). Phase D is the Cross-Country test itself over 30–45 immovable obstacles with heights and spreads requiring speed, endurance, jumping scope, and courage on the part of both the horse and the rider (Figs 51.3, 51.4).[4] The reasoning behind the third day's test, showjumping, is to determine which horses are best able to compete further after the rigorous second day of cross-country.

Internationally the sport is known as the Concours Complet d'Equitation International (CCI).[2,4] International 3DE are ranked by the FEI as one (CCI*) through four-star

Fig. 51.4
The 11-year-old Thoroughbred-crossbred gelding Southern Comfort, ridden by Diane Hall jumping the Boathouse, a more solid obstacle than in Fig. 51.3, but with a drop down into water, during the Cross-Country Test of the 1981 Badminton Three-Day Event. The spread of the jump at the base and at the top, as well as the drop down into the water, illustrate the potential for upper hindlimb injuries from striking a large immovable fence in three-day eventing. The boat is an optical illusion in that the horse and rider would never see it on approaching the fence; it merely provides interesting detail for the photographers in the landing side of the fence.

(CCI****).[3,4] Annual CCI**** include Badminton and Burghley in the UK and Rolex Kentucky in the USA. The abbreviation CCIO designates an Official (Officiel) CCI to which national federations are invited to send selected representative teams and individuals, such as for the Olympic Summer Games or World Equestrian Games.[2,4]

Table 51.1 Speeds, times, distances, and maximum fence heights, spreads, and number of jumping efforts for FEI-sanctioned CCI after rule changes enacted in 2002[4]

Fig. 51.5
Professor Leo Jeffcott, Foreign Veterinary Delegate, taking a facial artery pulse while examining a Danish three-day event horse between Phases C and D at the 1996 Olympic Summer Games in Atlanta, Georgia.

One- and most two-day events are usually termed horse trials and involve a Dressage Test followed by an abbreviated form of the Cross-Country Test (Phase D only) and the Jumping Test, the latter two tests in no specified order.[3] Only recently the FEI has recognized international horse trials with the designation CIC (Concours International de un jour: one- through three-star levels, Table 51.2).[4] American horse trials are sanctioned by USA Equestrian and are ranked in increasing difficulty as Novice, Training, Preliminary (comparable to CCI*), Intermediate (CCI**), and Advanced (CCI***) (Table 51.3).[3] Combined Tests usually include only two of the three disciplines on a single day.[3]

Eventing began as a cavalry competition in northern Europe and made its first appearance as an Olympic sport in Stockholm in 1912. Over the years the sport has evolved through many iterations. Prior to the 1960s, there was also a fifth phase on Cross-Country Day, Phase E, involving another warm-down Roads and Tracks phase after the cross-country phase. An additional rest stop (C Halt) became mandatory in CCI*** and CCI**** in 1999. In 2002, the recommended distances for all phases were shortened and the speed required for Phase C was decreased to allow more walking for increased recovery from Phase B (Table 51.1).[4] These changes were made in response to a spate of recent fatal rider injuries and were based in part on the results of thermoregulatory research on 3DE performed prior to the 1996 Atlanta Olympic Summer Games.[5–14] That research demonstrated that shortening Phase B,[9,10] inserting two additional rest stops (C Halt) on Phase C,[5–8] and some walking (not all trotting) on Phase C[5–8] increased recovery under hot and

humid conditions. Because a subcommittee of the International Olympic Committee in 2002 recommended abandoning eventing as an Olympic discipline, there is ongoing discussion about changing the Olympic CCIO format to a CICO (CIC Officiel) for safety and financial concerns.

Equestrian sports governance

The Fédération Equestre Internationale (FEI) is the international governing body for seven equestrian sports, including dressage, showjumping, eventing, driving, vaulting, endurance, and reining.[2,15] Each nation has its own national equestrian federation. Each national federation is a member of the FEI and governs competition at the national or regional level within that nation, whereas the FEI governs international competition. The national equestrian federation of the United States is USA Equestrian (USAEq), formerly known as the American Horse Shows Association (AHSA). The International Olympic Committee (IOC) oversees Olympic competition. The FEI reports to the IOC for Olympic equestrian sports, including dressage, showjumping, and eventing.

Demographics

At the introductory levels of both dressage and 3DE, innumerable different breeds are seen in competition, from ponies to Thoroughbreds and Warmbloods. In both sports, national or regional influences are seen, particularly in the use of native Warmbloods, owing to their ready availability and popularity as sport horses in any given nation. The USA lags considerably behind in a native Warmblood or sport horse

breeding and reward program compared with the European nations.

As riders progress toward upper levels, dressage horses tend more often to be Warmbloods, thus providing the size, stride length, balance, and agility required for upper level movements. According to the World Breeding Federation for Sport Horses, German Warmblood breeds routinely dominate the rankings of internationally competitive dressage horses and sires of dressage horses.[16] Hanoverians tend to be the most highly ranked dressage horses.[16] Recent gait and conformation analysis data on 3-year-old dressage horses (n = 142) have shown German Warmbloods (Hanoverians (n = 31), Westphalians (n = 16), and Oldenburgers (n = 6)) to be biomechnically superior to both Selle Français (n = 61) and purebred Spanish horses (n = 28) for use in competitive FEI dressage.[17] The superior stature and conformation of the German horses resulted in a longer stride length and decreased stride frequency. The authors concluded that the German horses had gait characteristics more adapted to dressage competition.[17]

At the upper levels of 3DE, horses are primarily Thoroughbreds or Thoroughbred crosses. The Thoroughbred influence is necessary to have the adequate fitness, stamina, and jumping ability required at the upper levels of 3DE. According to the World Breeding Federation for Sport Horses, all 10 of the top 10 sires of internationally ranked 3DE horses in 1999–2000 were Thoroughbreds.[16] Selle Français horses were also very successful in both 3DE and showjumping at the 2002 World Equestrian Games in Jerez, Spain.[18]

Dressage horses may not compete under FEI rules until they are at least 6 years old.[1,2] Horses competing in the Olympic Games or World Equestrian Games must be at least 7 years old.[2] Dressage horses may not compete in Grand Prix, Grand Prix Special, or Grand Prix Freestyle until they are at least 7 years old.[1,2]

Three-day event horses may compete in CIC* or CIC** at 5 years old.[4] They must be at least 6 years old to compete in CIC***, CCI*, or CCI**.[4] Event horses must be at least 7 years old to compete in CCI***, CCI****, the Olympic Games, or the World Equestrian Games.[2,4]

Dressage and 3DE horses have their most productive years at the upper levels between approximately 8 and 12 years of age. There are, however, always exceptions to be found, more often in older dressage horses continuing to compete at upper levels than in younger horses competing precociously. Because of the cumulative and repetitive training which must be accomplished by dressage horses to arrive at the upper levels, they tend to be somewhat older than their 3DE counterparts, who often have difficulty remaining competitively sound later in life due to the rigorous galloping and jumping required in their sport. After their peak competitiveness has passed, many older horses in both disciplines are used further to teach younger riders to compete on safer mounts as they aspire to the higher levels of competition. While these older horses are often difficult to maintain completely sound, their experience and demeanor make them invaluable mounts for upcoming young riders. They also present common challenges to practicing veterinarians who are asked to help to maintain their soundness and fitness to compete despite their advancing ages.

Due to the collection, impulsion, bending and circling (Fig. 51.2), and other types of movements required in dressage, common complaints include sore backs or hocks. Riders often complain of a horse's unwillingness to bend, perhaps worse in one direction than the other. The sore backs or hocks seen frequently in true dressage horses are often also seen in event horses, since they also must complete difficult repetitive dressage movements. Jumping and galloping cross-country (Figs 51.3, 51.4) also contribute to injuries sustained by event horses, as do the rigorous training regimens required to achieve sufficient fitness to compete at the upper levels. Bowed tendons and suspensory desmitis are common supporting leg lamenesses, especially after Steeplechase, and traumatic-origin injuries also occur during Phase D.

Veterinary services

Veterinarians are involved in both sports in various manners. Many are employed as primary healthcare providers on a daily basis. Others are secondary or tertiary healthcare providers, either in an elective or emergent manner. Elective referrals are often for more sophisticated diagnostic imaging techniques such as ultrasonography, scintigraphy, or thermography of musculoskeletal injuries. Emergent referrals are sometimes necessary for all types of emergency conditions typical in any equine practice. More recently, competitors in both sports have embraced alternative therapies, either in lieu of or in addition to conventional therapeutic measures, in an effort to maintain soundness and maximize performance in these elite equine athletes.

Many practitioners also have contact with these horses only at competitions, as treating veterinarians (the conventional 'horse show veterinarian'), team veterinarians, drug testers, or official veterinarians. Treating and team veterinarians are also healthcare providers, but in the crucible of competition. Treating veterinarians often have contact with many of the same owners, riders, and horses over the course of a horse show circuit, and develop a valid long-term doctor–client–patient relationship. Team veterinarians function as treating veterinarians but for only one team, thus allowing more focused and intensive care for a more limited number of horses. The most difficult part of the team veterinarian's job is remembering the FEI Code of Conduct,[19] which states that:

> In all equestrian sports the horse must be considered paramount. The well-being of the horse shall be above the demands of breeders, trainers, riders, owners, dealers, organizers, sponsors or officials. All handling and veterinary treatment must ensure the health and welfare of the horse,[19]

all while the team veterinarian is feeling the intense pressure of the team, governing federation, and home nation in

wanting to 'get a team through' the competition intact with sufficient competitors to achieve a composite team score.

Drug testers and official veterinarians also have as their goal the welfare of the horse, but their responsibility is more regulatory than as healthcare providers. Drug testers or medication control personnel are responsible for collection of blood and urine samples and for establishing an appropriate chain of custody to determine the validity of any evidence of wrongdoing which they may have collected.[19] Official veterinarians are responsible for the health of all the horses competing at a show or event, and make decisions appropriate for that care under the rules of that competition. The competition's Organizing Committee, with the approval of the FEI and/or the national federation, selects a Veterinary Delegate for any FEI-sanctioned competition.[19] The FEI determines the Veterinary Delegate for CCIO, CICO, or CDIO.[19] That Delegate is responsible to head the Veterinary Commission and is also responsible to the Ground Jury for veterinary matters. These responsibilities include: passport control; arrival examinations; control of veterinary practitioners within the stabling compound; recommendations to the Ground Jury about fitness to compete at official jogs or veterinary inspections (Fig. 51.5); and oversight of medication control.[19] Official veterinarians are sometimes at odds with treating or team veterinarians, but all should remember that the officials are ultimately responsible for the welfare of all the horses in the competition. The best relationships are those where the veterinary officials are somewhat flexible before the relationship becomes too adversarial. The treating veterinarians must also remember that the officials have as their primary mandate the welfare of the horse. These officials are often very experienced in their roles, and many have functioned as treating veterinarians in the past.

Common diseases and conditions

Horse competing in dressage or eventing may have all the same problems or internal diseases of any other horse. However, some conditions may be more common due to the type of activity in which they compete. As always, poor conformation also plays a significant role in many unsoundnesses. For example, post-legged or straight hindleg conformation may predispose a dressage horse to hock or stifle lameness, as will sickle hocks or the cow-hocked conformation more common in many Warmblood breeds.

Skeletal

Forelimb problems in dressage horses are less common than hindlimb problems. Improper hoof balance is not a rare problem and is best corrected with the farrier and veterinarian working together to achieve proper medial-to-lateral and left-to-right hoof balance. Because dressage does not occur at high rates of speed, supporting leg lamenesses such as bowed tendons or suspensory disease are less common than in event horses but may still occur, particularly when horses begin to attempt extended gaits (Fig. 51.1). Fetlock synovitis or arthritis is seen secondary to extended movements at upper levels (note fetlock hyperextension in Fig. 51.1), especially in former Thoroughbred race horses converted to use as dressage or event horses.

Foot balance is also of critical importance in event horses galloping over varying terrain with differing footing conditions, all possibly up, down, or sideways to the slope of the hills. Due to the repetitive stresses caused by jumping, event horses are predisposed to developing navicular disease. This predisposition is worsened by poor foot conformation, with underrun and contracted heels, common in many North American Thoroughbreds who are former race horses. Sole bruises, pedal osteitis, and other foot conditions may also be seen due to poor foot conformation, the high training mileage required to keep 3DE horses fit to perform,[20] and the varying surfaces encountered in training and in competition. Because of the high speeds and jumping at speed required in eventing, supporting leg injuries such as bowed tendons or suspensory desmitis are more common than in dressage horses. These injuries are more common as 3DE horses approach the upper levels where horses and riders must learn to negotiate steeplechase courses and fences at the required velocities.

Due to the stresses caused by the excessive hindlimb reaching required in dressage ('impulsion'), hock pain and bone spavin are common maladies of both dressage and event horses. Traumatic stifle injuries are more common in 3DE horses as they progress up the ranks, owing to the greater height and spread of obstacles (Figs 51.3, 15.4) at the upper levels (Tables 51.1–51.3).[21–23] These stifle injuries consist in increasing severity of dermal abrasions ('stifle rubs'), deeper soft tissue or patellar desmitis injuries, or patellar fractures.[21–23]

Corrective shoeing in dressage horses may be done with minimal concerns about shoe loss from over-reaching during high-intensity exercise. Event horses, however, are somewhat more restricted in the use of wedge shoes or bar shoes since they may be more prone to pulling or twisting them off while galloping and jumping cross-country. Horses in 3DE are often shod with threaded holes drilled into the heels of their shoes to allow heel caulks or studs of varying length to be changed before or even during the competition, depending upon the looseness and moisture content of the footing on the day of competition.

Muscular

Exertional rhabdomyolysis (ER), myopathy, or tying-up is not a common problem in dressage horses but is much more common in 3DE horses. This condition may be related to hereditary Thoroughbred ER[24,25] but more commonly has no apparent hereditary component.[24] Unfitness and overheating seem to play important roles in the development of ER,[8,24] as may excessive dietary carbohydrate intake.[24,26] Diets higher

in fat content have proven curative for many horses.[24] Up to 20% of the diet may be fed safely as fat, available in various commercial feed products.[27] One inexpensive and convenient manner of feeding more fat is to increase gradually the daily intake until as much as 2 cups (450 mL) of corn oil twice daily is top-dressed onto the horse's regular grain diet.[27]

Exertional rhabdomyolysis should be considered an emergency, whether it occurs during competition or training, and appropriate therapy should be instituted. Treatments should include cessation of exercise, provision of adequate cooling (oral water, water baths, shade, fans), administration of nonsteroidal anti-inflammatory drugs (NSAIDs), tranquilization (acepromazine for tranquilization and peripheral vasodilatory effects), and eventually diuresis with fluids (40–60 L i.v. of isotonic fluid per 500 kg horse over 6–12 hours).

Hyperkalemic periodic paralysis (HYPP) is a hereditary disease manifesting as muscular weakness in Quarter Horses.[28,29] All horses known to be afflicted with the disease trace their pedigree to a single Quarter Horse stallion who passed it on to his progeny as an autosomal dominant trait with incomplete penetrance.[29] Homozygous horses are more severely affected than heterozygous horses. This condition is not commonly seen in dressage or eventing horses since Quarter Horses compete in these sports less commonly than do Thoroughbred or Warmblood horses. A genetic test is available on EDTA-preserved blood.

Heavier-bodied horses such as Warmbloods tracing some of their ancestry to draft breeds may be predisposed to development of polysaccharide storage myopathy (PSSM).[24,30] This condition manifests as poor performance, tying-up, muscle weakness, or shaking or shivering. Feeding more fat and less carbohydrate as energy sources is curative in many cases.[30]

Back soreness occurs in horses competing in both of these sports, most commonly due to muscle soreness secondary to hindlimb lameness (primarily bone spavin). Back pain may also be secondary to poorly fitting or poorly stuffed saddles in some horses.[31] Less commonly back pain in horses may be due to primary back disease (Fig. 51.6),[32] comprised usually of over-riding dorsal spinous processes, and sometimes of painful spinous processes (Fig. 51.6B, C) without any actual over-riding onto adjacent vertebrae. Thermography (Fig. 51.6A) and scintigraphy (Fig. 51.6B, C) may be important adjunctive diagnostic tools in evaluating back soreness.[33,34] Acupuncture with application of needles[35,36] or cold laser[36,37] can serve as both a diagnostic and a therapeutic tool in back soreness. Massage therapy may only be palliative but can serve to assist in improving performance if the horse feels better afterward, even if only temporarily.[38–40] Chiropractic therapy is often used in horses with back soreness,[40–43] but may serve more to provide massage therapy than actual true chiropractic adjustment. Due to the size differences between patient and veterinarian, and the horse's large muscle masses, huge protected vertebral column, and flighty nature, some scientists argue that true chiropractic adjustment or manipulation of a horse's spine is virtually impossible in a standing athletic horse (LB Jeffcott, personal communication,

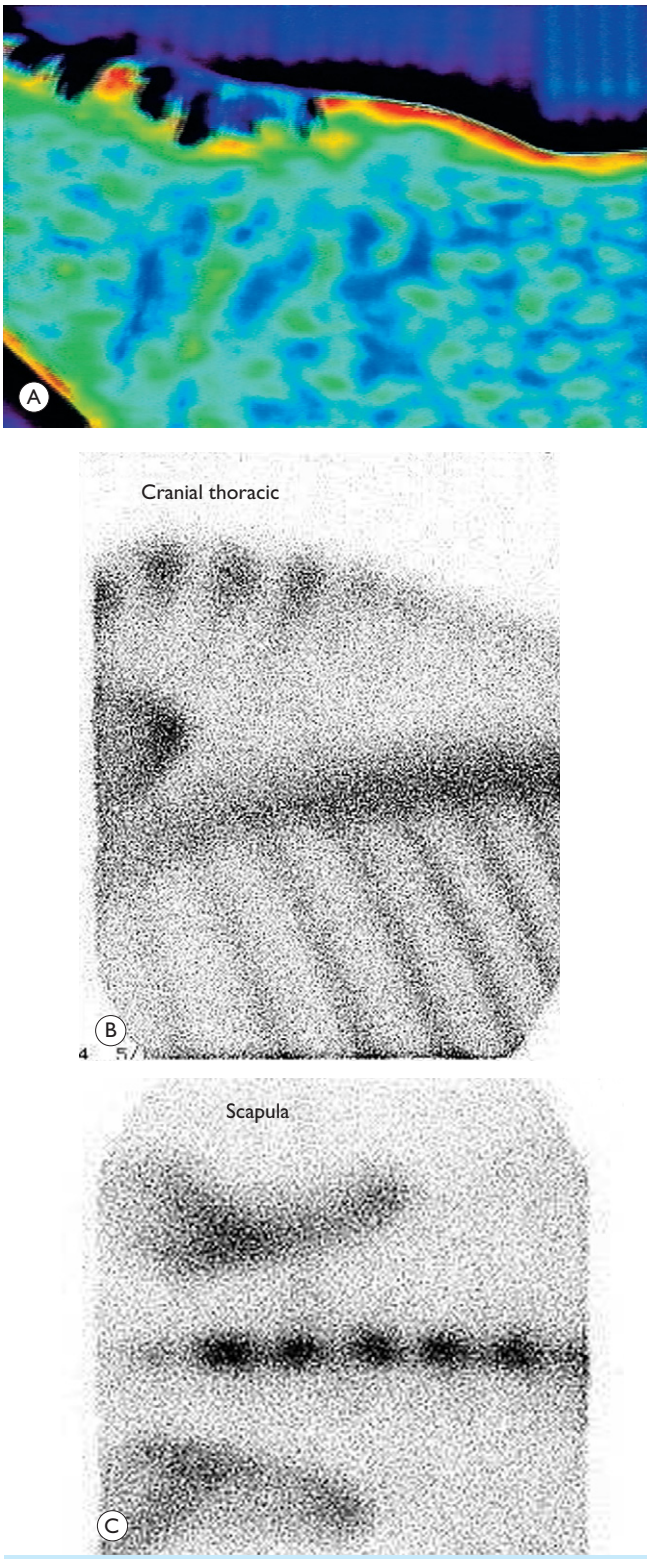

Fig. 51.6
Lateral thermograph (A) and lateral (B) and dorsal (C) scintigraphs from a dressage gelding demonstrating increased heat in the withers (A: red-to-white areas on point of withers) and abnormal radiopharmaceutical uptake (B and C: dark focal increased uptake) in the tips of the dorsal spinous processes of the withers (courtesy of Dr J. Waldsmith, San Luis Obispo, California).

1992–1996). Others feel just as strongly that spinal manipulation is possible and beneficial in athletic horses.[40–43]

Respiratory

Left laryngeal hemiplegia (LLH or 'roaring') is a common problem in both dressage and event horses because both sports emphasize the need for horses of larger stature. Both Thoroughbred and Warmblood horses are more likely to be larger and thus are more likely to be roarers. Surgery is corrective of the hemiplegia but not necessarily of the audible noise. Ironically, the pre- or postoperative LLH noise is considered a fault in the American hunter show ring, so horses that develop LLH as hunters may actually undergo lifestyle changes and become jumpers, dressage, or event horses. Other upper airway obstructions such as dorsally displaced soft palate or epiglottic entrapment may occur in horses competing in these sports but should not be considered to be more common than in other horse sports.

Sinus problems secondary to dental problems may be more common in these horses only because as they get older they are more predisposed to cheek tooth problems. Guttural pouch disease and strangles are not common occurrences in these horses because these are diseases of younger, not older, horses.

Lower respiratory tract problems may be more common in these horses owing primarily to their age and the stress of transport.[44] Depending upon the geographic location, dressage competitions may be more plentiful and require less transport distance for horses to compete. Three-day events and horse trials are much more common in the mid-Atlantic region of the eastern USA, so the distances between horse shows for both event and dressage horses are much greater in the midwestern and western USA. Pneumonia and pleuropneumonia in non-juvenile horses are clearly related to transport stress, particularly after transport greater than 500 miles.[45] Transport stress may be less of a factor in developing pleuropneumonia in European horses owing to the proximity of numerous competitions.

Exercise-induced pulmonary hemorrhage (EIPH) occurs in event horses during or after the Cross-Country Test. Epistaxis is occasionally evident at the end of Cross-Country (Fig. 51.7) but endoscopy is not used routinely for diagnosis as it is in the racing industry. EIPH is not associated with exercise intolerance as commonly in 3DE horses as it is in race horses. The industry-wide North American prophylactic treatment with furosemide (frusemide) is not possible in event horses since it is prohibited due to concern over its dilution of urine and possible masking of positive tests for other prohibited substances.

Heaves or chronic obstructive pulmonary disease (COPD) occurs sometimes in both event and dressage horses. Their occupations do not necessarily predispose them to allergic lung disease, but it is somewhat age-related in its onset and these tend to be older horses when they are at their prime competitive age. Management changes are critical but not curative since the allergy never disappears. Pasture turnout, wetting hay, and minimizing other dust exposure in bedding and diet minimizes allergen exposure and reduces the frequency and severity of exacerbations. Systemic treatment with corticosteroids and/or bronchodilators may be possible during training but is prohibited during competition.[19] Newer inhalation therapies may minimize the chances of a positive drug test but recent research with inhaled albuterol has shown that it is detectable in plasma for several hours after inhalation at therapeutic dosages.[46] Urine ELISA concentrations of inhaled albuterol are not detectable beyond 24 hours after administration, but those investigators recommended an additional 24 hours (48 hours total after the last dose) to avoid a positive urine test after use of the albuterol inhaler.[47] The best scheme should be to manage the disease as best as possible at home and to avoid therapy during competition while still maintaining exposure discipline even while away from home at a horse show or event.

Fig. 51.7
Epistaxis secondary to exercise-induced pulmonary hemorrhage in a three-day event horse during the Cross-Country Test at the 1999 North American Young Riders Championships in Wadsworth, Illinois.

Gastrointestinal

Dental problems in dressage and event horses may predispose them to misbehavior, head-shaking, or refusal to turn in the dressage ring or refusal of jumps in the Cross-Country Test or in stadium jumping. Sharp labial points may cause pinching of the cheek or even oral ulcers which result in oral soreness and sensitivity. Ill-fitting bits may cause similar problems in the rostral mouth area close to the first cheek teeth. Wolf teeth may interfere with proper bitting. Appropriate and regular dental care should be curative. The most common error is that the teeth feel properly floated on superficial examination of the rostral labial surfaces of the first cheek teeth, but caudal enamel hooks and/or buccal points may be present and may cause misbehavior even when not interfering with the bit. Proper and complete oral examination with a speculum and a light source should make the source of the problem evident.

Gastric ulcers may be caused in these horses by a number of factors. Dietary risk factors include high grain intake and minimal pasture exposure.[48] Intense exercise and training stress may be ulcerogenic, as may transport stress. Minimizing stress is important whenever possible, and common anti-ulcer medications (cimetidine, ranitidine, omeprazole) are curative. Ranitidine (but not cimetidine) and omeprazole are approved for use during FEI competitions.[19]

Colic is another stress-related illness in dressage and event horses. Predisposing factors include minimal pasture turnout, transport stress, changes in water and dietary intake at competitions, and stress of competition itself. Cross-country exercise in particular may cause dehydration, especially at upper levels in conditions of high heat and humidity.[49,50] It has been estimated that as much as 10–15% of the horse's extracellular fluid volume may be present in the large colon, and this water reserve is the first source for the horse to mobilize in the face of dehydration.[51] This increased colonic water resorption may result in dehydration of colonic contents and impaction colic. Treatment beyond oral and intravenous fluids and possibly mineral oil may require the horse to be removed from competition.[19]

Diarrhea is another transport, dietary, and competition stress-related illness which occasionally occurs in dressage and event horses. It should be considered an emergency, and is cause for withdrawal from competition and isolation from the general population within the home or competition stable.

Cardiovascular

Cardiovascular diseases are not common in event or dressage horses but may be important when they occur. As elite athletes, these horses commonly have normal athletic arrhythmias such as second-degree atrioventricular block, sinus arrhythmia, wandering atrial pacemaker, or split first and/or second heart sounds. Murmurs should be considered pathologic when loud and systolic. Aortic insufficiency with minimal clinical implications may be ausculted in older horses as an acquired diastolic decrescendo murmur.

Atrial fibrillation (AF) occurs occasionally in 3DE horses[8] more than in dressage horses. It is ausculted as an irregularly irregular arrhythmia and is heard most during the Cross-Country Test, either during the Second Horse Inspection between Phases C and D or after completion of Cross-Country. Typical idiopathic atrial fibrillation occurs as an exercise-induced arrhythmia for no apparent reason. Three-day event horses may be more prone to atypical AF due to fluid and electrolyte loss, especially during conditions of increased heat and humidity (Fig. 51.8A).[8] For example, two horses of 99 starters during the 3DE in the 1996 Olympic Summer Games in Atlanta developed AF during the Cross-Country Test (Fig. 51.8A).[7] In these cases, isotonic fluids (60 L i.v. over 6–12 hours) were administered after exercise and were curative (Fig. 51.8B). Many horses have successfully completed the Jumping Test after developing transient fluid-responsive AF during or after the Cross-Country Test. Rest should be enforced after the competition is over, but the horse may be predisposed to subsequent episodes of AF, especially under adverse weather conditions resulting in increased fluid and electrolyte loss. Dietary supplementation of electrolytes, proper water intake, and appropriate fitness coming into the event may help to minimize the development of AF in future competitions.

Fatal arrhythmia and ruptured aorta[52] are two of the most common causes of sudden unexplained death in 3DE horses. EIPH is rarely fatal in these horses.

Neurologic

Infectious neurologic diseases (e.g. equine protozoal myelitis, West Nile virus) are not more common in dressage and event horses than in older horses performing in other sports. However, 3DE horses occasionally sustain severe neurologic trauma in jumping accidents during the Steeplechase or Cross-Country phases.[53] Fractures of the cervical vertebrae

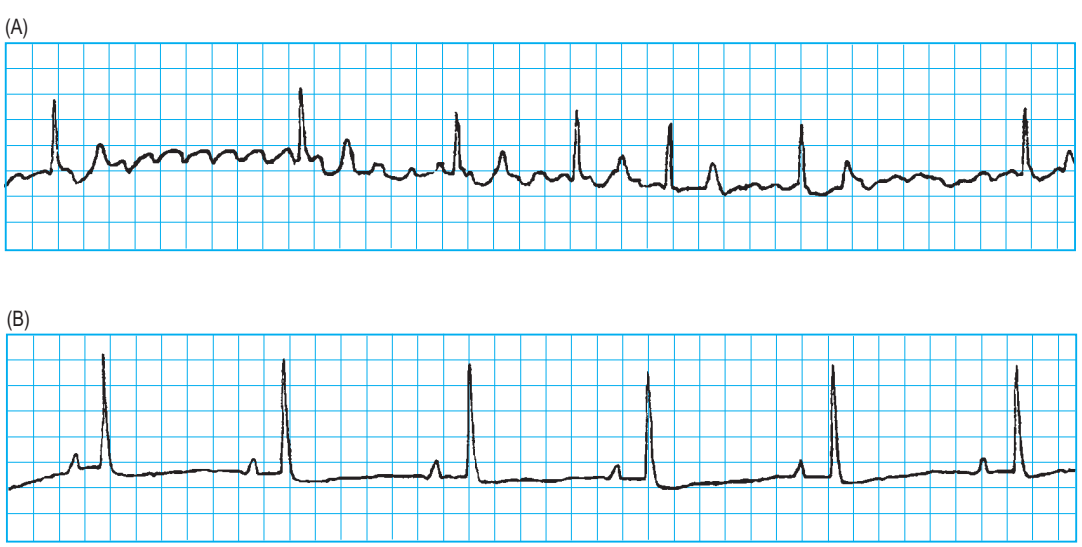

Fig. 51.8 Electrocardiograms performed after the Cross-Country Test in a three-day event horse at the 1996 Olympic Summer Games in Atlanta, Georgia (A) documenting atrial fibrillation before treatment and (B) normal sinus rhythm after intravenous treatment with 60 L of lactated Ringer's solution. Recorded at paper speed of 25 mm/s.

are generally due to falls at jumps, especially at drop fences or water jumps, and invariably prove to be fatal to the horse. Riders can sometimes be injured similarly in these falls.

Endocrine

Estrus behavior is the most common endocrine problem encountered in dressage and event horses. Cycling mares may act inappropriately during the dressage test when it is expected that they should be quiet and obedient. Altrenogest (Regumate) is currently prohibited under FEI rules[19] but not under USA Equestrian rules.[3] Judicious scheduling of competitions around heat cycles or neutering may be the only other alternatives when hormonal therapy is prohibited.

Hypothyroidism remains a controversial but often cited cause of exercise intolerance in horses.[27,54,55] Recent data have shown in a surgical model of hypothyroidism that affected horses have poor cardiac function due to poor myocardial contractility.[54] Affected mares had decreased resting heart rate and cardiac output. This effect is presumed to be due to downregulation of myocardial β-receptors evidenced by decreased cardiac responsiveness to isoproterenol. This poor cardiac function was further manifested in exercise intolerance when these same mares underwent treadmill step tests after thyroidectomy. Supplementation with thyroid hormone partially or completely reversed the various effects of hypothyroidism over one month's time. A commonly cited dose for thyroid hormone supplementation is 30 grains (1.95 g) orally twice daily, yielding approximately 2.5 μg/kg of thyroxine (T4) and 0.6 μg/kg of tri-iodothyronine (T3) with each dose.[27,54,55]

Cushing's syndrome is rare in competitive dressage and event horses because they are usually younger than the typical late-teenaged years of onset of Cushing's disease.

Dermatologic

Ringworm typically occurs in horses younger than those actively competing as dressage and event horses. Saddle-induced skin injuries are also rare as these riders usually take extra precaution to ensure that their saddles fit properly. Lacerations sustained during cross-country are common in event horses and pose particular problems since local anesthetics and sedatives are prohibited substances under all rules.[3,19] Permission may be obtained from the Veterinary Delegate and the Ground Jury for judicious use of small amounts of local anesthetic without sedation. Abrasions, or 'road rash' injuries, are also common from horses falling, slipping on wet grass or pavement, or rubbing their knees, hocks, or stifles over cross-country jumps. While the skin is raw and abraded, the concern in an unsound horse should be the probable underlying soft tissue injury such as patellar ligament pain after a stifle rub. These skin and underlying injuries are of genuine concern to the riders since they may be sufficiently painful to cause a horse to be eliminated at the Third Horse Inspection on the morning after the Cross-Country Test and before the Jumping Test. They require considerable icing therapy and possibly the use of cold lasers on underlying ligamentous pain. Use of alternative therapies such as cold lasers must be reported in writing at FEI competitions.[19]

Ocular

Ocular injuries are not common in these horses, and anterior uveitis is no more common than in other horses. Ocular disease should be investigated, however, as a possible problem whenever a horse suddenly becomes recalcitrant, unwilling to move forward or to jump as freely as usual.

Behavioral

Behavioral problems are sometimes the most difficult diagnoses, since the rider and trainer do not want to believe that it is not something physical that is causing the horse's failure to perform. Perhaps a horse and rider are simply not suited to one another. If either member of the pair is too inexperienced ('too green'), they may not be able to compete effectively despite being completely healthy physically. Some riders, in their nervousness, make certain horses more nervous and skittish than other riders. Horses often 'go better' for the trainer than for the owner/rider, and that rider simply has a difficult time dealing with the fact that he/she does not ride as well as is necessary to get the best performance out of that horse. Tack and bit problems are relatively uncommon but may be the source for some misbehaviors, as may poor dentition. The recycled Thoroughbred race horse is another problem, in that it often comes with poor foot conformation, other injuries such as bowed tendons, and racing-related inappropriate behavior for the show ring such as a frustrating willingness to be overly nervous and unwilling to quiet down at the appropriate time.[56] Some veterinary practitioners feel that acupuncture may have a calming effect in nervous horses prior to competition (A Young, personal communication, 2002).

Metabolic/heat-related

Anhidrosis is a rare problem but is sometimes seen in horses traveling to warmer climates from more temperate climates (e.g. from Chicago to Florida for the winter show circuit). Horses with anhidrosis fail to sweat effectively, although they may sweat in intermittent spotty patches but not diffusely as needed for proper thermoregulation. Diagnosis is by subcutaneous injection of epinephrine (adrenaline) followed by a failure to sweat in the injected area. Therapy is primarily by heat management (ride in cooler climates and cooler times of the day, fans on the stall, frequent baths). One commercial product (One-AC) has been touted as curative for many horses but controlled trials are not available.

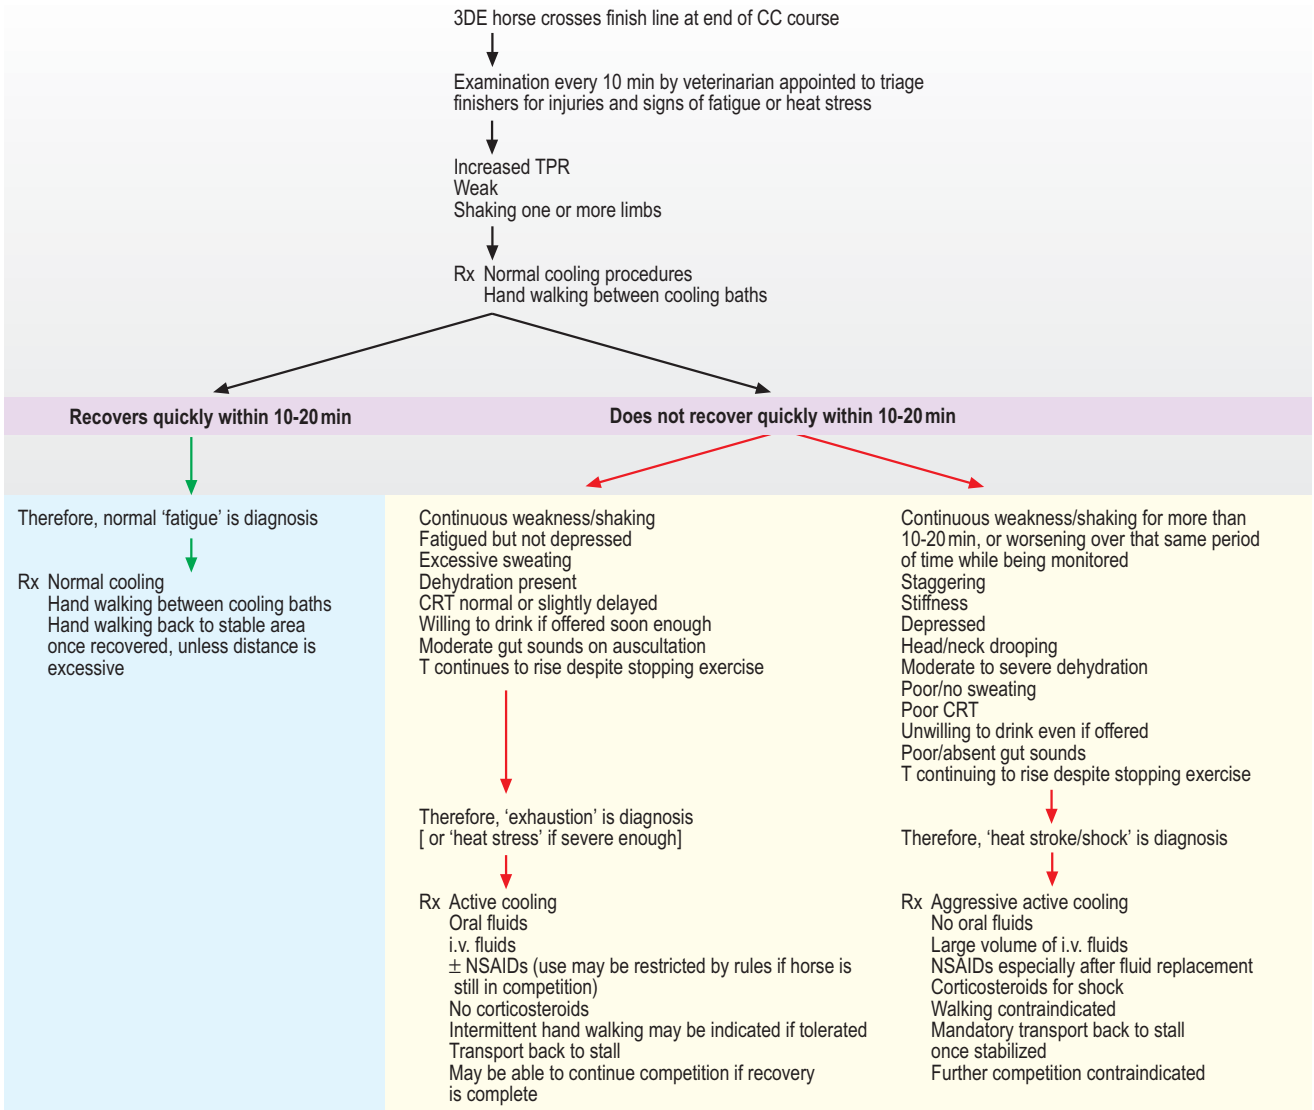

Fig. 51.9
Decision-tree for distinguishing between simple fatigue, exhaustion and heat stress, and true heat stroke. CC, cross-country; CRT, capillary refill time; NSAID, non-steroidal anti-inflammatory drug; Rx, treatment; T, temperature; TPR, temperature, pulse (heart rate), and respiratory rate.

Dehydration, fatigue, and heat-related illnesses are common in 3DE horses, especially when competing in conditions of higher ambient heat and humidity.[5–14,27,49,50,57–60] Heavily muscled dressage horses are also subject to heat-related illnesses. The most difficult decision for the practitioner examining a hot sweaty horse is distinguishing between simple fatigue, exhaustion and/or possible heat stress, and heat stroke (Fig. 51.9).[8] Fatigued horses recover in 10–30 minutes with simple bathing and voluntary water ingestion. Exhausted horses, and those with possible heat stress as part of their exhaustion, do not recover as rapidly but are still willing to drink, move around gradually, and seem moderately alert eventually.[8] Horses with heat stroke are in shock and are profoundly depressed, unwilling to eat, drink, or walk, and do not recover without intensive care in the form of large volumes of intravenous fluids and repetitive external cooling.[8]

Cooling procedures for 3DE and other hot horses have been the focus of considerable research in recent years.[5–8,13,14,61,62] A number of different studies have shown that horses may be cooled actively with large volumes of ice cold water placed repeatedly directly onto their backs and heavily exercised muscles (Fig. 51.10) without any complications such as overt tying-up or subclinical myopathy (manifested as increased plasma creatine kinase activity).[5–7,61,62] Use of this active cooling technique under conditions of adverse heat and humidity has been shown to accelerate the recovery of 3DE horses.[61,62] Shade and fans may also be used to improve heat loss, minimize radiant heat gain, and speed recovery.[5–8,63]

Fig. 51.10
Active cooling being performed on a British three-day event horse between Phases C and D at the 1996 Olympic Summer Games in Atlanta, Georgia. The team veterinarian is observing the bathing of the horse and standing by to administer additional advice or treatment if necessary.

An additional mandatory 10-minute rest stop on Phase C, now called C Halt, has been used in a number of hotter 3DE competitions since 1994 to ensure that horses are properly cooled after Steeplechase.[5–8,11–14] It was shown in the 1996 Olympic Summer Games,[13,14] and in treadmill laboratory simulations prior to Atlanta,[5–8] that C Halt was clearly beneficial to recovery after Phase B galloping in conditions of high heat and humidity. Since 1999, the FEI has mandated the use of C Halt in all CCI*** and CCI**** regardless of the weather conditions.

Horses will drink immediately after endurance exercise such as Roads and Tracks or Cross-Country, but only during approximately the first 5 minutes of recovery, so water or electrolyte water should be offered immediately.[64] If the horse fails to ingest water (i.e. it was not offered, or the horse was too exhausted to drink), water or electrolyte solutions may be administered orally via nasogastric tube (4–8 L of roughly isotonic fluid after exercise) with few complications once the horse has returned to its stall. Administration of intravenous fluids is indicated in horses with overt heat stroke, myopathy, and even simple fatigue and dehydration under severe climatic conditions (Fig. 51.9). Recommended volumes of isotonic fluid range from 10–30 L for simple fatigue and dehydration to 50–80 L over several hours for horses with more serious clinical problems.[8]

Prevention of heat-related illnesses is the purview of the treating veterinarian and should be undertaken aggressively to avoid problems during or after the competition. Horses' water intake should be monitored always, but especially after transport and when away from home. Bodyweight may be the best measure of monitoring hydration status if owners, riders, and grooms have access to a scale and are encouraged to use it.[9,11,65,66] Fluid-loading prior to competition has become more commonplace, especially prior to the Cross-Country Test.[7,8,13] Approximately 2–4 hours prior to competition, the horse may receive safely 4–8 L of oral electrolyte mixture in water (roughly isotonic) via nasogastric tube.[67–70] The only real risk from this procedure is iatrogenic epistaxis. For this reason, some riders or team veterinarians prefer to administer isotonic fluids (5–10 L) intravenously prior to exercise. Each rider must also learn to be constantly aware of his horse's performance, strength, gait pattern, forwardness, and breathing patterns to be sensitive to the possibility that the horse is not feeling well, is 'not itself', and may have some physical reason for performing poorly.[8] After exercise, proper active cooling techniques may assist in recovery and may help to prevent further possible heat-related illness (Figs 51.9, 51.10).[5–8,13,14,61–63]

Medications during competition

The different governing bodies of equestrian sport retain the right to set their own drug rules and penalties for violations. Since 1992 FEI has maintained a zero tolerance policy toward nearly all drugs, including NSAIDs, in horses in competition. The inherent philosophy is that there should be a level playing field for all horse and rider pairs, and that to allow any performance-altering drugs to be present on the day of competition might allow one competitor to have an unfair advantage over his/her counterparts by having better medication, not necessarily a better horse. There are a few substances for which FEI has set maximum allowable limits, since they can be present in horses to a slight extent due to natural exposure through feedstuffs or other environmental contamination.[19] Those substances for which maximum thresholds have been established under FEI rules include: total carbon dioxide (37 mEq/L plasma), dimethyl sulfoxide (DMSO: 15 μg/mL in urine or 1 μg/mL in plasma), hydrocortisone (1 μg/mL in urine), salicylic acid (750 μg/mL in urine or 6.5 μg/mL in plasma), theobromine (2 μg/mL in urine), total arsenic (0.3 μg/mL in urine), and the hormones nandrolone and testosterone.[19] FEI rules allow the use during competition of most antibiotics, anthelminthics, vitamins, fluids and electrolytes, ranitidine (but not cimetidine), and omeprazole.[19]

During or just prior to a competition, a horse may require treatment for any of dozens of different medical or surgical problems. In these various situations, the FEI General Regulations state:

> The Veterinary Commission/Delegate must give written approval on the appropriate form before any veterinary treatment or medication with a Prohibited Substance is administered to a horse during the entire course of an event. If during this period it is urgently necessary to treat a horse with a Prohibited Substance, the Veterinary Commission/Delegate must be informed at once and the circumstances reported to the President of the Ground Jury. Any treatment so administered must be indicated to the Veterinary Commission/Delegate by written certification. The Ground Jury must, on recommendation of

the Veterinary Commission/Delegate, decide whether the horse may take part or continue in the event, having regard to the welfare of the horse and to the possibility that the competitor may obtain an unfair advantage.[2]

Three examples of entirely different clinical circumstances follow to illustrate common but complex interpretations of FEI medication rules. (1) A horse sustains an eye injury or corneal ulcer which requires local medication but which may not require any medication that might unlevel the playing field. Systemic flunixin meglumine should be avoided in this horse but might be used in a similar injury out of competition. (2) A horse sustains a small laceration which will not prohibit further competition but which requires suturing. Judicious use of a local anesthetic might be approved by the Veterinary Commission but sedation might not be approved prior to suturing. The anesthetic will be in a small amount and should have no lasting consequence on the future of the competition. However, tranquilization might affect the competition since it might make a dressage horse, for instance, quieter for a test the following day, obviously depending upon the dose and drug used. Its legitimate use to suture the laceration might also make it more difficult to detect a second dose given illicitly the following day. Finally, (3) a horse develops colic signs severe enough to require systemic use of an NSAID. This horse should be treated and removed from competition since it (a) has a medical problem severe enough to preclude it from further competition for medical reasons alone, and (b) has received one or more doses of an NSAID which might affect the outcome of the competition since the NSAID will also have musculoskeletal effects that might benefit the horse and create an unlevel playing field.

The most commonly detected foreign substances in the FEI Medication Control Programme are analgesics (primarily NSAIDs including salicylic acid), comprising 58% of the positive samples in 1999 (AK Allen, personal communication, 2001). Corticosteroids, caffeine, theobromine, isoxsuprine, and tranquilizers are less commonly encountered. From 1990 to 1998, 79% of the positive drug tests in FEI competitions were from showjumpers, and only 9% and 8% were from 3DE and dressage horses, respectively.

USA Equestrian rules are just as restrictive as those of the FEI for most substances such as stimulants, tranquilizers, and other mood-altering drugs.[3] However, USAEq rules are much more liberal than FEI with respect to NSAIDs.[3] The philosophy simply put is that therapeutic medications allow some horses to continue to compete at an effective level over the course of a season or over the course of a long horse show. The rule specifically states, 'The full use of modern therapeutic measures for the improvement and protection of the health of the horse and/or pony is permitted'.[3] USA Equestrian rules prohibit the use of any drugs within 24 hours of competition, but they allow for fairly liberal use of five different NSAIDs up to 24 hours prior to competition. Furthermore, two different NSAIDs may be detected legally in horses in competition as long as: (1) phenylbutazone and flunixin meglumine are not detected in the same horse on the same test, and (2) each NSAID detected is below a maximum threshold established by USA Equestrian. Those maximum thresholds are set for plasma concentrations of phenylbutazone (15 μg/mL), flunixin (1 μg/mL), ketoprofen (0.25 μg/mL), meclofenamic acid (2.5 μg/mL), and naproxen (40 μg/mL).[3] Tranquilizers, cocaine, and NSAIDs above the allowable limits are the most commonly detected foreign substances under USAEq medication testing (AK Allen, personal communication, 2001).

Finally, there are innumerable unsanctioned or unrecognized horse shows that may not be subject to any drug testing by a governing body unless local law allows for testing. California law, for instance, allows state veterinarians from the California Drug and Food Administration to drug test any horse show in California, sanctioned or otherwise. Most European Union countries now have commonly restricted use of NSAIDs in horses in general, although veterinarians in the UK have fought what they see as a restriction on their ability to practice freely to promote optimal health and pain relief in their equine patients.

Depending upon the governing body, the rider may also be subject to drug testing during a competition. Any competitor identified by the national federation as an international level competitor is also subject to random, unannounced, out-of-competition drug testing by the national federation at any time.

CHAPTER 52

Veterinary aspects of endurance riding

Michael A. Foss and Steven J. Wickler

Overview of the sport

Endurance riding is an internationally recognized sport in which a horse and rider team covers a designated course within a set time. Although horses have been used for centuries to transport people over long distances, the sport of endurance racing originated in the USA relatively recently, and then spread rapidly to Australia and other parts of Oceania, Europe and the Middle East. The Western States (USA) 100 has run continuously since 1955 and involves a one-day event that has a 7500 foot elevation change over a challenging terrain. A well-known eastern US event, the Old Dominion, is a 100-mile event that has been run for 29 years. In the USA, the major endurance organization, the American Endurance Ride Conference (AERC), was started in 1972 and now sanctions over 700 rides annually. In 1990, an endurance event was held at the first World Equestrian Games in Stockholm. In 1992, the Fédération Equestre Internationale (FEI) recognized endurance riding. With this sanction, endurance racing became a truly international equine sport (Table 52.1). At the 2002 World Endurance Championship, a total of 36 countries participated. In 2002, the Pan American Endurance Championship had nearly 90 horses participating from nine countries. Some countries have established endurance programs dating back to the 1960s, while in other countries the sport is new. In most of these countries, the rules of endurance racing are very similar to the FEI rules, although the courses and climate can be quite different.

Endurance rides vary in distance from 20 to 480 km, although single day rides are usually between 40 and 160 km (25–100 miles). Single day events are the most common, although some rides last several days and cover several hundred kilometers. FEI-sanctioned rides must be over 80 km.[1] The course has multiple check points (known as 'vet gates') at which veterinarians inspect the horses and determine whether or not the horse may continue in the race.[2] The first horse and rider to cross the finish line are declared the winners, but only if the horse is judged to be sound upon completion. Emphasis is on completing the event safely (to finish is to win) and formal recognition is made of the top finisher (usually in the first 10 placings) that is in the best overall physical condition.[3]

The wellbeing of the horse is emphasized and the veterinarian plays a key role in this regard. The veterinarian has complete control concerning fitness to continue during an event. Riders also place a premium on welfare of the horse; they are generally very respectful of veterinary judgments, even in those situations in which the horse is removed ('pulled') from competition. The use of heart rate monitors for continuous assessment of the horse's heart rate is common.

Types of horses

Arabians and Arabian-crosses are the predominant breed used for endurance riding. This distinction is probably based on their muscle fiber composition[4] and a preferential ability to utilize lipid during submaximal exercise.[5] That said, mules, Tennessee walkers, and a mix of other breeds can be seen in any endurance event. The monetary value of horses participating runs a large gamut, ranging from horses trained in the stables of Sheiks to the 'backyard' horse.

Endurance horses are typically of a lean, medium build, 14-2 to 15-1 hands tall, with bodyweight ranging between 390 and 480 kg (850 to 1050 pounds). Deep chest, medium to short back, and correct legs are other desirable physical characteristics. The feet should be large, medium to short toed, strong walled and set to support the leg. The movement

of the horse's legs must be smooth and efficient. Any movement away from the axis of a leg during the swing phase of the stride, such as winging out, is a weakness. Long sloping pasterns that place the heels under the front of the cannon bone are also a weakness.

Control veterinarian

This individual takes responsibility for knowing the rules (regulations are provided by each sanctioning group, e.g. AERC or FEI) and controlling the flow of the ride. The control veterinarian determines and sets the criteria for heart and respiratory rates required for a horse to continue in a race (common criteria would be a heart rate of 60 beats per minute and a respiratory rate of 40 per minute). In hot and humid climates, particularly when the heat index is high, the time to reach target heart and respiratory rates may be lengthened to ensure adequate recovery. Throughout the ride, as weather conditions change, the control veterinarian can dictate changes in these control parameters. The control veterinarian also attempts to ensure uniformity in veterinary assessment throughout the race. There are likely to be several veterinarians seeing multiple horses, but not necessarily the same one throughout a race.

Treatment veterinarians

These individuals, acting under the supervision of the control veterinarian, participate in horse assessment pre-ride and during the ride itself. The role of the treatment veterinarian is to treat problems encountered at the ride. The intermingling of 50 to 250 horses at one venue increases the likelihood of infectious disease. As well, life-threatening metabolic conditions somewhat unique to horses engaged in endurance races are common. The treatment veterinarian must be skilled in the early recognition and treatment of these problems. Even a short delay in treatment until clinical signs are advanced can result in poor outcome. The treatment veterinarian must be prepared for the worst-case scenario that may occur in a remote area. Treatment rates at rides vary from 2% to 20% of the entries, and it is not unusual for 10% of the entries (at a high-profile ride) to require treatment for metabolic disease. One horse with a metabolic condition may require 50 or more liters of

intravenous (i.v.) fluid. Therefore, it is mandatory for the veterinarian to have a large supply of i.v. fluids.

Team veterinarian

The role of the team veterinarian is to help the horse and rider prepare for a competition (usually a championship) and assist them during the competition. This usually involves working with a team of people such as the farrier, physiotherapist, private veterinarian and the horse's support group.

Pre-ride inspection

Baseline data are collected prior to the start of the ride. A physical examination includes auscultation of the heart, lungs and abdomen, assessment of hydration state (skin pinch and capillary refill time), and examination for any pre-existing cuts, scrapes, bruises, tack sores, etc. The horse should then be trotted out (40 m) and back for assessment of gait and soundness. After the trot, a more complete lameness examination, including flexion tests and digital palpation (particularly to assess tendon/suspensory problems), may be indicated. Palpation of the back using gentle pressure is important for evaluation of soreness. Tone of the gluteal and semitendinosus muscles is also determined. Careful recording of these data on a ride card provides an important baseline for temporal monitoring of the horse's performance throughout the race.

Vet gates

Ride management, usually in consultation with the control veterinarian, determines the location and number of vet gates. Horses coming into these gates have their arrival time noted on the card and may not leave until a certain time has elapsed and/or they have reached the heart and respiratory rate criteria. A commonly used test is called the ridgeway trot or cardiac recovery index (CRI). After measurement of the pulse rate, the horse is trotted to a point 40 meters away and trotted back. The horse's pulse is recounted 60 seconds after the *start* of the trot. If the pulse rate recovers to the original pulse (± 4 beats), then the horse is considered metabolically stable. If the horse's pulse is more than 4 beats above the original value, the horse is examined more closely. If the recovery pulse is greater than 12 beats above the original value, an underlying metabolic problem should be considered. General physical and lameness examinations are also performed at many of these gates and the results are recorded on the ride card that accompanies the horse and rider.

Finish

A post-race physical and lameness examination is done to identify the 'best of condition' finisher (usually out of the top 10 finishers) but more importantly, to identify potential metabolic problems. Best Condition is the award given to the horse judged to be in the best condition after the completion of the ride – the soundness of the horse along with metabolic parameters and signs of wear and tear are scored. Some riders would rather win the best condition accolade than finish first.

Metabolic conditions

Metabolic conditions secondary to dehydration, electrolyte and acid–base abnormalities, heat accumulation and substrate depletion are common in endurance horses and can be life-threatening. Sweat fluid losses as high as 15–20 liters per hour may occur during the course of a ride. Therefore, some degree of dehydration is the norm rather than the exception.[6] Any endurance horse in metabolic distress should receive *at least* 15 to 20 liters of fluids, preferably via the i.v. route. Figure 52.1 provides one view of a field hospital where large amounts of fluid can be delivered on site.

Exhaustion

Exhaustion is due to the compound effects of dehydration, electrolyte imbalances, heat accumulation and substrate depletion.[7] The condition carries a favorable prognosis if recognized and treated early in the clinical course. On the other hand, a delay in treatment can lead to life-threatening complications such as laminitis and renal failure. Presenting history is variable but may include depression, stumbling or weak gait, lameness, depressed appetite, anorexia, dehydration and an unwillingness to drink, and a facial expression often described as 'glazed-over', 'blank' or 'grimaced'. Affected horses are often dehydrated with dry mucous membranes; membranes may demonstrate peripheral congestion

Fig. 52.1

(margination of the gum line). Heart rate recovery is often delayed, seldom dropping below 64 beats/min in the CRI test. Gastrointestinal sounds may be diminished or absent, and there may be signs of colic. The stool may be covered in mucoid material. Signs of hyperthermia, myositis, and synchronous diaphragmatic flutter also may be present.

Blood analysis usually reveals findings consistent with dehydration and electrolyte depletion. The total protein concentration can be greater than 8 g/dL, packed cell volume (PCV) greater than 50%, blood glucose concentration decreased, creatine phosphokinase and aspartate aminotransferase activities elevated, and total carbon dioxide or bicarbonate concentrations decreased (alkalosis). Electrolyte abnormalities often include hypocalcemia, hyponatremia, hypochloremia, hypokalemia and hypomagnesemia.

The primary goals of therapy are to rehydrate and refuel the horse. In mild cases of exhaustion, a longer 'hold' period (e.g. additional 30–60 min) in the vet gate often facilitates recovery. This extended rest allows the horse to eat and drink, thereby replacing fluid and electrolyte deficits. Importantly, the rider must be instructed to significantly slow the pace of the ride. If the horse is removed from competition, further treatments can be administered. It is important to consider the duration of transportation between race venue and the home farm or stable. Long transportation periods will place additional stress on the exhausted horse. Clinical experience has shown that aggressive rehydration will help the horse recover quickly and make the trip home less stressful. If the horse has a functional gastrointestinal tract, it is helpful to rehydrate by administering 4 to 6 liters of isotonic water through a nasogastric tube. This can be repeated every 30 to 60 minutes as needed. In most cases the authors prefer to employ the i.v. route due to ease of fluid administration and comfort to the horse – 15 to 20 liters should be given initially, with the administration of further fluid if the horse does not urinate.

The prognosis for uncomplicated exhaustion is good. However, exhaustion that is complicated by colic, persistent hyperthermia or laminitis carries a more guarded prognosis. Prevention of exhaustion is reliant on the skill of the rider in managing race speed in relation to horse fitness, weather, competition conditions, and trail conditions. More aggressive electrolyte supplementation regimens also may be indicated in horses with a history of exhaustion in previous rides.

Hyperthermia

The metabolic consequences of sustained exercise include the accumulation of a substantial heat load.[8] A failure to balance this heat gain with heat loss leads to an excessive elevation in body temperature that decreases athletic performance and can be potentially fatal. When the gradients for convective, conductive and radiant heat loss are small or non-existent (typical of a sunny, hot and humid day), the *only* mechanism for heat loss is evaporation. When humidity is high, heat loss by this mechanism is also inefficient. Some horses develop an inability to sweat (anhidrosis) that exacerbates the occurrence of excessive hyperthermia.[9] Typically these horses are raised in cooler climates and the onset is precipitated by transport to and performance in hot and/or humid climates.

At veterinary checkpoints, riders will complain that their horse is tired. If the horse is trotted out for a lameness examination, it will show poor impulsion. These horses have delayed recovery rates, and may present with an elevated heart rate. Respiratory rates are elevated and may be rapid and shallow (panting). Rectal temperature is often greater than 40°C (104°F). Borborygmi are diminished (or may be absent) and there may be signs of dehydration. Blood parameters may be normal or indicative of hemoconcentration (increased plasma total protein and PCV).

The primary goal of treatment is to cool the horse rapidly. All tack should be removed and the horse moved to a shaded area. Aggressive cooling can be done with large quantities of water applied with a hose or sponge. Cool (or, in very hot conditions, ice cold) water is preferred as it creates the largest gradient for heat transfer between the skin and the applied water. Water should be applied over the entire animal, including neck and legs. Repeated cycles of water application and removal (using a scraper) are necessary for continued heat loss at the skin surface. Controversy exists on the use of cold water over the lumbar and gluteal muscles.[10] One of the authors (MAF) avoids cold water in this area with the experience that this practice can result in muscular cramping. Isopropyl alcohol may be added to the cooling wash. The use of ice water enemas has been advocated in severe situations. Misting fans and sprayers are very useful when available.

The effectiveness of cooling procedures is easily monitored by frequent measurement of rectal temperature. Once rectal temperature falls below 40°C (103.5°F), cooling efforts can be discontinued. As hyperthermic horses are dehydrated, hydration status should be assessed and appropriate fluid therapy provided.

The prognosis for recovery is good, but failure to resolve the hyperthermia may lead to exhaustion, colic, heat stroke and potentially death. There are two facets to the prevention of excessive hyperthermia. First, the rider must be willing to decrease racing speed when environmental conditions compromise heat loss. Second, close attention must be paid to the monitoring of body temperature and hydration state during rides.

Colic

Endurance horses often experience colic during or soon after a ride. Although the etiology of these colic episodes is not known, it is likely that dehydration and acid–base and electrolyte abnormalities predispose to disturbances in gastrointestinal function, including ileus. Clinical signs are variable, ranging from mild to severe abdominal pain. In the authors' experience, failure to recognize and treat mild colic in endurance horses can contribute to the development of more serious conditions (anterior enteritis, impactions, strangulation, or even death).

Initial clinical complaints may be mild and vague. For example, a rider may state that the horse is 'just not right'.

During rest periods or even on the trail, the rider may report that the horse is unwilling to eat, or that it appears colicky after eating. Painful episodes vary from mild to uncontrollable. Greatly diminished or absent borborygmi are a consistent finding. Mucous membranes are often dry (dehydration) and may be congested. The horse's energy level will vary from slightly to severely depressed. Palpation per rectum should be done with extreme care because the rectal mucosa may be very dry and friable. In horses with ileus, small intestinal distension may be detected. Laboratory findings are non-specific, but may include evidence of metabolic alkalosis (pH > 7.5), hypokalemia, hypocalcemia, hypochloremia and hemoconcentration.

The therapeutic aims are to reduce pain and correct fluid deficits and electrolyte imbalances. Butorphanol, detomedine and xylazine are the first choice drugs for management of pain. Low doses of flunixin meglumine can be used but only after correction of dehydration. Intravenous fluids should be given, with a minimum dose of 15 to 30 liters administered over a 60 to 90 min period. Fluid therapy should be continued until the horse urinates and gut sounds return. In the authors' experience, as much as 80 liters of fluid can be required for complete rehydration and restoration of normal gastrointestinal function. It is advisable to leave a nasogastric tube in the stomach during treatment because in some horses small intestinal distension and gastric reflux develops during the rehydration process. For this reason, close monitoring is required if the oral route is used for fluid administration. If oral fluids are given, they should be administered in small amounts and frequently, e.g. 4 to 5 liters every 30 to 60 minutes. Some veterinarians also favor the use of intestinal stimulants in horses with non-obstructive colic (see the 'Medications' section).

A key to preventing colic during and after endurance rides is the early recognition of dehydration. Adequate electrolyte administration during the ride, provision of palatable drinking water, and modulation of the intensity of the ride based on ambient conditions are essential. When diminished gut sounds are first recognized, the horse should be rested and given time to eat and drink. Thereafter, the horse may continue the ride at a slower speed.

Exertional rhabdomyolysis (tying up, Monday morning disease)

Exertional rhabdomyolysis (ER) appears in two syndromes in the endurance horse. The first and most common syndrome is seen early in the ride, usually before the 20-mile point. The second syndrome is observed later in the ride, usually after 50 miles. They both are treated similarly but may have different predisposing factors.

The early-onset ER may occur within just a few miles of the race start. Often the rider reports an abnormal behavior of the horse, such as cantering but reluctance to trot, extreme anxiety or just not moving out normally. Upon clinical examination, the horse may be reluctant to move or lame with a shortened stride. Swollen gluteal or lumbar muscles are often detected. On rare occasions, the horse may be recumbent and unwilling to rise. Sometimes the first sign is simply an elevated pulse in the vet gate.

Horses with the later onset ER seldom have swollen muscles and may not be lame. The overall clinical picture is one of exhaustion and a diagnosis of ER is often based on recognition of myoglobinuria and/or elevated muscle enzyme activities. Some affected horses will be persistently tachycardic (usually above 60 beats/min), and it is often possible to elicit muscle cramping or spasm when the lumbar or hindlimb muscles are carefully palpated.

Measurement of serum muscle enzyme activities (creatine kinase (CK) and aspartate aminotransferase (AST)) is key to the diagnosis. In this regard, the advent of portable analyzers has been useful in facilitating rapid diagnosis.[11] Serum electrolyte values are usually within normal limits.

Prompt and aggressive treatment is required in horses with ER. In particular, horses with evidence of myoglobinuria require i.v. fluid therapy to avoid development of pigment nephropathy. Fluid delivery rates as high as 15–20 liters per hour are recommended until the horse urinates. The rate of administration should then be decreased to 5 to 10 liters per hour and maintained at this rate until the urine is clear. Pain may be controlled by use of butorphanol (0.01–0.02 mg/kg), detomidine (5–10 μg/kg) or xylazine (0.2–0.5 mg/kg). Flunixin meglumine must be used with caution as clinical experience has indicated that even low doses (0.5 mg/kg) have been associated with development of renal failure in dehydrated endurance horses. Acepromazine (0.02 mg/kg) for vasodilation can be used in conjunction with i.v. fluids. As dysregulation of calcium flux in skeletal muscle is one proposed mechanism for development of ER,[12] the use of dantrolene sodium (6–10 mg/kg via nasogastric tube) has been advocated in the treatment of clinical episodes. Massage and heat treatment of the affected muscles can be effective. Hot packs can be improvised by heating water, soaking a towel in the hot water and then enclosing the towel within a plastic bag. This approach will keep the horse's hair dry, thereby preventing chilling when the hot pack is removed. The horse should be blanketed during treatment. The protocol is to apply heat and massage for 30 minutes followed by 30 minutes of rest. Hot packing and massage are continued until the muscle softens. Electrical stimulation of affected muscles may also be effective for attainment of muscle relaxation. Acupuncture is another treatment modality favored by some clinicians. Transportation of the horse can exacerbate the condition and should be delayed until the horse is stabilized.

With appropriate and aggressive treatment, the prognosis for recovery is good. It is possible, but not recommended, to have a horse compete successfully within a few weeks of a very serious ER episode.

There are a number of theories relating to the pathophysiology of ER.[13,14] However, no specific etiology has been identified for ER in endurance horses, although, anecdotally, long-distance transportation has been identified as a predisposing factor. In addition, horses that develop ER during rides often have had a 1–2 week period of lay-up just prior to a competition. Preventive strategies in horses with a history of

repeated episodes of ER include feeding higher-fat, lower-starch diets, the elimination of grass pasture from the diet, and the maintenance of a regular training schedule in the weeks preceding the ride.[14,15]

Synchronous diaphragmatic flutter (SDF, thumps)

Development of SDF is relatively common in endurance horses[16] and is indicative of underlying fluid, electrolyte and acid–base disturbances (see Chapter 40). The incidence of SDF increases in hot and humid conditions, when the horse is ridden at speeds beyond its current level of conditioning, or when the first 20 miles of the ride are run at a fast pace. All of these factors promote large sweat fluid losses with attendant dehydration, acid–base and electrolyte disturbances. Riders often do not detect the SDF and require counseling regarding the underlying cause and prevention of the problem. Clinical signs of SDF can develop at various distances along the ride and are often noticed while evaluating heart rate.

The striking clinical feature is contraction of the diaphragm and flank that coincides with cardiac contraction. As a result, respiratory and heart rates are similar. Even after a mandatory hold when heart rate has returned to the release criterion (e.g. 60 beats/min), respiratory rate remains elevated. In severe cases the entire body appears to jump with the diaphragmatic contraction. Heart rate may be elevated and gut sounds are usually diminished or absent. Often the horse appears dehydrated and tired.

There are no other conditions that mimic SDF. However, the clinician must determine whether other conditions exist, e.g. dehydration, overheating, ER. Dehydration is usually the most significant additional factor. Results of a serum biochemical analysis can reveal some or all of the following: alkalosis, hypokalemia, hypocalcemia, hypochloremia, and hyperproteinemia.[17] Response to treatment with calcium is considered proof of the diagnosis.

The cornerstone of treatment is the administration of calcium-containing solutions. The horse should be withdrawn from the ride. Even in the absence of serum biochemical testing, it is reasonable to assume that horses with clinical signs of SDF are dehydrated, hypocalcemic and alkalemic. One of the authors (MAF) initially administers 125 ml of 23% calcium borogluconate that is diluted in 1 liter of saline or other polyionic fluid. The heart should be asculted during calcium administration; the rate of fluid administration should be slowed or discontinued if tachycardia or arrhythmias develop. Further calcium should be given until resolution of thumping. Large volume fluid replacement is usually indicated in horses with SDF; additional calcium may be added to these fluids and administered over the next few hours. If i.v. fluids and calcium are not available, the horse should be allowed access to forage, preferably leafy alfalfa, and encouraged to drink. Oral electrolytes with calcium should be provided when possible. An alternative approach to therapy is to administer 500 mL of calcium borogluconate by mouth.

The prognosis for SDF recovery alone is excellent when appropriate treatment is used. The underlying dehydration must be corrected. Prevention strategies are aimed at minimizing electrolyte imbalances during rides, specifically decreases in ionized calcium. Therefore, appropriate supplementation of oral electrolytes should be practiced during the ride (see 'Oral electrolytes' section). At times it is necessary to adjust the composition of the electrolytes to meet the needs of individual horses. The effectiveness of the supplementation strategy can be assessed by analysis of blood samples collected under competition conditions. It is recommended to reduce alfalfa intake prior to an event. Grass hay is preferred but oat hay is suitable when grass hay is not available.

Laminitis

Laminitis is a possible sequel of any metabolic problem, but may not be clinically apparent for several days after resolution of the metabolic crisis. Consequently, riders should be advised to observe the horse closely for several days after treatment of metabolic problems. Aggressive treatment of the primary problem, including correction of fluid deficits, is the most important preventive measure. It is beyond the scope of this chapter to address the treatment of laminitis.

Lameness

Lameness is the most common reason for elimination from competition. This section will briefly describe the lameness problems most commonly encountered in endurance horses. More in-depth description of these conditions can be found elsewhere in this text.

Suspensory desmitis

This condition is the most common cause of lameness in endurance horses. If not diagnosed early, it can lead to a long layoff or to termination of a competitive career. Although common, suspensory desmitis is often difficult to diagnose. For example, affected horses can appear sound after a warm-up. Important history includes recent competition in soft, sandy or muddy terrain.

Palpation of the leg is important. The ligament may be of normal size, shape, and texture; there seldom is visible swelling of the ligament. However, it should be noted that many sound endurance horses have enlarged suspensory ligaments that are not inflamed, although there may be some degree of sensitivity to palpation. In horses with clinical desmitis, it is usually possible to locate a point of sensitivity upon careful palpation. Pain level can be slight to extreme. Confirmation of suspensory desmitis requires a diagnostic workup that does not lend itself to the field. Nerve blocks may be diagnostic but are not always conclusive. Ultrasound and radiographs are the most commonly used tools. However, thermography is sometimes helpful.

Therapy is aimed at relieving pain, eliminating predisposing factors and rehabilitation. Anti-inflammatory drugs, rest and corrective shoeing are the main components of therapy. Phenylbutazone (2 to 4 mg/kg once daily) and methylsulfomethamine (MSM; 15 ml per 450 kg) are commonly effective in the relief of pain. In acute cases (first 12 hours), ice therapy is very useful (see 'Tendinitis' section, below).

Leg and foot conformation of affected horses should be evaluated to determine the need for corrective shoeing. Heel support is essential and can be achieved by several shoeing methods, including egg bar shoes, extended heels and the wide web plastic shoes. When viewed from the side, the heel of the shoe should be directly under some portion of the cannon bone. The use of shoes that extend behind the heel must be weighed against the tendency of the horse to pull off shoes that protrude behind the heel. The length of the rest period depends on the severity of the injury. Mild cases need only a few weeks of rest, whereas a 12- to 18-month lay-up may be required for a horse with substantial fiber tearing. The results of an ultrasound examination will guide recommendations for the duration of the rest period. Furthermore, regular ultrasound examinations are useful to monitor recovery. The horse can be slowly returned to regular exercise when pain has subsided.

The prognosis for mild cases is usually excellent. On the other hand, more severe cases are prone to recurrence and can result in termination of the horse's competitive career. Prevention is aimed at minimizing conformational predisposition. It is important to work closely with a knowledgeable farrier. Long toes and low heels can predispose to suspensory injury and should be avoided. Finally one must carefully evaluate the underfoot conditions used for training in relation to those present at rides. If the horse has only been conditioned in firm footing, a competitive ride in sandy conditions will unduly stress the suspensory ligaments. Accordingly, if the horse is going to compete in deep sand, a conditioning program that includes training in similar terrain should be designed.

Tendinitis (bowed tendon)

As with distal ligaments, tendons are at high risk for injury in endurance horses. There also appears to be a higher prevalence of hindlimb tendinitis in endurance horses compared with other disciplines. Most endurance horses can recover from tendinitis and depending upon the severity, can resume mild to moderate competition. However, such injuries can be career limiting in the elite, 100-mile horse.

Muscle pain (myositis, muscle cramps, stiff)

Horses with localized muscle pain may be acutely lame or present with subtler gait abnormalities (e.g. stiff; 'not moving right'). The gluteal and lumbar muscles are most often affected, followed by the gracilis muscle. Upon physical examination, hard and/or painful areas can often be found, but it should be recognized that in many horses it is difficult to identify a source of pain. If laboratory testing is available, muscle enzyme activities and serum electrolyte concentrations should be evaluated. Myositis can elevate CK and AST dramatically, aiding in the differential diagnosis. Low calcium and potassium may contribute to muscle problems, as might low selenium.

As with true exertional rhabdomyolysis, therapy for myositis includes the use of anti-inflammatory drugs and i.v. or oral fluids. If these are muscle cramps and the rider intends to remain in the ride, no medications may be used. Acupressure, massage, heat and stretching may be tried in these circumstances. After competition, butorphanol and non-steroidal anti-inflammatory drugs (NSAIDs) are recommended for analgesia. Electrical stimulation and acupuncture may also aid in recovery.

The prognosis for simple muscle cramps is good. Muscle cramping is often related to inadequate conditioning and holding an abnormal posture while working. Therefore, the level of conditioning should be tailored to meet the demands of the trail. Hill work often helps to decrease cramping. The identification and treatment of underlying lameness problems (e.g. sore back) may decrease the tendency for compensatory posturing.

Sore feet (stone bruise, corns, sore heels)

This lameness is usually recognized during a ride and may be intermittent, acute, chronic, related to shoeing, related to trail conditions or have no identifiable pattern. Standard diagnostic and therapeutic procedures should be applied, but particular attention should be paid to the hoof conformation and the need for corrective shoeing. Frequently, the heels of the shoe are too short and narrow. The heels should not be rolled in or crushed, and the shoe must be wide enough to support the heel even when the shoes have been in place for 5 or 6 weeks. Unbalanced feet and thin or soft soles also predispose to bruising, the former by promoting uneven loading pressures on the sole. Some variation of the egg bar shoe, wide web shoes or a combination of these designs can be used for horses with stone bruises or sore heels. Pads may be used, but it is preferred to have a correct shoe without pads. For horses with soft or thin soles, it is advisable to schedule shoeing appointments at least one week prior to a ride. Many riders will use sole 'toughener's' that consist of a mixture of tincture of iodine, acetone, alcohol and formaldehyde. If the horse lives in a moist environment and will be riding on a rocky trail, footpads should be applied. If the course is sandy, holes should be cut in the pads to prevent the trapping of sand under the pad.

Degenerative joint disease (DJD, arthritis, dry joint)

The signs of DJD include a vague lameness that progresses from lameness post-ride, to intermittent lameness during rides, and finally to a consistent lameness. Progression may

take more than a year. DJD is very common in endurance horses, perhaps because these animals are subject to very high concussive loads. The metacarpal-phalangeal joint is the most often affected, but may include the distal interphalangeal joint, and to a lesser extent, the distal tarsal-metatarsal joint. The prognosis for athletic performance is usually guarded to poor.

Therapeutic aims are to reduce inflammation, increase joint fluid quality and preserve the remaining joint. Training and competition workloads must be curtailed. Using hill and interval training techniques will allow for a decrease in the number of miles needed to condition a horse. Intra-articular steroids have limited use in endurance due to the 'no-drug' philosophy and inexact withdrawal times of the medications. However, glycosoaminoglycans and hyaluronic acid are commonly used in an attempt to improve the quality of joint fluid. Oral supplementation with glucosamine, chondroitin sulfate, and MSM is also widely practiced, although there are limited data from controlled studies to support the effectiveness of these supplements.

Interference

Interference injuries are common in endurance horses. The most common site is on the caudo-medial side of the metatarsal-phalangeal joints. Interference seems to occur when the horse becomes tired or when it is on a technical portion of the trail. Poor shoeing and conformation also contribute to this problem. Acute interference is best treated with ice, NSAIDs, and rest. Prevention is attempted through careful evaluation of hoof balance and shoeing. Boots can be applied to the leg but are not wholly protective in severe cases.

Trauma

Trauma is common in endurance riding. The terrain of the course is the most significant factor in determining the type and extent of injury. Horses are injured by events ranging from running into sticks to falling off cliffs. The veterinarian must be prepared to treat everything from a small cut to fractures and should be prepared to treat a horse in a remote area, many miles from a road.

Shoeing

Proper shoeing is essential to the endurance horse. Even a small error in shoeing will result in lameness as the hoof strikes the ground thousands of times. The most common error is the use of under-sized shoes. This results in weak support of the heels, and therefore the entire bony column of the leg. The small shoe also allows the heels of the hoof to expand over the shoe as the hoof grows, resulting in pressure on the sole rather than the wall and the development of bruising, pain and crushed heels. Hoof imbalance is also quite common. Correction of shoeing problems requires clear communication between the veterinarian, the owner and the farrier. A very useful tool is video gait analysis on a high-speed treadmill. This removes subjectivity and allows one to experiment with a variety of shoeing techniques in a short period of time.

Lameness of unknown source

During the ride, the principal role of the control veterinarian is to prevent injury (or further injury) to the horse. The first role, then, is to decide whether the horse is sound or lame, but it is beyond the expected duties to diagnose the source of pain. Rather, the team, advising or treatment veterinarian should investigate the cause of lameness. On many occasions the source of lameness will not be identified. If the horse recovers fully within two or three days it may not be necessary to establish a diagnosis, unless this is a recurring situation. In these situations, a very useful diagnostic tool is nuclear scintigraphy. Another approach for dealing with these vague lameness problems is chiropractic evaluation and treatment. While many veterinarians do not recognize the value of acupuncture and chiropractics, these modalities are used extensively in endurance horses.

Miscellaneous problems

Gastric ulcers

Clinical experience has indicated that gastric ulcer disease is common in endurance horses. Presenting clinical signs are variable but include poor appetite, weight loss, recurrent bouts of mild cold, behavioral changes after the administration of oral electrolytes, or simply a prolonged post-exercise recovery time. Physical examination may reveal little other than rough hair coat and thin body condition. A definitive diagnosis is made by endoscopic examination of the stomach. Standard anti-ulcer treatment (e.g. omeprazole) is usually effective and the prognosis is good.

Tack injuries

The endurance horse has more opportunity for tack injuries than most horses simply due to the time the tack is on the animal. Injury commonly occurs at the girth, over the back, at the corners of the mouth, rostral jaw and on the medial aspect of the metacarpal- or metatarsal-phalangeal joints. During a ride, the application of ice to these lesions is beneficial. If not in competition, NSAIDs along with topical cortisone are helpful. Insuring properly fitted tack is the key to treatment and prevention. Some materials do not work for certain horses and the rider must keep trying additional designs and/or materials. Sheepskin and neoprene products seem to work well. These materials still have to be kept smooth, clean and free of plant material.

The boots worn on the legs of horses can cause as many problems as they are supposed to prevent. 'Splint boots' and 'interference boots' must fit properly and not slide while the horse is working. In certain conditions the boots will trap sand and cause abrasion. The heavy boots that enclose most of the leg can trap heat and actually precipitate dermatitis. It is the authors' opinion that 'sports medicine boots' are inappropriate for endurance horses. Other types of protective boots should only be worn during the part of the competition where injury is likely, such as the last part of the ride or a particularly rocky section of the trail. There is no indication that boots reduce concussion.[18]

Back pain

Back pain is very common in endurance horses and is probably responsible for many cases of poor performance and 'sour' attitude. However, back pain tends to be underdiagnosed and poorly treated. Back pain can present as lameness, a reluctance to work, bucking/rearing, or more subtle changes. A thorough physical examination of the back begins with a soft touch using the palm of the hand and gentle stroking from the withers to the pelvis. Next, the same area is re-examined using fingertips and moderate pressure to identify individual muscles. It is important not to apply heavy pressure, as many normal horses will find this painful. Areas of edema and open sores can be detected using this technique. Treatment of acute back pain should be aggressive. Swollen or raw lesions should be iced. A topical solution of dilute DMSO containing dexamethasone (0.2 mg/mL) should be applied twice daily. Flunixin meglumine is the NSAID of choice. To continue training the rider may need to modify a saddle pad to prevent any pressure on the affected area (such as cutting out a piece of the pad over the affected area). The prognosis is generally good, but some horses can have recurrent problems and skill in acupuncture, chiropractic treatment and saddle fitting is required to manage these cases effectively.

Transportation-related problems

Endurance competitions attract riders from long distances. It is not unusual for horses to be transported hundreds of miles for a 'local ride'. Championships will draw horses from thousands of miles. It has become apparent that the athlete who travels long distances is at a disadvantage and is more predisposed to metabolic problems. The typical history involves a horse that competes without problems close to home but experiences metabolic problems when competing at a venue some distance from home base. This 'problem distance' is unique to each horse but approximately 500 miles is common. The most common problem in horses transported long distances to endurance rides is exertional rhabdomyolysis, followed by colic.

In many cases, no abnormalities are detected at the pre-ride examination. Some horses will be mildly dehydrated. If the transportation was undertaken in very high temperatures, dehydration can be more severe. Some horses will develop a cough if conditions are dusty. There is also risk of shipping fever (pleuropneumonia); horses with signs of depression should be evaluated for pneumonia or infectious respiratory disease. Results of serum biochemistry tests are usually within normal limits in transported horses. Any elevation in serum CK activity should be considered significant, and the horse considered at high risk for development of myositis.[19]

Experienced practitioners often think of a transported horse as a horse that will tie up unless treated correctly. This treatment focuses on rehydration and controlled exercise aimed at restoration of normal muscle function. Rehydration is accomplished through the administration of electrolyte solutions (see Chapter 64) via nasogastric tube two to three times daily until hydration is satisfactory. If CK activity is increased, a controlled exercise protocol should also be initiated. The exercise protocol begins with hand walking for 40 to 60 minutes two to three times a day for 3 days. On the fourth day, begin riding the horse twice daily. Start with only a walk and do not 'collect' the horse during these workouts. After the horse is adequately warmed up (30 minutes), begin adding a few trot steps. Trot for 10 seconds, walk for 3 minutes, trot for 20 seconds, walk for 3 minutes, trot for 30 seconds, walk for 3 minutes. Continue increasing the trot phase by small increments until the horse is trotting for 2 minutes. Walk to cool out and then stretch the horse. Thoroughly educate the rider about the very early signs of tying up. Exercise should be stopped immediately if the horse has any reluctance to trot or walk with a full stride. The horse can probably return to a normal routine when it has reached 20 minutes of continuous trotting. During this phase the horse must be carefully monitored. Measurement of CK activity on a daily basis is very important. Daily examinations and palpation of all back and leg muscles should also be performed. Muscle massage is also very useful.

Prognosis is good to excellent. Recurrence is likely in horses that have experienced metabolic problems subsequent to long-distance transportation unless a successful management plan is designed. Some horses simply do not seem capable of dealing with long-distance transport.

The cause of these conditions is speculative, although dehydration and restriction of movement during transport are suspected to be contributing factors. Most endurance horses are not kept in stalls, but rather in large paddocks where there is the opportunity for ample exercise. It is possible that when these horses are forced to stand in a small space such as a horse trailer or box in an airplane, their muscles are somehow compromised and prone to tying up.

Prevention requires planning and time. If the competitor is serious about giving the horse the best chance for optimal performance, careful planning of transportation is required. If the horse is being transported privately in a truck or trailer, the duration of transport should be not more than 10 hours per day and rest stops should be taken every 4 hours. At rest

stops, the horse must be taken out of the trailer and hand walked for 30 minutes. If possible, the horse should be allowed to graze. At one of the rest stops, it is recommended to ride the horse for 30 to 60 minutes. The horse should be fed only hay, with no grain or concentrate. The maintenance of hydration is critical. This is accomplished through the administration of water (6 to 8 liters) via nasogastric tube two to three times daily during transportation. If a veterinarian is not available for this treatment, an alternative is to dose with oral electrolytes twice daily and ensure free access to fresh drinking water (see 'Oral electrolytes' section).

If the horse is transported in a commercial vehicle, there must be adequate time to rest after the trip. Unless there is a unique circumstance, the horse must not be ridden until it has gone through the aforementioned exercise regimen. This usually requires a minimum of a week before normal exercise can be resumed. A long and strenuous trip requires two weeks.

It is now common practice to administer anti-ulcer medications prophylactically to horses traveling long distances. Omeprazole is the medication of choice.

Nutrition

The complete nutritional needs of the endurance horse are inadequately studied[20] and are beyond the scope of this chapter. A few basic ideas are presented here; further information about the nutritional management of equine athletes is presented elsewhere in this text.

Forage-based ration

Forage should be the foundation of the endurance horse's ration. If the horse has 'happy guts' it will perform much better. The ideal forage is high-quality grass hay. When grass hay is not available, oat hay is acceptable. The last and poorest choice is legume or alfalfa hay. Horses fed primarily alfalfa hay are more prone to metabolic problems, especially synchronous diaphragmatic flutter.

Concentrates

Endurance horses require less grain than other equine athletes. Many horses compete successfully when consuming less than 3 kg (6 lb) of concentrate daily. Diets high in corn seem to lead to metabolic problems. Vegetable oil and rice bran are used for the horse that cannot maintain weight.

Supplements

A wide variety of supplements are available. The value of many of these supplements is questionable given the lack of data regarding safety and efficacy. Many horses are on multiple supplements and the complete ration should be evaluated for excesses and imbalances, contraindications and possible illegal substances. Some metabolic enhancers contain caffeine.

Feeding during rides

The endurance horse must eat during a competition. The ideal caloric intake during a ride is controversial, but if the horse's intestinal tract is not functioning normally, the horse will not be able to complete. It is acceptable to let the horse eat whatever it wants. 'Smorgasbord' is a good description of offerings to the horse at a ride. Hay, the feedstuff usually identified as the favorite, must always be present. Some riders soak the hay in water. Grain and beet pulp can be offered separately or together as a slurry or mash. Apples, carrots and other treats may also be offered. Electrolytes are not usually mixed in with the food; instead they are administered after the horse has eaten. Vegetable oils are believed to be of little use during the ride.

Training

General considerations

Training of the endurance horse is an exercise in extreme patience. It takes approximately 4 years to develop a fit, 160 km competitor. The horse will always feel like it can do more than it should. It is up to the rider to prevent injury of the horse. A thorough explanation of training is beyond the scope of this chapter.

Regular health maintenance

Routine preventive health care of the endurance horse is paramount. It is best to schedule dental work in the resting season. In general, vaccination programs should be tailored to the region but horses traveling internationally have special vaccination requirements, the specifics of which will depend on the destination country. It is important to bear in mind that exposure to contagious pathogens is the rule rather than the exception as all horses drink from common troughs during competitions. Standard parasite prophylaxis should also be practiced, including routine fecal egg examinations.

Medications

Oral electrolytes

Oral electrolyte supplementation is used extensively.[21–25] The basic premise is that the horse will lose far more electrolytes via sweating during a competition than can be reasonably

replaced by voluntary consumption. There is limited research on the benefits of electrolyte supplementation in endurance horses during competitions but clinical experience strongly supports their use. Many supplements are available and the clinician must evaluate them carefully. The electrolyte mixture must replace what is lost in sweat and it must be absorbable (see Chapter 40). The dosing of electrolytes is more art than science. Weather and competitive factors are the largest influences on the amount of electrolyte needed. In general, the higher the heat and humidity and the harder the horse has to work, in terms of both speed and terrain (sand or mud footing; hilly course), the more electrolytes the horse needs. The general guidelines to use in planning an electrolyte supplementation protocol are: (1) electrolytes have optimal benefit prior to dehydration and electrolyte depletion; (2) the composition of supplements should be matched to losses; and (3) a functional intestinal tract is an absolute requirement for absorption and the administration of oral electrolytes is contraindicated in horses with ileus. Oral electrolytes are poorly effective once the horse is clinically dehydrated. A commonly used protocol is to give a dose of electrolytes the night before the ride, a second dose the morning of the ride prior to the start, and then a dose at every veterinary check. With experience, this regimen is either increased or decreased.

Analgesics

Pain relief is important in treating problems. Butorphanol is commonly used for many applications, especially ER and colic. Detomodine and xylazine are used for colic.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) are a very popular and effective class of medication. However, care must be taken when administering these drugs to endurance horses during competitions because of the potential for nephrotoxicity. Flunixin meglumine is the most popular NSAID and is used at 0.4 to 1.0 mg/kg for abdominal pain. Clinical experience has indicated that even the low dose can be nephrotoxic in some severely dehydrated horses. Phenylbutazone is commonly used for musculoskeletal pain. A dose of 2 mg/kg is given initially and only after the horse is known to be eating and drinking well. The dose may be increased to 4 mg/kg after return to normal hydration. Ketoprofen is used for abdominal and muscular pain at a dosage of 0.5–1 mg/kg. If any NSAIDs are used, adequate hydration must be assured.

Corticosteroids

Dexamethasone is rarely used in endurance horses. Experience has suggested an association between the use of dexamethasone and the development of laminitis in exhausted and dehydrated horses. Prednisolone sodium succinate (Soludeltacortef) has been used safely. Triamcinolone and methylprednisolone acetate (Depo-Medrol) are used in treating joint pathologies. The clinician must always consider withdrawal times as the rules of endurance riding prohibit the presence of any drug at the time of competition.

Intravenous fluids

Intravenous fluids are the most important medication for endurance horses. Rehydration with i.v. fluids is frequently the only treatment required for many medical problems. During competition, as much as 10 to 15 liters of fluid is lost per hour of exercise. In dehydrated horses, fluids should be administered until the horse urinates. This usually occurs after 15 to 20 liters of fluid has been administered. Once the horse urinates, the horse's clinical signs should dictate the rate and quantity of fluid administration. If all parameters are acceptable, the authors recommend the administration of 50% more fluid than it took to produce urination. Otherwise, continue fluids until clinical signs are resolved. Rate of flow is usually limited by the catheter size or fluid administration set. Many horses need infusion rates of 20 liters per hour. In our experience, over-hydration does not occur, rather the tendency is to be too conservative with fluid treatment.

To achieve an adequate fluid rate, a large bore catheter is needed (10- or 12-gauge catheters are recommended). If 14-gauge catheters are used, then it may be necessary to insert catheters into both jugular veins. Sutures or use of skin glue should anchor catheters. Thrombosis is a potential complication. Fluid delivery systems are very useful. One should take a pole to serve as an i.v. stand. Several models of extendable poles are available commercially, but one can always be inventive when in the field.

It is generally assumed that the dehydrated endurance horse is hypokalemic, hypochloremic, hyponatremic, hypocalcemic, hypomagnesemic and alkalotic. Accordingly, the i.v. fluid of choice is Ringer's solution. The next choice is normal saline (0.9%) supplemented with potassium (20 meq/L) and calcium. Multisol and Normasol are often used. Although these fluids contain alkalinizing agents (acetate and gluconate), they are still very useful. The last choice is lactated Ringer's solution. Again, although this fluid is alkalinizing it is suitable in situations where no other fluid types are available and i.v. fluid therapy is required.

Intravenous fluid additives

The working endurance horse develops abnormalities not adequately corrected by commercial preparations. Commonly used additives are listed below.

- Potassium is usually added as KCl solution. Normally 20 meq/L is added to appropriate i.v. fluids.
- Dextrose: Blood glucose can be supported by giving 50 to 100 g of dextrose per hour. A 5% dextrose solution is made by adding 100 mL of 50% dextrose per liter of fluid.
- Calcium: It is usually supplemented as a diluted bovine milk fever solution. The authors add 125 ml of

NorCalciphos to a bag of fluid and administer this solution to effect. Heart rate and respiration are monitored during treatment.

- Sodium bicarbonate. This is contraindicated in endurance horses since they are normally alkalotic when they are in metabolic distress.

Intestinal stimulants

Ileus is a common problem during competition rides. Intravenous fluids should be the first medication used in an attempt to restore intestinal motility. If i.v. fluids are not effective and the clinician has ruled out intestinal displacement or severe impaction, further medications may be used. One of the authors has used: prostaglandin $F_{2\alpha}$ (Lutalyse) at 10 mg i.m. for small and large intestinal ileus, and erythromycin lactobinate (200 mg/mL) at 100 mg i.v. for treatment of small intestinal ileus.

Use of oral laxatives is contraindicated until dehydration has been corrected. Saline cathartics (Magnalax) and dioctyl sodium succinate (DSS) are useful to break up impactions. Mineral oil is very widely used but has minimal effect in softening impactions.

Diuretics and miscellaneous medications

Intravenous fluids are the most effective diuretic and should be used before any other diuretic is considered. Furosemide (frusemide) depletes potassium and adequate hydration must be assured prior to its use.

Dopamine is most often used to treat myositis, but its use is controversial. Dopamine is used only after 20 L of i.v. fluids have been administered and no urine has been produced. Intravenous fluids must be continued while dopamine is administered. Dopamine should be given through a separate i.v. catheter to allow for a slow drip. The dose is 2 to 5 μg/kg per minute. One of the authors adds 120 mg of dopamine to 1 liter of saline and infuses 2 to 4 mL per minute to effect. Once urination occurs, the infusion is discontinued.

DMSO may be given either i.v. or orally. The i.v. dose is 100 to 250 mL as a 10% solution. Oral DMSO is given through a nasogastric tube. A maximum of 1 pint of DMSO can be given as a 10% to 20% solution.

Dantrolene is used in the treatment of acute myositis. It can be given orally and i.v. The oral dose is 3 to 5 g per horse. No dose is found in the literature for i.v. usage but one of the authors (MAF) feels there is benefit from as little as 500 mg.

Acepromazine is a potent vasodilator and useful in acute myositis. The horse must be adequately hydrated before acepromazine is given. The dose is 10 mg every 6 to 12 hours.

Methocarbamol is occasionally used for myositis. Its effectiveness is questionable, although its sedative action may offer some benefit.

CHAPTER 53

Veterinary aspects of training and competing polo ponies

Rebecca E. Posner

Polo ponies represent a unique subset of the sporting horse population. The nature of the game of polo and the standard management and training procedures associated with it predispose this group of horses to a variety of disease conditions.

History

The sport of polo can be traced back to the Persian court of King Darius, who reigned during the fourth century BC. From there polo spread eastward to China, Japan, Mongolia, and Tibet. The name 'polo' actually comes from the Tibetan word 'pulu', meaning root, from which the wooden ball was made. The sport was first played in the UK in 1860 by returning British army officers who had seen it played in India. In 1875 the English Polo Association was established. The British went on to introduce the sport to the East Coast of the USA in 1876. The United States Polo Association was formed in 1890.[1] Today there are over 2000 playing members in the British Polo Association, officially called the Hurlingham Polo Association.[2] There are more than 3000 playing members in the United States Polo Association. Polo is now played around the world in over 30 countries[1] including countries from South America, where Argentina has produced some of the most accomplished players. In the USA polo is a recognized National Collegiate Athletic Association sport, with both men's and women's teams from universities such as Cornell, University of Connecticut, University of Virginia, and University of Colorado competing, with each season culminating in National Finals.

The game

Polo is played either 'indoors' or 'outdoors', with many horses playing indoor polo in the winter months and outdoor polo during the summer months. Outdoor polo is played on a 10-acre grass pitch measuring 300 yards in length and 160 yards in width. There are four members on each team, and a game consists of six chukkas each lasting 7 minutes. Indoor polo is played in a high-walled, dirt-floor arena, measuring 300 feet in length and 150 feet in width. An indoor polo team comprises only three members per team and a game consists of only four chukkas. Each polo pony commonly plays only one or possibly two alternating chukkas in a given game. An average outdoor player must therefore have a minimum of three, but more commonly six or seven ponies to play in a game (A Flint, personal communication, 2000).

Because of the smaller playing area, indoor polo tends to demand more turning, bumping, and physical contact than its outdoor equivalent. Outdoor ponies, due to the size of the field they must cover, often have greater flat speed and endurance. The different demands of outdoor and indoor polo not only often cause different types of horses to be used but also determine the types of injuries that may occur (TN Christian, personal communication, 2000).

General strategy and positions

The object of both the indoor and outdoor polo game is to be the team that scores the most goals at the end of the game. The ball is hit forward, backward and diagonally off both sides of the polo pony. There are eight basic shots that the player hits with a mallet which ranges from 48 to 52 inches in length depending on the size of his or her mount. The rules of polo are lengthy and can be confusing even for seasoned

players, but the majority are aimed at ensuring the safety of horse and rider. Many of the rules are based around the 'line of the ball' to ensure a right- of-way system. When a polo ball is hit there is an imaginary line that extends in front and to the back of that ball dictated by the ball's trajectory. If a player crosses that line, and in so doing, impedes the action of an opposing player, the player is deemed guilty, by an umpire, of crossing 'the line' and a foul is then given.[1]

The most basic strategy of polo is to keep one player in front of the ball (offensive), one or two players in the action in the center of play, and one player behind the ball (defensive). The players play positions in a game, numbered 1 to 4 in an outdoor game and 1 to 3 in an indoor/arena game. The number 1 player indoors, and the 1 and 2 outdoors, are the most offensive and 'optimistic'. These players try to keep themselves ahead of the ball, ready to take a forward pass and score. The number 2 indoors and the number 3 outdoors is often the most skilled, and aggressive of the team. These players are also often the best mounted. This is the pivot position in which the player should have his nose in every play and be the one who must 'make things happen'. The number 3 indoors and the number 4 outdoors is the most defensive, 'pessimistic' player or 'the back'. They are responsible for initiating defensive maneuvers, closing the back door, and preventing the opposing number 1 from scoring (DE Eldredge, personal communication, 2000).

Rating

A handicap system is used in the sport of polo to try to ensure evenly matched games. Beginning players have low ratings or 'goals'. Starting at –2 goals, ratings increase to the ultimate rating of 10 goals. Professional polo players are usually rated 7 to 10 goals and are often paid by patrons who are lower rated. The remaining members of the team may be made up of medium rated players who are usually other patrons, lower-rated professionals, or young up-and-coming players. The mount of a 'high goaler' is expected to run faster, turn quicker, and be involved in more plays than its lower goal counterpart. Whilst the lower goal mount's job may seem easier its rider is often not as experienced. This mount may be asked to turn before being properly set up, or for a burst of speed at the end of a long chukka. Thus the polo ponies' job, and the injuries they are exposed to may also vary depending on the rating of the player (A Snow, personal communication, 2000).

Demographics

The United States Polo Association defines a polo pony as 'A horse or pony of any breed or size'.[1] The job of the polo pony does, however, tend to dictate the size, breed or 'type' of horse. The polo mount must be fast enough to outrun competitors, sturdy enough to bump another horse off a play and survive the rigors of a 7-minute chukka. They must also be able to accelerate quickly, then stop, turn on their haunches, and accelerate again. Finally, it must be sufficiently stable during galloping to allow the rider to hit a ball accurately. Depending on the particular flow of the game a chukka may be mostly galloping, or it may be filled with many stops in the action. Even low-goal (non-elite) polo has been shown to put moderate to high stress on the cardiovascular system.[3] Compared with racing Standardbreds or Thoroughbreds polo ponies have high blood lactate concentrations.[4] Because of these requirements, many polo ponies are Thoroughbred or Thoroughbred crosses. The Argentine Thoroughbred is stockier and somewhat shorter than its British and American counterparts and is particularly suited to the game. Many of these horses are transported worldwide and make up the majority of mounts in a high-goal game. American and British Thoroughbreds that may have been destined for the track are often successful on the polo field. In the USA the larger and longer American Thoroughbred may be crossed with the Quarter Horse to improve its turning and sprinting ability. Although originally there was a height limit for polo ponies of 12 hands this was abolished in 1919 and now 'polo ponies' are usually horses averaging 15.1 to 15.3 hands in height. Mares and geldings both play polo, whereas stallions are excluded due to their temperament and the close-quartered nature of the game (Fig. 53.1). Mares tend to be over-represented in the sport of polo and are thought to

Fig. 53.1
Polo game at the British Universities Championships demonstrating the close contact characteristic of the game.

be 'tougher' and have 'more heart' than their male counterparts (J Horsewell, personal communication, 2000).

Polo ponies are usually broken between the ages of 2 and 3, and then first played in slow or 'green' chukkas at the age of 4. Polo, like any equine discipline, takes time, experience, and training to develop a good mount, and the polo pony will be in its prime between the ages of 6 and 8. Often a 'high goal' pony will be 'retired' to a lower goal young player or a patron, and it is certainly common to have ponies playing well into their teenage years. These seasoned campaigners can be a challenge to the polo veterinarian as they more often have chronic or arthritic conditions that require management to prolong their playing career.

Polo is a game of physical contact, quick stops, turns, and rapid acceleration. Players of different experience and skill levels play it. The majority of injuries and unsoundnesses are related to these factors.

Traumatic injuries

While every precaution is taken to ensure the safety of the polo pony, traumatic injuries during the game do occur. The pony may be hit in the legs, body or head by a mallet or a speeding ball. Overreach injuries to the heel bulbs are also common in the galloping polo mount. Often cold therapy (icing, hosing), administration of non-steroidal anti-inflammatory drugs (NSAIDs) and rest are all that is required but more serious injuries such as fractures can occasionally occur. Proper leg protection is essential in polo and is required for play by both American and British polo associations.[1,2] Protection can be in the standard form of 'polo wraps', but neoprene and other synthetic leg protection are now also commonly used. These are thought to offer greater protection and support. Bell boots offer not only protection at the heel bulbs from an overreach, but also for the rest of the sensitive coronary band which may be inadvertently stepped on by another player's mount.

Due to the close contact inherent in the sport, a certain amount of muscle soreness and bruising occurs. These injuries can usually be treated with NSAIDs, massage and rest. Proper conditioning will limit the severity of these injuries.

Conditions of tendons and ligaments

Tendon and ligament injuries are common in polo ponies. Their treatment and management may depend on the value of the horse, the point in the season that the injury occurs, and the availability of alternative mounts for the player. For example, a player may be more inclined to rest a tendon for 6 months if it is late in the season and he has enough other ponies to mount him in the remainder of his games.

Proximal sesamoidian ligament injury is the most common injury amongst hard-playing ponies. The constant wear and tear caused by quick turns and stops affects the superficial, middle and lateral collateral sesamoidian ligaments. The damaged ligament is replaced by fibrous tissue and eventually the pony develops thickened fetlocks. This is a chronic injury and many affected horses are nursed through the polo season by icings after chukkas, good wrapping and the judicious use of anti-inflammatories. Eventually, these horses may have to be 'retired' down to lower goal polo.[5]

Suspensory ligament injury occurs regularly in the polo pony. The area usually affected is the distal body and the sesamoidian branches. Although acute injuries do occur, it is more likely that the polo pony will be suffering from a chronic desmitis. Veterinarians are often asked to see these injuries in the early season when fitness level may not be up to standard, and again late in the season as a result of constant pounding on hard ground.[5,6]

The proximal superficial digital flexor tendon is the commonest site of tendon injury in polo ponies and many horses will successfully play with a chronic 'bow'. Some retired Thoroughbred ponies, bought off the track, may have been retired due to an injury in this area. They may well, therefore, have a weakness at this point. Injuries to the palmar aspect of the proximal metacarpal also include problems with the inferior check ligament, specifically at its insertion to the deep digital flexor tendon. Sliding stops and spins add to the strain created in this region of the cannon bone.[5]

Treatment for any of these acutely occurring injuries demands rest, administration of NSAIDs and cold therapy. Repeated diagnostic ultrasounds are of utmost importance both to determine the size of the lesion and to track the healing process, thus determining when the pony is ready to play again.[6]

Many of the injuries seen in polo ponies are chronic lesions caused by the constant rigors of the game. These injuries tend to be managed rather than treated or cured, and can be challenging to the polo veterinarian. Chronic injuries are managed with NSAIDs, chondroprotectives such as hyaluronic acid and polysulfated glycosaminoglycans, along with judicious use of the horse.[6] Good nursing care by experienced grooms including icing, sweating and wrapping is invaluable, and allows many of these horses to continue playing season after season.

The most commonly used NSAID in the playing polo pony is phenylbutazone. There is no rule to limit the amount of phenylbutazone a polo pony can be given before or even during a game, but there is a general belief among polo players that one cannot play good polo on a horse that has received a large amount of phenylbutazone. Such a horse is said to 'lose' its mouth, becoming less sensitive to the bit, and therefore much less likely to perform the necessary quick turns and stops. This causes the use of phenylbutazone to be self-limiting and therefore the need for tight regulation on its use as in other equestrian sports is not required at this time (TN Christian, personal communication 2000).

Arthritic conditions

Navicular syndrome or caudal heel syndrome can affect all breeds and ages of ponies, but is often seen in older polo ponies, particularly those that are part Quarter Horse. Short stops on hard ground can cause this region of the foot to become chronically sore, especially in those horses who stop 'improperly' on their front ends, rather than stopping and turning with the majority of their weight on their hind ends. Improper shoeing and trimming, leading to a long toe and low heel, may predispose or exacerbate this condition.

Conservative therapy often allows many of these horses to continue their career for many years. This includes proper shoeing utilizing wide webbed or bar shoes, glucosamine supplementation, oral isoxsuprine and hyaluronic acid and steroid injections to the coffin joint.[7]

Quick turns and stops, on hard ground with little give, predispose polo ponies to hock arthritis. Usually the intertarsal and tarsometatarsal joints are affected. Often the first sign of this in polo ponies is the reluctance to pick up a given lead. These horses will be significantly positive on flexion tests. Glucosamine supplementation, NSAIDs and joint injections with a combination of hyaluronic acid and corticosteroid all often aid in managing these ponies.[7]

Exertional rhabdomyolysis

Polo ponies may be predisposed to conditions caused by overexertion. The physical demands, combined with playing in weather extremes puts the polo pony under considerable stress. This is compounded by long distance traveling to different games each weekend and the nervous and excitable temperament, which is common in the polo pony. Proper conditioning is vital, though early season games and lay-ups from injury may cause a pony to be inadvertently played harder than appropriate for its fitness level. It is easy, however, and essential to some degree, for players to forget about the horse they are riding and concentrate on the game at hand. This can result in a horse playing harder than the pony's fitness level should dictate.

Exertional rhabdomyolysis (ER), often called 'tying up', is common in polo ponies. It is reported to occur more frequently in this group of horses than in any other competition horses. The incidence rate is approximately 7% per year.[8] Unlike reports from studies in Thoroughbreds, management factors, age and sex appear to play little role as risk factors. However, predisposing factors in polo ponies have been shown to include excitable temperaments, playing early in the season or exercising harder than they are accustomed. In addition a hard chukka or one early in the season are also common risk factors for an episode of ER.[8] Polo ponies have not been reported to suffer from glycogen storage myopathies[9] and are presumed to suffer from ER due to overexertion.[8] Initial treatment relies on pain relief, and fluid replacement if needed.[10] Serum activities of creatinine kinase and aspartate aminotransferase should be measured at the initial onset, and measured again before returning to work.[11–13] ER is a significant cause of wastage in polo ponies.[8] In Thoroughbreds a heritable recurrent form of ER has been shown to exist. Therefore prevention is an area of management that needs to be addressed. This involves eliminating any known underlying cause.

Routine care

It is important not to overlook the value of routine veterinary care of the polo pony. Playing polo horses travel frequently from game to game, mix with many other horses, and are under considerable stress. A program of regular vaccinations and deworming are therefore of the utmost importance.

Regular dental care is also essential in the polo pony. Sharp hooks and points can interfere with the bit and make the horse generally uncomfortable in his mouth. A good mouth is one of the most important attributes in a polo pony; therefore dental checks at 6- to 12-month intervals are recommended.

Conclusion

The polo veterinarian faces unique challenges due to the rigors that polo ponies are exposed to, combined with the expected longevity of their careers. Chronic conditions must be managed and acute conditions must be acted upon promptly. There is a large and growing interest in the sport of polo throughout the world and it is becoming increasingly necessary for the equine veterinarian to become familiar with unsoundnesses or conditions that affect this large body of competition horses.

CHAPTER 54

Veterinary aspects of training Western performance horses

Brad R. Jackman

Introduction

The disciplines of the Western performance horse are varied and include rodeo and barrel racing, breed shows, cutting and reining, and Western pleasure. The majority of these horses are American Quarter Horses but there are also Paint and Appaloosa horses involved in these competitions. Despite the variety of breeds and athletic competitions, there are several common maladies that generally affect this population of horses.

Universally, there is tremendous growth of Western performance competitions in both number of competitions and the purse money at these events. Subsequently, selective breeding programs have been utilized to produce a competitive athlete and training programs begin earlier and are more intensified to enhance the odds of success in the competitive arena. These approaches have increased the value of these horses but have also increased the incidence and severity of disease problems with which the veterinarian must be familiar.

Demographics

The rising popularity of Western performance horses has led to a growth of competitions and demand for these horses within the USA and Canada as well as Europe, New Zealand and Australia. Rodeos have historically been in the USA, Canada and Australia and continue to be confined to these areas. However, the number of breed shows for Quarter Horses and Paint horses in addition to cutting and reining competitions has dramatically increased in the last 10 years in Europe and Australia (Table 54.1). The growth in European countries has mostly been in Germany, Italy and France.

Table 54.1 American Quarter Horse registry statistics for 2001

Location	2001 Horse population	2001 New horse registrations	% Growth
USA	2 749 784	132 619	4.8
Canada	214 134	13 181	6.2
International	81 133	5120	6.3

Common disease problems

Despite the variety of athletic events in which these horses compete, there are some similar traits in conformation, training and use that lead to universal problems. As with all horses, there are a myriad of problems and diseases that may develop. However, the purpose of this discussion is to become familiar with the most common problems inherent with these particular athletes.

Hyperkalemic periodic paralysis (HYPP)

Occasionally seen in rodeo and barrel racing horses, HYPP is primarily a condition of Quarter Horses and Paint horses used in the breed shows. This is a genetic condition that originated from a single Quarter Horse stallion. When the genetic trait was discovered and a diagnostic test developed, it was thought that this would lead to elimination of this disease by selective breeding. On the contrary, halter and Western pleasure judges often prefer the body type and muscling of horses with this gene and HYPP has become a selected trait for

horses in Western show disciplines. The genetic test can determine if the horse is homozygous positive (HH), heterozygous (NH) or homozygous negative (NN). The HH horses tend to have a higher incidence and severity of clinical signs of HYPP and are not the preferred breeding for most owners. Breeders often select for the heterozygous animals, as they tend to maintain the body type desired with a decreased incidence of HYPP episodes. Horses with any breeding predisposed to the condition should be tested to determine if they carry the gene for HYPP.

Hyperkalemic periodic paralysis is a disorder that affects the normal ion movement across cellular membranes and thus muscular function. The clinical signs can vary from episodic minimal muscular fasciculations to acute death from cardiac dysfunction or laryngeal spasm. Clinical episodes are often more pronounced in young horses; episodes may decrease in incidence and severity as the horse ages. The most common signs observed are muscle fasciculations in the shoulder and flank regions and prolapse of the third eyelid. Episodes usually last 15 to 60 minutes and may or may not increase in severity during an episode or with subsequent episodes.

Therapy for HYPP is divided into treatment of current episodes and prevention from further episodes. During episodes, there is an increase of potassium released from cells and treatment is directed at driving potassium intracellularly. Medications used to promote this movement of potassium include intravenous dextrose, sodium bicarbonate, calcium gluconate, and insulin. Prevention of HYPP clinical signs is directed at decreasing dietary potassium intake (i.e. reduction or elimination of alfalfa and brome hay) and daily administration of diuretics that increase the renal excretion of potassium (i.e. acetazolamide).

The prognosis for heterozygous (NH) HYPP horses is generally favorable with the majority of horses manageable throughout their performance careers. The HH horses and horses that exhibit more severe clinical signs are more difficult to manage and have a poorer prognosis.

Musculoskeletal diseases

Lameness is by far the most common reason for Western performance horses to suffer a reduction in performance, or an end to their athletic career. Cutting and reining horses are primarily Quarter Horses and Paint horses. These horses are bred with an emphasis on small stature (14 to 15 hands), agility, and the mental capacity to perform under pressure. During their individual events, these horses have to be under complete control while performing quick stops and high torque turns (Fig. 54.1). Additionally, most of these horses begin training as late yearlings and early 2-year-olds with the goal of competing in futurity competitions in the fall and winter as 3-year-olds. The small stature, agility and athletic use of these horses predispose to certain stresses and injuries.

Rodeo and barrel racing horses generally have longer careers and therefore start training at a slightly older age.

Fig. 54.1
Cutting and reining horses have to perform quick stops and high torque turns.

There is a wide variation in size and conformation for these horses, but the repetitive high-speed turns and hard stops over time make these horses prone to injuries and chronic wear and tear maladies.

The horses used for breed show halter conformation classes have a very different body type than most of the other horses used in Western performance events. Judges are selecting for large heavily muscled horses that have relatively refined lower limb bone structure. These horses are shown in halter classes initially as weanlings and rarely past 3 years of age. Because of the need for rapid growth and size, these foals are often exposed to excessive or imbalanced nutritional programs and are predisposed to metabolic bone disease abnormalities. These horses also tend to have small feet that, when combined with a large, heavy frame, predispose to distal limb problems.

Western pleasure horses also have a wider variation in size and conformation than halter horses. Western pleasure horses usually begin training as late yearlings or early 2-year-olds. Currently, the preference for owners and trainers is a large horse but without the heavy body style of the halter horse. Conformationally, these horses must be able to move 'flat kneed' and level, which requires hock flexion and hindlimb advancement at a slow jog to enable the hind end to support the front end. The slower gaits also cause significant front feet concussion.

A thorough and systematic lameness examination is necessary to localize the source of lameness. Examination of the horse in a proper setting with both hard and soft footing is helpful to a consistent examination. Occasionally, examining the horse when ridden is beneficial. Perineural and intra-articular anesthetic blocks are necessary to accurately locate the origin of the lameness. Once localized, further diagnostics are performed to identify the etiology and severity of the disease process. Proper radiographs utilizing good technique and the appropriate views are required. If soft tissue

injury is suspected, then an ultrasound examination should be performed and the contralateral limb should also be examined for comparison. Other diagnostic modalities that may be useful include nuclear scintigraphy, computerized tomography (CT) and magnetic resonance imaging (MRI).

Forelimb lameness

Western performance horses can have many different causes of forelimb lameness but several are more common. Forelimb lameness can be grouped into two different types – concussive and fatigue. To be competitive in today's horse industry, breeding programs have selected for agile athletes with the body style desired, but many of the horses are also being bred with small feet. When this is combined with beginning work at an early age, foot problems often develop. Fatigue plays a role especially in the cutting and reining horses. These horses have to be calm and completely in control when performing and are often exercised for extended periods of time prior to competing to achieve this effect. Thus, these horses are often tired while competing, which predisposes to fatigue injury.

Fig. 54.2
Lateral radiograph of a laminitic horse.

Laminitis

Inflammation of the lamina within the front feet is more common in the halter horses than in the other Western disciplines. As mentioned earlier, the judges select for horses that are extremely large and heavily muscled but with relatively small distal limb bone structure and feet. Therefore, there is a tremendous amount of concussive pressure on the front feet reflected through the lamina. Additionally, these horses are also frequently being fed a high concentrate ration to maintain their size. The severity of laminitis is variable and both rotation and distal displacement (sinking) of the third phalanx can occur.

Diagnosis is usually relatively easy as there is often the characteristic laminitic gait, increased digital pulses, reluctance to move and/or pick up the feet, and pain over the toe of the foot with hoof tester examination. Palpation of the proximal dorsal coronary band should always be performed to assess for an indentation characteristic of distal displacement of the third phalanx. Radiographs are taken to assess the degree of rotation, presence of gas lines, thickness of the sole, or osseous abnormalities of the third phalanx (Fig. 54.2).

Treatment of laminitis should be aggressive and consists of anti-inflammatory medications, medications to help promote blood flow to the foot, and support of the foot. Anti-inflammatory medications include phenylbutazone, flunixin meglumine and intravenous DMSO. Medications proposed to enhance blood flow to the foot include acepromazine, isoxsuprine hydrochloride and aspirin. Other medications have also been suggested but clinical evidence is lacking. If the horse developed laminitis while shod, the shoes should be removed. The foot is trimmed if the toe is long and support of the foot is usually initiated with thick Styrofoam padding. The horse should not be reshod until there is stabilization in the clinical signs and the horse is responding to therapy.

Many of the halter horses have excessive body condition when laminitis develops. Therefore, it is recommended that the horse lose weight to decrease force through the front feet and consume a diet with low soluble carbohydrate (i.e. starch and sugar) content. The owner or trainer often refutes these recommendations and compliance can be difficult.

The prognosis is dependent on response to therapy. The less severe the rotation and the faster and more complete the therapeutic response, the better the prognosis. Distal displacement of the third phalanx has a worse prognosis than rotation in most situations. Recurrent laminitis is not uncommon in show horses, perhaps because of the perceived need to feed high grain diets to maintain show condition.

Palmar heel pain/navicular syndrome

The most common source of lameness in the forelimb of Western performance horses is the heel region. The smaller feet of these horses as well as the early training and sustained use of the horses produces excessive concussion in the foot. Clinically these horses exhibit lameness in one or both of their forelimbs. Pain across the central one-third of the frog may be present on hoof tester examination and these horses

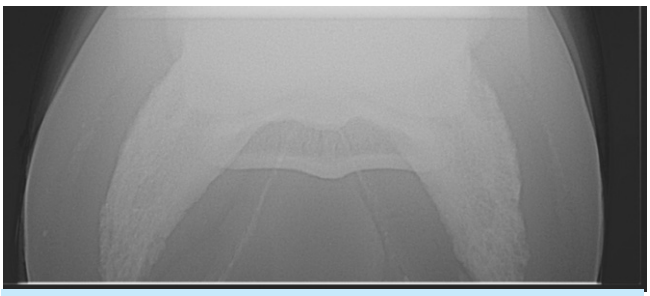

Fig. 54.3
Flexor skyline radiographic view of the navicular bone.

will have a tendency to land toe first instead of heel first. The lameness is alleviated with analgesia of the palmar digital nerves. Analgesia of the distal interphalangeal joint is often useful in further localizing the lameness. However, recently it has been suggested that the specificity of this block is questionable and can desensitize the sole when large volumes of anesthetic are used.[1]

Once the lameness has been localized, foot radiographs are made. It is imperative to take a complete series of good detail radiographs. Outside of the USA it is still common for a foot radiograph series to lack a flexor skyline view that may be the most important view to assess the navicular bone (Fig. 54.3). The radiographs are carefully examined for abnormalities as well as imbalance and angular deformities of the foot. Erosion of the flexor cortex, cystic-type lesions and medullary sclerosis of the navicular bone are more severe lesions and may warrant a lesser prognosis. If significant radiographic abnormalities exist, then a diagnosis of navicular syndrome is made.

Consistent and proper shoeing is the cornerstone of treatment of horses with palmar heel pain. The foot must be balanced and at an appropriate angle for the individual horse. An effort to hasten the break over of the foot should be made by rolling the toe or setting the shoe behind the toe of the hoof. Adequate heel support is also necessary. The shoeing interval should be a maximum of 5 to 6 weeks to maintain good hoof conformation. Additional therapy consists of anti-inflammatory medication and drugs that are purported to promote blood flow to the foot (e.g. isoxsuprine hydrochloride, aspirin). If more severe lameness is present or there is evidence of coffin joint inflammation, intra-articular injection of the coffin joint with hyaluronic acid and a corticosteroid may be beneficial. Despite aggressive shoeing and medical therapy, some horses remain lame. These more refractory cases usually require a palmar digital neurectomy to maintain athletic function.

Suspensory ligament desmitis

Damage and inflammation of the suspensory ligament is a common source of forelimb and to a lesser degree, hindlimb lameness of Western performance horses. The incidence of hindlimb suspensory desmitis has increased in recent years and is probably related to the greater athletic prowess of these horses together with the intensified level of competition. The severity of the inflammation can vary from slight pain on palpation to acute and, at times, severe lameness. Many of these horses have to exhibit a quiet and calm demeanor while performing, and therefore have to be worked until slightly fatigued prior to performing at their most demanding level. Aside from fatigue, other predisposing factors are improper shoeing (long toes, uneven feet, improper angles, lack of heel support), hindlimb soreness and poor ground conditions.

Injuries to the suspensory ligament most commonly occur at its proximal origin but may also involve the distal branches. The lameness observed is usually one to two grades more severe at a trot when the affected limb is on the outside of a circle (i.e. clockwise with a left forelimb lameness). Pain is usually elicited with palpation if the injury is present in the distal suspensory ligament but may be absent with proximal origin lesions. The location of the lameness is established with sequential local anesthetic injections. The proximal suspensory can be desensitized by local infiltration of anesthetic around the suspensory ligament or by perineural anesthetic injection around the lateral palmar nerve at the level of the middle carpal joint just distal to the accessory carpal bone.

After localization of the lameness, the affected region is radiographed to determine if osseous lesions of the fetlock or proximal metacarpus are present. An ultrasonographic examination of the suspensory ligament is performed to assess the integrity of the ligament and tendinous structures. If local infiltration of anesthetic was used to localize the lameness, then the ultrasound examination is often delayed for a day to minimize the possibility of distortion in the area. Fiber pattern, ligament size and percentage of damaged tissue should be assessed with the ultrasound examination. Additionally, the contralateral limb should be ultrasounded for comparison as individual variation can exist in the size and character of the proximal suspensory ligament. The severity of lameness does not always coincide with the degree of damage present ultrasonographically.

The treatment for suspensory ligament desmitis is rest, corrective shoeing, systemic non-steroidal anti-inflammatory medications and occasionally local injection of the proximal suspensory lesion. The duration of rest is determined by the severity of ultrasonographic abnormalities, degree of lameness and subsequent ultrasound examinations to monitor healing. In most cases, an initial 60 days of stall rest is recommended with a small amount of prescribed hand walking beginning 2 weeks after examination. The amount of walking exercise should be slowly increased. After 60 days, the horse should be re-examined, including ultrasonography of the affected ligament. Further rest and exercise regimens are recommended at that time depending on the response to therapy. Corrective shoeing involves maintaining the toes short and the foot at an appropriate

angle; usually an egg bar shoe is used to facilitate fetlock support. In horses where the lameness is minimal and there is a lack of ultrasonographic abnormalities, local injection of the proximal suspensory may be performed. Most often a corticosteroid is used in conjunction with polysulfated glycosaminoglycan (Adequan i.m., Luitpold Pharmaceutical Inc., Animal Health Division, Shirley, NY 11967). Occasionally, Sarapin (High Chemical Co., Levittown, PA 19056) is added as well. In cases where the lameness and lesion are severe or showing a slow or poor response to conventional therapy, ancillary therapies may be instituted. These horses may undergo injection of the affected proximal suspensory ligament with bone marrow aspirated from the sternum[2] or extracorporeal shock wave therapy.[3]

Cutting and reining horses frequently have a slight amount of proximal suspensory pain on palpation in association with a slightly shortened stride, but no obvious lameness. These athletes frequently have inflammation of the distal hock joints as the primary problem which causes the horse to place more stress on the forelimbs. Typically, the suspensory pain does not require direct treatmentand the pain is alleviated with resolution of the hock soreness.

The prognosis of Western performance horses with forelimb proximal suspensory desmitis is generally favorable. More severe lesions may be more prone to recurrent injury and efforts to reduce the incidence of reinjury are paramount. Proper conditioning is necessary to reduce the risk of fatigue. Appropriate shoeing is necessary to avoid long toes and improper angles; horses may be maintained in egg bar shoes for their entire athletic careers. Potentially, the most important preventive measure is to maintain these athletes as pain free as possible such that they are able to work off their hind ends and prevent excessive strain on the front limbs.

Fig. 54.4
High-speed stopping and turning can predispose to injury of the hindlimbs.

Hindlimb lameness

Despite the athletic riding discipline, all Western performance horses place a great deal of strain on their hindlimbs. These horses generally perform tasks that require them to have the conformation and willingness to move with their hindlimbs underneath themselves (Fig. 54.4). Moreover, they have to undergo extensive training at a young age to become proficient and consistent in these maneuvers. This repetitive stress predisposes the Western performance horse to injury of their hindlimbs, especially their hocks and stifles.

When evaluating the horse for hindlimb lameness it is important to perform a thorough and systematic examination and palpation of the horse. Specific areas to examine closely are the forelimb suspensory ligaments, the back and lumbar musculature, and any effusion or swelling in the hindlimbs.

Suspensory ligament desmitis

As mentioned earlier, inflammation and lameness of the proximal suspensory ligament in the hindlimbs is being diagnosed more frequently. The diagnosis and therapy are similar to the forelimbs. However, the prognosis is more guarded as the response to therapy can be unpredictable. In more severe cases, it may take 12 to 18 months for adequate healing to occur.

Inflammation/arthritis of the distal tarsal joints (distal tarsitis)

Lameness associated with the distal intertarsal and tarsometatarsal joints (distal tarsal joints) is the most common reason for a reduction in performance in the Western performance horse. Anatomically, the distal intertarsal and tarsometatarsal joints communicate in only 7–38% of horses; the distal tarsal joints very rarely communicate with the proximal intertarsal or tibiotarsal joints.[4–6] The distal tarsal joints are low motion joints that sustain repetitive torque force in these horses. Therefore, it is not generally a question if these joints will become inflamed but when they will become affected. The degree of soreness related to these joints can vary from severe, acute lameness to only a reduction in performance without notable lameness. Often the trainer will be suspicious of distal tarsal inflammation due to reduced performance of the horse prior to obvious lameness being noticed. Common complaints from cutting trainers about horses with inflamed distal tarsal joints are that the horse will not hold the ground or a cow, the horse is late making a turn on a cow, or the horse is backing off the cow and unwilling to get low in the ground. Reining trainers will complain of horses that are not stopping as well, seemingly uncomfortable on tight turns, or having difficulty with lead changes. Western

pleasure trainers will notice a reluctance of the horse to carry its head appropriately, unwillingness to pick up or maintain the appropriate lead, or just a slight shortening of stride length that affects the horse's gait.

Horses with distal tarsitis often palpate with soreness in their back and gluteal regions, especially in the lumbar area. Effusion within these joints is not palpable due to the narrow width of these joints. However, horses with extensive remodeling of these joints may have palpable thickening in the distal medial aspect of the tarsi. As this condition is related to occupational repetitive stress, it is often bilateral with one hock more affected than the other. Occasionally, the lameness is related to an acute injury and the lameness is generally unilateral and more severe. Typical inflammation of the distal tarsal joints has a characteristic gait where the stride is slightly shortened and the arc of flight of the hind leg is medially under the body with a quick lateral outward movement of the foot prior to placing the foot on the ground. An upper hindlimb flexion test exacerbates the shortening of stride and abnormal gait.

A presumptive diagnosis of inflammation of the distal tarsal joints is often made based on clinical findings. If there is any question about the source of lameness, a thorough lameness evaluation should be performed. Intra-articular anesthesia will localize the source of the pain; however, care must be taken not to infuse a large volume of anesthetic into the tarsometatarsal joint as this may also alleviate pain associated with injury of the proximal suspensory ligament. Sometimes it may be beneficial only to perform distal intertarsal joint analgesia initially, in an effort to differentiate distal tarsitis from suspensory desmitis.

Radiographs are taken of the hock to determine the presence or extent of arthritic changes. A complete study consisting of four radiographic views is necessary as abnormalities are often subtle. Radiographic abnormalities are frequently lacking in young horses with distal tarsitis. The radiographic changes frequently observed include narrowing of the joints, proliferation and/or lysis at the joint surfaces, and occasionally ankylosis of one or more joints. Infrequently, yearlings and 2-year-olds will exhibit significant lameness and have extensive lysis and proliferation associated with the distal joints. This condition has been termed juvenile arthritis and is most likely a form of osteochondrosis with delayed ossification of the tarsal cuboidal bones.

The treatment of distal tarsitis is often dependent on the future training and competition requirements of the individual horse. If the horse is young, lacks radiographic abnormalities and can have a respite from its training regimen, the horse is often prescribed rest and anti-inflammatory medication. However, most of the time a rest period is not preferred by the owner/trainer and a more aggressive treatment plan is instituted. Inflammation within the distal hock joints can generally be effectively managed throughout a horse's athletic career by intra-articular injection of hyaluronic acid and corticosteroids. Both the distal intertarsal and tarsometatarsal joints should be injected, as communication is unreliable. Additionally, these horses will also frequently benefit from concurrent use of intravenous hyaluronate sodium (Legend, Bayer Corp., Agriculture Division, Animal Health, Shawnee Mission, KS 66201) and/or intramuscular polysulfated glycosaminoglycan (Adequan i.m., Luitpold Pharmaceutical Inc., Animal Health Division, Shirley, NY 11967).

Many Western performance horses can sustain a productive athletic career despite the existence of chronic tarsitis. Injection of the distal tarsal joints should be performed when needed to maintain reasonable soundness and to allow these horses to continue to perform at a high level. Occasionally, a horse with distal tarsitis will begin to have a diminished response to intra-articular therapy. Radiographs are made at that time to determine the extent of arthritic development. If there is evidence of ankylosis, turnout and a temporary discontinuance of training and showing may be required. If the radiographs show a lack of significant arthritis, then a procedure to stimulate ankylosis of the joints may be indicated. There are two described techniques for the induction of ankylosis in the distal tarsal joint: surgical drilling across the joint[7] and injection of sodium monoiodoacetate.[8] In general, both techniques have mixed results and the natural process of ankylosis is preferred. The response to intra-articular injections of hyaluronic acid and corticosteroids in young horses with juvenile arthritis is often insufficient to enable these horses to compete at the lucrative futurities. In these horses, the surgical drilling procedure for hastening ankylosis may offer the best chance for future athletic performance.

Stifle lameness

Both developmental and traumatic conditions of the stifle occur in Western performance horses. Developmental conditions include osteochondrosis of the femoropatellar and/or femorotibial joints and upward fixation of the patella. Osteochondrosis in the femoropatellar joint is most commonly associated with the trochlear ridges of the femur or in the medial femorotibial joint as a cyst within the medial femoral condyle. Upward fixation of the patella is usually observed in younger horses that are conformationally predisposed by being straight through the stifles. Most often this is an intermittent condition with a gait abnormality and, rarely, slight lameness. Trauma can vary from mild inflammation to major soft tissue and cartilage damage associated with the joint.

Horses with stifle lameness are typically lamer than seen with distal tarsal inflammation. There is generally pain palpable in the back musculature and often there is effusion of the femoropatellar or medial femorotibial joint. The horse exhibits a shorter cranial phase of the stride that is especially evident at the gallop or canter most notably when the affected leg is on the outside of a lunged or round pen circle. There is usually a hip rise on the affected leg because of the shortened stride and reluctance to flex the leg fully. A positive res-

ponse to upper hindlimb flexion is evidenced with a further shortening of the stride and a more noticeable hip rise. The lameness is localized to the stifle with the use of intra-articular anesthesia. In general, the femoropatellar and medial femorotibial joints communicate while the lateral femorotibial joint does not.

A comprehensive radiographic study of the affected joint should be performed. A complete study includes lateral, caudal-cranial, and caudolateral-craniomedial views. It is relatively common for lesions to be evident only on one of the views. Recently, ultrasound examination of the stifle to visualize the cranial cruciate ligament, cranial aspect of the meniscus and collateral ligaments has been described and may be useful in determining the extent of the injury in select cases.[9]

Developmental stifle conditions

Intermittent upward fixation of the patella is most commonly observed in 2- and 3-year-old horses and can often be diagnosed with a good clinical history. Occasionally there will be slight effusion of the femoropatellar joint. Conservative management is preferred as transection of the medial patellar ligament can predispose to secondary arthritis.[10] A consistent exercise program is necessary to properly condition the hindlimb musculature. In more severe cases, further therapy is usually necessary and may include a regimen of intramuscular estrone sulfate (TD Swanson, personal communication), injection of the medial and sometimes middle patellar ligaments with a counterirritant, surgical splitting of the medial patellar ligament[11] and, as a last resort, medial patellar ligament desmotomy. Generally the prognosis is good and the horse can be managed with conservative therapy.

Osteochondrosis of the femoropatellar joint is treated with arthroscopic surgery. Lesions are most commonly located on the lateral trochlear ridge. The prognosis is dependent on the size of the lesion with smaller lesions having a superior prognosis, but usually the prognosis is favorable.[12] Lesions within the femorotibial joints are almost always observed on the medial femoral condyle. Lesions will vary from slight flattening or indentation of the articular cartilage to large subchondral cysts. Recommendations for treatment of medial femoral condyle cysts are controversial. Arthroscopic surgery has yielded mixed results and therefore is usually reserved for horses not responding well to more conservative treatment. If the lameness is not severe and the lesions are small, intra-articular injection of the medial femorotibial joint with hyaluronic acid and corticosteroids will often alleviate the lameness and allow the horse to remain in work. If the lameness is more severe and/or the cystic lesion is sizeable with a large communication with the joint, then intra-articular injection is often used in conjunction with confinement and rest. Recent research has been directed towards improving the healing of the defect in an effort to increase surgical success.[13,14] Currently, these methods are mostly experimental and further research and clinical trials are necessary.

Traumatic stifle conditions

Injuries to the stifle most commonly occur in the medial femorotibial joint. In cutting and reining horses, it is not uncommon for mild inflammation of the medial femorotibial joint to occur in conjunction with distal tarsitis. Traumatic injuries will vary from mild inflammation to career-ending soft tissue disruption. In the more severe injuries, rest is required. These horses require strict stall confinement, systemic anti-inflammatories, intramuscular polysulfated glycosaminoglycan (Adequan i.m., Luitpold Pharmaceutical Inc., Animal Health Division, Shirley, NY 11967) and re-examination at a later date. The prognosis is guarded at best and depends on the subsequent development of arthritis. Horses with minimal inflammation and no radiographic abnormalities can often be managed and kept in training and competition. If concurrent distal tarsal inflammation exists, intra-articular injection of the distal tarsal joints is often all that is required for resolution of the stifle inflammation. When more significant inflammation exists, the affected joint should be injected with hyaluronic acid and a short-acting corticosteroid. Further inflammation of the stifles can sometimes be avoided by maintaining the distal tarsal joints as pain free as possible.

CHAPTER 55

Veterinary aspects of training hunter/jumper horses

Duncan F. Peters

Introduction

It has long been recognized that horses have the ability to jump obstacles. This unique characteristic and man's domestication of the horse over time has led to refinement of this ability. The next logical step was the development of a competitive venue for jumping. The sport of showing horses over fences is rooted in England in the mid-nineteenth century. International competitions flourished in Europe and equestrian jumping events were introduced at the 1912 Olympic Games. A unique aspect of showing horses over fences is that men and women riders compete as equals.

The show hunter

The hunter classes at horse shows are intended to demonstrate the grace, elegance and jumping style of the horse and are scored subjectively by one or more judges (Fig. 55.1). Originally, the concept was to show over obstacles that might be encountered in the foxhunting field. Jumps would include natural building materials and mimic gates, coops, walls and a variety of natural brush vegetation. More recently, show hunter courses have the same basic jump style, but now are adorned with bright flowers and foliage which may entice the horse to jump more brilliantly over the jumps.

Hunters are supposed to jump with a style that appears easy to ride while at the same time folding their front legs tightly and squarely with knees elevated above the point of the shoulder. The head and neck should be extended forward and have a flexing curvature over the top of the fence (Fig. 55.2). The horse should appear to clear the required height with ease and the hindquarters should glide smoothly over the fence in a round, arcing style. The entire jumping motion should be fluid, effortless and controlled, and appear to be smoothly connected with the takeoff and landing strides.

Fig. 55.1
Show hunter exhibiting the jumping style, elegance and beauty necessary for success in the show ring.

Fig. 55.2
Classic jumping form in a hunter. Note that the front legs are square and the knees high as horse arcs over the jump. Also note the flexion through the neck and the extension of the hindquarters as the horse leaves the ground.

Fig. 55.3
Power, speed and colorful obstacles mark the showjumper arena.

The movement, pace and general impression of the show hunter around the course is important in the scoring by the judges. Movement at the trot and canter should be fluid, smooth and with a relaxed cadence that covers the ground with a minimum of effort. The horse should appear relaxed and comfortable with minimal noticeable commands by the rider. The horse and rider should approach fences in a balanced position and jump the obstacles 'in stride'. Show hunters compete over jumps of varying height (up to four feet) depending on their age, jumping ability, experience and the capability of the rider.

The showjumper

The showjumper is typically a horse that demonstrates a combination of power and speed. The main requirement is to jump a series of obstacles within a specified, allotted time. The objective is to jump the course with the least number of penalty faults. Scoring is done objectively based on penalty faults given for such things as jumps that are lowered in height by knocking them down, refusals to jump an obstacle, exceeding the time allowed on course, placing a foot in the water jump, and a fall of a horse/rider combination.

The showjumper has to be athletic and have a proclivity for jumping any kind of colored or configured obstacle that may be included in the competition course (Fig. 55.3). The horse must jump with precision and care, whereas the absolute form and style over the obstacles is of lesser importance. It is extremely important that the horse be well schooled and responsive to the rider due to the fact that competition courses have winding turns, combination fences and often varying number of strides between fences. The showjumper can be any breed, color, size and shape as long as the horse demonstrates a desire and willingness to jump the obstacles without incurring faults. The elite showjumpers tend to be naturally well-balanced athletes with an ease of movement that is fluid, loose and appears effortless, especially at the canter. Jumpers compete in a variety of classes based on age, fence height, prize money won and the ability of the rider.

The biomechanics of the jumping style in jumpers varies from that of the hunters. The strides preceding the jump are used to position the horse and to harness its horizontal energy in order to convert it to vertical energy in the takeoff stride. In the stride just prior to takeoff, the horse lowers its center of gravity, decelerates forward movement of the front legs and then thrusts vertically to raise the forequarters off the ground. The hind feet then plant close to the base of the fence and supply further vertical energy to propel the body over the obstacle. There is a rotation of the center of gravity over the top of the fence with extension of the lumbosacral region and the hip joint to allow the hindquarters to clear the obstacle. Landing requires the front legs to land in a staggered arrangement in order to gallop away from the fence (Fig. 55.4). This imparts very large vertical forces that must be absorbed by the structures of the front legs. The higher and wider the fence, the greater the forces involved and the greater the effort required by the horse and rider. When these factors of jumping biomechanics are combined with the variety of pace, obstacles and directional lines of the showjumping course itself, it requires a horse that is well trained, responsive, athletic and properly conditioned to compete successfully.

The demands of show hunting and jumping

As a year-round sport, show hunting and jumping is a demanding sport and it is difficult for owners, trainers and

Fig. 55.4
The soft tissues of the front legs have to withstand tremendous stress during takeoff, landing and tight turns in the jumper ring.

veterinarians to manage these horses such that consistent athletic performance is achieved throughout the year. Many factors must be considered to keep a training and showing program efficient and fresh for the horses while minimizing injuries and the need for veterinary medical intervention.

Show horses must be conditioned adequately to attain a level of 'fitness for the intended task'. Ideally, the required level of fitness is achieved before a horse is taken on the show circuit. Once a horse achieves a desired level of fitness, it is fairly easy to maintain that level with consistent exercise.[1] Hunters do not require the level of fitness demanded of the showjumper. Actually, many show hunters are kept slightly underconditioned and overweight in order to minimize the amount of exercise required to 'take the edge off' prior to entering the show ring. Judges tend to reward this overly relaxed expression in their scoring. Showjumpers, on the other hand, tend to be conditioned in a manner more appropriate to the level of athletic activity.

The show season and individual show schedules can be important to the success and health of hunters and jumpers. Most elite hunters and jumpers are vying for year-end awards, entrance to prestigious horse shows or participation on certain team events. This means that a horse either has to accumulate a large number of points compared with rival horses or has to perform well in specific qualifying shows. The show season may be 9 to 10 months in length with two to three shows per month. When combined with the rigors of travel and regular conditioning, it is clear that there are high demands on the show athlete. Hunters often have two to four jumping classes per show day. If they are entered in amateur rider as well as open hunter classes, these horses may compete on 4–5 consecutive days. These work demands are further increased by participation in warm-up classes and the need to school over fences prior to each class. In contrast, jumpers tend to be managed through a show in a manner that targets one or two specific classes. Most showjumpers either compete in the open classes, with a professional rider, or in the amateur classes. This more restricted performance schedule tends to maintain the showjumper's energy and mental alertness at a desirable level.

Show hunters and jumpers tend to travel more frequently and farther than other sport horses. This makes them susceptible to transit stress and to suppression of their immune system.[2] In this author's opinion, horses are more susceptible to infections for up to 7 days after prolonged transportation. This is especially true when traveling between time zones and internationally. As most large horse shows are scheduled over a 6–7-day period, there is often minimal time for recovery following transportation from one venue/event to the next.

Judging criteria also may contribute to the stresses imposed on show horses, particularly in the hunter classes. In many instances, a horse that is quiet and relaxed in the ring will be favored over a horse with superior jumping ability but a more 'playful' disposition. As a result, hunter horses are often exercised to the point of fatigue (lunging and/or under saddle) to 'take the edge off' before entering the ring to compete. Alternatively or additionally, many owners and/or trainers look toward medications or hormones to alter the 'appearance' of the hunter in the ring. Both practices may predispose these horses to problems that are ultimately performance limiting.

Arena footing has become a primary concern for horse trainers and owners, equestrian governing bodies, show managers and veterinarians. Poor footing (e.g. overly hard surface), both in the main arena and in the schooling and warm-up areas, appears to be a major predisposing factor for musculoskeletal injury. Many federations are now adopting stringent guidelines for the quality of footing at sanctioned events.

Veterinary services

The veterinarian plays a key role in the training, management and medical care of the hunter and jumper. The veterinarian wears many hats and has to coordinate the efforts of many people (e.g. farrier, massage therapist, trainer) in order to provide optimal care to the horses under his or her care. The scope of his/her responsibilities and efforts may be constantly changing to meet the needs of clients, patients and even equestrian governing federations. The veterinarian

must be willing and able to see the total picture from a variety of different vantage points and be adept at keeping all parties focused on the proper care of the horse.

It is also imperative that open and clear lines of communication are nurtured and maintained throughout the diagnosis and treatment of a given problem. In addition to veterinary care, the practitioner must be prepared to act as source of advice concerning nutrition, conditioning programs, equipment (tack), and transportation. This does not mean that he or she needs to have all the answers, but should be able to identify qualified people to assist in the overall management program of the horse. For example, the soliciting of advice from a nutritionist regarding a feeding program, referral to a specialized veterinary facility for advanced diagnostic techniques or surgery, or the acquisition of current research papers relevant to a current problem.

Additionally, the veterinarian should expect in return an open and honest dialogue with the trainer concerning any veterinary problems that arise while the horse is away at competitions. This is extremely important in light of the fact that trainers often travel long distances to compete and spend a large amount of time at competitions not attended by their regular veterinarian. Lameness or metabolic problems incurred at a show should be re-evaluated and discussed once the horse has returned home. Copies of medical records should be obtained from the attending veterinarian at the show. This will ensure proper care of the horse and help to determine if changes in veterinary care or other management of the horse are warranted. The veterinarian should rely on the trainer and his/her employees for day-to-day information concerning the horses under his or her care. It is important to have a good relationship with the grooms because they spend the most time with the horses and can usually provide reliable and timely information concerning an individual horse. For lameness or poor performance problems, insight provided by the rider can be invaluable in localizing subtle gait abnormalities. Similarly, a veterinarian with riding skills may, on occasion, wish to ride a horse as a component of the gait evaluation.

Proper care of hunter and jumper horses is also critically dependent upon a strong relationship between veterinarian and farrier. They must work together to maintain good lines of communication between themselves as well as with the trainer or owner. Ideally, the farrier and veterinarian work together in the development of a shoeing plan, although there are cases in which the veterinarian must request use of a specific shoe or shoeing technique.

Veterinary medical service can be provided to show stables in a variety of ways. In most instances, show stables have a primary ambulatory veterinarian who attends to the general care of the horses when they are not competing on the circuit. He/she maintains a preventive medicine program, works up and treats musculoskelatal problems, attends to emergencies and consults regarding many aspects of show horse care. In addition, this practitioner usually has a network of referral hospitals or their own hospital facility that can be utilized for problems requiring further diagnostic workup or treatment. It is important for the practitioner to provide veterinary referral contacts for their trainer/show stable for the geographic areas in which they compete. Some veterinarians travel with their clients on the show circuit, but this is the exception. More routinely, there are a number of ambulatory veterinarians that routinely travel the show circuit and attend to whichever horses or stables may need their services at a particular competition.

Pre-purchase examinations

The pre-purchase examination provides the potential buyer a 'point in time' veterinary assessment of the horse in the context of its intended use. The intent is to identify problems that may limit or hinder athletic performance. For the show hunter and jumper, this involves a comprehensive physical examination with particular focus on conformation, the musculoskeletal system and the assessment of gait.[3] Problems must be evaluated in light of the intended use of the horse, the potential impact on athletic performance, the prognosis, and the willingness of the buyer to accept risk regarding the problem. Radiology, ultrasound, endoscopy, thermography and clinical hematology are routinely employed in most performance horse pre-purchase examinations. Additional evaluations using acupunture, chiropractic techniques, nuclear scintigraphy, magnetic resonance imaging, computer aided tomography and kinesiology, as well as other evaluation modes, have been employed to aid the buyer in making an 'informed decision'. An important part of any pre-purchase examination is the necessity for accurate, readable records and clear communication with the buyer or buyer's agent.

Lameness examinations

Frequently, horses return from shows with lameness or gait abnormalities. It is imperative to obtain a detailed and accurate history regarding the problem, including the administration of any medications. The history may come from notes from an attending horse show veterinarian or repeated queries to the trainer, rider or groom associated with the horse. The physical examination should include palpation, work on a lunge line, flexion tests and, in some cases, observation under saddle. Regional perineural anesthesia and intra-articular anesthesia can be very helpful in localizing the area of lameness. Further diagnostic procedures to delineate the actual cause of lameness may be conducted at the stable or at a clinic.

Specific disease problems encountered in show hunters and jumpers

Show horses are susceptible to a wide array of veterinary problems, particularly those involving the musculoskeletal system. In many instances, proper identification of the

problem facilitates appropriate treatment and management that allows the athlete to return to competition in a short period of time. The demands on the elite hunter and jumper make them prone to both acute- and chronic-onset musculoskeletal injury. Chronic problems can develop from low-grade, subclinical pain and may compromise performance in the absence of overt lameness. Changes in jumping technique, stride length or work attitude, or an overall decline in performance can be signs of low-grade musculoskeletal problems. Acute-onset problems usually result in a distinct lameness and early diagnosis and treatment is imperative for optimum resolution. Unfortunately, these injuries have the potential to become chronic, thereby requiring recurrent treatment and/or a reduction in workload expectations.

Foot problems

The show hunter and jumper is prone to foot injury as a result of variations in exercise surfaces and excessive wetting and drying cycles due to repeated bathing and application of hoof coatings. It is not uncommon for horses showing in warm climates to be bathed three to four times per day and a commercial hoof oil to be applied to the feet every time the horse leaves the stable area and following schooling just prior to entering the show ring. In addition, the ring areas at horse shows are worked up and watered on a regular basis to provide good footing. These factors contribute to shelly, brittle hoof capsules and the development of cracks that may cause lameness or make it difficult to hold shoes properly. A variety of management tools have been used in an effort to mitigate the effects of repeated cycles of wetting and drying. The application of a clear acrylic coating to the hoof capsule at the time of shoeing and weekly thereafter can help to seal the hoof wall. Attempts should be made to preserve the periople at the time of shoeing. A decrease in the frequency of bathing is also recommended; a thorough grooming can usually achieve the desired appearance.

Quarter cracks and hoof capsule injuries can cause persistent lameness and poor performance. Quarter cracks are usually the result of hoof imbalance coupled with concussive trauma. Accordingly, the veterinarian and farrier should work together to identify and correct foot imbalance. In addition, corrective farriery should move the breakover caudally and unweight the affected area. The crack should be debrided followed by the application of a temporary shoe that evenly distributes weight over the foot (i.e. bar shoe). Systemic medication to curb inflammation may also be indicated. In more severe cases, stabilization of the crack is required to alleviate pain. This can be accomplished by an array of techniques including screw-in plates, glue-on plates, wire and Kevlar laces, acrylic compounds, and cast material. Frog support pads, pour-in soft hoof packing or steel pads also can be used to support the foot. Some reduction in exercise is necessary to prevent destabilization of these support devices. A 2- to 4-month period is often required for complete stabilization of the crack. However, with close monitoring the conditioning load can be slowly increased during this period.

Chronic concussive injury with resultant front foot soreness is a common occurrence in jumping horses performing on firm surfaces. Early indications of soreness may be a shortened, choppy stride, putting in a quick short stride at takeoff to a jump and refusal to jump. Injury may involve the soft tissues of the foot (i.e. bruise, hematoma, low-grade laminitis) and may progress to chronic remodeling of the coffin bone (pedal osteitis). The initial goal of therapy is to alleviate inflammation via the administration of anti-inflammatory drugs and medications purported to increase blood flow to the foot. Adjunct therapies included regional perineural anesthesia, foot soaking, poultice bandages and the use of Styrofoam hoof pads. Corrective foot trimming and shoeing should be undertaken once the inflammation has subsided. The foot must be trimmed and balanced to optimize its ability to absorb concussion. Simple, acute cases may only require the insertion of soft impression material under a flat pad, a rim pad or a soft pour-in pad under a regular shoe. In more severe cases, glue-on shoes, a rigid plastic or steel pad with acrylic impression material, enlarged bar shoes for support or the application of acrylic material to raise the heels may be indicated. It may take weeks to months for a 'sore-footed' horse to return to form. Exercise on soft ground, minimal jumping, lightweight riders and a reduced competition schedule will speed the process.

Caudal heel pain is a common cause of lameness in show hunters and jumpers. The diagnostic dilemma is to determine which structure, or combination of structures, underlies the pain. Regional perineural anesthesia, distal interphalangeal intra-articular anesthesia and navicular bursa anesthesia may help to differentiate the source. Magnetic resonance imaging of the heel region has been helpful and in many instances multiple problems have been identified. Acute cases respond well to therapy that involves the intra-articular or intrabursal administration of corticosteroids or sodium hyaluronate, a period of rest (3 to 6 weeks) followed by controlled light riding (3 to 6 weeks), anti-inflammatory medication and attention to shoeing (caudal heel support). Chronic caudal heel pain can be a challenge to treat and manage. Many affected horses can continue to compete if the condition can be managed such that lameness is no worse than a grade 2. However, the trainer and/or owner must be willing to accept lowered performance expectations, including a decrease in the number of shows and classes within a show expected of the horse. Regular low-intensity exercise to maintain conditioning is important to prevent other musculoskeletal problems. Regular (every 2–3 months) intra-articular therapy and the administration of anti-inflammatory medications at competitions can also aid in the management of these horses. Surgical interventions involving the innervation to or support of the navicular bone are last resort treatment measures.

Joint problems

Joint ailments in show athletes are related to an isolated traumatic incident or to repeated 'wear and tear' on joints. The goals of therapy for acute synovitis are to reduce pain,

swelling and inflammation in order to minimize chemical mediator induced damage to the joint. This is generally accomplished through physical therapy techniques and the administration of systemic and intra-articular medications. The prognosis is good and most affected horses are able to return to their previous level of competition after 3 to 4 weeks. An extended layoff and/or surgical treatment may be required if joint trauma results in chip fracture, cartilage damage or supportive ligament lesions.

Osteoarthritis (OA) and degenerative joint disease are the most common chronic joint problems in show horses. Both high motion/low load joints (metacarpal-phalangeal, metatarsal-phalangeal, carpal, etc.) and high load/low motion joints (interphalangeal, distal tarsal) can be affected. The extent of remodeling damage to the joint can influence treatment and management of the horse. It is important to utilize good shoeing principles in an attempt to reduce stress on joints. The use of rolled or rockered toes with the break-over moved caudally may aid a sore fetlock joint. Horseshoe pads or soft acrylic pour-in pads may help disperse concussive forces. Limiting the use of horseshoe or screw-in heel caulks can reduce shear forces on a joint. Periodic intra-articular injections of corticosteroids and sodium hyaluronate may alleviate inflammation and pain. Osteoarthritis of high load/low motion joints should be managed similarly; it is this author's opinion that intra-articular injections with sodium hyaluronate and/or corticosteroids should be done every 3–4 months. The duration of relief will depend on the severity of the condition, and the success of concurrent therapies and management practices. The systemic administration of hyaluronate and polysulfated glycosaminoglycans appears to be useful in horses with OA, and the judicious use of non-steroidal anti-inflammatory drugs is also recommended for the control of inflammation. The daily oral administration of chondroitin sulfate and glucosamine is now routine, although the efficacy of these treatments is unproven. Exercise should be regular, consistent and geared toward maintaining the necessary fitness for the show ring. For jumpers, tight turns and high-speed exercise should be undertaken sporadically and not when the horse may be fatigued. It is better to school over a few fences more frequently than to put many fences into one schooling session.

Osteochondrosis dissecans (OCD) is prevalent in show hunters and jumpers, perhaps because of the large number of Warmblood horses used in these disciplines. Many OCD lesions are identified during pre-purchase examinations or during the evaluation of an acute lameness associated with moderate to severe joint effusion. When lameness is present, arthroscopic surgical intervention is usually indicated. These horses have a guarded to good prognosis for return to competition depending on the severity of lesion(s). Occasionally, a conservative approach to therapy involving joint injections and extended rest is instituted.

Soft tissue injuries

Most soft tissue injuries to ligaments and tendons are acute in nature. Depending on the extent of that injury and the recovery time involved, they may then be classified as a chronic problem. The soft tissue structures most often injured in hunters and jumpers are the superficial digital flexor tendon, the accessory ligament of the deep digital flexor tendon and the suspensory ligament. Recurrence of these problems is common.

In the author's opinion, fatigue is a major contributing factor to superficial flexor tendon injury in hunters. Most hunters are overweight and underconditioned. Nonetheless, these horses are routinely worked to the point of fatigue just prior to entry into the show ring, often on uneven and inconsistent footing. It is likely that this fatigue contributes to the stress on this tendon with resultant tendinitis.[4] Diagnostic ultrasound should be performed to determine the extent of tendon damage and to aid selection of an initial treatment plan. An injury with peritendinous swelling and no major fiber damage should be managed with physical therapy (ice or hypertonic hydrotherapy), bandage support, systemic anti-inflammatory medication, rest and a follow-up ultrasound in 2 to 4 weeks. Light exercise can be incorporated into the rehabilitation program if the subsequent ultrasound examination demonstrates improvement. Cold laser or therapeutic ultrasound may be incorporated at this stage, if available. The rate of healing is variable but affected horses may be ready for a return to competition in approximately 2 to 3 months. An injury that results in a core lesion should initially be evaluated and treated as above, with re-evaluation of the injury in 45 to 60 days. A decision to continue rest, inject the lesion or perform a surgical procedure should be based on the change in appearance of the lesion. Most horses that develop a significant core lesion within the superficial digital flexor tendon require 6 to 8 months for recovery, after which a return to the previous level of exercise may be possible.

Inflammation and lameness associated with the accessory ligament of the deep digital flexor tendon (distal check ligament) is more common in the showjumper than the hunter. This is most likely due to the size of fences involved and the different jumping styles. The check ligament adjunctively aids the deep flexor tendon at takeoff to convert horizontal energy into vertical energy and to elevate the forequarters of the horse off the ground. In addition, during landing from a jump, the suspensory ligament and the check ligament of the front legs act as 'stops', converting vertical energy to horizontal energy as the deep flexor tendon loads and helps to move the horse away from the fence. In most instances of injury to the check ligament, there is an incident of a 'funny feeling' jump or a stumbling on landing. The initial management is directed at physical therapy with cold treatment and cooling gel bandage support, systemic non-steroidal anti-inflammatory medication, rest with hand walking, and evaluation of the injury by use of ultrasonography. A relatively minor sprain with fiber pattern edema and minimal amount of overall thickening is treated with medicated poultice bandages, continued anti-inflammatory medications, mildly raised heels, cold laser or ultrasound therapy, and a slow return to exercise over a 4-week period. For the first 4–6 weeks of training, it is generally wise to follow a conservative training and competition schedule, avoiding excessive

speed in jump-offs and utilizing supportive bandages or boots during work. The prognosis for this type of injury is favorable.

Chronic, recurrent thickening, inflammation, soreness and lameness attributed to the check ligament carries a poorer prognosis and can require a forced reduction in the level of competition or retirement. Affected horses will show some improvement following palliative treatment with corrective shoeing, rest, anti-inflammatory medications and other therapies. However, persistent lameness can occur due to the buildup of scar tissue in the check ligament. Surgical intervention with check ligament desmotomy has been beneficial, but generally more as a salvage procedure to make the horse comfortable in retirement or as a pleasure horse.

Suspensory ligament injuries are a cause of poor performance in hunters and jumpers.[5] The three distinct regions of the ligament (high or origin, body, and branches) can be affected. Injury to the suspensory ligament of the show hunter generally occurs more frequently in the front legs as a result of the aforementioned fatigue factors. Exercise in deep, heavy footing also increases the risk for this injury. In jumpers, about two-thirds of cases of suspensory desmitis occur in the fore legs. It is the opinion of this author that the increase in prevalence of suspensory desmitis in jumpers can be attributed to the desire for more 'grab' with the use of more and larger caulks or studs on shoes. The latter may cause the horse to load their support apparatus in a jerky, uneven and inconsistent manner, putting peak loads on the suspensory ligament over very short time periods as the caulks 'grab'. The increase in running speed that the rider feels is attainable with better traction also may predispose to suspensory ligament injury. Many of the hindlimb suspensory problems can be attributed to strain during takeoff biomechanics, while front limb desmitis is usually the result of injury during landing or while completing fast turns.

The suspensory ligament tends to heal slowly due to poor vascularization and the density of fibers. Even in cases in which there is minimal ultrasonographic evidence of injury, an 8- to 12-month period of rehabilitation can be required before a return to full exercise. Generally, desmitis that occurs at attachment regions (proximal metacarpal or metatarsal, abaxial sesamoids) has a poorer prognosis for return to previous level of competition compared with injuries at other sites. Therapeutic plans should focus on the next 8-week period, with re-evaluation of progress and treatment plans at the end of each period. For the first 4 weeks, treatment should focus on resolution of heat, pain, and swelling, along with rest. Then, adjunctive therapy (laser, ultrasound, extracorporeal shock wave), local injections (hyaluronate, corticosteroids, sclerosing agents), herbal preparations, and light exercise can be instituted. If clinical or ultrasound findings do not improve from one examination to another, a more aggressive therapeutic approach may be indicated. This may involve surgery for local fiber splitting or furage, bone marrow autograft injection, transplantation injection of stem cells, carbon/silicone injections or hyperbarometric oxygen treatment. Light exercise of walk and trot for a couple of months can slowly be increased over time to include some short canter work. Foot care should include attention to medial/lateral balance, caudal heel support, and a slight lowering of the heels to reduce stress on the injured ligament and ease breakover. In horses with good response to treatment, consistent exercise under saddle on the flat is generally possible around 7 to 8 months post-injury. Cavalletti and pole work can be started and progress to small jumps over the subsequent 6- to 8-week period, with an increase in jump height and training intensity over the next month. Return to the show ring should be gradual and great attention should be paid to footing, foot care, any changes in jumping style, swelling or heat of the suspensory, and any indication of gait abnormality or lameness.

Back problems

Back soreness is a frequent complaint in hunters and jumpers. The biomechanics and stresses placed on the bony vertebral column and the associated muscles and ligaments while jumping are not completely understood or documented.[6] Nonetheless, observation of horses jumping large fences with a rider suggests that considerable strain is placed on these structures. In hunters and jumpers, back soreness is often attributed to muscle problems, specifically muscle fatigue, muscle spasm or some neuromuscular interaction. Back pain can be precipitated by a sudden increase in the level of competition, a change in rider or rider ability, a change in saddle or other equipment, exercise on a lunge line, deep dry or wet ground conditions, or secondary to other lameness or muscle problems. For example, lower lumbar and gluteal muscle soreness is a fairly common finding in horses with distal tarsitis. Chronic, low-grade discomfort of the forelimb fetlock region may result in nagging lower lumbar and sacroiliac soreness. Therefore, effective management of muscle pain over the back region requires identification and treatment of these underlying primary problems.

Several treatments are effective for the palliative relief of back pain and inflammation. Ice and cold therapy can be effective in the management of acute pain or directly following exercise. Electromagnetic blankets, acupuncture, light therapy, massage and chiropractic techniques, stretching exercises, therapeutic ultrasound and liniments or poultices may also be beneficial. It also is important to ensure that the horse undergoes proper warm-up and cool-down when exercising. Horses that are reported to be stiff or tight through the thoracolumbar or the lumbosacral regions while ridden should be given 20 to 25 minutes of walk and slow trot together with bending and suppling exercises at the beginning and end of each strenuous flatwork or jumping session. Jumping sessions may involve more repetitions of an exercise but at a lower intensity and/or shorter duration. Although difficult and time-consuming for many riders, this approach is effective in the prevention of recurrent back pain. Quarter sheets or blankets over the large muscles of the lower back and hindquarters, while riding, are helpful in cold or inclement riding conditions. Other therapies that may be used include the local injection of corticosteroid and homeopathic preparations and the systemic administration of muscle relaxants, non-steroidal anti-inflammatory drugs, immune modulators or antioxidant supplements.

Back soreness caused by primary skeletal problems of the thoracic, lumbar or iliosacral regions is difficult to diagnose, treat and manage. An experienced rider may be able to detect subtle changes in gait, movement or jumping style subsequent to the infiltration of local anesthetic into suspect areas. Imaging studies (ultrasound, radiology, nuclear scintigraphy) can help in the localization of back lesions. In addition to the treatment and management measures discussed above, therapy often involves the use of local corticosteroid injections. Recently, epidural administration of corticosteroids has been used for the treatment of pain related to osteoarthritic changes between vertebrae or associated with nerve root inflammation.

Stress-related diseases

Frequent and prolonged transport, housing in confined areas with large numbers of horses, irregular exercise programs, changes in feeding management, continuous activity around the stable area, and heavy use of medications are some factors that may predispose show horses to disease conditions. Although there have been no epidemiologic studies, diseases that may occur at a higher incidence in show horses than in other groups include viral respiratory disease, pleuritis, laminitis, colitis and gastric ulcers.

Miscellaneous conditions

From a judging perspective, laryngeal hemiplegia is regarded as unsoundness in a show horse. Originally, the thought was that a field hunter with a restricted airway problem would develop exercise intolerance over the course of a day of fox hunting. Realistically, most show hunters are performing in the ring for approximately 90 to 120 seconds at a submaximal level in which laryngeal hemiplegia is highly unlikely to restrict performance. Nonetheless, some form of surgical intervention is generally recommended for treatment of laryngeal hemiplegia. The technique selected depends on the degree of hemiplegia and the inspiratory noise present when the horse performs.

Pneumovagina can adversely affect jumping style in some hunter and jumper mares. The main clinical signs are a clamping down of the tail during jumping and a tendency to drop the hindquarters and jump flat over the fence and to hit or knock down jump rails with the hind legs. Treatment involves closure of the vulval lips below the level of the brim of the pelvis by use of a Caslick procedure.

Owners and trainers of female show horses are often concerned about behavioral changes associated with the estrous cycle. Behavioral signs of estrus can render some mares reluctant to perform and otherwise difficult to move around the show grounds. Oral or injectable hormone therapy can mitigate this behavior. A glass ball device placed in the uterus shortly after ovulation will suppress behavioral estrus for up to 3 months.[7] In some cases, an ovariectomy may be the appropriate course of action. This is only contemplated if the mare is not to be used for future breeding or she develops an ovarian tumor that is causing behavioral problems.

Intact male horses can also develop behavioral and performance problems. Many stallions become hard to handle and a challenge to keep focused on exercise performance. Some stallions develop testicular and/or scrotal inflammation and pain related to irritation during exercise under saddle or while jumping. These horses will tend to move with their hind legs placed wider than usual, 'stick' off the ground at takeoff, and constantly tail swish, buck or kick out with their hind legs while exercising. The application of lubricating gels to the scrotum to minimize irritation, a reduction in exercise intensity or duration, or castration are possible approaches to this problem.

CHAPTER 56

The older athletic horse

Laurie A. Beard

Demographics of the older or geriatric athletic horse

The definition of 'older' or geriatric horse varies, but 20 years of age or older has been suggested as a guideline.[1] The average horse is reported to have a life expectancy of 25 years.[1] While it is difficult to determine accurately the number of older or geriatric horses, it is estimated that between 10 and 20% of the horse population is geriatric.[1,2] The total horse population in the USA is estimated to be 5 to 8 million.[2] Therefore, there may be roughly 500 000 to 1.5 million horses in the USA that are considered older or geriatric. The population of geriatric horses is likely to have increased over the last several decades. Many of these older horses perform various athletic activities well into their twenties.[1] Today, horses are valued for companionship rather than just their ability to compete or perform work. In addition, modern horse owners are willing to spend more money on health care and optimal nutritional management. Consistent with these trends, at one veterinary teaching hospital in the USA there was a 55% increase in the number of horses 20 years of age or older between 1990 and 1995.[3]

The effects of aging on the body systems in horses

Cardiovascular system

It is well documented that aging results in a decrease in aerobic capacity in humans.[4–7] Older human athletes have decreased maximal oxygen consumption ($\dot{V}O_{2max}$) and decreased cardiac output.[4–6] The decrease in maximal cardiac output appears to be the result of a decrease in both maximal stroke volume and heart rate.[6] Training in older humans can help maintain aerobic capacity and stroke volume.[6,8–10] However, the age-related decline in maximal heart rate is not affected by training.[6]

A similar decrease in exercise and aerobic capacity also occurs in older horses.[11] Older horses are not able to run as fast on a high-speed treadmill (mean ± standard error: 8.7 m/s ± 0.5 versus 10.8 m/s ± 0.5) or as long (275 ± 31 versus 419 ± 31 seconds) as are younger horses.[11] The $\dot{V}O_{2max}$ of unfit, older horses is 24% lower than that of unfit, younger horses.[11] In addition, the treadmill velocity at which $\dot{V}O_{2max}$ occurs is lower in older than in younger horses (8 m/s ± 0.4 versus 10 m/s ± 0.7).[11] Maximal heart rate appears to decrease with age.[12] The treadmill velocity at which blood lactate concentrations of 4 mmol/L occur (indicative of the anaerobic threshold) is lower in older horses (7.5 m/s ± 0.4 versus 10.2 m/s ± 0.7).[11] Unfit, older horses do not thermoregulate as well as unfit, younger horses because of aging-related decreases in resting plasma volume and central cardiac mechanisms.[13,14] Unfortunately, the effects of training on these variables have not been determined in horses.

Respiratory system

Aging results in several changes in respiratory function in humans, including lower partial pressures of arterial oxygen (Pao_2) and carbon dioxide ($Paco_2$) and a higher alveolar to arterial oxygen gradient ($P(A–a)o_2$).[15] Aging results in similar findings in horses. Older horses tend to have lower Pao_2, $Paco_2$, and higher $P(A–a)o_2$, and arterial pH values (Table 56.1).[16] A lower Pao_2 is reported in older horses during anesthesia.[17] The decrease in the $Paco_2$ in humans is thought to be secondary to metabolic acidosis.[18] In contrast, the low $Paco_2$ and higher pH in older horses may be due to hyperventilation in order to maintain Pao_2.[16] The increase in $P(A–a)o_2$ indicates that older horses have impaired transfer of oxygen from alveoli to capillaries.[16] The effects of exercise on the respiratory system have not been determined in older horses.

Table 56.1 Arterial blood gas values, hematologic and serum chemistry values (mean ± standard error or standard deviation) of young and geriatric horses

	Young horses	Geriatric horses	Reference
pH	7.404 ± 0.005	7.428 ± 0.007*	16
Pa_{O_2} (mmHg)	101.7 ± 1.6	90.2 ± 2.2*	16
Pa_{CO_2} (mmHg)	43 ± 0.7	41.5 ± 1.0*	16
$P(A–a)_{O_2}$ (mmHg)	7.2 ± 1.7	22.1 ± 2.5*	16
Mean cell volume (MCV) (fL)	47.8 ± 2.2	49.7 ± 2.2*	3
Mean cell volume (MCV) (fL)	43 ± 1	49 ± 2*	19
Mean cell hemoglobin (MHC) (pg)	16.3 ± 0.9	17.1 ± 0.8*	3
Lymphocytes ($\times 10^9$/L)	3.1 ± 1.1	2.2 ± 0.8*	3
$CD4^+/CD8^+$ cell ratio	4.07 ± 1.54	3.30 ± 1.31*	25
Ionized calcium (mEq/L)	3.00 ± 0.02	3.18 ± 0.05*	16
Ionized calcium pH corrected (mEq/L)	2.98 ± 0.03	3.14 ± 0.05*	16

* Significant difference between young and geriatric horses ($P < 0.05$).

Hematologic and serum chemistry values

The effects of aging of horses on hematologic and serum chemistry values are described in several studies. Older horses have significantly higher erythrocyte mean cell volume (MCV) and mean cell hemoglobin (MCH) than do younger horses[3,19] (Table 56.1), although none of these values in older horses exceeded the reference range.[3] The increase in MCH is thought to reflect the large red blood cell size rather than a true increase in MCH concentration.[3] An increase in MCV is also reported in older humans, and may be associated with decreased serum folate and vitamin B_{12} concentrations, as supplementation will often result in a decrease in the MCV.[3] Horses do not have an absolute dietary requirement for these vitamins because of their extensive synthesis and absorption from the large intestine. However, older horses may have decreased digestive capacity, which may limit their ability to produce or absorb some of these nutrients.[20] Total lymphocyte counts are decreased in geriatric horses when compared with younger horses (Table 56.1).[3] In this particular study, 17% of the geriatric horses had lymphocyte counts that were lower than the established lower limits reference range (1500 cells/μL).[3] An increase in ionized calcium (even with pH correction) is reported in older horses (Table 56.1).[16]

Immune system

The age-related decrease in immune function is termed immunosenescence, and occurs in humans and other animals.[21] Immunosenescence could reflect alterations in the function of T cells (responsible for cell-mediated responses), B cells (responsible for antibody-mediated responses) or nonspecific or innate immunity. It appears that older horses have decreased immunocompetency.[22–24] Older horses infected with equine viral arteritis develop more severe clinical signs than do younger horses housed under similar situations.[22] The ability of horses to produce antibodies to equine influenza virus vaccination gradually decreases with age.[23] Older horses have a 10-fold lower antibody titer to equine influenza virus vaccination than do younger horses.[24]

Older horses have lower lymphocyte numbers (mean ± standard deviation; 2.2×10^9/L ± 0.81 versus 3.1×10^9/L ± 1.1) and lower lymphocyte function when compared with younger horses (Table 56.1).[24,25] Total lymphocyte count and lymphocyte subset cell counts (including T cells, $CD4^+$ and $CD8^+$ cells, and B cells) decrease with age in horses.[25] There is a significant decrease in the percentage of $CD8^+$ lymphocytes, and an increase in the ratio of $CD4^+$ to $CD8^+$ lymphocytes in older horses compared with younger horses (Table 56.1).[25] The increase in CD4:CD8 cell ratio may indicate a pro-inflammatory state in geriatric horses.[25] However, serum concentrations of fibrinogen, an acute phase protein, production of which increases with inflammation, and albumin, which decreases with inflammation, are unchanged in older horses.[25] Older horses have a significantly lower lymphoproliferative response to phytohemagglutinin (PHA), concanavalin A, and pokeweed mitogens compared with younger horses.[24] Serum concentrations of IgG, IgG(T), IgM, and IgA do not differ with age.[25]

The age-related decline in somatotrophin, or growth hormone, secretion may at least be partially responsible for the functional impairment of humoral and cell-mediated immune responses in older humans.[26] Daily administration of equine somatotrophin results in an increase in total leukocyte numbers in geriatric horses.[27] However, only the granulocyte counts were increased, not the lymphocyte numbers.[27] The effect was transient, and not dose related. Granulocytic oxidative burst activity was not affected by equine somatotrophin administration. However, the lymphoproliferative response to mitogens (including PHA and pokeweed) was increased at 2 weeks following cessation of treatment.[27]

Exercise has been shown to substantially alter cell-mediated immune responses in younger horses.[28] However, even though older horses have reduced immune function,[25] geriatric horses are more resistant to exercise-induced immune suppression than younger horses.[24] Exercise adversely affects the lymphoproliferative responses of peripheral blood mononuclear cells of young horses, but not old horses.[24]

Endocrine system

Age does not appear to affect endocrine function or values in normal, older horses at rest.[24,29] Plasma renin activity, atrial natriuretic peptide, arginine vasopressin, aldosterone, and endothelin-1 concentrations are similar in young and aged horses.[29] Aged horses have similar resting cortisol concentrations to younger horses.[24] There are no apparent changes in oral glucose tolerance, insulin secretion, dexamethasone suppression tests, or adrenocorticotrophin (ACTH) concentrations that can be attributable to age alone.[19]

Age-related differences in the endocrine responses to exercise do occur in horses. Exercise increases plasma renin activity, atrial natriuretic peptide, arginine vasopressin, and aldsosterone, but not endothelin-1 concentrations in both young and old horses.[29] Older horses have a greater exercise-induced increase in plasma renin activity and aldosterone concentrations than do younger horses.[29] However, older horses have a smaller exercise-induced increase in atrial natriuretic peptide and arginine vasopressin concentrations than do younger horses.[29] Younger horses have a greater exercised-induced increase in cortisol concentrations than do older horses.[29] The significance of these findings are unclear as all these values are within the reported reference range.[29]

Somatotrophin's role in slowing or even reversing the effects of aging can be documented in younger humans, where somatotrophin deficiency results in changes in appearance, decreased body mass, decreased immune function, and other sequelae of aging.[30] Chronic administration of somatotrophin increases strength and may improve the 'quality of life' in aged humans.[30,31] However, somatotrophin administration to humans does not affect maximal aerobic capacity or endurance performance.[30–32]

The effects of exogenous administration of equine somatotrophin to geriatric horses on feed intake, body score, digestion, aerobic capacity, and immunocompetence is reported, and the results are mixed.[29,33,34] Bodyweight, body condition scores, and feed intake are not affected by administration of equine somatotrophin to older horses.[33,34] However, greater 'muscle definition' was reported in one study.[33] Daily administration of equine somatotrophin to older horses may improve nitrogen balance and fiber digestion.[34] Somatotrophin administration does not affect aerobic capacity (measured by $\dot{V}o_{2max}$, maximum running velocity, or total running time) in older horses.[33] However, administration of equine somatotrophin to older horses appears to have a beneficial immune effect, by increasing the number of granulocytes, and the lymphoproliferative response to mitogens following treatment.[29]

Musculoskeletal system

There is less known about the effects of aging on the skeletal system in horses. Degenerative joint disease is reported to be a frequent cause of death in older horses.[35] Osteoarthritis is commonly observed in joints of older horses.[36] There is a loss of biomechanical function of human articular cartilage with increasing age.[36] However, the biochemical characteristics of the collagen component of equine cartilage are not influenced by age of the horse.[36] The effects of aging, calcium and phosphorus supplementation, and exercise are investigated in a few studies. Skeletal systems of horses of different ages respond differently to calcium and phosphorus supplementation.[37] Younger horses may have the ability to respond to inactivity and exercise more quickly than mature or aged horses.[37]

The effects of age on muscle in humans are responsible for a number of physical impairments, such as a decrease in muscle strength and impaired mobility. The decrease in muscle function is attributed to a decreased ability to generate and sustain power output in association with changes in muscle structure and function.[38,39] A decrease in muscle mass is attributed to a decrease in diameter of the muscle fiber. The slow (type I) to fast twitch (type II) muscle fiber ratio appears to increase with age, due to motor unit remolding.[40]

The effects of age on MHC isoform distribution and activity of marker enzymes of fuel metabolism in horses have been addressed in a few studies. In contrast to humans, older trained horse have a greater percentage of fast myosin heavy chain (MHC) fibers (type II) than do younger trained horses.[41] Among five age groups of trained horses (the oldest group ranging in age from 11 to 24 years of age), the oldest group had a greater percentage of fast MHCs than did younger horses.[42] In contrast, untrained Thoroughbred horses have an increase in the percentage of type I fibers and a decrease in type IIb fibers associated with aging.[43] However, the horses only ranged in age from 1 to 6 years in this particular study and could not be considered old.[43] The effects of age on MHC isoform distribution, activity of marker enzymes of fuel metabolism, and effect of exercise have not been investigated in horses.

Equine Cushing's disease (pituitary adenoma, pituitary pars intermedia dysfunction)

- Equine Cushing's disease is a common disease in older horses.
- Clinical signs range from delayed shedding, muscle wasting, abnormal fat distribution, and laminitis.
- Diagnosis is best based on an overnight dexamethasone suppression test.
- Dysfunction of the pars intermedia is due to loss of dopaminergic innervation and increased production of pro-opiomelanocortin.
- Recommended therapy in most cases is improved husbandry.
- Pergolide is the recommended medical treatment in horses with more severe clinical signs.

Recognition of the disease

Pituitary pars intermedia dysfunction, also known as equine Cushing's disease (ECD), is probably the most common endocrine disease of geriatric horses. The clinical signs vary widely, but can result in either loss of use of an athletic individual or need for humane euthanasia.

History and presenting complaint

Equine Cushing's disease is recognized in horses, ponies, and donkeys ranging in age from 12 to 30 years.[44–46] Presenting complaints include delayed hair shedding, weight loss, laminitis, lethargy, hyperhidrosis, polyuria, and polydipsia.[44–46]

Physical examination

The majority of horses with ECD have a normal temperature, heart and respiratory rate. Hair coats can vary from very long and curly, to only a few longer hairs on the limbs, withers, thorax, and croup.[44] Muscle wasting is often noted by the 'sway-backed' or 'pot-bellied' appearance of the horse.[44] Abnormal fat distribution is often apparent as bulging supraorbital fat pads.[44] Owners often complain of exercise intolerance, excessive sweating, and lethargy. Immunosuppression may be recognized by various infections such as sole abscesses, skin infections, periodontal disease, and sinusitis.[46] Laminitis is a serious clinical sign associated with ECD, which often results in the loss of use of the horse, or even the need for humane euthanasia. Other clinical signs include delayed wound healing, infertility, pseudolaction, bilateral blindness, and seizures.[46]

Special and laboratory examination

A complete blood count in horses with ECD may reveal a stress leukogram, characterized by a mature neutrophila and lymphopenia.[46] Abnormalities on the serum chemistry may include mild increases in serum activity of liver-derived enzymes (including aspartate aminotransferase, alkaline phosphatase, sorbitol dehydrogenase, and gamma-glutamyl transferase).[44,46] Between 25% and 75% of horses with ECD are reported to have hyperglycemia.[46] However, Couetil reports that hyperglycemia occurs in 45% of horses with ECD and in 33% of normal (control) horses.[47] Insulin concentrations are increased in 70% of horses with ECD.[48] However, elevated serum insulin concentrations also occur in horses that do not have ECD.[4]

Necropsy examination and diagnostic conformation

The gold standard for diagnosis of ECD is necropsy and histopathology.[45,49,50] At post-mortem examination there is usually evidence of pituitary hyperplasia or an adenoma. The adenoma appears as a firm, lobulated mass several centimeters in diameter on the ventral aspect of the brain. Visual evidence of compression of the hypothalamus or optic nerves may be evident.[45] Thirteen of 26 horses with ECD had macroadenomas of the pars intermedia that replaced most of the pars distalis.[49] The adenomas were sharply delineated without a defined capsule, causing varying degrees of compression and atrophy of the pars distalis or pars nervosa.[45,49]

An ante-mortem diagnosis of ECD is most often based on endocrinologic testing of the pituitary–adrenal axis.[50–56] Endocrine function tests of the pituitary–adrenal axis include the overnight dexamethasone suppression test (DST),[50] thyrotrophin-releasing hormone stimulation test (TRH stimulation test),[51] combined DST/ACTH (adrenocorticotrophin hormone) stimulation test,[50] or DST/TRH stimulation test.[54] Other tests reported include measurement of serum ACTH,[53,55,56] insulin,[57] and glucose concentrations,[57] glucose tolerance tests,[57] and resting or serial cortisol concentrations.[50]

The overnight DST has excellent sensitivity and specificity (100%) when the post-cortisol blood sample is obtained 19 to 20 hours after administration of the dexamethasone.[50] Dexamethasone (40 μg/kg) is administered intramuscularly at 5 p.m. Blood is collected for measurement of plasma cortisol concentration, immediately before and 19 hours after administration of the dexamethasone. Plasma cortisol concentrations greater than 1 μg/dL 19 hours after dexamethasone concentration are diagnostic of ECD. The DST has been compared to the gold standard (post-mortem examination) in both diseased and healthy horses.[50] Due to infrequent association between corticosteroids and laminitis, and frequent existence of laminitis in affected horses, some clinicians prefer to use other tests.[51,53,55,56] However, for the majority of these tests the sensitivity and specificity is unknown.[51,55,57] Even the reported sensitivity and specificity should be questioned, as the presence or absence of the disease was based on clinical signs of ECD, not post-mortem examination.[53–56] Therefore, despite the concerns of inducing laminitis, which have not been substantiated, the DST is considered to be the diagnostic test of choice.

One of the earliest diagnostic tests, the TRH stimulation test, was reported by Beech and Garcia in 1985.[51] Plasma cortisol concentrations 15 to 90 minutes after TRH stimulation, are higher in horses with ECD when compared with normal horses.[51] In contrast, Eiler et al reported that TRH stimulation did not result in any significant differences in plasma cortisol concentration between ECD and normal horses.[54] However, the diagnosis of normal and ECD was based on clinical signs, not the gold standard (histopathology) in both studies.[51,54] Examination of circadian rhythm in cortisol concentrations, the ACTH stimulation test, a combined ACTH/DST test did not discriminate between normal and ECD horses (the diagnosis was confirmed at necropsy).[50]

The use of plasma ACTH concentrations for the diagnosis of ECD was recently reported.[53,55,56] The sensitivity ranges from 82 to 100% and the specificity ranges from 78 to 100%.[53,55,56] The majority of the reports based the diagnosis of disease or control on clinical signs, not post-mortem exam-

ination.[53,55] There are several reported 'normal' ranges for plasma ACTH concentrations (18.68 ± 6.79 pg/mL[53] to 30 ± 5 pg/mL[56]). The ACTH concentrations considered to be diagnostic of ECD also range from > 27 pg/mL for ponies,[53] > 35 pg/mL,[55] > 50 pg/mL for horses,[53] and > 55 pg/mL.[56] The differences may be due to differences in types of assays used (chemiluminiscent enzyme immunoassay or radioimmunodiffusion assay),[53,55] differences between ACTH concentrations for different breeds (ponies versus horses),[53] and delay in sample processing (plasma ACTH is only stable for 3 hours in whole blood).[53] There is no significant difference in ACTH concentrations between 'clinically normal' older and younger horses.[3] However, the authors noted that ACTH concentrations exceeded 100 pg/mL in both groups of the normal younger and older horses.[3]

Treatment and prognosis

Therapeutic aims

There is no cure for ECD. Therefore, the therapeutic aims are to reduce the clinical signs associated with the disease first through careful management, and in the more severely affected cases through medical management of the disease. The most important aspects in dealing with ECD are excellent basic husbandry and vigilance for any concurrent disease complications. In mildly affected horses regular dental care, deworming, regular foot care, responsive nutritional management, and close attention to clean stable conditions are generally sufficient. Body clipping may be necessary in some affected horses in the summer.

Medical therapy is indicated in horses that have persistent recurrent infections, are hyperglycemic, or develop laminitis. The goal of the medical therapy is to reduce the production of pro-opiomelanocortin (POMC)-related peptides that are responsible for the clinical signs (see 'Etiology and pathogenesis' section). Use of a dopamine agonist is recommended based on the fact that loss of dopaminergic innervation of the pars intermedia results in increased production of POMC-related peptides. Pergolide and bromocriptine are both long-acting type 2 dopamine agonists. The low oral bioavailability of bromocriptine makes it impractical for use on a long-term basis.[58] Therefore, pergolide administered orally is more frequently used.

Therapy

Cyproheptadine has antihistaminic, anticholinergic, and antiserotonin effects. Cyproheptadine was initially recommended because serotonin had been shown to be a potent secretagogue of ACTH in rat pars intermedia tissue.[59] The importance of serotonin in ECD is unknown, as levels within the pars intermedia do not differ from control horses.[60] There is no basic pharmacokinetic information about this drug in horses. Anecdotal clinical information indicates that a positive response to therapy is achieved in 35% of affected horses.[61] Treatment with cyproheptadine in 16 horses with ECD resulted in improved clinical signs in 75% of the horses, but plasma ACTH concentrations rarely returned to normal.[52] Cyproheptadine treatment resulted in improvement in the DST or TRH stimulation test in only 1 out of 7 horses.[48] The recommended doses vary from 0.25 to 0.5 mg/kg orally,[61] 0.25 mg/kg twice a day,[61] or 0.6 to 1.2 mg/kg$^{0.75}$.[44,48]

Pergolide is the treatment of choice for ECD in horses. Controlled studies to establish the bioavailability, pharmacokinetics, and metabolism of this drug have not been reported for the horse. Therefore the dose and frequency of administration is based on anecdotal information. Some recommended doses are: 0.0017 mg/kg divided in two daily doses,[62] 0.25 to 1 mg/horse/day,[63] or 0.002 mg/kg once a day.[48] Beech reports an improvement in clinical signs in 22 out of 25 horses treated with pergolide mesylate after several weeks of therapy.[63] The dose of pergolide was increased over several weeks, if there was no 'clinical response' to treatment.[63] Dybdal reported clinical improvement in more than 25 horses treated with pergolide over a 1-year period.[64] Monitoring of blood glucose concentrations is recommended to determine the dose and response to pergolide therapy.[61] The pergolide dose is increased 0.25 mg to 0.5 mg/day/horse every 4 to 6 weeks until normal blood glucose concentration is obtained.[61] The use of clinical signs (laminitis and obesity) and hyperglycemia to initially diagnose and then follow response to therapy may result in erroneous information.[48,65] There is a newly recognized endocrine disease (termed peripheral Cushing's disease) which results in clinical signs (laminitis and obesity) and laboratory data (hyperglycemia and hyperinsulinemia) that are similar to ECD.[48,65,66] In these reports ECD was ruled out based on post-mortem examination, or a normal DST.[48,65,66]

Several investigators have attempted to provide more objective assessment of the effects of pergolide and cyproheptadine for treatment of ECD. A single dose of pergolide resulted in a decrease in plasma POMC concentrations in a mare with ECD.[67] Unfortunately, measurement of plasma POMC concentrations is not commercially available at this time to assess response to therapy. Some investigators recommend repeating the DST to confirm the return of a functional pituitary–adrenal feedback loop.[61] Pergolide treatment resulted in a normal DST in 2 out of 9 horses with ECD, and the DST 'became closer to normal' in 7 horses after several months of therapy.[62] However, another author reports that pergolide treatment, in 10 horses, resulted in improvement in clinical signs, but insulin concentrations, TRH stimulation or DST test results did not return to normal.[44] The data, unfortunately, were not reported.[44] It is difficult to critically determine the effects of therapy, as none of these reports compared the treated horses with an untreated control group. There is only one report in which a small group of control horses were compared with treated horses.[48] Horses with ECD (diagnosed by TRH stimulation or DST) were treated with cyproheptadine (n = 7), pergolide (n = 20) and no treatment (n = 5) for 6–12 months.[48] Clinical improvement occurred in most of the pergolide-treated group, some of the cyproheptadine-treated group, but not in the

untreated control group. The DST or TRH stimulation test returned to normal in 7 out of 20 horses treated with pergolide, 1 out of 7 horses treated with cyproheptadine, and 1 out of 5 in the untreated control group.[48]

Prognosis

There is no published information regarding prognostic indices for this condition. From clinical experience it would appear that the prognosis of ECD depends on the clinical signs. Horses with hyperglycemia, persistent secondary infections, and laminitis tend to have the worst prognosis. Laminitis frequently results in the end of the horse's athletic career and in most situations progresses to the need for humane euthanasia. There are no published reports about progression of the disease. It is unknown if all horses with ECD will eventually develop the more serious clinical signs.

Etiology and pathogenesis

Equine Cushing's disease has been previously described as a pars pituitary ademona, but it may be more correctly due to hyperplasia or dysfunction of the pars intermedia.[49,60,67,68] The hyperplasia or dysfunction of the pars intermedia has been shown to be due to loss of dopaminergic innervation of the pars intermedia, resulting in increased production of POMC.[46,49,67,68] Post-translational processing of POMC in the pars intermedia results in increased plasma concentrations of ACTH, α- and β-melanocyte stimulating hormone (MSH), corticotrophin-like intermediate peptide (CLIP) and β-endorphin.[49,67,68] Horses with ECD are highly resistant to glucocorticoid negative feedback inhibition of plasma ACTH secretion as glucocorticoids inhibit the pars distalis, but not pars intermedia.[67] However, dopamine infusion resulted in a decrease in ACTH, β-MSH, CLIP and β-endorphin concentrations.[67,68]

The clinical signs of ECD are often attributed to the effects of ACTH and subsequent cortisol production. Muscle wasting, laminitis, insulin-resistant hyperglycemia, and immunosuppression are often attributed to ACTH and loss of the diurnal variation of cortisol. Polyuria and polydipsia can be attributed to hyperglycemia or diabetes insipidus. Diabetes insipidus may be peripheral, due to antagonism of antidiuretic hormone (ADH) at the collecting duct, or central and due to reduced ADH synthesis and/or secretion following compression of the supraoptic nuclei and infundibulum by the space-occupying hyperplastic pars intermedia.[46] While plasma concentrations of ACTH are greater in affected horses, the levels of α-MSH, β-MSH, CLIP and β-endorphin are disproportionally increased.[67] The role of these other hormones in development of the clinical signs of ECD is not well understood. It has been proposed that abnormal behavior (such as docility) may be attributable to increased β-endorphin production.[60] Corticotrophin-like intermediate peptide (CLIP) may be involved in the pathogenesis in hyperinsulinemia detected in some horses with ECD, as it is known to be an insulin secretagogue in obese mice.[68] The pathogenesis of the hyperhidrosis and hirsutism is not known, but may be due to compression of the thermoregulatory center of the hypothalamus.

Peripheral Cushing's disease

Recognition of the disease

There is a well-recognized syndrome in middle to older aged horses characterized by laminitis, obesity, and hyperglycemia.[65] These horses have previously been identified as having 'hypothyroidism', or being diagnosed with ECD.[65,66] However, necropsy examination, thyroid stimulation tests or overnight DST have failed to confirm these diagnoses.[48,65,66] These horses appear to have a disorder in cellular cortisol metabolism. This syndrome has been termed 'peripheral Cushing's disease'.[65] A similar syndrome exists in humans, which is called central (or visceral) obesity, or the metabolic syndrome.[69,70]

History and presenting complaint

Middle to older aged horses may present with a complaint of obesity and chronic laminitis. The distribution of body fat involves the neck and gluteal muscles. Geldings may present for a swollen sheath. Owners frequently complain that it is difficult to reduce the weight of these horses by diet restriction. Many of these horses have been diagnosed with 'hypothyroidism' or even with ECD.

Laboratory examination

A complete blood count and serum chemistry often reveals hyperglycemia. Elevated insulin concentrations[48,65,66] and an abnormal glucose tolerance test (documenting insulin resistance) are described.[65] These horses will often have low circulating concentrations of thyroid hormone.[65] However, thyroid-stimulating tests fail to support the diagnosis of hypothyroidism.[65] Moreover, experimentally induced hypothyroidism does not produce horses with obesity and laminitis. Confirmatory testing for ECD, using either a DST or TRH stimulation test, is normal in these horses.[48,65,66]

Necropsy examination

Necropsy examination fails to reveal pars intermedia hyperplasia or adrenal gland pathology in horses with peripheral Cushing's disease.[65,66]

Diagnostic confirmation

The diagnostic confirmation of peripheral Cushing's disease at present is recognition of clinical signs and laboratory data, and ruling out of either ECD or hypothyroidism.[48,65,66]

Treatment and prognosis

Therapeutic aims

At the present there is no specific treatment for peripheral Cushing's syndrome in horses. Therapeutic aims are to reduce the clinical signs associated with the disease by management. Exercise may help improve glucose tolerance and insulin function. Laminitis should be treated as necessary. Dietary supplement with chromium (5 mg/day) may improve peripheral insulin function and glucose tolerance.[65,71]

Prognosis

There are no published reports on prognosis of this syndrome in horses.

Epidemiology and pathogenesis

The exact etiology of peripheral Cushing's disease in horses is unknown, but it is proposed these horses have a disorder in cellular cortisol metabolism similar to the human syndrome.[48,65] Central obesity or the metabolic syndrome in humans is associated with hypertension, dyslipidemia, diabetes, accumulation of intra-abdominal (visceral) rather than subcutaneous fat, and premature death.[69,70] There is an increase in the 24-hour cortisol production, but circulating basal cortisol concentrations and a DST are normal in these patients.[69] Corticosteroid action is in part regulated by 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1) which converts active cortisol to inactive cortisone.[69] Adipose stromal cells from omental fat, but not subcutaneous fat, can generate active cortisol from inactive cortisone.[69] In addition, the expression of 11β-HSD1 in adipose fat is further increased after exposure to cortisol and insulin.[69] Johnson and Ganjam report that horses with peripheral Cushing's syndrome have increased blood pressure, insulin resistance, and hyperlipidemia.[65] Other clinical signs in horses include abnormal fat deposits, reduced fertility, laminitis, and difficulty in losing weight.[48,65] The lowered circulating thyroid hormone levels may be due to elevated cortisol production that can lead to inhibition of the thyroid-stimulating hormone (TSH) produced by the pituitary gland.[65]

CHAPTER 57

General principles for the vaccination of equine athletes

Hugh Townsend

In addition to aiding in the prevention of devastating and life-threatening diseases, vaccination programs for equine athletes should be directed towards the prevention of diseases known to have significant adverse effects upon athletic performance. The emphasis should be on those diseases that place individual or group performance at substantial risk. Wherever possible, decisions on vaccination and its timing should be based on published data, such as reports of vaccine safety, efficacy and duration of immunity as well as current disease surveillance data. In those cases where the data required for evidence-based decisions are not available, decisions on vaccination must be taken based on expert, practitioner and client experience, opinions and objectives. Steady improvement in the effectiveness of these decisions can be achieved through the application of knowledge gained through ongoing vaccine and epidemiologic research.

Reaching the best decisions on the vaccination of the equine athlete requires knowledge of the timing and circumstance of significant risk of disease. Our incomplete understanding of the epidemiology, pathogenesis and immunology of all infectious diseases, combined with limited information about the efficacy and duration of immunity of existing vaccines, makes this a challenging process. This is further complicated by the highly variable response of individual horses to all vaccines. Nonetheless, if used strategically, some vaccines are capable of reducing the risk and severity of disease at both the individual and herd or group levels.

Currently, many vaccines are marketed for use in horses in North America. Most are multivalent, designed to meet a market that wishes to provide wide and convenient protection against a broad spectrum of diseases. Generally, the intent is to achieve this through yearly vaccination following an initial prime and boost series. In reality, however, it is difficult to stimulate a serviceable immunity against most diseases, particularly the important contagious diseases, that will last for more than 6 months. In fact, the desire to provide protection against several diseases with a single, yearly administration puts unrealistic expectations upon all current multivalent vaccines. Vaccination programs in all horses, including the athletic horse, could be much improved through acceptance of reasonable expectations for their role in the prevention of disease and by accommodating these limitations in the design of disease prevention programs.

The wide array of equine vaccines currently on the market in North America has resulted in considerable confusion in our attempts to develop appropriate vaccination programs. However, this process can be simplified by limiting consideration to those diseases that pose real and significant risk and for which we possess vaccines of known efficacy. The logic of this approach is supported by the recognition that vaccination is never completely without risk and can, in some situations, be completely without benefit. Vaccination on the sole premise that it 'might do some good' may provide psychological support for horse owners and veterinarians but it is unlikely to benefit the horse. Designing programs without due attention to the requirements and claims of the manufacturer as well as the cost, benefit and risks of vaccination may lead to procedures that are either oversimplified and ineffective (e.g. one multivalent vaccine per year) or unduly complex and expensive.

Each of the major infectious diseases of the athletic horse along with preventive strategies, including vaccination, are described in other chapters of this book. Taken one by one, developing an appropriate vaccination strategy should be fairly straightforward, especially when we have some data upon the epidemiology of the disease (circumstance and timing of significant risk), vaccine efficacy,

Table 57.1 Vaccination against common diseases of horses

Disease	Agent	Vaccine	Program	Vaccination rate[69]	*Justification/comment*[a]
Influenza	Equine influenza virus A2			63%	*High prevalence, predictable periods of risk, herd immunity critical in preventing outbreaks of disease*
		Killed	Prime and boost, then every 6 months or 2 weeks prior to risk		Efficacious (European vaccines)
		Modified-live (intranasal)	Every 6 months or 2 weeks prior to risk		Efficacious (North America)
		ISCOM	Prime and boost, then every 6 months or 2 weeks prior to risk		Efficacious (European vaccine)
Equine herpes virus	EHV1, 2 and 4	No commercial vaccine against EHV2		43%	*Limited – prevalence of EHV respiratory disease is not known*
		Killed (EHV1 and 4)	Prime and boost followed by revaccination every 6 months		Efficacious (European vaccines)
		Modified-live (EHV1 and 4)	Prime and boost followed by revaccination every 6 months		No published data on efficacy
Strangles	*Streptococcus equi*			13%	*Limited – equine athletes not usually at high risk*
		M protein	Prime and boost and then every 6 months or 2 weeks prior to risk		Efficacy demonstrated in challenge and field trials
		Live attenuated (intranasal)			Challenge data not published
Tetanus	*Clostridium tetani*	Tetanus toxoid	Prime and boost and yearly revaccination and/or at time of deep wound or surgery	70%	*Clinical disease tends to be severe with a high case fatality rate* No published efficacy in horses
Rabies	Rabies virus	Killed	Prime and boost and yearly revaccination or prior to risk	24%	*Fatal disease* No published efficacy in horses
Viral encephalitis	EEE	Killed	Prime and boost and yearly or 6-monthly revaccination	63%	*High disease prevalence in some regions – high case fatality rate* No published efficacy data
	WEE	Killed	Prime and boost and yearly revaccination prior to risk		*Traditional in areas where disease is or has been prevalent* No published efficacy data
	West Nile	Killed		n/a	*High incidence in endemic regions – prolonged treatment and high case-fatality rate* Results of challenge trials not published
EPM	*Sarcocystis neurona*	Killed	Prime and boost and yearly revaccination	n/a	*High prevalence in endemic regions, potentially devastating disease. Treatment prolonged and expensive* No published efficacy data – multicenter trial in progress
EVA	EVA virus	Modified-live	Prime and boost and yearly revaccination	1.8%	*Limited – low prevalence of clinical disease* Published efficacy data
Potomac horse fever	*Neorickettsia risticii* (formerly *Ehrlichia risticii*)	Killed	Prime and boost and yearly revaccination prior to known period of risk	18%	*Acute severe disease with high complication rate and cost of treatment* Published evidence suggests vaccines are not effective

[a] Logically, only vaccines for which there is published evidence of efficacy are likely to provide benefit to the equine athlete and then only when those animals are at significant risk (see justification/comment).

safety and duration of immunity. The real challenge is how to combine these various strategies into a program that will provide real benefit to horse and owner.

The following paragraphs cover diseases of potential importance for the equine athlete for which vaccines are available (Table 57.1). The focus of the material is principally upon North America but the general approach to the assessment and use of vaccines is meant to be applicable on an international scale. This chapter is based upon the premise that there is no such thing as a fully effective 'one size fits all' vaccination program for the equine athlete. In each case, the costs, risks and the benefits of vaccination must be carefully considered with both the individual animal and the group in mind. Clearly, the combined effect of all of the factors involved in the effective use of vaccines will change over time. The unique and critical role of the veterinary practitioner in this process is not the physical delivery of vaccine to the animal but the careful and considered monitoring of each situation and the ability to make informed, effective program modifications as conditions change and new information becomes available.

Influenza

Influenza is the most commonly diagnosed infectious disease of horses against which vaccination is currently possible. Outbreaks among large groups of young equine athletes, particularly race horses, occur regularly and such populations are frequently and predictably at risk.[1–12] More is known about the epidemiology, diagnosis, strategies for prevention, utility of vaccination, efficacy of the vaccines and the effectiveness of vaccine strategies in the control of equine influenza than any other disease of the horse. Efficacious killed and immunostimulating complex (ISCOM) vaccines are marketed in the European Community[13–15] and an efficacious, cold-adapted, temperature-sensitive, modified live, intranasal vaccine is marketed in North America.[16–19] Based on current published reports, all these types of vaccines reduce rates of infection, amounts of virus shed and rates of clinical disease among individuals and within groups of animals for at least 6 months. A number of killed influenza vaccines are also marketed in North America. Although these vaccines may be useful, neither the manufacturers nor independent investigators have published data demonstrating their efficacy.

Prevention of influenza outbreaks is dependent upon appropriate control measures including regular and constant surveillance, use of rapid, point of care diagnostic tests,[3,20–22] national and international disease surveillance and the institution of effective vaccination programs at the level of the individual and the group.[2,4,6,23,24] The principal reason for occurrence of regular outbreaks of influenza in North America and elsewhere is almost certainly the failure to apply existing knowledge about this disease and its prevention. At most large facilities, particularly racetracks, the risk factors for disease outbreaks and the likely time of their occurrence are reasonably well understood. For example, a 3-year study at a racetrack where few precautions were taken to prevent introduction or spread of disease showed that outbreaks of influenza occurred once each year, in the middle of the racing season, when the horse population at the track was near its maximum.[25] According to the results of another study, movement of weanlings, not vaccinated within the previous 6 months, from the sales ring into racing yards in Newmarket resulted in outbreaks of influenza in those yards.[3]

Co-mingling of young equine athletes significantly increases the risk of outbreaks of influenza. Often, this occurs in controlled environments where preventive strategies could be instituted with little difficulty. All horses entering an athletic venue should have received a vaccine of published efficacy within the previous 6 months. In doing so, the risk of disease in the individual and more importantly, among the group of animals comingling in the environment, will be reduced. Horses that exceed this 6-month limit while resident in the environment should be revaccinated. The risk of adverse responses to these vaccines is small and the potential benefit to the population of this regime is large.

Perfect protection of individual animals following vaccination cannot be expected. Response to vaccination and duration of immunity among individual animals is varied and unpredictable following the administration of even the most effective vaccines. For this reason, vaccination must be combined with other strategies, including regular surveillance of the population, rapid diagnosis of disease, quarantine or removal of affected animals from the group and revaccination of the group at the first sign of an outbreak. Finally, any outbreaks that do occur should be properly documented. A plan should be in place for collection of the appropriate data needed to determine the cause and chart the course of any significant outbreak of disease.

Equine herpesvirus

Experimental infection of susceptible horses with equine herpesvirus 1, 2 or 4 results in typical signs of respiratory tract infection; malaise, fever, cough and nasal discharge.[26–37] Vaccination prior to experimental challenge can reduce the occurrence and severity of clinical signs and the amount of virus shed, but does not prevent viremia or persistent infection.[30,33,38–42] There is good evidence to show that most horses become infected with these viruses by the time they are weaned[43,44] and should therefore be capable of recurrent viral recrudescence and shedding for the rest of their lives. It is not known if any vaccination is capable of influencing either EHV infection or recrudescence.

Although it is commonly held that EHV1 and EHV4 are important causes of respiratory disease among equine athletes, particularly young race horses, there are no published studies to show that this is true. Although there is evidence of seroconversion of horses to both EHV1 and EHV4 during the course of racing seasons,[45–49] there are no descriptions of outbreaks of EHV respiratory disease that follow an epidemic curve typical of a contagious disease. In all published

longitudinal epidemiologic studies, seroconversions to EHV occurred sporadically and in some cases were clearly associated with concurrent equine influenza infections.[45,50,51]

Clearly, until more information upon the epidemiology of EHV respiratory disease and the efficacy the EHV vaccines becomes available it will prove difficult to provide clear recommendations on the use of vaccination against these diseases. At the present time, most of these vaccines are marketed as a component of a multivalent vaccine, often in combination with influenza antigens. Certainly there is no evidence that these vaccine combinations are harmful, but there may be no benefit in selecting multivalent respiratory vaccines based upon the EHV antigens they contain.

Strangles (*Streptococcus equi* infections)

Under most circumstances, equine athletes should not be at high risk of developing clinical signs of strangles. Classical outbreaks were first described in army remounts.[51,52] More recent epidemics have involved brood mare farms,[53–58] rescue farms,[59] groups of experimental animals,[60,61] horse feedlots[62] and riding stables[63] but there are no recent reports of strangles outbreaks among groups of equine athletes.

Horses suffering from classical strangles are easily identified. The signs are well known to all veterinarians and most knowledgeable horse owners and trainers. The identification of non-clinical carriers does provide a challenge but more sensitive methods for detecting these animals are being developed. The key to prevention and control of strangles rests with the early identification of both clinically diseased and non-clinical carrier animals and the institution of appropriate control procedures including appropriate quarantine and sanitation procedures.[63] Using this approach it should be possible to limit or prevent direct contact between infected animals and susceptible equine athletes.

There is reasonable experimental and field trial data to show that the use of intramuscular vaccines containing the M protein of *Streptococcus equi*[64,65] or submucosal injection of a live attenuated vaccine[66] will reduce both the occurrence and severity of clinical signs of disease. However, because strangles in equine athletes is uncommon, the rate of vaccination among these animals is low. As well, the strangles vaccines have been dogged by the perception that severe local reactions may occur following their use, even though published safety data show that these reactions may be infrequent.[65]

Use of the live, attenuated intranasal strangles vaccine has been associated with some reports of abscess formation at the site of other injections given on the same day as well as reports of classical disease from which the vaccine strain of the organism has been isolated.[67] Importantly, although the manufacturer has conducted experimental challenge trials of this vaccine, none of the details of these studies have been presented in peer review publications.

Increasing knowledge about the pathogenesis and epidemiology of equine strangles and the development and testing of control procedures based upon identification of non-clinical carriers, sanitation and quarantine may result in decreased urgency to develop safe and efficacious vaccines against this disease. Based on our current understanding, there appears to be no clear justification for vaccination of equine athletes against strangles unless it is known that these horses are likely to be placed at high risk of exposure and disease. At best, current vaccines reduce the rate and severity of clinical disease in vaccinated animals by approximately 50%.[65,68] Under most circumstances, instituting other preventive procedures should provide a higher likelihood of success in the prevention and containment of outbreaks of this disease among equine athletes.

Equine rabies

Rabies is a rare but fatal disease of horses. The National Animal Health Monitoring Scheme (NAHMS) survey[69] reports that approximately 25% of horses in the USA over 12 months of age are vaccinated annually against this disease. Despite a widespread conviction that the equine rabies vaccines are highly efficacious, as well as verbal and written assurances from the vaccine industry and regulatory authorities, the only published information upon the efficacy of rabies vaccination in horses relates to instances when vaccinated animals developed the disease.[70,71] Assuming that successful challenge trials have been conducted, it is highly regrettable that there are no published data on the serologic or protective response of horses to the vaccines presently on the market. Paradoxically, the use of rabies immunoglobulin, including equine rabies immunoglobulin, is considered an essential component of post-exposure treatment in people and there are published field trials demonstrating the efficacy of this procedure.[72–76] This appears to provide clear evidence that protecting horses through vaccination should be possible.

The duration of immunity following administration of an efficacious vaccine against equine rabies will vary among individual animals but based on data from humans and other animals, it should exceed 12 months. Assuming a close correlation between serologic status and protection against this disease, those seriously interested in preventing equine rabies might be advised to focus some of their efforts upon developing a commercially available serologic test for protective antibody in horses. Knowing whether or not individual horses possess protective concentrations of serum antibody would be extremely useful. If vaccines were administered on this basis, the rate of revaccination would probably be reduced and it would soon become evident which vaccines on the market gave the best response. The cost of such a service might prove comparable to the cost of annual vaccination programs, and would be more useful.

Tetanus

Like rabies, equine tetanus is a rare disease, even amongst horses that have not been vaccinated. Tetanus toxoid is the most commonly used vaccine in horses 12 months of age and older. In North America, approximately 70% of horses in this age range are vaccinated on an annual basis.[69] To be judged satisfactory by the United States Department of Agriculture, Center for Biologics, tetanus vaccines must provide a serologic response in guinea pigs that is at least four times higher than that thought necessary to protect them against a natural challenge.

Experimental challenges showing protection following vaccination of horses have been reported[77] but these studies were not conducted using commercial vaccines. There is no published information upon the magnitude or duration of serologic response or protection against toxin challenge among horses vaccinated with any of the tetanus toxoids currently marketed in North America. Equine tetanus has been reported among vaccinated animals[78] although these animals were less likely to die than non-vaccinates.

The decline in the incidence of equine tetanus since vaccination became common practice and the fact that equine tetanus antitoxin is effective in the treatment of the disease in people[79–81] has naturally led to the conclusion that most, if not all, of the current tetanus toxoid vaccines are effective. Arguably, some of the decline in incidence of the disease may be related to other factors, including improvements in general husbandry practices and methods of wound management, including the common use of antibiotics.

The duration of immunity following vaccination with any of the currently marketed toxoids is not known. There is some evidence to suggest that it is likely to exceed 1 year[14] and perhaps be as long as 8.[77] Data on the serologic status of vaccinated and unvaccinated horses of different ages and an assessment of variation among the different vaccines would be very useful in helping us refine current vaccination programs. Until this information becomes available, the practice of yearly vaccination of horses, following an initial prime and boost vaccination, will continue to be standard practice for equine athletes.

Eastern and western equine encephalomyelitis

There is little information on the efficacy of the eastern (EEE) and western equine encephalomyelitis (WEE) vaccines. Virtually every manufacturer of equine vaccines in North America produces at least one vaccine against equine encephalomyelitis and most textbooks and articles on the prevention of these diseases claim that vaccination is key. However, there are no results from well-designed challenge or even serologic studies to support this claim.

Eastern equine encephalomyelitis is prevalent in the south and east of North America, particularly the southern USA. The case fatality rate is high. Until the critical challenge experiments, field trials, outbreak or case control studies are done to assess vaccine efficacy, it is likely that horses in endemic regions, or traveling to them, will continue to receive vaccine once or twice each year.

Clarifying the impact of vaccination upon the occurrence of western equine encephalomyelitis will likely prove even more difficult than it will for EEE. Appropriate challenge models have not been published so experimental studies upon which to gauge the potential efficacy of existing vaccines cannot be performed. Similar to EEE, vaccination programs against this disease have become ingrained in our disease prevention strategies. The practice of annual WEE vaccination prior to the mosquito season continues in regions of North America where extensive surveillance programs have not detected the presence of virus or disease for over 20 years. At this time, there appears to be no evidence to suggest that routine vaccination against this disease is providing any benefit to equine athletes.

West Nile virus

At the time of preparation of this book, West Nile virus was spreading rapidly across North America and resulting in alarming numbers of clinical cases and subsequent death of horses in both the USA and Canada. There is tremendous public concern regarding this disease and because it is a zoonosis, there are large-scale programs in place to track the spread of the virus. These data are important to the prevention of the disease in horses as they permit realistic assessment of risk of exposure of horses maintained or traveling in different regions. The first and probably the most effective strategy for prevention is related to decreasing exposure of horses to the mosquito vector. This is accomplished through programs to reduce or eliminate sources of standing water in areas where horses are kept, spraying the environment, stabling horses in screened facilities, and the application of insect repellents to horses.

In response to this crisis in North America, a commercial vaccine has been licensed for use in the USA and Canada. Experimental challenges of susceptible horses with live virus have not resulted in clinical signs of disease but have caused infection and detectable viremia. At least two challenge studies assessing the ability of the vaccine to prevent viremia and a field safety trial have been conducted by the manufacturer. The full results of these studies have not yet been published but reports from the manufacturer state that local reactions to the vaccine are mild and uncommon and that in comparison to controls, vaccinated animals experienced a significant decrease in the occurrence of viremia in both studies.

It may be some time before accurate estimates can be made regarding the benefit of vaccination of athletic horses against

this disease. There is an urgent need to conduct both retrospective and prospective studies aimed at providing accurate estimates of the rate of clinical signs of disease among herds of horses maintained under various levels of risk of exposure. Due to the circumstances of their general care and management, equine athletes should be at or near the lowest risk of exposure and disease. However, until more is known about the vaccine and the current epidemic, vaccination of valuable animals will be a common practice. Hopefully, veterinary practitioners and scientists will seize the opportunity to study this disease and the effectiveness of control procedures throughout the present epidemic. With careful assessment of the evidence, vaccination programs should not become fully entrenched without the data to support this practice.

Equine protozoal myelitis

Equine protozoal myelitis (EPM) is an infectious disease of horses requiring prolonged and expensive treatment. Serologic studies show high prevalence of infection in endemic regions and although almost certainly overdiagnosed, the incidence of this disease is much greater than the combined incidence of rabies and tetanus. Equine athletes are at risk in endemic regions through contamination of their feed. A killed vaccine has been provisionally licensed and marketed in the USA and Canada. The efficacy of vaccination is currently under study through a large-scale multicenter study. Research is also proceeding on the development of an experimental challenge model. There seems to be a reasonable prospect that published results will one day become available, providing the critical data upon which informed decisions on vaccination can be made. In the mean time, the decision whether or not to vaccinate will be made on a case-by-case basis by individual owners and their veterinarians.

Equine viral arteritis

Infection with equine viral arteritis (EVA) virus may be followed by clinical signs of respiratory disease. EVA should be included in the differential diagnosis of viral respiratory disease, particularly when combined with evidence of vasculitis (subcutaneous edema, petechial hemorrhages and thrombocytopenia). Occasional outbreaks of the disease may occur in athletic animals[82] but most infections are subclinical. Serologic surveys performed in a number of countries have generally shown relatively low numbers of seropositive horses, particularly among equine athletes.[83–88] Vaccination with a modified live vaccine is followed by seroconversion and one challenge study provides evidence of protection against clinical signs of disease.[89] However, given the infrequency of outbreaks of clinical disease, routine vaccination of equine athletes should not be recommended. Vaccination should be considered for stallions destined to become breeding animals.[90] However, antibody responses stimulated by commercial vaccines cannot be distinguished from natural infection with the virus. This is relevant to management of the equine athlete, as some countries do not permit importation of seropositive animals.

Potomac horse fever

Infections caused by *Neorickettsia risticii* (*Ehrlichia risticii*) are capable of causing acute endotoxemia, colic, diarrhea and hypoproteinemia in horses. Laminitis is a common and sometimes fatal complication.

Although the epidemiology of the disease has not been completely described, substantial progress has been made in understanding the seasonality, distribution and modes of transmission. All published evidence indicates that the disease is not contagious. Infection follows ingestion of infected snail metacercariae. Regions and farms of high prevalence have been identified and equine athletes traveling to or kept in these regions are logically at some risk of infection and disease, particularly when kept at pasture.

Several killed vaccines against *N. risticii* are marketed in the USA and Canada. Data from an experimental challenge of one of these vaccines showed a significant decrease in disease among vaccinates as compared with control animals.[91] However, subsequent studies failed to demonstrate field efficacy.[92,93]

Efforts aimed at limiting disease and fatalities directly related to infection with *N. risticii* should include close attention to limiting exposure, careful monitoring of animals in endemic regions and prompt diagnosis and treatment of individuals developing signs of disease. In the face of questionable evidence of vaccine efficacy, the decision to initiate a program will depend on the experience, judgment and opinions of individual horse owners and their veterinarians. If vaccination is effective, the duration of immunity would not be expected to exceed 6 months. If horses are to be vaccinated, the initial prime–boost strategy should be completed shortly before the onset of the expected period of risk and followed by similar timing of annual revaccination.

However well reasoned the above approach may turn out to be, it is clear that further studies should be conducted to test these and other logical strategies. Horse owners and veterinary practitioners should encourage vaccine manufacturers, research scientists and regulatory agencies to perform more studies aimed at developing a better understanding of the prevention and control of this disease.

Summary

Vaccination programs for all horses, athletes included, should be based upon an understanding of the risk of disease, vaccine efficacy, the concepts of herd immunity, duration of

immunity, variation in response to vaccination among vaccines and among horses and a cost–benefit analysis. There is no doubt that veterinarians wishing to design vaccination programs for equine athletes are hampered in their efforts due to lack of adequate information upon which to base many of their decisions. However, this situation is improving. Regulatory authorities are gradually refining and increasing their demands for relevant efficacy data during the process of vaccine registration and there are many individuals within the vaccine industry seeking to meet or exceed these requirements. Veterinarians and educators have a critical role to play in this process. We must do a better job of teaching and understanding the principles of vaccinology and the strengths and limitations of vaccination as a method of disease control. Practicing veterinarians should be more insistent upon obtaining relevant data on the efficacy, duration of immunity and safety of the vaccines that they recommend and use. The effectiveness of all equine vaccination programs could be substantially improved through more appropriate use of vaccines based on the rigorous application of current knowledge; through realistic assessment of risk, efficacy, costs and benefits of vaccination; and by making sure that all reasonable, alternate strategies of disease prevention are used in combination with vaccination.

CHAPTER 58

Parasite control for the athletic horse

Cliff Monahan

Introduction and background

Parasite control programs for performance horses will differ from those for pleasure horses in two principal areas: they will differ in intensity by virtue of the need to maximize the performance horse's athletic abilities, and could shift in scope of parasite targets because travel to events may expose a performance horse to a wider spectrum of parasitic infections than encountered by a sedentary horse. These may be ectoparasites serving as vectors for bacterial and viral pathogens; thus avoidance of the disease is predicated on the parasite control program.

This chapter will begin with coverage of three universally prevalent equine gastrointestinal parasites that define the most important concepts of anthelmintic control programs. Control of all other gastrointestinal parasites of horses will be achievable within a framework to control these three parasites. *Parascaris equorum* is an age-related nematode problem and defines the need to treat prophylactically at regular intervals related to its life cycle. The strongyles, both large and small, are the principal nematode targets of equine parasite control programs worldwide. *Anoplocephala perfoliata* is a common cestode of Equidae worldwide and is susceptible to a limited spectrum of available drugs, thus defining the need to understand how to shift drug choices when necessary.

This chapter will then address ectoparasites and their control, which include management or husbandry practices coupled with a few chemicals having a broad spectrum of activity. The intensity of the ectoparasite control program is based on the importance of the potential transmission. All permanent equine facilities should employ ectoparasite control programs, but the intensity would increase when hosting an event. Extreme measures would be warranted for the sponsors of an international event where horses could be carriers of foreign diseases.

The reader must be cognizant of additional differences between programs designed for all residents of a large training facility as compared to programs for individual horses while traveling off-premises to events. Both styles of control program must be based on rational expectations of management practices and antiparasitic compounds, coupled with a rational list of the anticipated parasites that need to be controlled. As a brief example, a trainer traveling with a small number of performance horses to an international event could employ a labor-intensive and costly preventive program that would be unreasonable to implement for all the residents of a large training facility where residents are exposed only to a local parasite fauna. The traveling horse will usually be stabled, which greatly reduces exposure to parasites ingested on pasture. The residents of a training facility may graze significantly or recreationally; thus the focus shifts to protection of the pastures from heavy contamination through a comprehensive, herd deworming program.

Although parasitism is undesirable because it can drain nutrients and energy otherwise applied to growth or performance, a parasite-free horse is an anomaly and is not a realistic goal of a parasite control program. Many of the equine parasites are prevalent worldwide, so exposure to infective stages should be viewed as inevitable unless the horse remains in a very controlled environment. Horses should develop an acquired resistance to the normal, anticipated spectrum of equine parasites (ascarids and cyathostomes as examples), through controlled exposure.[1–3] Anthelmintic programs are intended to manage these parasitic diseases, not eliminate them completely.

In contrast to the anticipated spectrum of gastrointestinal parasites, there are regional or sporadic infections for which no immunity would be expected to develop. For these, a prevention program is desirable and rational, but not always possible. Many viral, bacterial, rickettsial and protozoal diseases are transmitted by biting arthropods; thus an ectoparasite control program would become the front-line of defense against exposure. This type of prevention program should be

applied while horses are traveling to events even if these potential diseases are not endemic in that area because there is a chance that another competitor is a carrier.

Our understanding of the relative contribution to equine disease by gastrointestinal parasites has evolved since the advent of the macrocyclic lactones (ML) during the early 1980s. *Strongylus vulgaris* is the cause of verminous arteritis or thromboembolic colic,[4] thus the most pathogenic of the horse parasites, but *S. vulgaris* has been tremendously reduced in prevalence through regular use of ivermectin.[1] Without *S. vulgaris* to shoulder the blame for the incidence of colic, we learned of the contribution by the small strongyles or Cyathostominae, previously considered of minimal pathogenicity.[5,6] Widespread benzimidazole resistance of the cyathostomes[7,8] led to reliance on ivermectin as the backbone of anthelmintic control programs. Ivermectin and the entire class of macrocyclic lactones have no activity against tapeworms, and *Anoplocephala perfoliata* is the most important tapeworm of equids. In identical fashion as seen with the cyathostomes, *A. perfoliata* was dismissed as insignificant until the evidence became undeniable.[9,10] As history has demonstrated, our perception of the important equine parasites has been influenced tremendously by the activity of our anthelmintics. Control programs must be designed to target the parasites of importance and shift the choice of anthelmintic as appropriate.

Gastrointestinal parasitic diseases

Parascaris equorum

Parascaris equorum is a common and important parasite of foals, weanlings and yearlings before they can be considered true performance horses, but ineffective control of this infection can result in damage during the growth phase with ramifications for later performance.

Infection and pathogenesis

Ingested ascarid eggs hatch in the small intestine where the larvae penetrate the wall. Their migration follows the path of least resistance because the larvae are swept by the venous blood flow through the portal system to the liver. The larvae are trapped first in the liver and migrate within the parenchyma for several days before reaching vessels that carry them into the caudal vena cava to the heart, then to the lungs. Clinical signs stemming from migration through the liver may be more vague than those of pulmonary migration.

Following passage through the liver, the pulmonary capillary beds next trap the larvae. Most *P. equorum* larvae find their way through the thin walls of the alveoli into the lumen. *Parascaris equorum* can cause an eosinophilic pneumonitis with ramifications on pulmonary function that extend beyond the duration of larval migration.[11,12] Pulmonary changes can range from a mild cough to bacterial pneumonia accompanied by a purulent nasal discharge, typically bilateral. A peripheral neutrophilia or eosinophilia is often observed on a complete blood count (CBC).[11,12]

Ascarid larvae in the lungs are coughed up the trachea to the pharynx and swallowed. Larvae arrive in the small intestine measuring just millimeters in length, but grow eventually as long as 50 centimeters when mature. Their contact with the mucosal surface leads to truncation and thickening of the villi and alteration of the cellular components of the mucosal lining. These changes reduce digestion and absorption of nutrients. Large masses of ascarid larvae and adults can lead to impactions and intussusceptions when ascarids develop unchecked by regular anthelmintic administration.[13]

Diagnosis

During the prepatent, migratory phase, diagnosis of *P. equorum* infections is problematic because confirmation by a fecal examination is not possible for at least 70 days after infection. A provisional diagnosis can be made based on the age and associated clinical signs. Clinical chemistry changes associated with liver damage include elevated serum activity of aspartate transaminase (AST), but this enzyme is not specific for liver damage. Serum activity of sorbitol dehydrogenase (SDH) and gamma-glutamyl transaminase (GGT) are likely to be elevated secondary to the hepatic damage by the larvae, and are more specific for liver involvement. For diagnosis of patent infections by a fecal examination, both passive flotations and centrifugation techniques are effective, but centrifugation techniques are more sensitive. The eggs will be characteristic of ascarids: thick-shelled, brown in color, usually with a proteinaceous coating, and will measure 90–100 μm in diameter.

Treatment and control

Treatment and control of *P. equorum* infections should be achievable with the benzimidazoles, pyrantel salts or piperazine. A recent report from Europe indicates that *P. equorum* populations have developed resistance to both ivermectin and moxidectin.[14] Published reports of this resistance have not yet been made from other regions of the world, but recent personal experience in North America with several yearlings carrying patent infections of *P. equorum* included a recent history of ivermectin treatments. These experiences are indicative that the macrocyclic lactone class is no longer reliable for *P. equorum* treatment or control. Clinicians are advised to perform follow-up fecal examinations at 14 days after treatment to verify success or failure.

A major consideration in choice of anthelmintic is the absorption from the intestine for systemic activity against migrating larvae. Pyrantel pamoate and fenbendazole have limited absorption, so would not be the first choice for targeting the migratory larval stages in either the liver or lungs. Fenbendazole could be given over 5 days for activity against migrating larvae. Ivermectin and moxidectin both have systemic activity against migratory larvae at the therapeutic

dosage, but the recent drug resistance question of *P. equorum* must be answered. Moxidectin should not be used for foals less than 4 months of age, nor for debilitated horses.

Preventive anthelmintic treatments should be initiated by 6 weeks of age and not delayed until a fecal examination confirms the presence of *P. equorum*. These treatments should be repeated at 6-week intervals and are aimed at removing larval ascarids before their adult size becomes problematic or egg production begins. As mentioned previously, contamination of the soil will lead to years of ascarid transmission. At 6-week intervals, an anthelmintic with systemic activity is not necessary as the immune response will develop and block further migration.

Colic, impaction and intussusception can occur following anthelmintic administration to heavily infected young horses, but the root cause of this sequela is the inadequate parasite control program rather than the drug administration. Many practitioners feel that half doses of anthelmintics are safer to use in this situation, as if this would only affect half of the ascarids. Clinicians are advised to use the label dosage and prepare for the potential with such precautions as mineral oil. Piperazine is contraindicated in this setting.

Epidemiology

Ascarid infections of most animals are diseases of neonates and juveniles that will develop resistance or immunity through exposure. Infections in 2-year-old horses are rare. Ascarid eggs have a thick, proteinaceous shell that resists desiccation and protects the infective larva, facilitating survival in the environment for years.[15] Because the egg is infective, transmission of *P. equorum* can occur in any season, and can occur in young horses confined to stalls or paddocks.[15,16] This transmission is in contrast to strongyle infections that require warm temperatures for activity of the infective larvae and pasture settings for grazing transmission.

Strongyle infections

The large and small strongyles are associated taxonomically by morphological characteristics, but differ significantly in their development in the horse. The large strongyles include three most important species within the genus *Strongylus*: *S. vulgaris*, *S. edentatus* and *S. equinus*. The cyathostomes, or small strongyles, constitute several genera with over 40 species worldwide; thus the terms 'small strongyles' or 'cyathostomes' are preferred for convenience.

Large strongyles

Infection and pathogenicity

Strongylus vulgaris has, historically, been regarded as the most pathogenic nematode parasite of Equidae worldwide due to its migration through the cranial mesenteric artery (CMA), causing verminous arteritis or thromboembolic colic. This migration follows the arterioles of the cecal and colonic submucosa moving craniad along the arterial system. Damage to the endothelium promotes platelet adherence. When sufficient numbers of *S. vulgaris* larvae are funneled to the CMA, their numbers destroy the normal, elastic architecture of the artery, disrupting laminar flow of blood. Turbulent flow promotes clot formation, seeding the distal capillary beds with thrombi of varying sizes. The size of the distal artery blocked by a thrombus will affect the size of the ischemic area of the intestine. If the area is small, collateral circulation can be established and the horse may suffer a transient bout of colic. If large, ischemia will lead to an intractable colic, endotoxemia and death. Resolution of small lesions can result in serosal attachments between loops of the intestine, which can be associated with future entrapments. Architectural changes of the CMA remain for the life of the horse; thus an active infection is not required for repeated bouts of thromboebolic colic. The elastic nature of the CMA will not return.

Diagnosis

Fecal examinations easily recover both large and small strongyle eggs. This typical strongyle-type egg cannot be differentiated morphologically as either a large or small strongyle. Today, the assumption that any eggs recovered are all small strongyles is justified by the sporadic to rare appearance of large strongyles in well-managed horses.

Treatment and control

The large strongyles are best controlled by regular deworming with a macrocyclic lactone because of their potent systemic effects against migrating larvae. Due to their prepatent period (6–11 months), the large strongyles can be eliminated from a well-managed horse farm by semiannual use of ivermectin or moxidectin, although *S. vulgaris* does still occur.[17] Daily deworming with a pyrantel tartrate feed additive is useful while traveling, but does not replace regular deworming with a macrocyclic lactone.[18] Daily deworming is intended to kill the larvae as they exsheath before penetrating the intestinal wall; however, a single, morning feed additive may not have sufficient concentration in the lumen if horses graze later in the day. Nonetheless, daily dewormers are a useful product for horses traveling to events where they may be allowed recreational grazing on pastures of unknown contamination. For maximum protection, the product should be fed just prior to grazing.

Epidemiology

As mentioned previously, the prevalence of large strongyles has been reduced by ivermectin usage and the cyathostomes are now the focal point of equine deworming programs. Transmission requires grazing for exposure to infective larvae. For the athletic horse, the greatest risk of exposure will come off premises at events, where recreational grazing may expose horses to pastures of unknown infectivity. Age-related resistance to the large strongyles does develop

through exposure, but is not complete and owners or trainers should be diligent to protect horses off premises.

Cyathostomes

Infection and pathogenicity

The life cycle of the cyathostomes is complex and reviewed elsewhere.[19,20] The small strongyles do not migrate through the body as do the large strongyles; instead, they penetrate no further than the mucosa or submucosa of the cecum and ventral colon where they encyst for variable periods of time. During encystment, the small strongyles are hypobiotic, rendering them less susceptible to normal anthelmintic treatments. Over 90% of the million or more cyathostomes will be hypobiotic or encysted larval stages.[21,22] Their presence in the wall of the cecum or ventral colon causes thickening of the mucosa, which decreases absorption of nutrients. Their presence also disrupts the myoelectrical conduction of the smooth muscle, which can manifest as spasmodic colic.

There are two manifestations of cyathostome infections, both related to the larval stages. The acute form, larval cyathostomosis, is better known and stems from a synchronous emergence of larval stages analogous to type II ostertagiasis in cattle. Synchronous activation can destroy the cecal and colonic mucosa, resulting in severe, protein-losing, life-threatening diarrhea. This is a medical emergency with a guarded prognosis.[23] The mechanism triggering the emergence of encysted cyathostomes is not well characterized and is multifactorial.[23,24]

The second manifestation is also due to the larval stages, is subtle, develops slowly over a grazing season, and is difficult to diagnose because fecal examinations may be negative as few adult cyathostomes may be present in the lumen. This condition will also be seen most commonly in horses less than 6 years of age.[24] When a horse grazes an infected pasture, the mucosal population of hypobiotic larvae grows daily, which develops into a progressive thickening of the cecal and ventral colonic mucosa until a point at which absorption of nutrients is impaired. Afflicted horses typically show a progressive loss of body condition in spite of sufficient feed intake. Typically, regular anthelmintic treatments remove the egg-laying adults with limited activity against the mucosal stages. This leads to the misconception that a horse receiving regular anthelmintics and negative on a fecal examination could not be suffering from parasitism.

Diagnosis

The small strongyle egg-laying adults in the lumen of the cecum or ventral colon produce a typical strongyle-type egg during patent infections. These eggs are easily recovered by normal fecal examination techniques. Unfortunately, the clinical signs associated with cyathostome infections are secondary to the encysted or hypobiotic larvae. Acute cyathostomosis can be differentiated from other causes of acute diarrhea by the presence of blood-red larvae in the feces or on a palpation sleeve. High numbers of strongyle-type eggs would not be recovered on a fecal examination of acute cyathostomosis because few adults are present in the lumen. Diagnosis may be aided by a CBC demonstrating an eosinophilia, or by finding low plasma protein values and normal to elevated levels of fibrinogen in the face of a protein-losing enteropathy.

Treatment and control

The most important distinction to make is between treatment of the lumen-dwelling adults and the mucosal-dwelling encysted larvae. Treatment of acute cyathostomosis is a medical emergency to replace the fluid and protein losses. Anthelmintics are of secondary importance for these cases.

Anthelmintic programs are aimed at control of the egg-laying adults, which should translate into lower mucosal burdens through reduction of pasture contamination. Small strongyles have developed widespread benzimidazole resistance, which is widely reported,[7,8] thus the benzimidazole class of anthelmintics should be reserved for the 5-day course of daily treatments at elevated dosages to remove the encysted larvae.[25] Cyathostomes have also developed resistance to pyrantel salts, although not as widely reported as for the benzimidazoles. Their periodic use is rational and effectiveness should be confirmed with a fecal examination.

This leaves the macrocyclic lactone class as the backbone of an anthelmintic control program. Both ivermectin and moxidectin have excellent activity against the lumen-dwelling adults. Ivermectin has little or no reported activity against the mucosal larvae, probably due to its short plasma half-life.[26] Moxidectin, in contrast, has an extended half-life with measurable levels at 80 days post-treatment.[26] This extended activity does provide additional protection to grazing horses,[27] but may select for drug-resistant cyathostomes.[28,29] The author prefers the exclusive use of ivermectin for cyathostome control, with elevated benzimidazole treatments for 5 days to target mucosal stages. Since the advent of ivermectin in the early 1980s, there has never been a report of macrocyclic lactone-resistant cyathostomes. Recent reports of ascarid resistance highlight the importance of avoiding drug-resistant horse nematodes.

The 5-day course of benzimidazole treatments should be useful in horses under 6 years of age during the later part of a grazing season. They would be beneficial when a young horse enters training where stabling may reduce or eliminate exposure on pasture. By killing the larvae in situ within the mucosa, larval degeneration should seed the immune system with antigens in the fashion of a drug-abbreviated vaccination, theoretically engendering a level of acquired resistance at an earlier age.

The periodicity of anthelmintic treatments will depend on the drug employed, and is important to horses with access to pasture, not those confined to stalls. Use of pyrantel salts would require retreatment at 4- to 6-week intervals. Use of ivermectin or moxidectin allows 8- to 12-week intervals before egg shedding recurs. Regardless of the anthelmintic, fecal examinations should be used to verify the effectiveness of treatments, then to identify the egg reappearance time

that will dictate subsequent treatments.[30] Excessive drug treatments are not necessary and are likely to speed the development of drug resistance.[29]

Epidemiology

In contrast to *P. equorum*, both large and small strongyles are transmitted seasonally during the grazing season through ingestion of the infective larvae on pasture. Cyathostome infections are of greatest severity or risk in horses less than 6 years of age with access to pasture.[1,6,24,31] Acute cyathostomosis also has an association with season (late winter or early spring), and a recent history of deworming that apparently triggers the synchronous emergence of larvae. Older horses should have developed an acquired resistance through controlled exposure, but will still carry infections and serve as a source for pasture contamination. Encysted larvae survive for years past ingestion. Gibson[32] demonstrated that the encysted population was sufficient to repopulate the lumen after anthelmintic treatments for almost 3 years when the experiment was terminated. This finding highlights that acute diarrhea in a stall-confined athletic horse could stem from larval cyathostomosis even when previous exposure to pasture is a year or more in the past. All horses, regardless of age, will experience some degree of larval emergence but few will reach the magnitude necessary to trigger acute cyathostomosis. Athletic horses confined to stalls and fed hay are still at risk of acute cyathostomosis if they have grazed on pasture earlier in life. Any young horse turned out to pasture for rest or rehabilitation after an athletic campaign would be at higher risk and should receive regular monitoring by fecal examinations and appropriate anthelmintic treatments. On large farms or boarding facilities, the efficacy of the control program will have a direct effect on the incidence of colic seen on that farm.[5]

Equine tapeworm infections

The importance of tapeworm infections to the owner or trainer of performance horses lies less in their degree of pathogenicity, but more from an understanding of the life cycle and transmission, and then the requirement for a shift in anthelmintic choice for treatment and control.

Infection and pathogenesis

Tapeworms utilize an indirect life cycle that requires an orbatid mite as the intermediate host for transmission to horses. These tiny, free-living mites live and feed on fecal debris or other organic matter, whether on pasture or in stalls, so transmission to a stabled performance horse can occur. The prepatent period for *Anoplocephala perfoliata* is 4 to 6 weeks following ingestion of an infected mite.

Anoplocephala perfoliata is the most pathogenic horse tapeworm because its predilection site ranges from the terminal ileum into the cecum, with particular clustering at the ileocecocolic valve.[33] Erosive lesions can penetrate into the submucosa and smooth muscle of the valve, affecting its function, which will promote spasmodic colic and intussusception.[9,10,34–36]

Diagnosis

Tapeworm infections of horses are diagnostic problems for two reasons: (1) because progottids break down in the intestinal tract rather than being passed intact, thus a gross examination of the feces rarely reveals the presence of the tapeworms; (2) the eggs liberated by a degenerating proglottid are unevenly distributed in the feces. The eggs can be recovered from a fecal sample with several examination techniques. However, the concentration or uneven distribution of eggs within feces decreases the confidence in negative results. Coprological examinations are not a reliable indicator of the infection status; only 50–60% of tapeworm-infected horses (positive identification at necropsy examinations) will be positively identified by normal fecal examination techniques.[33,37] Centrifugation techniques using larger quantities of feces increase sensitivity somewhat, but never to a heightened level of confidence. A quantitative technique, such as the McMasters or modified Stolls is definitely contraindicated as the sensitivity would be lower. Both sugar and zinc sulfate flotation media of 1.20 specific gravity can be used; sodium nitrate should be avoided because it will disrupt the egg more than will sugar or zinc solutions. The anoplocephalid eggs recovered on an examination are asymmetrically shaped and can easily be mistaken for debris, particularly when few eggs are present.

Treatment and control

Anthelmintic choices for tapeworm treatments are limited. The benzimidazoles as a class have activity against tapeworms in other domestic animals, but fenbendazole was reported as ineffective using a 5-day regimen at 10 mg/kg.[38] Pyrantel salts have cestocidal activity.[39,40] Pyrantel tartrate as a daily dewormer is effective at 2.6 mg/kg given daily for 30 days, and reported to be more effective than a single dose of pyrantel pamoate at 19.8 mg/kg.[41,42] Praziquantel and epsiprantel are related compounds with excellent cestocidal activity. Praziquantel is highly effective against *A. perfoliata*,[43] and will be marketed worldwide in combination with ivermectin. This single combination will be effective for treatment of the most important parasitic infections of horses, which suggests that moxidectin will soon be formulated with epsiprantel in the near future to remain competitive.

Due to the low reliability of ante-mortem diagnosis, control is better achieved through scheduled, periodic treatments with an effective compound. At the present time, treatments twice yearly with a pyrantel salt should be adequate for tapeworm control, as well as activity against nematodes, such as small strongyles.

Epidemiology

Anoplocephala perfoliata has a worldwide distribution, and should be anticipated in horses regardless of the housing

conditions. Mite activity, essential for transmission, will be temperature-dependent, so tapeworm transmission can have a seasonal component in colder climates.[44] Year-round transmission has been reported in more temperate regions.[45] In colder climates, heated barns may support mite activity during cold periods. Transmission can certainly occur in stables; thus an athletic horse in training can become infected. There is some acquired resistance through exposure to tapeworm infections; however, many or most athletic horses are within the younger population.

As a final note to owners and trainers of athletic horses, the author advises that all feeds be protected from access by other animals, domestic, feral or wild. The author has recovered cat ascarid eggs passed by horses that ingested contaminated feeds, as barn cats will defecate in grain bins and hay barns. Contaminated feeds represent a route of infection for *Toxoplasma gondii* spread by barn cats, or *Sarcocystis* spp., such as *Sarcocystis neurona* passed by opossums in North America. Both grain and hay should be protected.

Ectoparasite control for athletic horses

Athletic horses will be exposed to a wider spectrum of ectoparasites than sedentary horses by virtue of travel to different regions, or contact with other participating horses. The importance of such exposure can span from contact transmission of a nuisance ectoparasite to the potential exposure of a life-threatening arthropod-borne infection at an event, such as an encephalitis virus. Most ectoparasite problems are irritating, not life-threatening, but a night spent under a relentless attack by biting midges or mosquitoes may drain the energy or focus otherwise available for performance.

Control programs and procedures will differ as significantly as the spectrum of disease or pests of concern, ranging from those applied to an individual competitor, to procedures employed by the sponsors of an international event concerned with prevention of arthropod-borne diseases. Facilities personnel can employ management practices directed towards controlling the habitats of important ectoparasites, whereas a trainer traveling with horses has little or no influence over the environment where the event is held, and instead, must rely on treatments applied directly to their competitors.

Equine facilities, whether a permanent training or boarding facility, or the temporary sponsors of an event, should address the ectoparasite habitat at their location rather than rely solely on chemical control. Simple management practices can reduce the ectoparasite potential, such as mowing, improving drainage, and effective composting of manure and bedding as examples. Fans, baited traps and lights can be added to barns. Rodent control can have a profound influence on the local ectoparasite population and arthropod-borne disease risk, as rodents serve both as a source of blood meals and as amplification hosts of several arthropod-borne diseases. Management practices should be implemented and improved annually, as these physical interventions will reduce the need for chemical interventions, and will improve their efficacy when applied. Within a reasonable timeframe before the start of an event, chemical control measures could be implemented as an adjunct to the management practices employed continuously. The degree of this chemical control may increase in proportion to the level of risk, as in the case of an encephalitis outbreak, or hosting an international event. An understanding of the biology and habits of these vectors or pests is essential for implementation of rational control measures, as is an appreciation of the effects that area sprays may have on an ecosystem.

Environmental insecticides and acaricides cannot discriminate between the parasitic or the beneficial arthropods, such as bees or the various insects responsible for natural recycling of manure. Chemical sprays can translate into damaging effects on the fish, reptile, amphibian and bird populations that act as natural forces balancing the arthropod populations. Most ectoparasiticides for environmental use are long-acting synthetics that accumulate progressively up the food chain. Alterations of this balance can be self-defeating for an equine facility. Priority should be given to environmental improvements that decrease the reproductive potential of ectoparasites and foster an increase of the insectivorous populations. Indiscriminate use of area insecticides has led to the development of drug-resistant pests rather than their elimination.

Situations do arise, however, that warrant the rational and controlled use of area chemicals, such as an outbreak of mosquito-borne encephalitis, or hosting an international event where carriers of a foreign, arthropod-borne disease may be a realistic concern. The 1996 Olympic Games held in Atlanta, Georgia, represent one case in point, when extensive measures were implemented over the concern that *Babesia* spp. could become introduced into the local *Dermacentor* population through feeding on carriers in competition.[46] The sponsors of the Olympic games began with environmental measures to reduce the tick habitat before using chemicals prior to the arrival of competitors.

In all situations where environmental sprays or fogs will be employed, the facilities managers must follow the local, state or federal regulations concerning the use of such compounds, and follow the safety precautions for specific formulations. If unusual circumstances dictate extensive, environmental measures, permits may be required and the application process may require months or more before a ruling.

In contrast to the environmental control measures are those that can be applied directly to the horse. There are just a few classes of effective insecticides and acaricides available, most of which are also formulated as environmental sprays. One very important rule of thumb is that the active ingredient may be identical in two formulations, but the vehicle or propellant will differ. Formulations made for area or environmental sprays should never be used directly on animals as toxicity or blistering of the skin may occur based on the propellant or vehicle.

The remainder of this chapter will focus on the ectoparasites and their control rather than on the arthropod-borne diseases because those diseases are not unique to the performance horse. A thorough knowledge of these ectoparasite control measures will be important to trainers and riders while traveling, and to facilities managers, particularly when hosting an equestrian event.

Mosquitoes

Mosquitoes are best known as the vectors of many equine encephalitis viruses. All mosquito genera and species require standing water in varying quantities for their replication, ranging from ponds or puddles to seemingly insignificant quantities in a hoof print or remaining in the axillae of leaves and branches of plants. The principal management practice for their control resides in the identification of possible replication sites at an equine facility because the majority of mosquitoes move only a few hundred meters from their hatching sites to feed on animals. This will become an important radius for chemical treatments immediately prior to the arrival of participants at events. These sites can be areas of tall grass, irrigation ditches, ponds, puddles, small accumulations around the roots of trees or rain gutters with leaf clutter blocking complete drainage. Regular and critical inspection of the premises can reveal many inapparent sites that will be important for both the physical interventions and to identify these sites if environmental sprays are to be used. As insignificant as these sites may seem, these small sites do not support fish or amphibian species that would devour the developing larval stages, and thus may contribute more feeding mosquitoes than the obvious, larger sites. The edges of ponds, lakes or canals where vegetation blends into water are much more important than the open water of these larger bodies. Walls or banks can be constructed at these interfaces such that the transition is sharply divided between vegetation and water.

Several of the most important species of *Aedes* and *Ochlerotatus* (formerly designated as a subspecies of *Aedes*), lay eggs in temporarily dry areas that will accumulate water after a rain or irrigation. The eggs of these genera can withstand varying degrees of desiccation and may remain dormant for months before activation. Improving drainage and filling depressions are obvious interventions. Mowing tall grass and weedy areas will increase sunlight penetration, which will speed drying where replication occurs.

Mosquitoes are weak fliers and the addition of fans to barns can prevent mosquito feeding on stabled horses. Many but not all mosquito species are evening or night feeders, so stabling horses during crepuscular periods can reduce their exposure. Many mosquito species are attracted to sodium vapor lights but not towards yellow light; thus sodium lights can be placed at the periphery and yellow lights used inside and around stables and arenas. Several devices that electrocute flying insects use appropriate light or bait, such as carbon dioxide (CO_2), and are worthwhile additions to mosquito control. Several vertebrates are well known for their consumption of large quantities of flying mosquito adults. Thus the addition or promotion of bat housing or bird-nesting sites is beneficial, as is nurturing the frog populations in ponds or lagoons on or near the premises.

Chemical control of mosquitoes will have three approaches: environmental sprays or fogs over exterior sites; environmental sprays with residual activity on the interior structures of barns or stables; direct application of repellents or insecticides to horses. Fogs are formulated to produce microscopic droplets that remain in airborne suspensions, extending their potential contact time with flying adults. These should never be used indoors when animals are present. Fogs kill flying adults through contact, so logic dictates their dispersal only at mosquito feeding times, only when calm wind conditions permit, and only near important mosquito sites. Fogs are the most toxic formulations for birds and bats, and thus require caution and rational use. Because fogs have limited duration as aerial suspension, potent but short-acting insecticides such as pyrethrins are sensible choices. Although a seemingly semantic difference, sprays are intended to disperse droplets over some solid substrate, whether vegetation or facilities. Insecticidal sprays can be applied to breeding sites when needed, and long-acting compounds with weeks of activity are available, but these will have the greatest impact on the non-parasitic fauna. Formulations containing pyrethroids have the lowest mammalian toxicity but can have adverse effects through accumulation in reptile, fish and bird populations. *Bacillus thuringiensis* is a bacteria that produces an insecticidal compound and is available as a dust that can be applied to areas of mosquito larvae development and this may be more environmentally sound than long-acting synthetic compounds. If permitted in specific localities, organophosphate sprays such as malathion or diazinon could be employed when conditions warrant. Imidacloprid is a potent insecticide approved in many countries for use on crops intended for human consumption or as topical flea control on pets, implying excellent tolerance by vertebrate species. Insect growth regulators, such as methoprene, pyriproxyfen or diflubenzuron, can inhibit development of mosquito larvae, have little or no vertebrate toxicity, but have little residual activity, and thus require repeated application. Any of these environmental treatments should be applied only to those sites where the problem exists rather than as an indiscriminant broadcast of chemicals.

Mosquito females will rest on a physical structure following a blood meal; thus environmental sprays can be applied to the walls and doors of a barn or arena. Compounds with residual activity, such as the synthetic pyrethroids or the organophosphates, are logical choices in this situation as they can provide several weeks of activity. While this strategy does not prevent mosquito feeding, it plays an important role in halting transmission of mosquito-borne diseases by killing replete females that may have ingested an equine pathogen.

Appropriate repellents and insecticides can be applied directly to the skin of horses if so directed. If not formulated specifically for horses, these compounds should be used with caution. The identical active ingredients on the label of two

products can be misleading because differences in the vehicle suspension may be a toxic factor for horse skin. Repellent formulations with botanical derivatives, such as citronella, limonene and linolool, are available but not highly effective repellents. The synthetic repellent butoxypolypropylene glycol is formulated for horses. Several pyrethroids approved for use as wipes on horses, such as cypromethrin, resmethrin and permethrin, are attributed with repellent qualities that may stem from rapid killing of the mosquitoes that alight on the treated skin. The pyrethroids are the backbone of on-horse ectoparasite control as they have potent activity against mosquitoes, biting flies, midges, ticks, mites and lice. Many pyrethrin or pyrethroid formulations contain piperonyl butoxide, which is not itself insecticidal but which inhibits the arthropod enzymes that inactivate pyrethrins. Piperonyl butoxide, therefore, potentiates the action of pyrethrins. Wipes applied to horses for mosquito control should be applied to the entire body due to their more indiscriminate feeding pattern, whereas ticks tend towards feeding in protected areas of the ventrum or head and ears.

Ticks

Ticks are best known as vectors of *Babesia caballi*, *Theileria equi* and *Anaplasma phagocytophilum* as well as several other arthropod-borne viral and bacterial diseases, and tick paralysis. Tick-borne diseases will have a regional distribution and seasonal pattern of occurrence directly related to those patterns of the vector tick, and vary from year to year according to environmental factors and cycles, including weather and influences on the host populations.[47,48] Ticks themselves do not travel far from their hatching sites but can be carried great distances by the roaming of animals or the migration of birds. Survival or establishment at the new site will be dependent on hospitable climatic and environmental characteristics. Equine facilities can make reasonable, physical or environmental changes that reduce this hospitality but management of climatic changes are beyond the scope of this chapter.

Ticks favor habitat of grasses and shrubs with sufficient moisture that their egg masses can develop before desiccation. Several genera populate the interface between forest and meadow. As a generality, ticks favor turf and cross-country terrain over dirt and arenas; thus the risk of tick-borne diseases is reduced but not eliminated at urban facilities. Mowing areas of scrub, brush and long grass will aid the overall control program by reducing the tick reproductive potential, reducing the vegetation they climb while questing for hosts, and by removing the excessive vegetation that would diminish the efficacy of a chemical spray if or when necessary in the control program. These areas should be cleaned of fallen branches or logs that could serve as reproductive sites or impede effective mowing. As questing ticks will climb to the top of vegetation and wait for a host, the height and density of vegetation will influence the number of ticks and their success in contacting hosts. The height of this vegetation will also influence the height on the legs of horses where acaricidal wipes must be applied. These areas can be monitored for tick populations by dragging a cotton or muslin sheet over the ground and collecting ticks for identification and enumeration. Tick traps can be made that use CO_2 release as a bait. Questing ticks are lured towards the CO_2 and climb into a collecting sack, sheet of muslin or an adhesive pad. Monitoring will help demonstrate the effectiveness of the control program and highlight those areas that may need additional modification or receive an area spray of acaricide. Such monitoring may be required of the sponsors for an international event, but should be practiced occasionally at all permanent horse facilities where ticks exist.

Larval and nymphal tick stages often rely on nestling and neonatal rodents or rabbits for their first blood meals. These mammalian populations also serve as the reservoir or amplification hosts for many bacterial or viral diseases for which ticks serve as vectors. Therefore, rodent control is a particularly important facet of tick control. Along with rodent control, equine facilities should make every effort to exclude wildlife from their premises due to the risk of importing ticks attached to those hosts, as well as the other problems that wildlife can create.

Chemical control measures include applications to the horse or the environment, bearing in mind that these different formulations should not be interchanged even though the active ingredient may be identical. Pyrethrins, pyrethroids, organophosphates and carbamates are commonly used as active ingredients. Pyrethroid and organophosphate compounds have been developed that will provide 3–5 weeks of residual activity following application. Pyrethrin formulations owe much of their safety on the horse or in the environment to the fact that pyrethrin is metabolized or oxidized quickly. Organophosphates and carbamates share a mechanism of action and can have additive effects that can lead to toxicity if used concurrently with other acetylcholinesterase inhibitors, particularly when long-acting compounds are used.

Sprays can be applied to areas of scrub, brush or grass that have been mowed. Wipes or sprays can be applied to horses, particularly covering the legs, ventrum and neck, head and ears, as ticks tend to congregate in these areas rather than spread across broad, exposed areas of the flanks and back. Several pyrethroid compounds in these formulations can provide 3–4 weeks of residual activity on the horse, and are effective against ticks and insect pests, such as mosquitoes, biting flies, gnats and midges.

Face flies, house flies and stable flies

These flies, *Musca autumnalis*, *M. domestica* and *Stomoxys calcitrans* respectively, are widespread pests and vectors of disease in and around barns and stables, and are daytime feeders. Stable flies actively bite, painfully, usually around the legs, and have been implicated as mechanical or biological vectors of several arthropod-borne diseases of equids, surra and equine infectious anemia being examples. Face flies and house flies are attracted to secretions and transmit diseases by contact, for the most part. They can serve as the intermediate

host of several nematodes of horses. Collectively, these three flies utilize manure and decaying materials of different types for egg laying and larval development. Thus the most important measure in their control is hygiene within and around the stable area, and composting effectively the bedding, manure and decaying vegetation that supports their larval development. These flies may travel from neighboring farms where conditions are more favorable, but this potential does not alter the need to maintain a high level of sanitation at a stable.

Face flies both feed and rest on the faces of cattle and horses; thus topical repellents and insecticides can be applied to the face for the most effective chemical control, which will also work for house flies. Both are attracted to wounds as well as nasal or lacrimal secretions, implying that wounds should be dressed and the bandage treated with a topical insecticide, or small wounds treated directly with an appropriate repellent or insecticide. Stable flies bite the lower legs, so repellents and insecticides can be applied directly to these susceptible areas. House flies and stable flies rest on a solid surface when not feeding; thus barn walls, doors, windows and screens can be sprayed with long-acting insecticides that kill these flies on contact. Likewise, they can be lured to baited traps impregnated with insecticide, or composed of an adhesive. Manure or compost piles could be treated with an insecticide to kill developing maggots, but such treatment will also kill the beneficial arthropod fauna responsible for manure degradation. Manure piles can be covered with plastic to increase the pile temperature and speed composting.

Tabanid flies

The tabanids include the horse flies (*Tabanus*) and deer flies (*Chrysops*). These are significantly different from the house, face and stable flies in both their feeding habits and their sites of replication. The tabanids are best known as vectors of equine infectious anemia and implicated in the transmission of other blood-borne infections. The tabanids have slashing mouthparts to draw blood and feed, and it is the interrupted feeding that is implicated in the mechanical transmission of several diseases as they fly to another animal to continue a blood meal.

The tabanids are more difficult to control than the other flies because their larval stages occur in the leaf litter of forested areas that are not reasonably accessible for environmental or chemical interventions. Tabanids fly some distance to feed, in contrast to mosquitoes. As such, their sites of replication may be miles from an equine facility. Tabanids are daytime feeders and prefer hosts outside of barns, so stabling horses during the peak tabanid season will help prevent bites. Tabanids target moving objects in pastures or paddocks, a characteristic exploited by traps made of moving parts, usually wind-driven but sometimes mechanized. These traps have an adhesive surface, which could be augmented by application of a contact insecticide. Repellents and insecticidal wipes, such as those containing pyrethroids, will also have some effect, though it may be negligible, against tabanids.

Black flies and biting midges

Black flies or buffalo flies are fierce biters within the genus *Simulium*, and the biting midges or 'no-see-ums' are members of the genus *Culicoides*. Both have been implicated as vectors of various filarial diseases of humans and animals, and *Culicoides* is also well known as a vector of several important viral diseases, the most important for international events being African horse sickness.

Both the black flies and midges are ferocious blood-feeders that inflict very painful bites relative to their small size, and many horses develop hypersensitivity reactions to the saliva. *Simulium* is a daytime feeder, principally early mornings, whereas *Culicoides* is an evening or early nightfall feeder. Both feed in swarms that are extremely irritating to afflicted horses. Neither pest is a strong flier, and both prefer open spaces for feeding. Thus stabling horses with fans creating a light breeze is an effective measure, perhaps more than repellents.

Both *Simulium* and *Culicoides* require water in some form for their larval stages, but differ tremendously in the type of water source. *Simulium* requires moving water and can utilize both raging currents or slow. *Culicoides*, in contrast, requires stationary water, such as marshes, ditches and irrigated pastures, and some species can utilize moist soil. This makes control measures directed at the sites of larval development more difficult if not impossible. Both have a seasonal occurrence that could allow sponsors of an event to avoid those peak times when scheduling the event. Chemical control on horses can be attempted with repellents and insecticides, but those horses with hypersensitivity reactions should be stabled at the respective feeding times and provided with a fan to inhibit swarms from reaching the horse. During an outbreak, or to prevent an outbreak of a viral disease as devastating as African horse sickness, environmental sprays or fogs could be delivered over larger areas that serve as the breeding grounds of *Culicoides*.

CHAPTER 59

Anesthesia of the equine athlete

John A.E. Hubbell

The initial question when discussing anesthesia of the equine athlete is 'Are there any horses that aren't athletes?' Compared with many other species, such as cows and cats, the answer is probably no. Having answered this initial question, there are suggestions in the literature that 'fit' horses, particularly 'fit' Thoroughbred horses, are more difficult to anesthetize than other horses.[1,2] Anecdotally, this increased level of difficulty seems to center on lower respiratory rates in 'fit' horses and issues of temperament. A search of the literature reveals few differences in respiratory and cardiovascular function in horses at rest, whether untrained, trained, or detrained. Training increases peak oxygen uptake without changing peak minute ventilation, thus the ratio of minute volume to oxygen uptake (the ventilatory equivalent for oxygen) decreases.[3] A reduction in the ventilatory equivalent indicates that a fit horse exchanges a smaller ventilatory volume to maintain a given oxygen uptake than the same horse when detrained. Further, the respiratory pattern in trained and untrained horses is similar, implying increased efficiency of oxygen extraction at the pulmonary level. This increased efficiency of oxygen extraction may partially account for the decreased respiratory rates observed in anesthetized 'fit' horses. Alveolar tensions of anesthetic gases rise at a slower rate in horses with slow respiratory rates, potentially delaying the attainment of brain anesthetic gas tensions sufficient for anesthesia. The potential decreases in respiratory function could be further exacerbated by the effects of anesthetic drugs and body position on the function of respiratory muscles and interruption of the normal, unique breathing strategy seen in this species.[4] Training does not alter resting heart rate, stroke volume, or cardiac output in the resting horses, but total red cell volume increases and plasma volume increases as much as 29%.[5–7] The increase in plasma volume may increase preload and enhance cardiac output in exercising 'fit' horses.[8] Other changes potentially pertinent to anesthesia include an apparent increase in muscle glycogen, muscle capillarization, and muscle mitochondrial density in fit horses.[9]

History

These questions should be asked of the responsible party prior to anesthesia:

1. Has the horse been anesthetized previously? If so, what were the circumstances and were there any problems associated with the anesthetic period? Many athletic horses have been previously anesthetized, most without incident. Potential problems that could be uncovered by this question include untoward reactions to drug administration, excitement during induction or recovery, prolonged recovery, or rhabdomyolysis.
2. Is the horse tolerant of exercise? Horses that are intolerant of exercise may not tolerate anesthesia. Potential causes of exercise intolerance include respiratory insufficiency, upper airway obstruction, and cardiac insufficiency, including atrial fibrillation or other arrhythmia, or rhabdomyolysis.
3. Has the horse recently experienced any respiratory disease? Anesthesia compromises resistance to respiratory disease in a number of ways including depression of mucociliary and immune function, loss of the cough reflex, drying of the airway, and inhibition of nasal and laryngeal function. In normal animals these changes are short-lived, but in horses incubating respiratory disease, anesthesia may predispose to worsening signs and exacerbation of disease.
4. Does the horse make a respiratory noise at rest or during exercise? Anesthetic agents, notably the α_2-adrenoreceptor agonists, cause relaxation of the upper airway.[10,11] This relaxation may augment a pre-existing condition resulting in partial or full respiratory obstruction. Such obstructions can be overcome with endotracheal intubation but may be problematic during recovery.
5. Has the horse ever tied up (rhabdomyolysis)? There is considerable evidence of genetic, gender, and breed predilection for rhabdomyolysis.[12] Anesthesia can be a triggering event.

6. How does the horse react to new experiences? There is considerable variation amongst equines in their ability to adapt to new situations and experiences. Some horses are apparently calm despite being placed in stimulus-intensive environments while others become agitated without apparent provocation. The demeanor of the patient potentially affects the required doses of sedatives and may change preparations for anesthesia and recovery.
7. Is the horse receiving any medication? When was the last time the horse was medicated? Some individuals utilize long-acting tranquilizers and other drugs as part of their training regimens. The administration of drugs such as acepromazine and reserpine can affect the required doses of anesthetic agents and the resultant pharmacologic response.

Physical examination

The physical examination is the centerpiece of preanesthetic data collection. The examination should focus on the cardiovascular, respiratory, neurological and musculoskeletal systems.

Examination of the cardiovascular system

The cardiovascular system is easily evaluated by palpating the pulse of a peripheral artery, checking the color of mucous membranes, measuring the capillary refill time, assessing skin turgor, and ausculting the heart. Normal pulse rates in quiet adult horses range from 25 to 45 beats per minute. Interruptions in the regular rhythm (pauses) are not uncommon in fit horses and are usually the result of sinus arrhythmias or second-degree atrioventricular blockade. A brief period of exercise should stimulate an increase in heart rate and resolve the arrhythmia. The most common pathologic arrhythmia in horses is atrial fibrillation.[13] Presumptive diagnosis of atrial fibrillation can be made on physical examination by palpating pulses of unequal strength occurring at irregular intervals and by ausculting variable intensity heart sounds at varying intervals. An electrocardiogram should be obtained if pauses in the pulse rhythm do not respond to exercise or if there are pulses of variable intensity occurring at variable intervals. Heart murmurs can be ausculted in the majority of race horses.[14] Most are systolic murmurs, heard best at the heart base. Murmurs of grade II (out of V) or less are interpreted as innocent flow murmurs if there is no other evidence of heart disease. Murmurs of potential significance include those that result from mitral valve insufficiency, aortic insufficiency or congenital ventricular septal defects; but they comprise less than 0.1% of the population. Additional information can be obtained via electrocardiography and echocardiography.

Transient periods of sinus tachycardia (heart rates greater than 50 beats/min) are not of concern but sustained tachycardia should be interpreted as an indicator of cardiovascular or metabolic disease. Atrial and, less frequently, ventricular premature contractions are observed in horses prior to surgery. Abnormal atrial and ventricular rhythm disturbances are a warning that there may be systemic illness, myocarditis, or associated cardiovascular compromise. Infrequent atrial or ventricular extra systoles (< 5/min when the heart rate is normal) without clinical evidence of cardiovascular compromise are tolerated in horses under general anesthesia. Horses with frequent ventricular premature contractions, paroxysmal ventricular tachycardia, or persistent ventricular tachycardia should not be anesthetized for elective procedures.

Examination of the respiratory system

Examination of the respiratory system is best accomplished in a quiet room or stall and is facilitated by stimulating the horse to breathe deeply. The lung fields over both sides of the thorax should be ausculted. Auscultation of the trachea may be useful in detecting the presence of mucopurulent material. Light squeezing of the trachea in a normal horse does not induce a cough but may produce a cough in a horse with upper respiratory tract infection.

Horses with suspect respiratory disease should receive a further diagnostic workup, potentially including a complete blood count, plasma fibrinogen, tracheal wash and culture, and thoracic ultrasound and radiography. Horses with a history of severe respiratory tract infection may retain large quantities of mucopurulent material in the trachea and have abnormal respiratory sounds in the lung fields upon careful auscultation. Horses with respiratory tract infections should not be anesthetized for elective procedures because the added stress of surgery and general anesthesia predisposes to pneumonia and pleuritis.

Horses with respiratory stridor due to upper respiratory tract obstruction require special evaluation because sedation produces relaxation of the muscles of the upper airway which may worsen the stridor. Many normal horses make upper airway noises during recovery from general anesthesia because of congestion and edema of the nares and nasal turbinates. Horses with preoperative stridor are more likely to do so. Nasal congestion is easily relieved by passing a 12 to 18 mm endotracheal tube into the nares past the site of the obstruction. Additional causes of stridor after anesthesia include dorsal displacement of the soft palate and partial or complete laryngeal paralysis. The soft palate normally displaces dorsally with orotracheal placement of an endotracheal tube. When the endotracheal tube is removed the palate remains displaced until the horse swallows and the palate returns to its normal position below the epiglottis. An endotracheal tube can be used to stimulate swallowing if a horse makes a noise suggestive of dorsal displacement after removal of the endotracheal tube. The degree of obstruction of airflow should be evaluated by assessing the amount of airflow through the nostrils while noting the amount of effort (abdominal movement) required to produce airflow. A temporary tracheostomy may be required prior to

induction or during recovery from anesthesia in horses with severe obstruction.

Examination of the nervous and musculoskeletal systems

The nervous and musculoskeletal systems should be examined to determine if the horse can see, ambulates normally, and bears weight on all four limbs. Horses that are blind in one eye may require special handling during induction and recovery. Slight gait deficits are usually inconsequential, but significant weakness, ataxia or lameness may pose problems during induction to and recovery from anesthesia. Simply walking the horse a short distance and circling it in a small circle provides a sufficient assessment of the horse's stability. Horses that are ataxic or not bearing weight on all four limbs may prove difficult to move while sedated. Thus they should be moved to the area of anesthetic induction prior to administering sedatives.

Preanesthetic hematologic evaluation

The baseline hematologic evaluation of horses prior to anesthesia is dependent on the results of the physical examination but should include determination of the packed cell volume (PCV), total plasma solids, white blood cell count, and plasma fibrinogen. The PCV should be 55% or less to prevent blood sludging and achieve adequate tissue perfusion under anesthesia. Packed cell volumes less than 20% are associated with compromised oxygen delivery. Plasma protein levels below 3.5 g/dL are associated with the formation of peripheral and pulmonary edema because of inadequate plasma oncotic pressure. The hemogram of most horses in our referral hospital suggests mild leukocytosis with neutrophilia and lymphopenia that can be attributed to the effects of excitement and stress associated with transportation, hospitalization or pain. Total white blood cell (WBC) counts greater than 13 000/μL or less than 5500/μL are indications for further evaluation. Elective surgical procedures should be postponed in horses with abnormal WBC counts until the WBC count returns to normal. Plasma fibrinogen levels are used as an index of inflammation but are not specific to any disease. Plasma fibrinogen levels in excess of 300–400 mg/dL are considered abnormal and a reason to delay anesthesia. Preoperative serum chemistry and acid–base evaluations are not necessary unless specifically indicated. Muscle enzyme levels should be measured in horses with a history of rhabdomyolysis.

Preanesthetic medications

Preanesthetic medications in the horse include anticholinergics, tranquilizers/sedatives, and analgesics (Table 59.1).

The administration of the anticholinergic agents atropine and glycopyrrolate is not recommended for routine use prior to anesthesia in horses. Anticholinergics decrease salivation and increase heart rate, but neither excessive salivation nor bradycardia is a frequent problem in the horse. The potential disadvantages (postoperative ileus, tachycardia, and increased myocardial oxygen consumption) are significant; thus anticholinergic administration should be limited to those cases where it is specifically indicated. Common cardiac arrhythmias that respond to anticholinergic agents include atrioventricular conduction disturbances, interference dissociation, and sinus bradycardia (heart rate less than 25 beats/min) with hypotension.

Sedatives and tranquilizers are used to produce a calm, tractable patient by decreasing excitement and unwanted

Table 59.1 Drugs used for standing chemical restraint and as preanesthetics

Drug	Dose and route	Onset of effect	Comments
Acepromazine	0.02–0.06 mg/kg, i.m., i.v.	30 to 40 min i.v., i.m.	Caution in stressed, hypotensive horses
Xylazine	0.5–1.0 mg/kg, i.v. 1.0–2.2 mg/kg, i.m.	3 to 5 min, i.v. 10 to 20 min, i.m.	Ataxia produced with head down posture Begin with low dose and repeat as needed
Detomidine	0.01–0.02 mg/kg, i.v. 0.02–0.04 mg/kg, i.m.	3 to 5 min, i.v. 10 to 20 min, i.m.	Ataxia produced with head down posture Begin with low dose, repeat as needed
Butorphanol	0.01–0.03 mg/kg, i.v.	3 to 5 min	Use in combination with a sedative or tranquilizer
Morphine	0.3–0.5 mg/kg, i.v.	3 to 5 min	Sedate with xylazine or detomidine before administering morphine Potential for excitement

behavior (movement) during induction and recovery. Sedatives and tranquilizers potentiate the action of anesthetic agents, so that the dose of the more potent agent can then be lowered, decreasing the potential for deleterious side effects including hypotension and hypoventilation. Horses that are weight bearing on all four limbs may benefit from intramuscular administration of sedatives because intramuscular administration produces a more prolonged effect than intravenous administration and potentially reduces the magnitude of the deleterious changes in cardiorespiratory function. Some drugs, particularly the phenothiazine tranquilizers (acepromazine), require up to 45 minutes to reach peak effect. Intravenous administration produces a quicker onset of action and an increased intensity of effect, but a shorter duration of effect, than does intramuscular administration. Ataxic or severely lame patients that are non-weight bearing on one limb should be moved to the induction area before administering the agent of choice intravenously.

Phenothiazine tranquilizers are used to produce calming by decreasing locomotor activity, reducing apprehension and increasing tractability. Phenothiazines should be avoided in horses that are severely stressed, have had excessive hemorrhage, or are hypovolemic because the drugs may cause excessive hypotension. Clinical doses usually produce minimal ataxia and weakness. The primary cardiovascular effect produced by phenothiazine tranquilizers is vasodilatation with resultant hypotension. The incidence of clinically significant hypotension following clinical doses of phenothiazines to normal horses is low, and horses that become hypotensive after phenothiazine administration usually respond to intravenous crystalloid administration. The risk of persistent paralysis of the retractor penis muscle should be noted before tranquilization of male horses, and the dose should be carefully limited to the minimum necessary to produce the desired effect.

α_2-Adrenoreceptor agonists produce sedation, muscle relaxation and analgesia when administered intravenously or intramuscularly to horses.[15–17] Horses that have received α_2-agonists assume a 'head-down' or 'sawhorse' stance and may frequently shift their weight from side to side (Fig. 59.1). Arterial blood pressure is initially increased due to drug-induced increases in peripheral vascular resistance. Hypertension may be sustained (20 to 60 minutes), particularly when detomidine is used. Decreases in heart rate, sinus arrhythmia, and first- and second-degree atrioventricular blockade are common. These decreases in heart rate result in significant decreases in cardiac output, often to levels 50% of predrug values. Respiratory rate is usually decreased, but tidal volume increases. Relaxation of the muscles of the upper airway can predispose the horse to stridor. The administration of an α_2-agonist decreases salivation, gastric secretions, and gastrointestinal motility and increases urine volume. Other incidental effects of α_2-agonist administration include increases in intrauterine pressure, hyperglycemia and hypoinsulinemia.

Two α_2-adrenoreceptor agonists are approved for use in horses in the USA. Xylazine, a relatively short-acting α_2-agonist, has a rapid onset (1–3 minutes) and short duration of action (30–60 minutes) after i.v. administration. Xylazine is relatively non-specific, activating both α_2 and α_1 receptors. Detomidine, a more specific α_2-agonist, is approximately 100 times more potent than xylazine and has a duration of action at least twice as long.

Fig. 59.1
The posture of a horse after the administration of 1.0 mg/kg of xylazine intravenously. Note the ventral position of the head and neck, the relaxed facial muscles, and the unequal distribution of weight on the rear legs.

Sedative-opioid combinations are useful for standing procedures in the horse, producing sedation, analgesia, euphoria and a stuporous 'sawhorse' stance. Butorphanol and morphine are two drugs with opioid activity that have been used in combination with α_2-agonists to produce standing chemical restraint.[18,19] Opioids other than butorphanol are not routinely administered prior to anesthesia but can be used to supplement analgesia intraoperatively.

Many surgical procedures benefit from the administration of antibiotics preoperatively. Antibiotics, particularly sodium or potassium penicillin, should be administered before anesthesia is induced because of their potential to cause hypotension during anesthesia.[20] Aminoglycoside antibiotics, including gentamicin, can cause neuromuscular weakness in some species, but this side effect is uncommon in horses. If antibiotics must be administered intraoperatively, cephalosporins, such as cefazolin, have been shown to produce minimal cardiovascular depression.[17]

Timing of anesthesia and animal preparation

Horses that are transported to the site of anesthesia should be given time to acclimate to the environment. Horses that are injured should be administered first aid, including splinting of the injury, to stabilize their condition. Superior anesthetic and surgical planning is possible if induction is not rushed. The author withholds food for 4 to 6 hours before anesthesia if possible in an attempt to reduce the amount of feed

material in the upper gastrointestinal tract. The mouth should be rinsed prior to induction because foreign material left in the mouth could be pushed into the trachea during orotracheal intubation, leading to upper airway obstruction during or following anesthesia. A large-bore intravenous catheter should be placed in either jugular vein prior to induction of anesthesia. Pre-existing fluid deficits should be corrected prior to anesthesia. During anesthesia, 10 mL/kg/hour of balanced electrolyte solutions should be administered to promote perfusion, replace the lack of fluid intake, and replace insensible losses.

Induction of anesthesia

The smooth, safe and uneventful induction of anesthesia is dependent upon trained personnel, proper premedication of the animal, proper and timely administration of induction agents, appropriate equipment and facilities, and an atmosphere free of unnecessary stimuli that may excite the patient. Indoors, horses should be restrained against a solid wall with their hindquarters in a corner, if possible (Fig. 59.2). One assistant should be positioned at the horse's shoulder and another at the horse's hip. The anesthetist should administer the induction agent and hold the horse's head in a neutral posture until recumbency occurs. Some facilities utilize a 1.5 by 2.0 meter door securely mounted on a wall to facilitate restraint for induction (Fig. 59.3). Horses that must be anesthetized in the open benefit from having a head and tail rope applied before induction. As the horse begins to fall, it can be pulled to the appropriate side. Alternatively, the horse can be made to walk in small circles after the induction drugs are given. The horse will tend to fall toward the outside of the circle as the drugs take effect. The person holding the head should protect the head from sharp blows during the induction period and maintain control at all times.

Fig. 59.2
Correct placement of a horse for induction of anesthesia. The horse is positioned against a wall with its hindquarters in a corner. One attendant pushes on the point of the hip and another on the point of the shoulder. The attendant holding the head lifts the head as the anesthetic drugs take effect.

Fig. 59.3
A padded door, firmly attached to a wall, can be used to control a horse's movement as anesthetic induction occurs.

Many drugs and drug combinations have been used to induce general anesthesia in horses (Table 59.2).[21] Most intravenous anesthetic techniques involve the combined use of dissociative anesthetics (ketamine, tiletamine-zolazepam) or thiobarbiturates (thiopental) and muscle relaxants (guaifenesin, diazepam). Horses that are non-weight bearing on one limb benefit from rapid induction techniques in order to minimize the period of ataxia that occurs as the drugs take effect. The administration of any drug or drug combination regimen designed to produce recumbency should always be preceded by the administration of sufficient doses of sedatives and/or tranquilizers to produce a calm, manageable patient.

Intravenous xylazine followed by intravenous ketamine produces 10 to 15 minutes of general anesthesia.[22] Xylazine-ketamine anesthesia produces recumbency with maintenance of reasonable cardiovascular function and acceptable respiratory depression. Recovery from anesthesia is relatively rapid and uneventful, with the horse rising to its feet 25 to 30 minutes after induction. Characteristically, an apneustic or breath-holding respiratory pattern occurs. The xylazine-ketamine technique has been modified in order to improve the quality of anesthesia. The addition of diazepam and/or butorphanol to xylazine-ketamine improves muscle relaxation and analgesia with minimal cardiorespiratory depression and increases the duration of anesthesia to 20–25 minutes.[23,24] Alternatively, the proprietary combination of tiletamine and zolazepam can be administered after xylazine to produce intravenous anesthesia or to induce anesthesia prior to inhalant anesthesia.[25] Tiletamine-zolazepam is usually administered after sedation with an α_2-agonist and produces a longer duration of anesthesia than diazepam-ketamine. Thirty minutes of anesthesia is produced with the horse returning to standing posture within 60 to 75 minutes. The recovery from anesthesia after tiletamine-zolazepam anesthesia is not as controlled as recoveries

Table 59.2 Drugs used for induction and maintenance of anesthesia in sedate horses

Drug	Dose	Comments
Ketamine	1.5–2.0 mg/kg, i.v.	Horses must be maximally relaxed prior to administration. Relaxation can be produced with xylazine, diazepam, or guaifenesin
Thiopental	4–6 mg/kg, i.v. with guaifenesin, 7–12 mg/kg without	Potential for apnea with administration of large boluses. Use with guaifenesin to allow a reduction in dose
Guaifenesin	50 mg/kg, i.v., to effect	Primarily a muscle relaxant. Do not use alone. Use in sedate horses in combination with ketamine or thiopental
Diazepam	0.06–0.1 mg/kg, i.v.	Primarily a muscle relaxant. Used primarily with ketamine
Tiletamine-zolazepam	0.7–1.0 mg/kg, i.v.	Horse should be fully sedate before administration. Produces 30 minutes of anesthesia with good muscle relaxation. Hypoventilation may occur
'Triple-drip' (mixture of guaifenesin 5%, ketamine 0.1%, and xylazine 0.05%)	2 mL/kg/h	Not used for induction in adult horses. Used to extend xylazine-ketamine or xylazine-diazepam-ketamine anesthesia. Monitor ventilation and the degree of muscle relaxation

from xylazine-ketamine anesthesia because of residual weakness, presumably produced by the zolazepam.

Horses that bear weight on all four limbs benefit from the gradual administration of guaifenesin and guaifenesin drug combinations. Guaifenesin can be rapidly administered in 5% or 10% concentrations until the horse begins to show signs of muscle weakness and ataxia (weaving side to side, knees buckling). When sufficient muscle relaxation is present, ketamine or thiopental is administered to produce recumbency.[23] Guaifenesin combinations can also be used to extend the anesthetic period if inhalant administration is not possible or impractical.[26,27] Guaifenesin (5%) solution can be combined with xylazine (0.5 mg/mL) and ketamine (1–2 mg/mL) to produce a solution that is called 'Triple Drip'. The combination is administered to effect up to a rate of 2 mL/kg of bodyweight/hour producing total intravenous anesthesia (TIVA) with excellent muscle relaxation and suitable analgesia. The quality of recovery is generally good if the anesthetic period is kept to less than one hour. 'Triple Drip' should not be used to produce anesthesia for greater than 90 minutes unless oxygen supplementation and respiratory support are provided.

An endotracheal tube should be placed if the administration of inhalation anesthesia is anticipated or if oxygen supplementation is desired. Twenty to 30 mm (internal diameter) endotracheal tubes should be used in adult horses. A piece of plumber's pipe (5.0 cm in diameter) covered with non-slip tape is a useful bite block (Fig. 59.4). The tube is passed blindly while extending the head dorsally. Successful placement is confirmed by the minimal resistance to advancement when the tube is in the trachea and the passage of air with respiration.

Fig. 59.4
A 10 cm section of plumber's pipe is a useful speculum for endotracheal tube placement. The plastic pipe is covered with adhesive material to reduce slippage.

Padding and positioning

Horses anesthetized and positioned on their side (lateral) or back (dorsal) recumbency are prone to myositis or neurogenic paralysis because of their great weight. Practical steps toward preventing these complications include the maintenance of adequate arterial blood pressure (mean arterial blood pressure greater than 60 mmHg), assuring proper ventilation and oxygenation, minimizing anesthetic duration, and padding and positioning the patient properly. All weight-bearing surfaces of the horse should be padded when the

Fig. 59.5
An appropriately padded anesthetized horse in right lateral recumbency. The weight of the left leg is supported by a pad placed between the hocks to reduce compression of the vessels of the right leg.

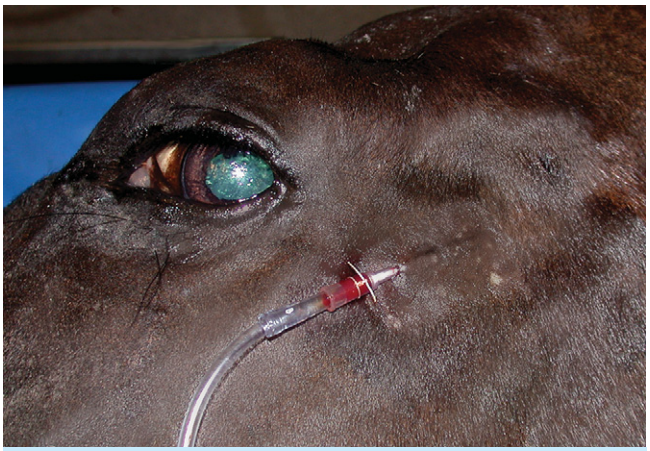

Fig. 59.6
A 20-gauge over-the-needle catheter placed in the transverse facial artery.

horse is recumbent with particular attention paid to bony prominences (Fig. 59.5). A 2 m by 3 m foam rubber pad 20 cm thick works well for horses anesthetized and placed in lateral recumbency. Additional pads should be placed between the rear legs to support the upper leg.

Maintenance of anesthesia

Halothane, isoflurane and sevoflurane are the primary inhalation anesthetics used in the horse. All three drugs can safely be used to anesthetize horses, and the choice is left to personal preference.[28,29] Halothane produces relatively rapid induction to and recovery from anesthesia. Isoflurane and sevoflurane produce more rapid induction and recovery than halothane.[30] There is better maintenance of cardiac output with isoflurane, but arterial blood pressures may be lower than with halothane anesthesia. The cardiovascular profile of sevoflurane is similar to isoflurane. Respiratory depression is greater with isoflurane and sevoflurane than with halothane. Horses anesthetized with isoflurane or sevoflurane may benefit from the administration of a small dose of xylazine (0.1–0.2 mg/kg, i.v.) during recovery from anesthesia.[31]

Monitoring anesthesia

Careful attention is paid to the cardiovascular system, the respiratory system, and ocular reflexes. Evaluations of these systems should be regularly recorded (every 5 minutes). As inhalant anesthesia deepens to surgical planes, the eye rotates medially, the eyelids cease voluntary closure, and tear production decreases. Lateral nystagmus may continue until surgical anesthesia is reached. The palpebral reflex (eyelid closure following brushing of the lids) should decrease as anesthesia deepens, and is generally weak but present during surgical anesthesia. Corneal reflexes (closure of the eyelids in response to pressure on the cornea) should be present at all times during anesthesia. The anal reflex can be used to evaluate the depth of anesthesia if the head is covered; its absence indicates that the animal is too deeply anesthetized.

The heart rate in anesthetized horses normally ranges between 25 and 50 beats/min and does not usually change as the plane of anesthesia deepens or lightens. Anticholinergics should be given to increase rates when less than 25 beats/min. Heart rates in excess of 50 may indicate inadequate planes of anesthesia, hypotension, hypercarbia or hypoxemia. Directly measuring arterial blood pressure and recording the electrocardiogram accomplish more definitive monitoring of the cardiovascular system. The facial, transverse facial, and great metatarsal arteries are all easily palpated and catheterized (Fig. 59.6). Mean arterial blood pressure should range between 60 and 90 mmHg during anesthesia. A mean arterial blood pressure less than 60 mmHg is associated with postanesthetic rhabdomyolysis and the loss of autoregulation of blood flow to vascular beds.[32] Mean arterial blood pressures greater than 90 mmHg are a sign of light anesthetic planes, and movement should be anticipated.

Hypotension is treated by decreasing the delivery of anesthetics (if possible), administering intravenous fluids, and administering vasoactive drugs. If the anesthetic plane is appropriate, the rate of fluid administration should be increased. The choice of fluid is determined by the horse's physical condition, acid–base, and electrolyte status. Hypotension that does not respond to fluid therapy is treated with vasoactive agents such as dobutamine or ephedrine. Dobutamine (1–5 μg/kg/min) is given by infusion and titrated to maintain the desired arterial blood pressure.[33] Signs of dobutamine overdose include tachycardia, hypertension, and supraventricular and ventricular premature arrhythmias. The infusion should be reduced or discontinued if signs of toxicity occur. Ephedrine administration increases arterial blood pressure and cardiac output.[34] Ephedrine (0.05–0.1 mg/kg) is given as an intravenous bolus and

produces effects that persist for 20 to 30 minutes or longer. The administration of calcium solutions may produce increases in arterial blood pressure, particularly if ionized calcium levels are marginal or decreased.

Respiration and oxygenation should be monitored by measuring ventilatory rate and measuring arterial blood gases and pH. Horses that are kept anesthetized for longer than 60 minutes can be expected to hypoventilate. If anesthetic durations of 60 minutes or greater are anticipated, intermittent positive pressure ventilation should be instituted, if possible, as soon as adequate arterial blood pressures are assured. Measurement of the end-tidal concentration of carbon dioxide in the expired airway gas can be used as an indirect assessment of arterial carbon dioxide tension, but the only consistent measurement of adequate ventilation and oxygenation is the measurement of arterial blood gases.[35] If spontaneous ventilation is inadequate, controlled ventilation should be instituted. Initial tidal volumes should be set at 12 to 18 mL/kg. Peak inspiratory pressure should be 20 to 30 cm of water. Respiratory rates should range from 5 to 8 breaths/min.

Horses that are being ventilated correctly ($Paco_2$ of 40 mmHg) occasionally become relatively hypoxemic (Pao_2 less than 100 mmHg) during anesthesia. The cause of the hypoxemia is primarily attributed to mismatches of ventilation and perfusion that occur when horses are placed in lateral or dorsal recumbency. Increasing cardiac output by the administration of fluids and drugs promoting cardiac contractility may help to prevent or reduce arterial hypoxemia. Positive end-expiratory pressure can be used to increase arterial oxygenation but this occurs at the expense of cardiac output because of limited venous return.[36]

The postoperative period

Recovery is the most difficult phase of equine anesthesia to control.[30,37] Optimally, horses should lie quietly for 20 to 35 minutes and regain the standing position in one attempt. Horses may attempt to rise too soon, particularly if sevoflurane or isoflurane are used as maintenance anesthetics. Horses attempting to rise too soon should be sedated with small doses of xylazine (0.2 mg/kg, i.v.). If the horse has not attempted to rise one hour after the end of anesthesia, a handler should enter the recovery stall and stimulate the horse.

The most important feature of any area for recovery of anesthesia is a non-slip flooring surface. Horses exert considerable force as they rise and it is imperative that their feet do not slip as they place them to stand. There are a number of commercial surfaces available. The most consistent surfaces are wrestling or tumbling mats (Fig. 59.7). Three meter by four meter pads, 3 to 4 cm thick, work well. The mats compress as the horse rises, providing secure footing whether wet or dry. The recovery area should be quiet and have lights that can be dimmed. The walls should be padded with secure rings placed 2–3 meters from the floor to facilitate the use of ropes for assisting recovery. Ideally, a ceiling hook should be present for a hoist and sling. Two handlers should remain in the immediate area until the horse is standing. The horse can be helped to its feet by placing a head rope and tail rope (assisted recovery) and running the ropes through rings on opposite sides of the recovery stall (Fig. 59.8). The head and tail ropes are tightened for support as the horse rises to its feet, helping it to balance. More experienced handlers may prefer to remain in the recovery stall with the horse and simply grasp its halter or tail to steady it as it rises. If recovery is to occur out of doors, turf provides excellent footing for recovery and some padding should the horse fall.

Some horses become hypoxemic when they are disconnected from the anesthetic machine for recovery because of the sudden decrease in inspired oxygen concentration. Oxygen can be insufflated during the recovery period with a

Fig. 59.7
A horse resting on a 15 cm thick foam rubber pad in a recovery stall. A wrestling or tumbling mat is placed to provide good footing when the horse attempts to rise. Cotton ropes run from the halter and the tail to rings affixed to the walls of the recovery stall.

Fig. 59.8
A cotton rope running through a ring affixed to a concrete block wall with expansion bolts. The rope is used to assist and control recovery from anesthesia.

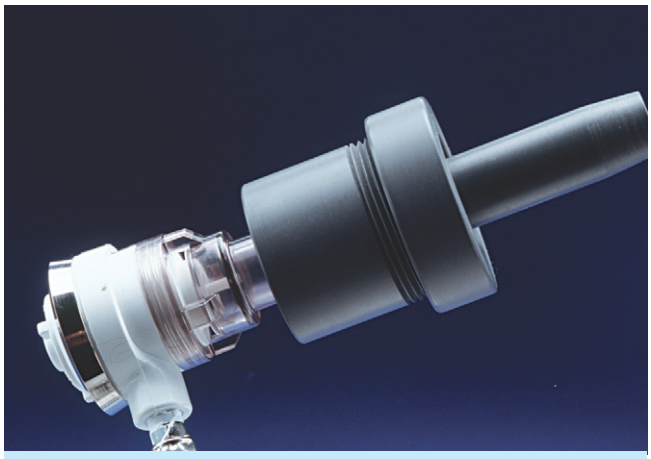

Fig. 59.9
A demand valve is used to ventilate horses in recovery. Depression of the button on the end of the valve causes oxygen to flow. The button is depressed until a normal chest wall excursion is produced. The button is released and exhalation occurs.

Fig. 59.10
A 14 mm endotracheal tube placed in the ventral nasal meatus to facilitate respiration in the horse recovering from anesthesia. The tube is tied to the halter to ensure it can be retrieved after the horse stands.

nasal oxygen catheter or demand valve.[38] For insufflation, oxygen flow rates should be set at a minimum of 15 L/min to effect a demonstrable change in arterial oxygen tension. More efficient methods of delivering oxygen can be achieved by using a demand valve, which supplies oxygen at high flow rates during the inspiratory phase of respiration (Fig. 59.9). Extubation is performed when the horse begins to swallow and attempts to chew. Prolonged anesthesia in dorsal recumbency can lead to edema of the nasal folds and mucosa of the turbinates. Upper airway obstruction due to edematous nasal folds or turbinates can be relieved by manually holding the nasal cartilages open or by nasotracheal intubation if the obstruction is severe (Fig. 59.10). Rarely, laryngospasm or laryngeal paralysis occurs after the endotracheal tube is removed.

Horses that fail to rise within 90 minutes after the end of anesthesia should be evaluated for possible weakness, rhabdomyolysis or neuropathy. Postoperative weakness can result from lingering drug effects, hypotension, or electrolyte abnormalities (hypokalemia or hypocalcemia). Horses that attempt to stand but are non-weight bearing on one or more limbs should be evaluated for orthopedic injuries, rhabdomyolysis or neuropathy. Distinguishing rhabdomyolysis from neuropathy may be difficult in the horse recovering from anesthesia. Rhabdomyolysis most often affects the gluteal and the quadriceps muscles, whereas neuropathy affects the peroneal nerve supplying the extensors of the rear leg. Large quantities of myoglobin in the urine and the presence of swollen, hardened, affected muscles help differentiate rhabdomyolysis from neuropathy. Other conditions encountered in recovery include femoral and radial nerve palsy and paralysis. The incidence of these conditions is greatly reduced if appropriate padding and positioning are used. Horses that can stand on three legs have a good prognosis for recovery from rhabdomyolysis or neuropathy and generally respond to treatment within 72 hours. Horses that are bilaterally affected and unable to stand have a poorer prognosis.

Emergency sedation and anesthesia of the exhausted horse

Veterinarians and other personnel providing emergency care to horses injured while exercising are often faced with patients that are exhausted, excited, painful, and physically challenged (they may be recumbent or non-weight bearing on one or more limbs). This presentation, coupled with an animal whose evolutionary response to danger is flight, creates the potential for complicated patient management.

Horses that are injured when exercising may be unable to undergo the active 'cool-down' period that is usually incorporated into exercise regimens. This interruption delays the return of hemodynamics and acid–base values to pre-exercise levels.[39] Cardiac output remains increased when horses walk after exercise, leading to more rapid reductions in venous blood lactate concentrations and increases in serum bicarbonate concentration (Fig. 59.11). Most indices return to pre-exercise levels within 60 to 90 minutes whether the horses walk or stand stationary, but increases in rectal temperature persist.

Horses that are injured and cannot ambulate should have an intravenous catheter placed as soon as is practically possible. The early placement of a catheter allows replacement of lost fluids (perspiration, hemorrhage) and facilitates the delivery of sedatives, analgesics and anesthetic agents, if necessary. Injured horses, if agitated, may refuse to drink, thus delaying complete recuperation. The potential for the development of shock is common to most such situations. Volume replacement with balanced electrolyte solutions is of

benefit regardless of the need for chemical restraint. Other supportive care may include non-steroidal anti-inflammatory drugs, antibiotics and oxygen administration.

The need to provide sedation and analgesia must be carefully assessed. First aid should include immobilization of the injury if possible and cessation of hemorrhage if present. Sedatives and tranquilizers can be safely administered to exhausted horses if indicated.[40] The doses required to produce full effects are approximately twice those needed in horses at rest, but unless the animal is completely uncontrollable, smaller doses should be given and repeated to effect.[41] Xylazine (2.2 mg/kg, i.v.) alone and in combination with acepromazine (0.04 mg/kg) administered to horses immediately after exercise produces heavy sedation with pronounced muscle relaxation sufficient for subsequent induction of anesthesia. Alternatively, detomidine (0.04 mg/kg, i.v.) can be used. The cardiorespiratory depression produced by the administration of these doses was qualitatively similar to that seen when standard doses are administered to horses at rest but does prolong recuperation and exercise-induced increases in body temperature (Fig. 59.12). If less pronounced sedation is desired, standard doses of detomidine (0.01–0.02 mg/kg, i.v.), xylazine (1 mg/kg, i.v.), or a combination of acepromazine (0.02 mg/kg, i.v.) and xylazine (1 mg/kg, i.v.) can be given and the response assessed in 2 to 5 minutes. The need for additional incremental doses is likely. The drugs should be repeated at a rate of one-half the standard dose to effect.

Calming and sedation should be produced before opioids or other analgesic agents are administered. Opioids (morphine, butorphanol, hydromorphone) carry the potential of producing excitement. This effect is most often seen in pain-free animals, but prior administration of a sedative or tranquilizer reduces its likelihood. Butorphanol (0.01–0.02 mg/kg) augments sedation and provides analgesia of short duration. Morphine (0.05–0.1 mg/kg) can provide more profound analgesia. With larger doses horses may head-press and try to move forward. Horses receiving morphine should be carefully monitored for 6 to 8 hours after administration because of the potential for hyperactivity due to residual opioid concentrations. Hyperactivity can be controlled with the administration of small doses of sedatives.

Anesthesia can be safely induced if sufficient sedation is produced.[42] Anesthesia is rarely indicated but can be utilized to facilitate removal of the horse from a public or precarious situation, to prevent further exacerbation of an injury, or to provide an opportunity for further diagnostic tests including radiography. The combinations of diazepam-ketamine or zolazepam-tiletamine cause anesthesia of 20 to 30 minutes' duration when administered to sedate horses. The cardiorespiratory effects of these combinations in exhausted horses are qualitatively similar to those seen when horses at rest are administered the same drugs. The return of exercise-induced increases or decreases in cardiorespiratory and metabolic indices to pre-exercise levels is delayed when short-term anesthesia is performed. Intravenous anesthesia can be safely extended with inhalant agents when indicated.[43] Larger ventilatory volumes may be required to maintain normal arterial partial pressures of carbon dioxide. Exercise-induced changes in metabolic indices such as pH and serum bicarbonate can be returned to normal if intravenous fluids are administered and 'light' anesthetic levels are utilized. Exercise-induced increases in body temperature may persist for the duration of the anesthetic period.

CHAPTER 60

Emergency procedures and first aid

Joanne Hardy

The most commonly encountered emergencies in the athletic horse involve the musculoskeletal system. These include fractures, luxations, lacerations, puncture wounds, infection, and exertional rhabdomyolysis. Other injuries include head and ocular injuries. Although most of these conditions cannot be treated in the field, accurate identification and provision of appropriate emergency treatment are essential for a successful outcome.

Fractures and luxations

- A thorough physical examination is warranted for any athletic horse injury.
- Completion of physical examination can be complicated by the severity of the injury, and other factors such as anxiety, exhaustion, dehydration, and owner/trainer anxiety.
- The goals of initial coaptation of fractures are to relieve anxiety; prevent further injury; and allow safe transportation for additional evaluation.
- Emergency coaptation of unstable limbs should be performed before radiographic evaluation or transportation to a surgical facility.
- Appropriate transportation of the injured horse is important.

Initial assessment

History

Fractures or luxations should be suspected if a loud crack is heard, there is acute non-weight-bearing lameness, the limb is misaligned, or the limb is visibly unstable.

Physical examination

Physical examination of the injured horse should be completed in the best possible setting to avoid further injury to the horse, or to bystanders. Help should be obtained to facilitate crowd control. A knowledgeable handler should be identified to help with horse restraint. While the veterinarian is examining the horse, the person responsible for making decisions on the patient should be sought, and emergency transportation (ideally, an equine ambulance) should be organized.

If the horse is recumbent, examination should be completed before attempting to stand the horse. If the horse is standing, examination should be completed before attempting to move the horse. Sedation and a twitch can be used to help restraint. For sedation, an α_2-agonist such as xylazine, or xylazine and acepromazine can be used. If sedation is needed immediately after maximal exercise, up to double the standard dosage regimen may be required to achieve effective sedation.[1] Butorphanol or detomidine should be reserved for horses that are not controlled with xylazine. It is important to remember that α_2-agonists will often cause the horse to lean forward, which may increase the weight on an injured forelimb and decrease the ability to manipulate the limb. Therefore the minimal effective dose should be used. In addition, heavy sedation will prolong the exercise-induced increase in body temperature, which may be significant in hot humid environment. Active cooling by washing with cold water is an effective method of facilitating heat dissipation.[2] If the horse is recumbent and there is concern for a serious injury, general anesthesia should be induced and maintained until further assessment is made. General anesthesia can be safely induced in horses following maximal exercise using sedation with a combination of xylazine and acepromazine, followed by induction of

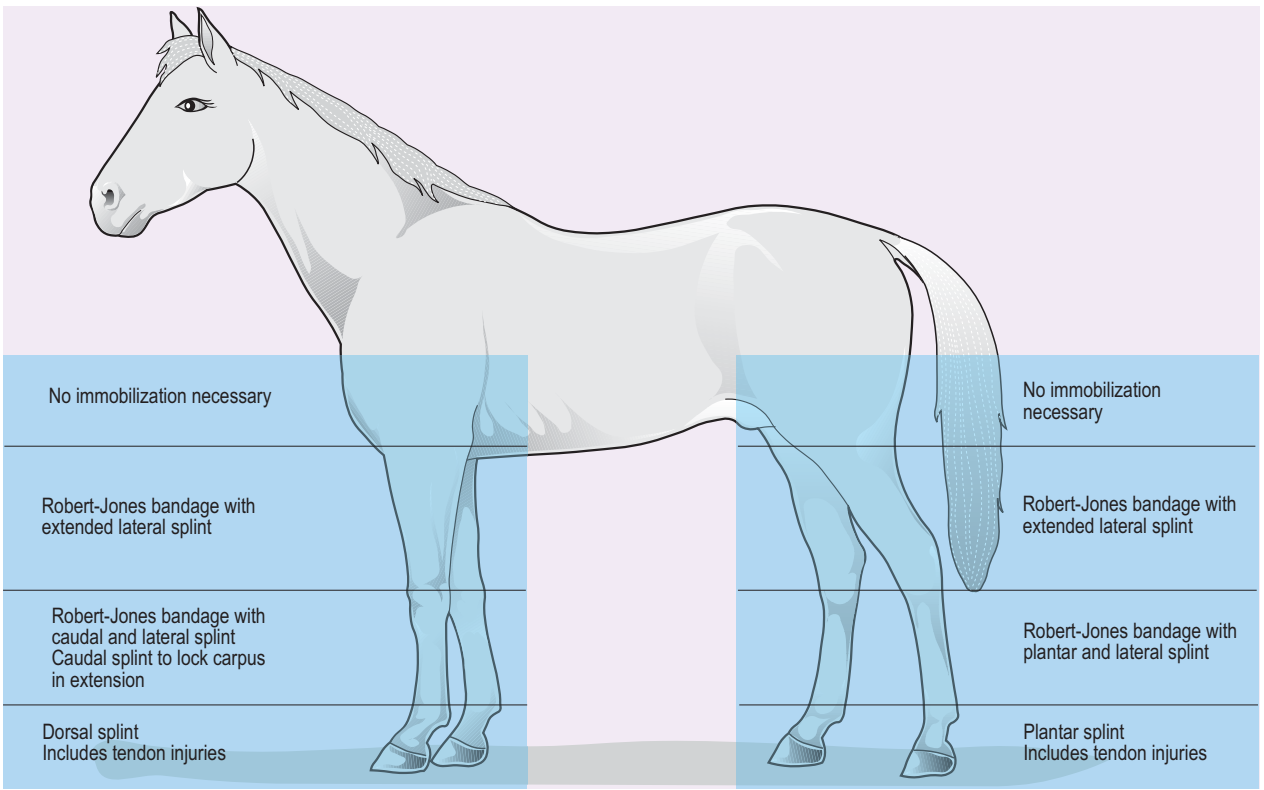

Fig. 60.1
Classification of the level injury system used to understand methods of external coaptation. (After Bramlage LR. First aid and transportation of fracture patients. In: Nixon, AJ, ed. Equine fracture repair. Philadelphia: WB Saunders; 1996:38, with permission.)

anesthesia with ketamine and diazepam or tiletamine-zolazepam. The combination of guaifenesin and thiopenthal produces more hypotension and is less desirable.[3]

Once restraint is achieved, a brief assessment of circulatory status should be made, by evaluating heart rate, mucous membrane color, capillary refill time, and pulse quality. Identification of a heart rate of greater than 80 beats per minute accompanied by a delayed capillary refill time and poor peripheral pulse quality indicates the need for intravenous fluid support.

Once the general status of the patient has been assessed, location and assessment of the injury follows. It is useful to divide the limbs into four levels, which will help define the method of coaptation (Fig. 60.1).[4] Note that flexor tendon injuries located at the level of the metacarpus/metatarsus are considered level 1 injuries.

The presence of a fracture can be determined by instability, crepitus, or abnormal motion. Luxations can be suspected when there is abnormal lateral to medial motion at the level of a joint, and can be confirmed with stress radiographs.

Special examination

Radiographic examination is indicated to confirm the presence of a fracture or luxation. If radiographic equipment is unavailable on site, external coaptation should be applied as if a fracture or luxation exists and the horse transported to a referral facility for further examination.

It is important also to remember that incomplete (hairline) fractures of the radius, tibia and other bones can be difficult to demonstrate radiographically, particularly in field conditions. Therefore, in the presence of severe lameness with pain localized to a long bone, external coaptation should be completed before transportation, to avoid catastrophic displacement of a fracture.

Laboratory examination

Laboratory determinations of biochemistry profile indices are more commonly available even in field situations. If available, parameters of hydration and electrolyte balance are useful to dictate fluid volume and type.

Emergency treatment

Therapeutic aims

- Relieve anxiety.
- Immobilize fracture or luxation for transportation.
- Prevent further damage.
- Provide safe transportation.

Therapy

The principles of emergency coaptation include:

- appropriate wound care before application of external coaptation
- provision of adequate padding to prevent skin abrasions
- immobilization of the joint below and above the area of injury
- prevention of latero-medial and cranio-caudal motion
- never ending a splint in the middle of a long bone segment, or at the end of a fracture line.

Bandage and splint application

Any wound should be carefully cleaned and debrided. An antiseptic ointment can be applied and held in place with conforming gauze. Cotton padding is applied to the entire length of the segment to be immobilized, and held in place with gauze followed by non-stretch bandage material. The bandage should be snug, to avoid loosening with packing of the cotton material. The splint(s) is(are) then applied and held in place, ideally with fiberglass casting tape. This is particularly useful if there is a luxation, as these can be difficult to keep stabilized. If unavailable, heavy tape can be used. It is important to make sure the splints are well padded to avoid the development of sores.

Materials needed for emergency coaptation of fractures or luxations:

Cotton padding
Conforming gauze
Non-elastic bandage
Tape
Casting tape
Splints: PVC pipe material or 2 inch × 4 inch boards of different lenghts

Immobilization of level I injuries Level 1 injuries include phalangeal fractures, fetlock, pastern or coffin joint luxations, and severance of one or more flexor tendons. Although technically a level 1 injury, extensor tendon lacerations require a different mode of splint application and will be presented separately. Forelimb and hindlimb immobilization differ slightly, because of the presence of the reciprocal apparatus in the hindlimb.

Forelimb In forelimb injuries, immobilization is best accomplished by aligning the cannon bone with the phalanges, to establish a straight column (Fig. 60.2). The horse will bear weight on its toe. To accomplish this goal, the forelimb is held above the carpus, bandaged, and the splint is applied on the cranial aspect of the distal limb, extending from the toe to the carpus. If there is latero-medial instability, a lateral splint can also be applied.

Hindlimb In the hindlimb, the reciprocal apparatus prevents extension of the distal limb if the animal is non-weight bearing. Therefore the limb is best immobilized by applying the splint on the caudal aspect of the limb, from the toe to the point of the hock (Fig. 60.3). Again, if there is latero-medial instability, a lateral splint should also be placed.

Use of the Kimzey apparatus (Kimzey Leg Saver, Kimzey Metal Products, Woodland, CA; www.kimzeymetalproducts.com).

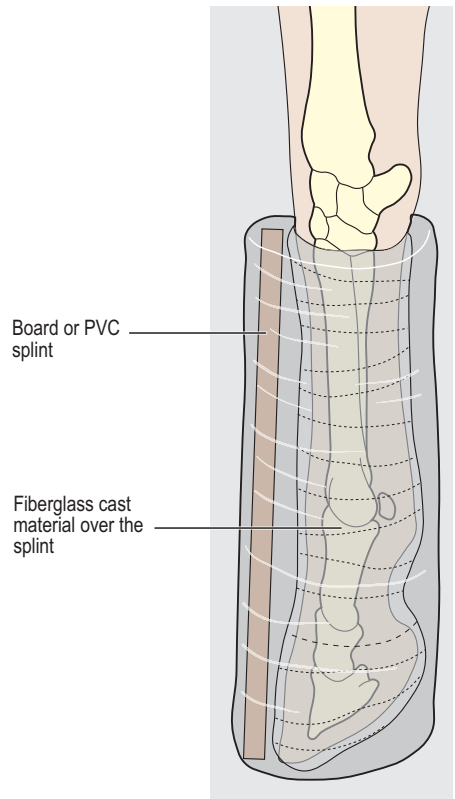

Fig. 60.2 Application of a splint for level 1 injury of the forelimb.

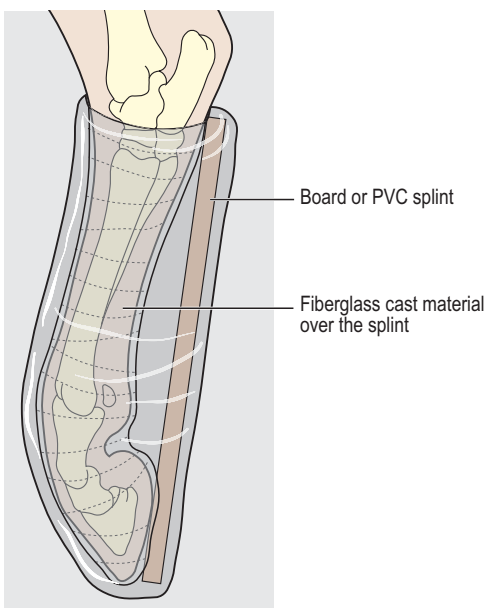

Fig. 60.3 Application of a splint for level 1 injury in a hindlimb.

A commercially available splint is available for level 1 injuries (Fig. 60.4). The advantages of this splint are that it is readily available, easy to apply and is effective in achieving immobilization. Two configurations are available: one with a slightly forward angled bar (for the forelimb) and one with a backward angle with the curve at the level of the fetlock (for the hindlimb). In the author's experience, the forward angle configuration is more effective for either fore- or hindlimb injuries. The hindlimb splint has a heel piece to facilitate

Fig. 60.4
Illustration of the Kimzey Leg Saver (reproduced by permission, John W. Kimzey, Kimzey Metal Products, CA).

weight bearing. Alternatively, a heel piece can be welded onto the splint to increase weight-bearing surface area. Non-slip tape should be placed on the foot plate to make it less slippery, particularly on cement floors.

Extensor tendon injuries With complete severance of both extensor tendons of the forelimb or hindlimb, the horse will knuckle over, which can cause injury to the dorsal aspect of the fetlock and further disruption of the wound. In this instance, external coaptation is needed to prevent knuckling over at the fetlock. A splint is applied to the cranial aspect of the fore- or hindlimb, with the hoof flat on the ground.

Immobilization of level 2 injuries Examples of level 2 injuries include cannon bone fractures, wounds of the carpus or hock, olecranon fractures and radial nerve paralysis. Forelimb and hindlimb immobilization will again be discussed separately, because the angle of the hock requires a different splint configuration.

Forelimb In level 2 injuries, two splints are needed, applied at a 90° angle, with one splint lateral and one splint caudal. The splints need to extend from the hoof to the elbow (Fig. 60.5). For olecranon fractures and radial nerve paralysis, the goal of immobilization is to prevent tendon contracture and injury to the dorsal aspect of the limb. Only a caudal splint is needed for these types of injuries.

Hindlimb As in the forelimb, two splints are needed, one applied laterally and the other applied caudally, from the hoof to the stifle. The angle of the hock makes it difficult to apply a caudal splint. Therefore the caudal splint can end at the point

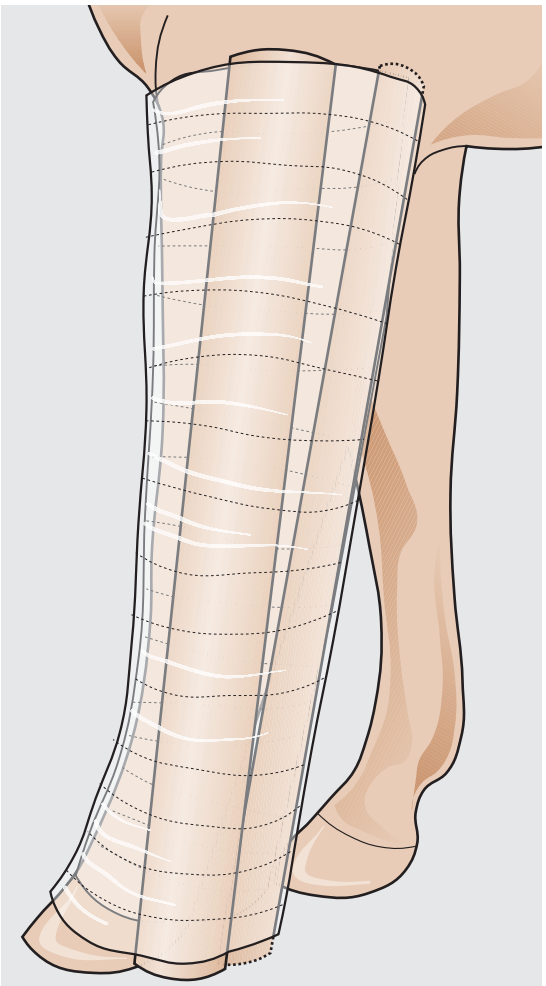

Fig. 60.5
Application of splints for level 2 injury to the forelimb.

of the hock, rather than at the stifle (Fig. 60.6). Alternatively, if possible, a splint can be molded to the hock so it can be applied.

Immobilization of level 3 injuries Level 3 injuries include fractures of the radius or tibia. With fracture, the flexor muscles become abductors, resulting in displacement and comminution of the medial aspect of the limb. The medial aspect of both the radius and ulna does not include a muscle mass to help prevent penetration of the skin by fractured bone. Therefore the goal of external coaptation is to prevent abduction of the limb.

Forelimb The splint is applied to the lateral aspect of the limb, and must extend from the hoof to the withers (Fig. 60.7). The tip of the splint can be taped around the chest for further stability.

Hindlimb The splint is applied to the lateral aspect of the limb, extending from the hoof to the hip (Fig. 60.8).

Immobilization of level 4 injuries Level 4 injuries include fractures of the scapula, humerus, femur or pelvis. External coaptation is not recommended for these injuries as these areas are not amenable to bandaging. Reliance on the hematoma and swelling around the injury for immobilization is needed. A bandage should not be applied to the distal limb,

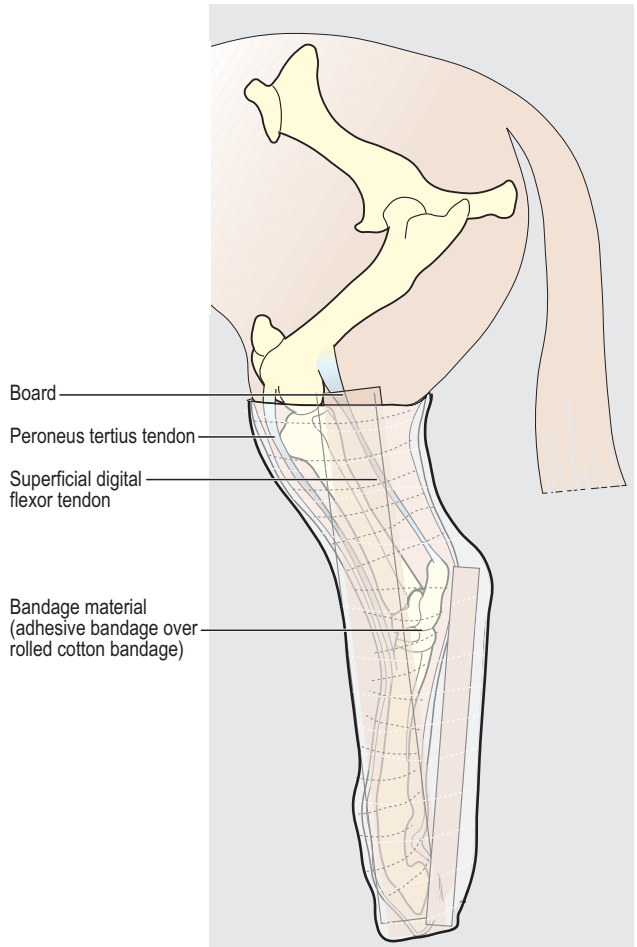

Fig. 60.6
Application of a splint for level 2 injury in a hindlimb.

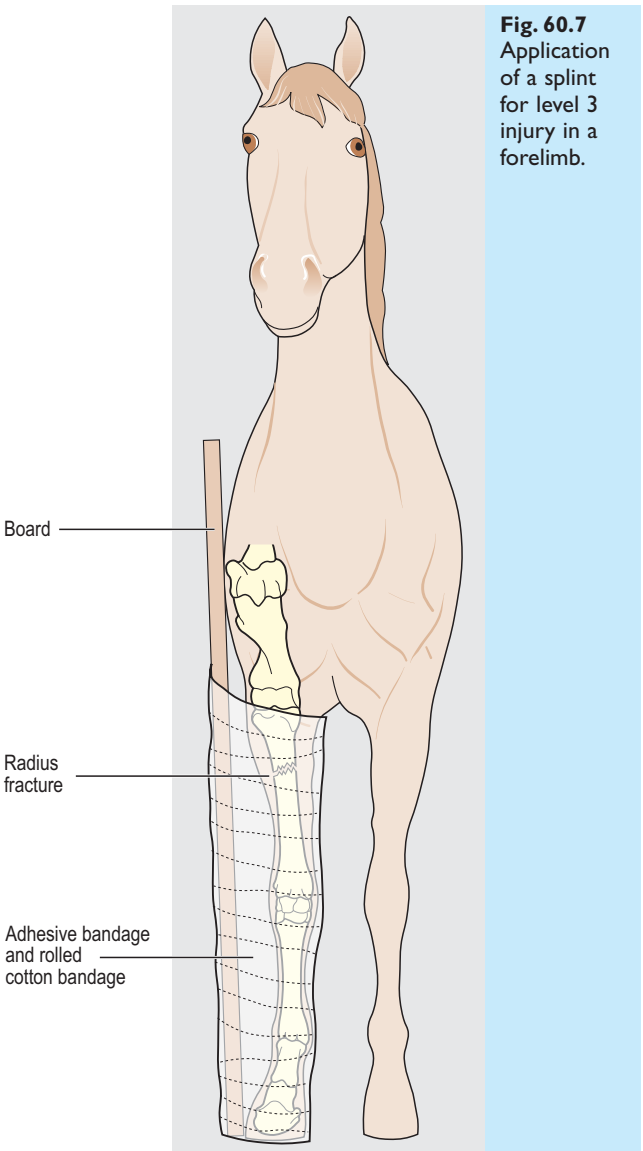

Fig. 60.7
Application of a splint for level 3 injury in a forelimb.

as it will make it more awkward to move, and may increase motion at the fracture site. If a fractured pelvis is present, the need for transportation should be discussed, as moving of the fracture segments can result in lacerations of major vessels. General anesthesia for pelvic fracture should be delayed for 3 to 4 weeks, to avoid fatal hemorrhage.

Guidelines for safe transportation

Before loading an injured horse, proper functioning of the vehicle should be assured. The horse should be stabilized, and the injury immobilized as best as possible before loading. All relevant paperwork (medical records, insurance information, contact numbers and map to referral facility) should be gathered, and the referral facility contacted.

The injured horse will need to negotiate loading and unloading a trailer with a potentially cumbersome splint applied to the injured leg. A low ramp will facilitate this process. While in the trailer, the horse may lean on the wall and partitions to help reduce the load on the injured leg. It will be easier for the horse to travel with partitions in place rather than loose in a makeshift stall. A sling can be placed under the horse's abdomen to help the horse take weight off the injured limb. Many trailers today have standing stalls at 45° angles (slant load trailer), which helps horses balance during transport. If a regular straight-load trailer is used, the horse should face backward for a forelimb injury, and forward for a rearlimb injury, to help cushion sudden stops. Finally, providing hay will help relieve anxiety, and frequent stops should be made to check on the status of the horse and provide drinking water. If significant cardiovascular compromise exists intravenous fluids can be administered while in transit.

If the horse is deemed severely injured and needs to remain recumbent, it can be pulled onto the trailer using a large tarp or blanket. The horse should be kept sedated during transport, to avoid injuries. A head protector (Equine head protector, Jupiter Veterinary Products, Harrisburgh, PA) or bandage can be used to protect the eye and head from self-induced trauma. Bandages should be applied to the lower limbs, also to avoid trauma caused by paddling.

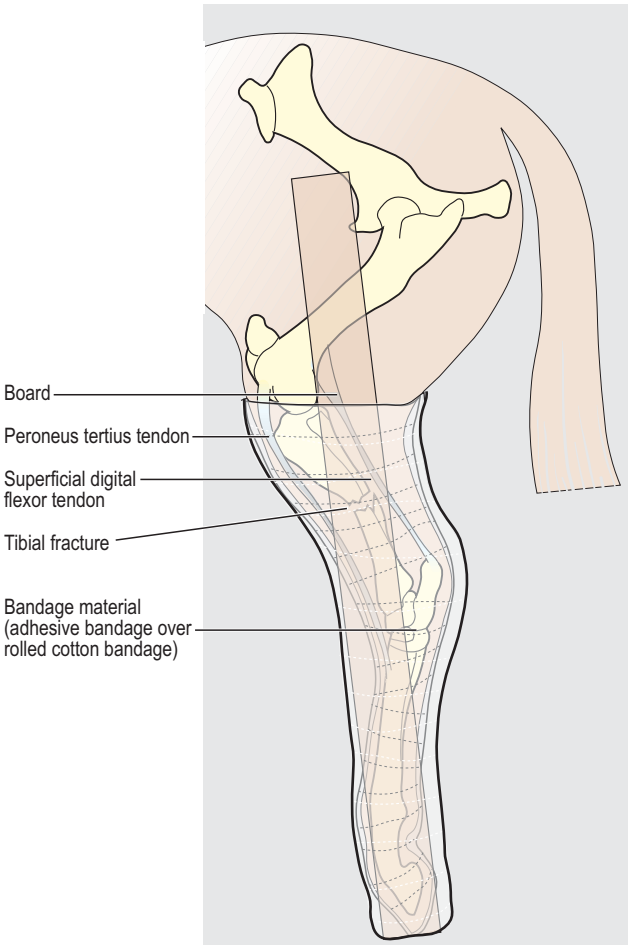

Fig. 60.8
Application of a splint for a level 3 injury in a hindlimb.

Wounds and lacerations

- First step: identification of all involved structures.
- Control of hemorrhage.
- Determine need for referral based on the presence of:
  tendon injury
  penetration of synovial structure
  extensive degloving injury
  severe blood loss.
- Provide tetanus prophylaxis, analgesia, and appropriate antibiotic therapy.
- In severe blood loss, provide cardiovascular support.

Assessment of wounds and lacerations

As with any condition, a general physical examination should be briefly completed before addressing the primary problem. If the wound is located on a limb, the presence and degree of lameness should be noted. The presence and severity of lameness is an important sign of a potentially more serious injury.

The wound is then evaluated for the following findings.

Location

Wounds in the following locations should be explored in detail for injury to important underlying structures:

- wounds over joints or tendon sheaths
- wounds over tendons, particularly flexor tendons
- wounds that have bone exposed, or that are down to bone.

Hemorrhage

The presence of severe hemorrhage may require hemorrhage control before further wound assessment is possible. Severe hemorrhage is best controlled using a pressure bandage applied directly over the bleeding area. Attempts to find the bleeding vessels are usually not successful.

Wound configuration

Certain wound configurations may lead to significant damage to blood supply to the skin and subcutaneous tissues and will result in sloughing. Examples include an inverted 'V' configuration, or significant bruising or trauma to adjacent tissue.

Penetration of a body cavity

Wounds over the chest or abdomen have the potential for penetrating injuries to important organs. In the case of thoracic wounds, development of an open or closed pneumothorax can lead to severe respiratory distress. Any horse with chest trauma and respiratory distress should be evaluated for the presence of pneumothorax.

Determination of synovial structure involvement

The potential involvement of a synovial structure should be *immediately* determined. To evaluate penetration of a synovial structure the following steps can be taken:

- The horse is restrained and sedated as needed.
- A site of entry of the joint or tendon sheath remote from the wound is chosen.
- The site is clipped and prepared aseptically.
- Using sterile technique, saline or a balanced electrolyte solution is injected into the synovial structure, using an amount sufficient to achieve distension. The amount can vary from a few milliliters in the case of a distal tarsal joint injury to 100 mL or more for the femoro-patellar joint (Fig. 60.9). It is also important to assess all possible joint compartments. The wound is observed for leakage of the injectate.

Determination of tendon involvement

Extensor tendon injury of the distal limbs will result in inability to appropriately place the hoof on the ground, resulting in

Fig. 60.9
Injection of the middle carpal joint showing communication of the joint with a wound.

the horse knuckling over. For this to occur, both tendons will have to be involved in proximal metacarpal/tarsal injuries.

Flexor tendon injuries will result in hyperextension of the fetlock (superficial digital flexor), lifting up of the toe (deep digital flexor) (Fig. 60.10) or complete dropping of the fetlock to the ground (severance of the suspensory ligament). In order to observe this the horse must bear weight on the limb at least transiently. Importantly, in the case of complete suspensory breakdown, there can be severe stretching of digital vessels, which can lead to thrombosis and avascular injury to the hoof. In complete breakdown injury, it is therefore critical to support the fetlock and not allow weight bearing until further stabilization can be performed.

Emergency treatment of limb wounds and lacerations

Wound care

The goal of initial wound care is to decontaminate the wound as much as possible, and prevent further contamination during transportation. Lavage with saline and sharp debridement of gross contaminants are used to accomplish this goal. Local antiseptics or antibiotics can be then packed in the wound to further decontaminate it.

Fig. 60.10
Hyperextension of the coffin joint in a horse with a completely severed deep digital flexor tendon.

Limb immobilization Immobilization of the limb will be needed if there is injury to a supporting structure (bone tendon) or significant instability (luxation). Refer to the above section for a description of the appropriate method of immobilization.

Emergency treatment of wounds involving the chest or abdominal cavity

Pneumothorax An open chest wound (Fig. 60.11) can result in the development of pneumothorax. Pneumothorax will cause respiratory distress manifested by a restrictive pattern of breathing. On auscultation, there will be absence of sound in the dorsal lung fields. Because of the incomplete mediastinum in horses, a unilateral chest wound can lead to bilateral pneumothorax.

An open pneumothorax is managed by providing a temporary seal over the chest wound. This is accomplished by bandaging the wound and applying an impervious airtight layer of a material such as plastic (Fig. 60.12). The chest is then evacuated by inserting a 14-gauge catheter using aseptic technique in the dorsal aspect of the 12th intercostal space, and aspirating the air out of the chest. The use of a three-way stopcock will facilitate this procedure.

Penetrating abdominal wounds Penetrating abdominal wounds are serious and potentially fatal injuries. They can lead to penetration of a viscus, or development of peritonitis. If a penetrating wound is suspected, the wound should be cleaned, explored for the presence of a foreign body, and debrided. An abdominocentesis can be performed to detect fecal contamination indicative of a ruptured viscus. However, abdominocentesis may not be diagnostic in this early stage of peritoneal contamination, as indicators of peritonitis take several hours to develop. The wound can be bandaged, and broad-spectrum systemic antibiotics initiated. In the presence of a large wound, or if abdominal musculature is involved, the abdomen can be

Fig. 60.11
Open chest injury and pneumothorax in a horse. Note the placement of a 14-gauge catheter at the 12th intercostal space dorsally to evacuate air from the chest.

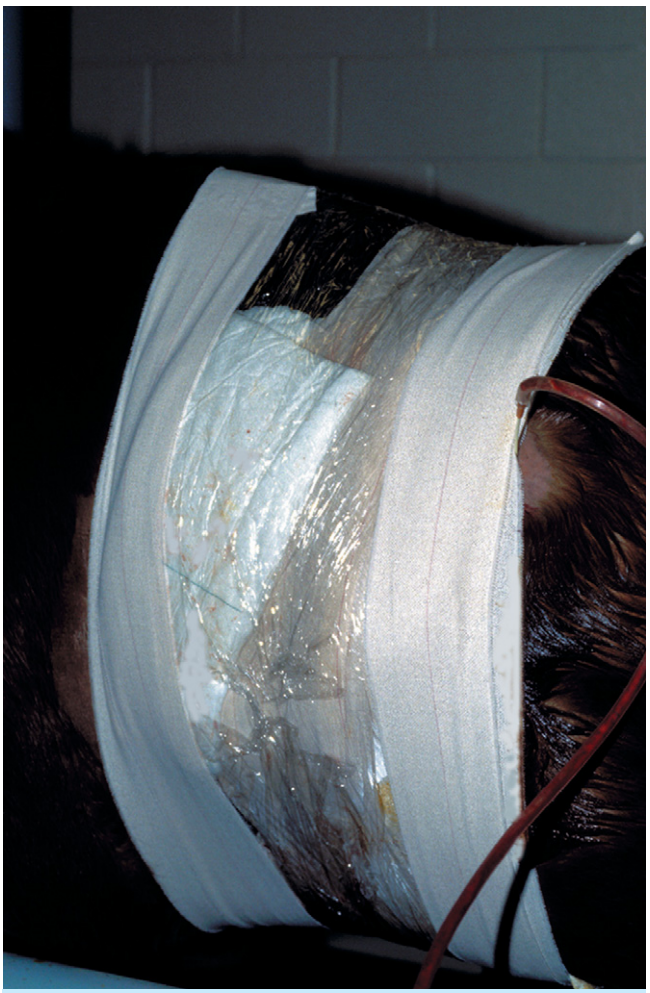

Fig. 60.12
Application of an airtight bandage to a horse with open pneumothorax.

supported (Equus Sta-Put equine abdominal support, Equus Therapeutics, Inc, Afton, VA).

Head injuries

Head injuries can result in severe central nervous system damage. Central nervous system (CNS) injury can be primary where contusions, lacerations and hemorrhage cause the acute damage, or secondary, when subsequent edema, reperfusion injury and necrosis result in worsening of the injury. Therapy for head injury is aimed at minimizing secondary CNS damage.

The causes of head injury in athletic horses include direct trauma from a fall, a blow to the head or falling over backwards onto the poll region. The associated injuries include basisphenoid fractures and avulsion of the ventral straight muscles of the head.

Basisphenoid fractures

The location of this injury can result in acute optic nerve damage, and cerebral signs. Temporary blindness can result. The diagnosis is made by radiography (Fig. 60.13), and treatment is targeted towards minimizing secondary brain damage, and supportive care.

Rectus and longus capitis muscle rupture

This injury occurs most commonly from falling over backwards. The muscles attach to the base of the cranium, and with injury hematoma, and even avulsion fractures of the muscular insertion, can result. Because of the location of these muscles within the guttural pouch septum, hematomas can rupture into one of the guttural pouches, resulting in epistaxis. This epistaxis can be severe, and may require blood transfusion.

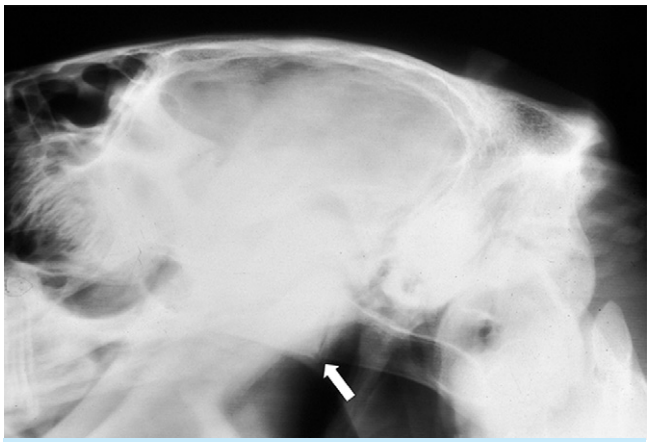

Fig. 60.13
Lateral projection of the head of a horse with a basisphenoid fracture (arrow).

The diagnosis of this injury is made by endoscopy, where an epistaxis of guttural pouch origin is identified, in conjunction with a large hematoma in the guttural pouch septum. Radiographs are useful to demonstrate an avulsion fracture accompanied by a soft tissue opacity overlying the guttural pouches (Fig. 60.14).

Fig. 60.14
Lateral projection of the head of a horse with avulsion of the longus capitis muscle. Note the avulsion fractures located at the attachment of the longus capitis to the basisphenoid bone (arrow).

Treatment is supportive, with anti-inflammatory drugs and edema-reducing agents.

Treatment of acute head injuries

Horses with head injury can be severely ataxic, and need to be handled and moved with extreme caution. If the horse is down, a short-term general anesthesia is best used to move the horse to a referral facility for further evaluation.

Non-steroidal anti-inflammatory drugs (NSAIDs) are used to minimize inflammation. Although controversial, corticosteroids may be indicated if used in the immediate phase of injury. DMSO is often used to minimize secondary edema. Magnesium has recently been proposed as another therapeutic agent for acute head injury.

Ocular injuries

Ocular injuries encountered in the athletic horse are traumatic in origin, and include periocular lacerations, corneal lacerations or foreign body penetrating injury, or direct blow to the eye with retinal detachment.

Evaluation of acute ocular injury includes evaluation of the different structures of the eye, as well as evaluation of cranial nerve function. Eyelids, conjunctiva, cornea, lens and fundic examinations can be performed to assess the degree of damage (Fig. 60.15). Vision can be assessed by the menace

Fig. 60.15
Horse with severe chemosis resulting from contact with an irritant.

response, supplemented with obstacle course testing. Oculomotor, trochlear and abducent nerve function are assessed by the position of the eye, and pupillary light responses. Facial nerve and sympathetic innervation to the eye are assessed by eyelid tone, and position of the eyelashes.

Treatment of acute ocular injuries includes minimizing pain and inflammation, preventing infection, and preventing further injuries. If penetration by a foreign body is suspected, rapid surgical intervention is indicated to prevent further injury.

Anti-inflammatory drugs that are used to minimize pain and inflammation associated with ocular injuries include NSAIDs, DMSO, and topical osmotic agents. Pain from pupillary spasm can be minimized by dilating the pupil with atropine. Direct sunlight should be minimized by protecting the eye. Acute injuries can be associated with ulceration and secondary bacterial invasion. A broad-spectrum topical antibiotic can be used to prevent secondary infection of an ulcer.

Horses that are acutely blind will not negotiate their environment well. Further injury should be prevented by protecting the blind eye (Eye Saver, Jupiter Veterinary Products, Harrisburgh, PA), and by carefully handling the horse.

Acute rhabdomyolysis

Recognition

History and presenting complaint

Acute rhabdomyolysis (tying up) is a generalized inflammation of skeletal muscles. Predisposing factors include genetics, intense exercise, exercise following a period of confinement, dietary practices, particularly the feeding of a high percentage of carbohydrate in the diet, general anesthesia, and sex (higher prevalence in females).

Physical examination

The manifestations of acute rhabdomyolysis (AR) will vary from mild stiffness to recumbency. The most common signs include a stiff gait with reluctance to move, tachycardia, tachypnea, focal or generalized sweating, hardness of large muscle groups such as the glutei, quadriceps and triceps, and muscle fasciculations. The urine will be dark to black as a result of myoglobinuria. Occasionally, particularly if the episode follows exertion, there will also be signs of endotoxemia (injected mucous membranes, poor peripheral pulse). Ileus as manifested by absence of auscultable motility, presence of nasogastric reflux, and palpable small intestinal distension, can also be present, particularly if hypocalcemia is present.

Laboratory findings in AR include elevation of plasma muscle enzymes: early (within 6 hours) creatine kinase (CK) often reaching 50 000 to 100 000 units/dL followed by a later rise in aspartate aminotransferase (AST). Azotemia may be present, and may result from dehydration or from primary renal damage (acute tubular necrosis resulting from pigmenturia). Common electrolyte abnormalities include ionized hypocalcemia, and a metabolic alkalosis.

Treatment

Therapeutic aims

- Pain control.
- Muscle relaxation.
- Fluid support:
  – correction of electrolyte abnormalities
  – prevention of acute renal failure.

Therapy

Acute rhabdomyolysis can be a very painful condition. Adequate fluid replacement should be ensured to prevent renal toxicity of some of these drugs. Drugs used for pain control include flunixin meglumine, phenylbutazone, and ketoprofen. In severe cases, morphine can be added to the therapeutic regimen. If practical, lidocaine (lignocaine) can be given as a constant rate infusion for additional pain relief.

Muscle relaxants are often added to therapy, particularly when the large muscle groups are hard and painful. Methocarbamol, dantrolene, and guaifenesin are recommended, although efficacy is uncertain.

Acepromazine, a peripheral vasodilator, has been recommended to improve muscle blood flow.

Fluid therapy is an essential part of the treatment of acute rhabdomyolysis. Renal tubular necrosis and subsequent renal failure can result from the combination of dehydration, pigmenturia, and nephrotoxicity of NSAIDs. Balanced electrolyte solutions are preferred. Calcium supplementation is indicated as low ionized calcium concentration is often present.

Emergency fluid therapy in the athletic horse

Injuries with blood loss, or horses suffering from exhaustion, acute rhabdomyolysis or overheating, are conditions that require emergency fluid replacement as part of the management of these conditions. This section will discuss the basics of fluid therapy in shock states with emphasis on fluids used for resuscitation. Mention will be made of emergency treatment of the horse with an HYPP (hyperkalemic periodic paralysis) event.

Designing a fluid therapy regimen

Fluids can be administered for maintenance purposes, when fluid intake is physically not possible, or for replacement purposes when excessive losses have been incurred and/or

ongoing losses are anticipated. In the athletic horse, replacement therapy is the mainstay of fluid therapy and will be discussed here. The first section will discuss the mathematics for fluid administration in horses, and the next section will outline the materials commercially available to achieve this goal.

Designing a replacement fluid therapy regimen requires the clinician to answer the following questions:

- What volume of fluids is required?
- What type of fluid is required?
- What route of administration is available/optimal?
- What will be the rate of administration?

Calculating the volume of fluid to give

The volume of fluid to give on a daily basis can be calculated using the following equation:

Total volume to give in the next 24 hours (in liters) =
maintenance (60 mL/kg bodyweight/day)
+
estimate of dehydration (% of bodyweight)
+
ongoing losses

Maintenance volumes will be equivalent to approximately 1 liter of fluid per hour for an adult horse.

An estimate of dehydration can be made by using clinical and, if available, laboratory parameters, as outlined in Table 60.1. These numbers will be weighed in relation to the horse's clinical condition. For example, a nervous horse may have a transiently high heart rate in response to excitement, and a high hematocrit because of splenic contraction. The clinician will therefore have to use judgment in the interpretation of each parameter.

Ongoing losses can be the most difficult estimation, as losses through the gastrointestinal tract are difficult to measure. The equine gastrointestinal tract secretes and reabsorbs the equivalent of the extracellular volume (approximately 30% of bodyweight) on a daily basis. If ileus is present, the amount of reflux can be quantitated. If the large colon is not reabsorbing water, as in diarrhea, significant losses can occur. With severe diarrhea, approximately 50% of extracellular fluids can be lost on a daily basis.

The clinician must be aware that this calculation is a crude estimate, and volumes are then adjusted based on objective responses to fluid administration such as heart rate, pulse quality, capillary refill time, urine production, hematocrit, total protein, and creatinine. These monitoring parameters will need to be repeated as often as dictated by the horse's clinical condition. With a horse in severe shock, monitoring cardiovascular parameters may need to be continuous, or at least every 15 minutes until an improvement is noted. In a horse with severe ongoing fluid losses, cardiovascular parameters should be monitored at least every 4 hours, and laboratory parameters as frequently as four times a day until stabilized. Following these evaluations, an adjustment in the estimate of fluid requirements can be made.

Table 60.1 Physical and laboratory parameters used to estimate the percentage of dehydration in horses

% Dehydration	Heart rate (beats/min)	CRT (s)	PCV/TP (%/g/L)	Creatinine (mg/dL)
6	40–60	2	40/7	1.5–2
8	61–80	3	45/7.5	2–3
10	81–100	4	50/8	3–4
12	> 100	> 4	> 50/> 8	> 4

Deciding the type of fluids to give

Fluids available for administration in horses are of two categories: *crystalloids* are fluids containing substances that freely cross the capillary membrane; these include balanced electrolyte solutions, saline solutions, and dextrose solutions; and *colloids*, which are made up of fluids that are retained in the vascular space for a certain number of hours, because of their larger molecular size; these include plasma, albumin solutions, dextrans, and hydroxyethylstarch. Crystalloids are most commonly used for replacement fluid therapy in the athletic horse, whereas colloids are reserved for resuscitation purposes.

Crystalloids There are two basic types of crystalloid available for horses: *balanced electrolyte solutions* (BES), which consist of electrolyte solutions in concentrations similar to plasma; and *saline solutions*, which contain only sodium chloride. Although considered a crystalloid, dextrose solutions are rarely used alone. Table 60.2 outlines the different composition of crystalloid commercially available for horses.

The decision to choose BES or saline is based, if available, on a serum chemistry profile. Saline is chosen if the sodium concentration is less than 125 meq/L, or the potassium is greater than 5.9 meq/L. Otherwise, a BES is used. If unavailable, a BES is safe, unless HYPP is suspected, in which case saline should be used. Several portable point-of-care monitoring devices that can measure blood gas and electrolytes are now available (IRMA Blood Analysis System, Diametrics Medical Inc. St Paul, MN. www.diametrics.com, I-Stat Portable Clinical Analyzer, I-Stat Corporation, East Windsor, NJ. www.istat.com).

Colloids The addition of colloids to a fluid therapy regimen serves two purposes: addressing the problem of edema formation in hypoproteinemic states; or sustaining the intravascular circulating volume. Selected products containing targeting antibodies are also available for the treatment or prevention of endotoxemia, *Rhodoccocus equi* pneumonia, and clostridial diseases. These products will not be discussed in this section. Colloidal solutions are available in two forms: natural or synthetic. Natural colloids are plasma, serum products or albumin. Table 60.3 summarizes the characteristics of each product. In general, plasma is selected when an increase in oncotic pressure is needed, but in addition, coagulation factors or specific anticoagulants such as antithrombin III are required by the disease

Table 60.2 Composition of crystalloids commonly used for fluid therapy in horses

Product	Approximate pH	mOsmol/L	Na (meq/L)	K (meq/L)	Ca (meq/L)	Mg (meq/L)	Cl (meq/L)	Buffer (meq/L)
Lactated Ringer's	6.5	273	130	4	3		109	Lactate 28
PlasmaLyte A	7.4	294	140	5		3	98	Acetate 27 Gluconate 23
PlasmaLyte 148	7.4	294	140	5		3	98	Acetate 27 Gluconate 23
PlasmaLyte 148	5.5	294	140	5		3	98	Acetate 27 Gluconate 23
5% Dextrose	4	252						
0.9% NaCl	5	308	154				154	
7% NaCl		2400	1196				1196	
5% $NaHCO_3$	8	1190	595				595	
1.3% $NaHCO_3$		308	154				1541	

process. Albumin solutions are not commonly used, as the intravascular half-life of albumin in states of compromised vascular permeability is short, and this solution does not have the added benefits of plasma. Synthetic colloids commonly used in horses include dextran 70 and hydroxyethylstarch (HES). These products are used to increase plasma oncotic pressure, and their effect is best evaluated either by clinical response (decreased edema) or by increased oncotic pressure (measured by colloid osmometry).[5,6] A refractometer cannot be used to monitor the effect of synthetic colloid administration.

Table 60.4 Fluid properties and dosages used for resuscitation in the horse

Fluid	Properties	Dosages
Lactated Ringer's	Crystalloid	Shock: 60 mL/kg
Hypertonic saline	Crystalloid	4 mL/kg rapidly; follow with isotonic fluids
Hetastarch	Synthetic colloid	4 mL/kg rapidly; do not exceed 10 mL/kg

Products used for resuscitation

The goal of fluid therapy in shock states is to rapidly expand circulating blood volume to improve perfusion and oxygen delivery. Isotonic crystalloids can serve this purpose, but must be administered at a rate of 60 to 80 mL/kg in the first hour (approximately one blood volume), for beneficial effects. Hypertonic solutions can be used to rapidly expand circulating volume by redistributing extravascular fluids into the vascular space. Because of redistribution, the duration of effect of hypertonic solutions in horses is short. Colloid solutions can be used to sustain the effect of hypertonic crystalloid solutions to several hours. For resuscitation, a combination of hypertonic saline and hetastarch would have the most beneficial and sustained effects. Table 60.4 lists the properties and dosages of fluids commonly used for resuscitation in the horse.

Table 60.3 Composition of colloids commonly used for fluid therapy in horses

	Characteristics of colloid fluids			
Characteristics	*5% albumin*	*Dextran 40*	*Dextran 70*	*Hetastarch*
Molecular weight (Da)				
weight average	69 000	40 000	70 000	450 000
number-average	69 000	25 000	39 000	70 000
range		10 000–80 000	15 000–160 000	10 000–3 400 000
Solvent		0.9% saline or 5% dextrose	0.9% saline or 5% dextrose	0.9% saline or BES
Concentration (%)	5	10	6	6
Half-life	14–16 days	2.5 h	6 h	25 h
Extravascular percentage (after 24 h)		22	33	39
Overall survival in blood		44 h	4–6 weeks	17–26 weeks
Colloid oncotic pressure (mmHg)	20	40	N/A	30

Table 60.5 Selected traumatic injuries, recommended treatment and prognosis in adult horses

Injury	Recommended treatment	Prognosis
Coffin bone fracture	Corrective shoeing or internal fixation	Extra-articular: good Articular: guarded
P2 fracture	Pastern arthrodesis	Good to guarded
P1 fracture	Internal fixation	Non-displaced: good Displaced or comminuted: guarded
Sesamoid fracture		
Apical	Surgical: extraction	Good
Midbody	Surgical: internal fixation	Guarded
Basilar	Medical or surgical	Guarded to poor
Comminuted/biaxial	Medical or surgical	Poor
Sagittal	Medical or surgical	Poor
Cannon bone fracture	Internal fixation	Guarded to poor depending on degree of comminution
Carpal fracture	Arthroscopic removal or internal fixation	Good for small fracture guarded for large fracture poor if carpal instability
Radius fracture	Hairline: stall rest Displaced: internal fixation	Hairline, non-displaced: good if no displacement occurs Displaced: grave
Olecranon fracture	Non-articular: stall rest Articular: internal fixation	Good unless extreme comminution or open
Humeral fracture	If > 200 kg, stall rest If < 200 kg, internal fixation	Guarded. Risk for contralateral laminitis if stall rest. Implant failure rate high with internal fixation
Scapular fracture		
Supraglenoid tubercle	Non-displaced: medical Displaced: surgical	Guarded
Body/neck	Surgical	Poor
Hock fractures		
Calcaneus	Large fragment: internal fixation Small or comminuted fractures: medical	Guarded Guarded
Tibial fracture	Hairline: stall rest Displaced: internal fixation	Hairline, non-displaced: good if no displacement occurs Displaced: grave
Femoral fracture	If > 200 kg, stall rest If < 200 kg, internal fixation	Guarded. Risk for contralateral laminitis if stall rest. Implant failure rate high with internal fixation
Patellar fracture	Fragmentation: arthroscopic removal Sagittal or comminuted fracture: internal fixation	Guarded to good Guarded
Luxations: hock, fetlock	Reduction and external immobilization	Good for light exercise if no articular injury

Materials for fluid therapy

The flow rate of fluids through an administration system is directly proportional to the diameter of the line and inversely proportional to the viscosity of the fluid and the length of the line. For routine use, 14-gauge catheters made of Teflon or polyurethane are used in adults. When gravity flow is used, a rate of 2 to 3 liters per hour can be achieved when fluids are approximately 10 feet higher than the jugular vein. For more rapid flow 10- or 12-gauge catheters with large-bore connecting sets can be used, but it should be remembered that 10-gauge catheters are more thrombogenic. Finally, both jugular veins can be cannulated for increased fluid administration and a pressure bag system or a pump can increase the rate of fluid flow. Peristaltic pumps can cause endothelial damage and increase the risk of thrombosis.

Materials needed for high-volume fluid therapy in field situations in horses:

Catheters
- 12- or 14-gauge, cm
- Large bore extension set

Administration set
- Coiled set
- Pressure bag

Fluids
- Balanced electrolyte solutions, 5 liters

Epidemiology

Injuries occurring at equine athletic events are best documented in the Thoroughbred racing industry. Fatal musculoskeletal injuries are the most significant cause of death in horses during training or racing activities. In these horses, the injury is so severe as to warrant euthanasia, usually within 2 days of the injury. Forelimb sesamoid bone fracture, suspensory ligament rupture or third metacarpal fracture represent the most common training or racing-related injuries in Thoroughbred race horses. Other fatal musculoskeletal injuries include carpal fractures, fractures of the scapula, tibia or pelvis, and first phalangeal fractures.[7] The influence of training intensity on the prevalence of injury is variable. In California, horses with intense racing schedules (35 furlongs of race in 2 months) were at greater risk of fatal musculoskeletal injury.[8] In contrast, Kentucky horses with injuries had less cumulative high-speed exercise in the months preceding the injury.[9] In one study, horses with toe grabs were at increased risk for fatal musculoskeletal injury, specifically suspensory apparatus failure or condylar fractures.[10] In one study, pre-race examination findings, particularly abnormalities of the suspensory ligament, were highly associated with an increased risk of injury during racing.[11] Table 60.5 describes the current recommended treatment, and prognosis of common injuries in the athletic horse.

CHAPTER 61

Reproductive management

Nigel R. Perkins

Reproductive management of equine athletes has traditionally focused on control or prevention of reproductive behavior to minimize any adverse effects on performance. Although this area remains of interest to owners, trainers and riders of competition animals, recent advances in reproductive techniques provide opportunities for breeding horses during their competitive careers.

Control of reproductive behavior in horses

Male and female athletic horses commonly train and compete together. Day-to-day management under such conditions is often facilitated if sex-steroid-induced sexual or aggressive behavior is suppressed.

Suppression or prevention of estrus in mares

The presence of an estral female in close proximity to other horses may be disruptive and present risk of injury to horses or people. Some female horses become more difficult to handle in estrus, and there is anecdotal evidence linking variation in athletic performance to stages of the estrous cycle in horses.[1] There is a lack of evidence demonstrating an association between stage of cycle and behavior-associated interference with training or athletic performance.

Mares presented for estrus-associated changes in behavior or athletic performance should be examined prior to any treatment. A detailed history should be collected including times of onset of behavioral change, and duration, to determine if the pattern is consistent with normal reproductive cyclicity. Examination should include the following procedures:

- general physical examination with particular consideration to ruling out other causes of a change in performance (musculoskeletal pain or disease involving another body system)
- observation of mare behavior when exposed to an intact stallion
- transrectal palpation and ultrasound examination of the genital tract at a time when the mare is showing behavior suggestive of estrus
- measurement of blood concentrations of reproductive hormones such as progesterone, estrogen, testosterone and possibly inhibin
- potential repetition of the examination to correlate changes in behavior with findings of clinical and laboratory procedures.

Diagnostic confirmation requires observation of clinical signs consistent with estrus behavior, changes in the genital tract that are consistent with estrus,[2] and low circulating progesterone concentration. Response to test treatment of the mare with altrenogest, a progesterone analogue, may be a useful diagnostic aid. Improvement in mare behavior when estrus signs are suppressed using a known effective product adds confidence in a diagnosis of estrus-associated behavioral change. Absence of ovarian follicular development and low or undetectable levels of circulating progesterone or estradiol may indicate a lack of association between behavior and ovarian activity. The presence of constant estrus-like or aggressive behavior may be observed during spring transition, functional ovarian neoplasia and in some cases of behavioral psychosis. Pathologic conditions that account for behavioral change should be treated specifically. Mares without detectable lesions of the genital tract and where behavioral change can be attributed to estrous cyclicity may be considered as candidates for one or more of the treatment options outlined below.

Pharmacologic suppression of estrus

An ideal estrus control product should be highly effective at suppressing signs of estrus, easily administered, rapidly absorbed, require infrequent dosing, and be safe for both animals and people.[3] It should have no residual effect on fertility, allowing treated animals to begin a breeding career following withdrawal of treatment.[3] There should ideally be no restriction on use of the product by rules controlling athletic horse events.

A number of products used for estrus control are not registered for use in horses. Care must be taken when administering products to animals that are not registered for that species. In addition to rules regulating administration of drugs to horses during competition, attention should be paid to drug residues in those countries where horses are classed as 'food-producing' animals.

The mare is seasonally polyestrous. During winter most mares are in a reproductively quiescent state with small inactive ovaries in response to reduced pituitary secretion of follicle-stimulating hormone (FSH), and luteinizing hormone (LH), and reduced secretion of hypothalamic gonadotrophin-releasing hormone (GnRH).[4,5] Increasing hours of daylight after the winter solstice result in an increase in production and secretion of GnRH, with a resultant increase in production and release of pituitary gonadotrophins.[4,6] FSH dominates the initial rise in gonadotrophin secretion in late winter and early spring, stimulating the development of ovarian follicular waves that do not result in ovulation.[4] This endocrine environment results in spring transition, with large, anovulatory follicles, and irregular expression of estrus behavior. Spring transition may persist for several weeks, ending with the first ovulation of the breeding season. Once the first ovulation occurs mares usually enter a regular ovulatory cycle for the remainder of the ovulatory season.

During the ovulatory season the estrous cycle is characterized by a relatively constant diestrus lasting 14 to 15 days and dominated by the corpus luteum, and a more variable estrus dominated by the developing ovulatory follicle. Estrus length is variable both between and within mares, ranging from 5 to 9 days.[7] In spring estrus tends to be longer and more variable in length while in late summer it becomes shorter and less variable. The combination of rising estradiol and low progesterone concentrations seen during estrus is responsible for expression of estrus behavior. Progesterone concentration in peripheral blood rises within 24 to 36 hours after ovulation and is largely responsible for cessation of estrus behavior.[7]

The hypothalamic–pituitary–ovarian (HPO) axis controls ovarian function and expression of reproductive behavior, and offers a range of control points at which intervention may allow suppression of either estrus alone or both estrus and ovulation.

Progestagens The two most commonly used progestagens in mares are natural progesterone and altrenogest (Regumate, Intervet, Millsboro, Delaware, USA).

Daily intramuscular injection of 150 mg or more progesterone in oil will suppress behavioral signs of estrus within days even if started in early estrus. Estrus suppression was also achieved in mares treated with 50 or 100 mg per day if treatment started during diestrus while the same doses failed to suppress estrus behavior if treatment was begun on the first day of estrus.[8] The requirement for ongoing daily injections makes long-term use of this product impractical. Controlled release implants containing progesterone and estradiol have a longer duration of action, and may offer some promise for estrus suppression.[9]

Altrenogest (Regumate) is generally used at the recommended dose rate (0.044 mg/kg by mouth, once daily), for estrus suppression. Continued expression of estrus behavior has been reported in mares being treated with altrenogest and may be due to incorrect dosing, failure to administer the product effectively, errors in estrus detection, treatment during estrus and individual mare variability in response to the product.[10] There are unsubstantiated reports of mares being maintained on lower daily doses of altrenogest for estrus suppression (NR Perkins, unpublished data, 1993).

Little work has been done on assessment of effects of long-term estrus suppression. Mares treated with altrenogest for 88 days showed effective suppression of estrus, no evidence of adverse effects, and normal fertility when bred following resumption of cyclicity.[11] Progestagen therapy has been shown to enhance uterine infection in mares exposed to intrauterine bacteria and in mares with a history of uterine infection, and this may represent a potential adverse effect of long-term treatment for estrus suppression in some mares.[12]

Progestagens have only moderate control over follicular development in the mare, and luteal ovulations are relatively common in mares receiving progestagens, compared with other domestic species.[13] Corpora lutea resulting from ovulation during progestagen treatment may have a prolonged lifespan due to failure of the normal luteolytic mechanism.[13,14] During the ovulatory season mares can be expected to show estrus within 3 to 5 days and ovulate within 9 to 11 days after the end of progestagen therapy.[15]

A wide range of other progestagens has been administered to mares for suppression of estrus with little or no supporting data concerning efficacy or safety.

Intravaginal progestagen-releasing devices have been used for estrus synchronization[16] and appear to offer little value as a means of estrus suppression for any length of time due to the lack of safety data following repeated or long-term vaginal insertion of such devices.

Melengestrol acetate (MGA), chlormadinone acetate (CAP), and norgestomet (Synchromate-B), are all effective at suppressing estrus in cattle and have been used in mares. MGA is effective in cattle at a dose of 0.4 mg/day but appears to be ineffective in mares even when used at doses as high as 20 mg/mare/day.[17] The limited evidence available for both CAP,[17] and norgestomet[18] indicates they are similarly ineffective at inhibiting estrus behavior in mares.

Anecdotal reports have also supported the use of steroid-containing implants registered for use in cattle, as a means of suppressing estrus in mares. Administration of Synovex-S implants to mares, each containing 200 mg progesterone and 20 mg estradiol benzoate, did not result in increased peripheral blood progesterone concentration, did not inhibit

expression of behavioral estrus, and did not prevent ovulation, even when mares received a dose equivalent to 10 times the bovine dose.[19]

Proligestone and medroxyprogesterone acetate (MPA) are synthetic progestagens with prolonged activity registered in some countries for estrus suppression in dogs and cats. There is anecdotal evidence indicating that intramuscular administration of 1500 to 2500 mg proligestone, or 250 to 500 mg MPA, to a mare during diestrus may suppress behavioral signs of estrus for up to 2 to 3 months. The author is not aware of scientific evidence to support this claim.

A number of synthetic progestagens have been shown to be ineffective at maintaining pregnancy in ovariectomized mares, including hydroxyprogesterone caproate and hexanoate, medroxyprogesterone acetate, norgestomet, and megestrol acetate.[20,21] Although not a primary objective of these studies, the authors observed that treatments appeared ineffective at inhibiting signs of estrus and follicular development.

Caution is urged when considering the use of non-registered products in mares for estrus suppression. In most cases scientific assessment of such products has dismissed anecdotal claims of efficacy, and there is little or no information available on safety.

Anabolic steroids Administration of anabolic steroids to mares commonly results in a dose-dependent reduction in ovarian size and cessation of estrous cyclicity, with a gradual return to normal cyclicity occurring after the end of treatment.[22] Anabolic steroids also commonly result in masculinization of behavior and appearance with behavioral changes persisting for several months after cessation of chronic steroid treatment.[22–24] Reduced fertility has been reported experimentally in mares treated with anabolic steroids,[24] although Bourke reported no long-term effect on fertility in brood mares that received anabolic steroid treatment during their racing careers.[25]

Anabolic steroids are more commonly administered to performance horses because of beliefs regarding their influence on physical or performance attributes. Drug detection systems associated with penalties for detection of anabolic steroids or their metabolites currently limit the use of these drugs in most countries.

GnRH immunization

Immunization of females with a GnRH analogue resulted in cessation of estrous cycles in many species including horses.[26–29] Immunization of fillies resulted in an increase in circulating anti-GnRH antibodies, and suppression of gonadal function and sexual behavior for up to 25 to 30 weeks.[28,29] This approach offers promise in the management of undesirable reproductive behavior in athletic horses. Limited data indicate that animals resume cycling and have normal fertility after treatment,[29] though there is little information on the effects of long-term or repeated immunization. Further studies on such effects are required before this methodology can be considered for use by equine athletes in which the option of a future breeding career is desired.

Intrauterine glass balls

Placement of a glass ball in the uterine body one day after ovulation may be effective at suppressing estrus in mares.[30] A single, sterilized, 35 mm glass ball (www.glassmarbles.com) was manually passed through the cervical lumen and into the uterine body on the day following detected ovulation. Five of 12 (42%) treated mares showed prolonged luteal function for a mean of 89 days (range 76 to 109 days), following insertion of the ball.[30] Prolonged luteal function was associated with elevated endogenous progesterone concentration and suppression of behavioral estrus. There appeared to be no evidence of uterine damage in response to the treatment. It is suggested that treated mares be examined to ensure that endometritis does not develop, particularly in the period soon after placement of the ball. This approach may offer a non-pharmacologic alternative for estrus suppression that is effective for reasonable time periods in some mares.

Ovariectomy

Bilateral ovariectomy is occasionally performed in performance mares to prevent estrus and pregnancy, or improve behavior though it is not consistently effective at inducing either outcome.[31] The author routinely advises that clients considering bilateral ovariectomy as a behavioral management aid should initially treat the mare with altrenogest for several weeks. If the mare's behavior improves on altrenogest treatment, then ovariectomy may be expected to result in a similar level of behavioral improvement. If the mare's behavior does not improve on altrenogest then there is an increased risk that ovariectomy will not result in any improvement in behavior.

Bilateral ovariectomy may be performed in the standing sedated mare or through ventral midline or paramedian approaches in the anesthetized recumbent mare.[31] Laparoscopic techniques for ovariectomy have been described recently and may be associated with reduced complications and more rapid recovery.[32]

Control of reproductive behavior in the stallion

Effective control of reproductive behavior in stallions during a performance career can be achieved in most cases using training techniques.[33] Castration or pharmacologic treatment are sometimes considered in horses that are poorly responsive to training alone.[33,34] Interventions should always be combined with training and handling when attempting to modify male sexual or aggressive behavior.

Surgical castration

Castration of male horses is commonly performed to prevent breeding and as a method of behavior modification.[35] Castration may be performed in the standing sedated horse using local anesthesia or in the recumbent horse under general anesthesia.[36] A number of sources provide

information on options for anesthesia and restraint.[35–38] The choice of method and type of restraint are influenced by a large number of factors including: owner and veterinary preference and experience, horse behavior, physical location of the testicles, available equipment and the facilities or surgical environment.[35]

Castration may be performed at any age.[35] There appear to be little scientific data on which to base a recommendation regarding timing of castration. Normal animals are commonly castrated between weaning and 3 years of age. Reasons for delaying castration in animals that do not have a potential breeding career are poorly defined and may include allowing the animal to benefit physically from endogenous testosterone production. Children experience a pubertal growth spurt associated with a rise in circulating sex steroid concentrations.[39] It is not clear whether horses are subject to the same rapid growth phase and limited studies in male dogs have not consistently identified a pubertal growth spurt.[40] In male dogs prepubertal castration delays physeal closure and results in increased long bone length.[40] The clinical significance of this change on musculoskeletal development and function remains unclear. There is a need for research to investigate the impact of age at castration on male horse growth and performance. It is suggested that castration of non-breeding animals may be better performed prior to weaning though advantages appear to be primarily associated with ease of surgery, shortened recovery time and reduced risk of complications either during or after the procedure.[35] Conversely, delaying castration until after puberty may have a beneficial effect on musculoskeletal development. There does appear to be little benefit in delaying castration until a horse is more than 2 years of age except in animals that may be subsequently used as sires in a breeding program.

Castration is effective in modifying male behavior though geldings can continue to display aggression and male sexual behavioral traits including erection, teasing, mounting and copulation.[37] No difference was observed in sexual and aggressive behavior between geldings castrated when less than 2 years of age, and geldings castrated when greater than 3 years of age.[41] These findings indicate that sexual and aggressive behavior in male horses is only partially dependent on the presence of circulating sex steroids. Training and behavior modification may be more effective in geldings than in stallions and this may explain much of the perceived difference in behavior between geldings and intact males.[33]

Pharmacologic modification of male behavior

Administration of progestagens is the most commonly used pharmacologic method for modifying male horse behavior.[42] There is little information concerning mechanism of action, safety, or efficacy in the horse. Progestagens have been shown to decrease the occurrence of male sexual behavior in castrated male monkeys even when circulating plasma testosterone levels were maintained within the range of intact males by testosterone implants.[43] This suggests that the behavioral effect of progestagens is not dependent on reduction in plasma concentration of testosterone concentration, even though progestagen administration in intact animals may also result in suppression of plasma concentrations of LH and testosterone. The behavioral effect of progestagens is mediated by a reduction in uptake of either androgens or estradiol within areas of the brain known to influence male sexual behavior, and both estradiol and androgen levels in the brain influence male behavior.[44] Anecdotal evidence indicates that progestagen administration to male horses results in suppression of sexual and aggressive behavior as well as a general calming effect.[42,45] Progestagen therapy may be combined with training in an attempt to modify unsuitable behavior in male horses.[45]

Treatment of stallions with 0.044 mg/kg altrenogest per day for 30 days had no effect on sperm production or measures of sperm quality.[46] Most behavioral parameters did not change though time to mount and ejaculate was increased in altrenogest treated stallions after the completion of treatment, returning to pre-treatment values by 60 days after cessation of treatment. Reductions in circulating concentrations of LH, testosterone, inhibin and estrogen conjugates were also detected in treated animals at the end of the treatment period, returning to pre-treatment levels within 30 days of cessation of treatment. In a similar experiment stallions treated with 0.088 mg/kg altrenogest per day for 8 weeks, showed reduced scrotal circumference and sperm production, and increased sperm abnormalities.[47] Treated animals also showed reduced male sexual and aggressive behavior, and reduction in serum testosterone concentration. These studies suggest that altrenogest does have an impact on reproductive parameters, and that longer treatment periods may be necessary to obtain measurable changes in male behavior. The effects of altrenogest on behavior and fertility in stallions appear to be reversible.

It is possible that certain progestagens may affect both behavior and fertility while other products may have little or no effect on fertility. Evidence in monkeys indicates that both medroxyprogesterone acetate and progesterone are effective at reducing male behavior, while they have different effects on circulating testosterone levels. Animals treated with medroxyprogesterone acetate showed reduced plasma concentrations of LH and testosterone while animals treated with progesterone did not.[44] Further work is needed to investigate the effects of progestagens on behavior and fertility in stallions.

Tranquilizers such as phenothiazine derivatives and reserpine have been used in the past in stallions as aids for behavior modification.[42] They are no longer recommended for use in male horses because of the small but important risk of adverse sequelae including penile paralysis, paraphimosis and psychotic behavior.[42]

Immunomodulation of male fertility and behavior

Immunization of male horses against GnRH results in reduction in circulating testosterone concentration, testicle size,

and sperm numbers. Young colts also show reductions in male sexual behavior and aggression though behavioral effects are less noticeable in mature animals.[28,48,49] Treatment effects appear to be fully reversible over time.

GnRH vaccination may offer an alternative treatment modality for controlling reproductive behavior and fertility in male horses during their athletic career. However, more research is required, particularly on the possible adverse effects of long-term or repeated treatment, before this approach can be recommended.

Combining breeding and athletic careers

Developments in assisted reproductive technologies have allowed increased flexibility in managing the breeding careers of mares and stallions while still performing as athletes.

Stallion

Advances in techniques for producing and managing chilled and frozen semen, improved pregnancy and foaling rates, and increased market demand for such services, have seen a progressive increase in the proportion of mares bred using chilled or frozen semen artificial insemination (AI) in all breeds except Thoroughbreds. Semen may be collected from stallions for processing throughout the year, including during periods of training or competition. Training techniques providing clear distinction between performing and breeding may help to ensure that periodic breeding opportunities do not disrupt a stallion's training performance or general behavior.[33]

Individual stallion semen quality is one of the most important factors influencing the success of artificial insemination programs and a breeding soundness examination should be performed on any stallion being considered as a semen donor in an AI program. Detailed description of procedures and techniques involved in breeding soundness examination of stallions may be found elsewhere as well as discussion of factors influencing semen production and quality.[50–54]

It is particularly important to be aware of individual variability in fertility of thawed–frozen stallion semen, even in stallions that have excellent fertility when bred naturally or using fresh AI.[55] Results of laboratory analysis of either fresh or thawed–frozen stallion semen are poorly predictive of pregnancy rates in mares bred with thawed–frozen semen from the same stallion and test mating of a small number of mares remains a useful method of determining whether a particular stallion has fertile, thawed–frozen semen. Continued developments are expected in techniques for freezing and thawing semen, and laboratory assessment of the potential fertility of thawed–frozen semen.

Mare

Developments in assisted reproductive technology have had a dramatic impact on breeding options available to mares during an athletic career.

Natural breeding

Mares are occasionally bred while still competing, perhaps in an attempt to gain some benefit from the calming effect of endogenous progesterone secretion that occurs during pregnancy.[45] There is little information on the effect of different exercise levels in mares on fertility, pregnancy development, or risk of pregnancy loss. The first two-thirds of pregnancy in the mare are characterized by little or no increase in nutrient requirements[56] or bodyweight over the non-pregnant state. Animals that tolerate the stresses and demands of training and competing are likely to have minimal risks associated with continuation of an athletic career during the first few months of pregnancy. Exercise-associated risks to pregnancy appear to be mediated through effects such as reduction of uterine blood flow due to redistribution of blood to the musculoskeletal system, reduction of available glucose due to increased muscle metabolism, and exercise-induced temperature rise.[57] There appears to be no information in horses on the effects of pregnancy on performance. Studies in women report a progressive decline in all aspects of athletic performance during pregnancy.[58] It seems plausible to expect a similar effect in horses.

Embryo transfer

Use and availability of embryo transfer (ET) has increased tremendously over the past decade, particularly with development of techniques for short-term storage and shipment of embryos. Embryos can now be shipped from the site of collection to a centralized facility for transfer to recipients or long-term storage, removing the necessity for recipient mares to be maintained at the same site as donors.[59] ET techniques have changed little over the last decade and are well described.[59–63] ET use in performance mares can allow multiple foals to be produced from mares while they continue to train and compete.[64] In seasonal sports such as polo, mares may move from intensive athletic performance to being embryo donors, depending on the time of year.[60,65] The lack of a reliable, commercially viable method for superovulating donor mares continues to be a major limitation on embryo recovery rates.[66] Reported pregnancy rates following transfer of thawed–frozen equine embryos have been disappointing and preference is given to transfer of fresh or chilled embryos to avoid the necessity of freezing, though this is expected to change as techniques are refined.[59]

Other assisted reproductive techniques

Commercial in vitro fertilization (IVF) and embryo production is now being offered for cattle industries in several countries. Similar procedures have been performed in mares

and selected facilities offer these techniques on a commercial basis.[67] Oocytes are generally collected by transvaginal ultrasound-guided follicular aspiration, from either immature or mature follicles. Oocyte maturation may be combined with intracytoplasmic sperm injection (ICSI) to circumvent the requirement for sperm capacitation and even for sperm motility.[68–70] Oocyte transfer procedures have also resulted in pregnant recipients.[70, 71]

The use of ICSI or low-volume insemination with sexed semen provides the added option of obtaining sex-selected offspring from performance mares during their competitive career.[72] Other assisted reproductive techniques that may offer potential in future equine breeding programs include freezing of oocytes, cloning and production of transgenic animals.[66]

Until recently many breed registries that allowed assisted reproductive techniques such as embryo transfer allowed only one foal per mare per year to be registered. In mid 2002, legal action in Texas resulted in the American Quarterhorse Society overturning this restriction and removing all numerical restrictions on the number of foals that may be eligible for registration in any one year. This action has ramifications for other breed registries that may be considering, or already have, restrictions on the number of foals that may be registered in one year.

Management of performance horses to optimize future reproductive potential

In most cases little consideration is given to the reproductive potential of performance horses until they are reaching the end of their performance career. This is expected to change in the future. Management of performance horses will involve increasing attention to both short- and long-term impacts on fertility of disorders, management procedures and treatments. In some instances this may result in changes in management or treatment because of a possible adverse impact on fertility.

Many female horses for example are subjected to a Caslick's (vulvoplasty) procedure during their performance career because of a belief that pneumovagina during periods of intense physical exertion may interfere with performance. In some cases the vulval lips are sutured further ventrally than the general Caslick recommendation of 1 cm below the ischial arch. It is possible that an overzealous Caslick may interfere with normal ventrocaudal urine flow during urination with urine splashing cranially into the anterior vagina. This may lead to chronic urine-induced inflammation involving the vagina, cervix and uterus. The author has observed maiden mares at stud with a very low Caslick in place and severe degenerative changes in the uterine epithelium on examination of endometrial biopsy.

In stallions, improper application of a stallion ring to prevent erections during a performance career may result in penile scarring and interference with the long-term ability to obtain a normal erection.

Some treatments administered to horses during their performance careers may also have long-term adverse effects on future fertility. Anabolic steroids, anti-cancer drugs and GnRH vaccines are examples of treatments that may have a long-term effect on fertility. Anabolic steroids can cause cessation of estrous cyclicity in females and reduce testis size, sperm production and sperm quality in stallions.[22,73–75] Limited data in horses appear to indicate that effects are generally reversible following cessation of treatment.[25,76] The long-term effect of administering combinations of different steroids, or using dose rates or treatment frequencies that differ from manufacturer guidelines, remains unknown. Evidence from chronic misuse of anabolic steroids by human athletes indicates that there may be serious and long-term effects on fertility and general health.[77]

Management of performance horses during their performance career will need to be modified to pay more attention to breeding potential. Drugs that may have adverse effects on fertility and cyclicity should be avoided in animals that are to be used for breeding purposes during their performance career. In addition every effort should be made to avoid administering drugs associated with any risk of adverse effects in pregnant animals. There is little specific information on safety of products during pregnancy in horses. Information is predominantly extrapolated from studies in laboratory animals and reports from human medicine. Lists of common drugs used in veterinary medicine have been produced with comments on their safety during pregnancy.[78] Effects of administration of harmful drugs during pregnancy depend on the action of the drug, dose and duration of exposure, and stage of pregnancy. Possible effects include pregnancy loss, induction of fetal malformations, alteration of normal fetal development, abnormal parturition and reduced fetal viability.[78]

CHAPTER 62

Examination of the equine athlete prior to purchase

Brian H. Anderson, Andrea Ritmeester, Brendon Bell and Andris J. Kaneps

- Aim and philosophy of the prepurchase examination.
- General approach and examination procedure.
- Special considerations and ancillary tests.
- Examination of different types of equine athlete.

A rigorous and thorough examination of the athletic horse by a veterinarian who understands and is familiar with the sporting endeavors of a particular athlete is a challenging and potentially troublesome task. With practice and diligence it can be a very rewarding professional and financial experience. In order to conduct such examinations proficiently, knowledge of the types of injuries and diseases affecting athletic horses and which may shorten or cause problems in a career should be understood. In this chapter the aim and philosophy of the prepurchase examination, general approach and examination procedure used, the use of special examination techniques and the differences in examination approach between various athletes will be discussed. The prepurchase examination of horses intended for breeding will not be discussed but has been reviewed elsewhere.[1,2]

Aim and philosophy

The selling and buying of athletic horses is essential for a vibrant and profitable equine industry. Breeders of horses strive to produce well-grown athletic individuals from superior blood lines in the hope of selling a product that will be successful on the racetrack, cross-country course or in the dressage arena. Horses are sold privately or at public auction sales. High-quality animals command high dollar prices from thousands to millions. Purchasers of high-quality animals want to ensure that their investment has a good chance of providing a successful return. Purchasers decide on the breeding, type and quality of the horse they desire and seek from the veterinarian an assurance that what they are about to buy does not have any problems currently or in the future that will inhibit the investment from performing up to expectation.

The ultimate decision on the purchase of any horse resides with the purchaser. As part of the decision-making process the veterinarian provides information to the purchaser on the health status of the horse. Successful athletes are seldom injury free and older athletes in particular have invariably suffered some 'wear and tear'. In the case of young unbroken athletes, a variety of congenital and acquired defects, which may interfere with an athletic career, might be present. For these reasons it should be understood by the purchaser that the veterinarian essentially conducts a *risk assessment* for the purchaser.

The aim of the examination of the equine athlete prior to purchase is to first identify, and second assess, the relative significance of factors of a veterinary nature, which at the time of examination might impair athletic performance in the occupation for which the horse is intended.[3] In addition, conditions that have the *potential* for impairment of athletic performance in the future should also be identified and an opinion of their significance made in light of the horse's intended use.[3–5]

The way in which the opinion of the examining veterinarian is presented to the purchaser has become very controversial. Unfortunately, it is a frequent perception by the purchaser that a veterinarian's examination prior to purchase provides a warranty that the prospective animal is free of all impediments currently and in the future and that such an examination in some way guarantees a risk-free purchase. This perception has been perpetuated to some extent by the use of the terms 'sound', 'suitable' or 'serviceable', all of which when used in the context of a prepurchase

examination imply a degree of warranty. Using these terms when giving an opinion may leave the examining veterinarian legally vulnerable if the horse should prove to be unusable by the purchaser and they are not recommended.[6] Another reason why it is unwise to use such terminology is that in many instances a complete examination of the horse to be purchased is not possible. Providing an opinion on suitability or serviceability based on an incomplete examination is fraught with difficulties.

The veterinarian should confine his or her opinion to the functional significance of relevant examination findings.[7] A decision to purchase the horse or a decision on the suitability or serviceability of a horse for a specific intended purpose is a business judgment that is the sole responsibility of the purchaser and is made on the basis of a variety of factors, only one of which is the report provided by the examining veterinarian.[6,7]

It is common to find some clinical problems in athletic horses. Rather than take the easy road of advising against purchase where problems are recognized it is better to provide the purchaser with a balanced assessment of risk. Probably the most practical method is to assign a measure of likelihood or percentage chance that an abnormality or clinical finding will impair athletic performance.[4,8] In forming such an opinion the veterinarian draws on her or his own experience, the experience of others and the scientific literature. For example, recent evidence suggests that the presence of dorsal medial intercarpal disease identified on presale radiographs of the carpus of Thoroughbred yearlings is associated with a 20% chance of an affected horse not starting a race.[9]

It should be noted that the way in which the veterinary opinion is presented to the purchaser differs around the world. The variation often reflects the results of court decisions in cases of dispute and the establishment of legal precedent.[6] For example, the British Equine Veterinary Association recommends that the opinion given on examination for purchase be that a horse is 'suitable or unsuitable' for the purpose for which it is intended.[3] The equine industry accepts this method and the British legal system recognizes it as reasonable.[10]

Requirements for the prepurchase examination

In order to perform a successful prepurchase examination a number of requirements should be met and include the following:[10]

- Clear communication with the purchaser or purchaser's agent, vendor or vendor's agent before, during and after the examination. This communication should be both verbal and in writing. The limitations of the veterinary examination should be discussed with the purchaser together with an explanation of how the examination findings will be reported. The results of the examination are privileged and confidential and are the property of the purchaser.
- If the vendor is a client of the veterinarian (current or past) this represents a potential conflict of interest. All parties should be consulted and if the examination is to go ahead this agreement should be made in writing.
- Written confirmation of what portions of the examination the purchaser requires (see buyer's statement in Appendix at the end of this chapter). The requirement of additional ancillary tests should be indicated. Where regular examination procedures are unable to be performed (e.g. horse is not broken to lead) this should be detailed in the written report furnished to the purchaser. Other than for young stock, the horse should be in full athletic work and it is unwise to perform examinations on animals not in regular work because previous lameness or back problems may not be apparent.[8] These issues should be discussed carefully with the purchaser or purchaser's agent.
- A vendor's statement (see Appendix) should be completed in writing prior to examination of the horse.
- It is ideal although often not possible to have the vendor and purchaser present during the examination. A methodical and thorough examination process is required which includes examination before and after strenuous activity, preferably similar to that performed by the horse in its chosen occupation. Adequate personnel and conditions throughout this procedure are necessary.
- A thorough knowledge of the intended use of the horse.
- The veterinarian should have the skill necessary to differentiate normal and abnormal variations in physical and gait evaluations and be able to relate these to the horse's intended use so that an assessment on current and future performance can be made.
- Precise and detailed recording of examination findings.
- Be able to advise on the necessity of ancillary diagnostics and perform these or refer on for specialist examination.
- If the horse is to be insured or is being purchased for resale these issues should be discussed thoroughly with the purchaser. While some conditions identified during the examination will be acceptable risks for a certain intended use they may cause problems if the horse is to be insured or resold. For example, a distal intermediate ridge osteochondral fragment not resulting in clinical signs may be a low risk for purchase in a Thoroughbred yearling that is to be trained and raced by the buyer. If the purchaser, however, intends to condition the horse and sell it in a '2 year old in training sale' such a radiographic finding might deter a future purchaser. In addition, an insurance exclusion could be put in place on such a horse if the purchaser opted to surgically remove this fragment prior to further sale.

Examination procedure

Veterinarians use a variety of protocols for examination of the athletic horse prior to purchase.[6–8,11,12] Some veterinary societies recommend a standardized procedure that should be

used by their members.[7,8,11] By following such methods a degree of protection is afforded the veterinarian in case of litigation and a standard method reduces the chances of missing problems. However, other veterinary associations such as the American Association of Equine Practitioners have not produced an official step-by-step protocol because of the legal ramifications that may arise if a veterinarian did not strictly adhere to the policy. In addition, by not using a standard protocol veterinarians are free to adopt their own methods of examination.

One method used by the authors, and one that has been well accepted in Australia, New Zealand and Great Britain, is based on a five-stage procedure and this is described below.

Stage 1. Preliminary examination

An accurate description of the horse is required. A vendor's statement should be completed. The current state of work should be noted and the resting examination conducted. This part of the examination is usually performed within the horse's stall or stable having been at rest for at least 30 min. Access to a dark area is useful for examination of the eyes. A nose to tail examination should be conducted and the hands passed over every part of the body. Each foot should be picked up, examined and a hoof tester applied. The limb joints are checked for effusion and flexed to detect pain or limitation of movement. The palmar/plantar flexor tendons, ligaments and soft tissues are evaluated for swelling, heat and pain. The accompanying checklist (see Appendix) should be followed precisely so that no part is overlooked. With experience the veterinarian develops an automatic inspection procedure. The horse is then brought out of the stable and inspected thoroughly from all sides. Conformation is evaluated with the horse standing on a level surface. At this stage if any obvious defect is present which would impair the function of the animal the examination is stopped with the consent of the purchaser. The premature termination of the examination and the reason is explained in the report.

Stage 2. Examination during walking, trotting, turning and backing

A competent attendant should handle the horse. The horse is walked 20 m away from the examiner and then back. The horse should be viewed from the front, back and sides. The horse is then trotted for 30–40 m and trotted back and then trotted in a circle both ways. The horse should be turned one way and then the other in tight circles and then backed a few paces. Coordination and proprioception are carefully assessed and to test for hindlimb strength a 'tail pull test' is used. Following this a full series of flexion tests as outlined in the guidelines are performed. The significance and interpretation of flexion tests are controversial. Force applied, duration of application, age and work history can all influence the outcome of these manipulations. Flexion tests should not be interpreted in isolation. Positive flexion tests without concurrent lameness or other clinical abnormalities may have little clinical significance.[13] In our hands flexion tests have proved useful to detect signs of disease. The radiograph in Fig. 62.1 shows a subchondral cyst-like lesion in the proximal phalanx of a 2-year-old unbroken Paint gelding that had been paddock rested for 12 months. A repeatable response to forced flexion and lameness following this was the only sign evident. Joint effusion was not present.

Fig. 62.1 Dorsopalmar view of the right front fetlock of a 2-year-old Paint gelding. Note the small subchondral lucency communicating with the fetlock joint in the medial proximal aspect of the first phalanx. A positive distal limb flexion test was present in this horse.

The clinician should develop a consistent and repeatable technique and this is probably the best way of achieving reproducible results. If during this examination signs of lameness are present the examination may be terminated. Sometimes the purchaser wishes to continue with the examination – this is ill advised – but if the purchaser or vendor wishes to know the source of the lameness, the format, cost and person responsible for payment of this extra examination needs to be clarified.

Stage 3. Examination during and immediately after strenuous exercise

Within the confines of the animal's age, condition, training, fitness and only after the vendor's consent, exercise of sufficient intensity and duration should be performed so as to:

- induce rapid deep breathing so that unusual breathing sounds can be heard
- tire the animal so that strains and injuries and other exercise-related problems (e.g. epistaxis) may be revealed after a period of rest
- increase the action of the heart so that exercise-related cardiac abnormalities may be detected, e.g. atrial fibrillation.[7]

Examples of such exercise for the race horse include a sufficient warm-up followed by a gallop for 400–600 m. The examiner should position himself or herself close to the horse to observe and listen to the breathing pattern. A normal horse has only a single respiratory sound heard on expiration. When an inspiratory sound is heard this typically is due to impaired arytenoid function (e.g. laryngeal neuropathy).

Upper respiratory tract obstruction that results in loud inspiratory and expiratory sounds can be caused by conditions such as intermittent epiglottic entrapment, arytenoid chondritis or pharyngeal collapse. Excessive production of airway secretions and alar fold collapse are other possibilities. The horse should be pulled up as quickly as is safe and the breathing pattern closely observed to detect sounds of dorsal displacement of the soft palate, inspiratory noises typical of laryngeal neuropathy, abnormal nasal discharge and signs of respiratory distress. The horse should then have an endoscopic evaluation. Untrained animals, those too young or unable to be ridden should be lunged and the duration and intensity of exercise recorded.

Stage 4. Examination during the period after exercise

The animal should be allowed to 'cool down' quietly over a period such that respiratory and heart rates return to normal. A crude assessment of fitness and respiratory function can be made by evaluating heart and respiratory rate over this period. This period allows for any injuries or musculoskeletal problems to 'stiffen up' (e.g. degenerative changes within the fetlock joints).

Stage 5. The final examination during walking, trotting, turning and backing

The horse is examined as in stage 2 paying careful attention to any signs of lameness. Lunging in the circle both ways for a few rounds is also advised. Hoof tester and flexion tests may be repeated if signs of lameness are present.

Avoiding problems in the prepurchase examination

Examination of claims made against veterinary surgeons relating to the prepurchase examination show they are of two broad types.[14] In the first instance the veterinarian is accused of not detecting an abnormality that subsequently becomes a problem. This most commonly relates to lameness occurring soon after purchase. A careful and thorough examination procedure should help reduce the chances of inadvertently making such errors. Testing for drug administration may also act as a deterrent to the use of agents that may hide lameness problems or help confirm the presence of such agents at the time of examination.

In the second instance the complaint is that the purchaser was not informed of a condition or abnormality (e.g. sarcoid) that could become a problem. To avoid this situation good communication before, during and after the examination with the purchaser is necessary. Most importantly the limitations of the examination procedure must be carefully discussed. Having a clear understanding of the expectations and intentions of the purchaser with respect to the future use and training of the horse is critical.

Another frequent problem is dissatisfaction expressed by the vendor. This may be that the veterinarian improperly discriminated against the horse in question by providing the purchaser with incorrect opinions regarding the significance of the clinical findings of the examination. Such examples include the diagnosis of lameness, response to flexion tests, significance of conformational defects and opinion on the significance of radiological findings. It must be remembered that the vendor is of course trying to *sell* the horse and a balanced opinion regarding any defect or abnormality present is naturally tainted by some bias.

Notwithstanding this, it behooves the examining veterinarian to confine his/her opinion to fact, which is supported by experience and knowledge of the scientific literature. A second opinion from a respected colleague may be very useful. Because opinions between veterinarians differ it is best to confine any opinion given in terms of the degree of risk that any defect or abnormality may have currently or in the future on athletic performance. It is recommended that the veterinarian does not express his or her opinions relating to the outcome of the examination procedure to the vendor.

Special considerations and ancillary tests

Conformation assessment

The assessment of conformation is a very important part of the prepurchase examination. Many veterinarians believe that conformation, or more specifically, deficiencies in conformation, play a significant role in the maintenance of athletic soundness and contribute to the ability of elite performers. For example, it is well known that some conformational faults predispose athletic horses to injuries and lameness.[15–19] In addition, many astute observers of horses believe that the way horses are 'put together' has a major effect on how successful they are in various disciplines.[16,19] Unfortunately, objective scientific data to support these commonly held opinions is limited. Moreover, very talented individuals appear to compensate for deficiencies in conformation. It is probably true to say, however, that marked discrepancies from what is considered optimal conformation result in injuries that limit athletic performance. Limitations in the short term, especially in gifted individuals, can be overcome, but in the long term recurrent injury and lameness is more likely. Issues relating to the conformation assessment of various athletic horses are discussed below under the examination of each athlete. The reader is directed to more extensive recent reviews on the subject.[15–19]

Laboratory evaluation

Although a variety of laboratory evaluations may be useful as ancillary aids during the prepurchase examination,[20,21] drug testing and those tests required for insurance purposes or certification of disease status when horses are transported between states or countries are the most common. Blood tests such as evaluation of the hemogram, plasma fibrinogen and

serum chemistry are not routinely performed but would be indicated to determine if observed clinical symptoms were significant, e.g. nasal discharge, cough, elevated rectal temperature or submandibular lymph node enlargement. The vendor's permission should be sought and, to avoid confusion with the interpretation of results, blood should be collected prior to exercise.

Because equine athletes are frequently medicated and because unscrupulous vendors might use drugs to mask musculoskeletal pain, many purchasers now request drug testing. Drug testing is thought to provide insurance against 'foul play' but the purchaser should be advised carefully as to the limitations associated with such testing. For instance, the range of drugs tested by some laboratories may be limited (e.g. only testing of non-steroidal anti-inflammatory agents), testing is expensive, results are not immediate, some drugs are difficult to detect (e.g. some intra-articularly injected agents) or are no longer traceable but still exert a pharmacologic effect. Therefore, a negative test is not always commensurate with an animal that has not been medicated. Blood is usually the fluid sampled but in fact urine, although more time-consuming to collect, is the preferred sample because many drug metabolites are concentrated in urine and many agents can be detected for extended intervals in urine.

It is probably always wise to take a blood sample at the time of examination.[20] The simple act of collecting the sample, especially if the vendor is advised in advance, can have a deterrent effect. If the purchaser does not want the sample tested it should be kept for at least 2 weeks in case they change their mind. If testing is requested the samples should be packaged appropriately and dispatched by courier immediately. Regardless of when the sample is tested the process must be transparent and the vendor and purchaser should have an opportunity to witness collection and each party should acknowledge this by signature on any paperwork and on the tubes of collected blood. In some countries (e.g. Britain) a standardized collection process is used.[8]

The Coggins test for equine infectious anaemia (EIA) needs to be performed on horses that will travel interstate. For those horses imported into the USA and which might compete internationally, tests for piroplasmosis, dourine, glanders and EIA should be performed. When breeding stock are examined, tests for equine viral arteritis and contagious endometritis may be required.[8,20] In each case the client should be warned about the cost of such tests and the delays that testing might incur. Horses would ideally not be purchased until the results of such tests were known.

Examination of the cardiovascular system

During the clinical examination before and after exercise the cardiovascular system should be carefully examined. Chapter 32 discusses the evaluation of the cardiovascular system in detail. Principally the examiner determines if there is evidence of overt cardiac disease (elevated resting heart rate, elevated resting respiratory rate, distended jugular veins, dependent edema and exercise intolerance) cardiac murmurs or cardiac arrhythmias. Second it is important to differentiate between physiologic cardiac murmurs and arrhythmias and those that are pathologic. Where there is doubt an electrocardiographic examination and an echocardiographic examination may be required. It is advisable to seek specialist opinion in these areas. The following points should be kept in mind:[22]

- Physiologic murmurs (flow murmurs) are usually localized, of low intensity (grade 1 and 2), short in duration and sometimes musical. They are usually early to mid systolic, early diastolic or presystolic.
- Pathologic murmurs are often (but not always) louder, radiating and holo-pansystolic (mitral and tricuspid valve regurgitation) or holodiastolic (aortic valve regurgitation).
- Mild localized regurgitant murmurs may be associated with a low risk for athletic performance. Echocardiography is best.
- Sinus arrhythmia, sinus block and second-degree atrioventricular block are relatively common and of no clinical significance.
- Atrial fibrillation and premature beats (atrial premature complexes, ventricular premature complexes) are usually not acceptable in athletic animals. Exercise or 24-hour electrocardiographic examinations may be required to determine clinical significance.

Imaging and the prepurchase examination

The most common ancillary diagnostic aid used to evaluate the musculoskeletal system in the prepurchase examination is radiography. Radiography was performed in 49% of all prepurchase evalutions in one review[23] and this was more likely if the examination was performed at a clinic. The principal indications or reasons for prepurchase radiography include:[24]

- Clinical examination findings indicating an abnormality that requires quantification/clarification (e.g. fetlock joint effusion with pain on flexion).
- Intended use of horse (e.g. dressage competitor versus low-level pleasure horse).
- In young unbroken horses or in horses unable to be rigorously exercised, or athletic horses that have been rested, survey radiographs may help identify clinically silent or quiescent lesions which may cause future problems when training starts or is recommenced.
- Client's instructions. Clients may instruct the examining veterinarian to perform a radiographic examination. The reasons for this can be many and include the desire to sell the horse in the future, previous bad experiences or because of advice from others.[24]
- A standard set of radiographs is required as part of the examination of Thoroughbred horses being exported for racing to some countries (e.g. Hong Kong and Macau).
- Purchase price.

The routine use of radiography in the prepurchase examination can be problematic. Opinions differ as to the reliability of radiographs to be of predictive value for future athletic

soundness.[24] Some veterinarians believe that radiography should be avoided if it will not influence the opinion given on clinical grounds. The added expense and the possibility that radiographs will only 'confuse the picture' especially if questionable changes are identified should also be considered. Regardless of these issues, radiographic lesions or changes can only be properly interpreted when combined with examination findings and clinical history. Radiographs by themselves may be meaningless. In addition, high-quality images with sufficient views are required.[25] The minimum number of radiographic views required to examine a specific anatomical site during prepurchase radiography are presented in Table 62.1.[24,25] The radiographs must be permanently marked with the name or number of the horse, date, name of the veterinarian or veterinary hospital and identification of the leg examined. A method for recognizing which oblique view has been taken (e.g. always placing markers on the lateral aspect of the film) is necessary. The radiographs belong to the veterinarian and are part of the animal's medical record and need to be kept for the period determined

Table 62.1 Minimum recommended radiographic views for prepurchase radiography

Distal phalanx

[a] By angling the X-ray beam distally by 5° in the front fetlocks and 10° in the hind fetlocks the palmar or plantar aspect of the proximal phalanx can be clearly visualized to identify bone fragments at this site.

Table 62.2 Estimate of risk that various observed radiological changes result in reduced athletic performance[a,b]

Region	Radiological diagnosis
Distal phalanx	■ **Laminitis**[26] – high. ■ **Pedal osteitis complex/concussive trauma**[26] – moderate – manageable. ■ **Hoof imbalance** – low to moderate – manageable. ■ **Degenerative joint disease (DJD) distal interphalangeal joint**[26] – high. ■ **P3 Osseous cyst like lesions**[26] – if communicate with joint risk is high. Upright pedal or D45° Pr-Pa (PL) DiO required. ■ **Ossification of hoof cartilages**[26] – low. ■ **Mineralized opacities adjacent to extensor process of P3**[24,26] – low, usually insignificant. ■ **Round smooth densities adjacent to palmar processes** – low, secondary centers of ossification or old fracture.[26,27]
Navicular bone	**Navicular syndrome** – controversial since radiological changes can be similar in sound and lame horses. Those most likely to be significant include:[24–26] ■ Increased number of enlarged synovial fossae. ■ Medullary sclerosis/loss in corticomedullary definition. ■ Medullary lucency. ■ Flexor cortex erosions/new bone formation. ■ The above changes in combination with clinical findings are indicative of navicular disease/syndrome which represents a high risk for impairment in future athletic performance.
Pastern	■ **DJD** – generally risk is high. Proximal P2 osteophytes may be incidental in Warmbloods.[8] ■ **Osseous cyst-like lesions (distal P1 or proximal P2)** – risk is high if communicate with proximal interphalangeal joint (especially if medial or lateral of midline) and if accompanying evidence of DJD, low if isolated from joint. Centrally located cyst-like lesions in the distal aspect of P1 in yearling Thoroughbreds appear to have a low risk for future lameness. ■ **Osteochondral fragments palmar/plantar eminence of proximal P2** – risk is low–moderate.[28]
Fetlock	■ **DJD**[26] – Generally risk is moderate–high in any performance horse. If supracondylar lysis and osteophyte formation on the sesamoid bones are present, risk is high. Reduced risk if only slight modeling, correlate with age, occupation and clinical findings. ■ **Palmar/plantar proximal P1 fragments** – origin may be proximal sesamoid bones or P1, can be articular or non-articular and could be avulsion fragments or OCD. Risk is considered low and articular fragments can be removed arthroscopically with a good prognosis. Little effect on ability to start a race (presale findings in Thoroughbred yearlings[9]) and little effect on racing performance in Standardbreds.[29] ■ **Ununited proximoplantar tuberosity** – suggested clinical significance 12.5%[30] when recognized in young animals. May heal back to parent bone in young animals. Correlate with exam findings. Evidence of periosteal proliferation, calcification of distal sesamoidean ligaments and articular involvement increases risk. ■ **Proximal dorsal P1 fragments** – possibly developmental in yearlings but most likely traumatic in adults. Risk is low if other signs of DJD are absent. Correlate with age, occupation and exam findings. Prognosis following arthroscopic removal is very good.[9,25,26] ■ **OCD** – distal MC3/MT3 and distal 2/3 of MC3/Mt3 sagittal ridge[9] – risk is variable. Large defects, those with fragments and those showing subchondral bone changes represent a moderate–high risk. Follow-up on yearling Thoroughbreds and Standardbreds showed these changes to have little effect on starting a race (Thoroughbred) or on racing career (Standardbred) – amenable to surgery with a reasonable prognosis.[9,25] ■ **Osseous cyst-like lesions of Mc3/Mt3 and proximal P1** – risk is high if communicate with articular surface. Some cysts, however, can be incidental findings.[25]
Proximal sesamoid bones	■ **Sesamoiditis**[26] – conflicting opinion and research evidence on risk. Proposed etiology varies between occupations.[26,31–34] Radiological changes include osteophytes, enthesophytes, osteolysis and enlarged vascular channels. If multiple changes ultrasound of suspensory apparatus is warranted. Correlate with age, occupation, conformation (e.g. upright pasterns), exercise history and exam findings. Increased numbers of enlarged, irregular vascular channels especially if enthesophytes are present represent an increased risk.[9,34] Check for DJD of fetlock joint. Presale radiography of Thoroughbred yearlings showed > 50% of proximal sesamoid bones had irregular vascular channels but this did not affect the ability of horses to start a race when 2 or 3 years old.[9] Young Standardbreds with sesamoid changes showed improvement over time and earnings as 3- and 4-year-old horses were not different to those horses without sesamoid changes.[33] ■ **Fractures**[32] – sesamoid fractures identified on presale radiographs of yearling Thoroughbreds did not appear to influence the ability to start a race at 2 or 3 years of age.[9] These fractures (some of which may be separate centers of ossification), often occur when the horse is a foal and healing can result in a complete bony union.[32] An elongated or malshaped sesamoid bone can result if the fracture was displaced. Ability to start a race was not affected by these changes.[9] Hindlimb apical sesamoid fractures in particular appear to be low risk.[9] Fracture size, position and evidence of other changes should be evaluated in young horses to estimate risk. In mature horses sesamoid fractures are often clinically significant and careful evaluation of the suspensory apparatus and fetlock joint is required.

Table 62.2–cont'd.

Region	Radiological diagnosis
Metacarpus/ metatarsus	■ **Exostoses/splints**[26] – active splints represent a short-term moderate–high risk for impaired athletic performance. Palmar soft tissues may require ultrasonography. ■ **Proximal MT3/MC3 sclerosis**[26] – may alert clinician to conduct an ultrasound of the proximal suspensory ligament but the presence of this change alone may have little clinical significance.
Carpus	■ **DJD**[26] – generally risk is moderate–high for any performance horse. Mild changes, including mild articular osteophyte production, especially in the radiocarpal joint, have reduced risk. Assess with respect to age, conformation, occupation, work history and intended use. Smooth/mature non-articular enthesous bone formation on dorsal carpal bones – low risk.[24] Some third carpal bone sclerosis in race horses is expected. Significant focal lucency and marked loss of trabecular pattern – high risk. Presale radiography of yearling Thoroughbred race horses showed the presence of dorsal medial intercarpal disease reduced the chance of starting a race at age 2 or 3 by 20%.[9] ■ **Osseous cyst-like lesions** – can affect any of the carpal bones, usually incidental findings.[24] Osseous cyst-like lesions of the radial carpal bone or distal radius may cause lameness – correlate with clinical signs.
Tarsus	■ **DJD (tarso-metatarsal and distal intertarsal joints)**[26] – generally risk is moderate – high for any performance horse. Assessment of risk can be difficult based on radiographs alone because correlation between radiographic findings and lameness is poor. Therefore, clinical examination, age, occupation and exercise history is important. Smooth mineralized enthetic osteophytes on the dorsoproximal aspect of MT3 may be incidental findings without other articular changes – risk is low.[25] Thoroughbred yearlings with evidence of osteophyte or enthesophyte formation at the distal intertarsal or tarso-metatarsal joint margins were significantly less likely to start as 2- or 3-year-olds (difference was 7%).[9] The presence of periarticular osteophytes dorsomedially in Icelandic Ponies had a 53% predictive value for lameness.[35] ■ **OCD**[26] – generally risk for affecting athletic performance is considered low–moderate but site, size, subchondral bone changes and other joint changes should be considered. Studies in conservatively treated Standardbred race horses that were evaluated as young horses show racing performance to be similar to unaffected horses.[29,36] Other studies show mild reductions in earnings and numbers of starts (especially in 2-year-olds).[37,38] Small or well-attached fragments are low risk but effusion and lameness may result (unpredictably) when workload increases.[24] Evidence of OCD of the tarsus had little effect on the ability of a Thoroughbred yearling to start as a 2- or 3-year-old.[9] Success rates following arthroscopic surgery are good (75–80%).[39] ■ **Wedged, third and/or central tarsal bones** – represents a moderate–high risk for reduced athletic performance and may predispose to fractures.[40]
Stifle	■ **OCD (osteochondritis dissecans)**[26] – most horses show clinical signs within the first 2 years of life. However, clinical signs can manifest at any age. In addition, radiographic changes may correlate poorly with intra-articular pathology. Therefore, clinical examination findings are most important and should be assessed together with site, size, subchondral bone change, presence of concurrent DJD, age, occupation and exercise history to assess risk. Mild changes (flattening, irregularity) without effusion – low risk. Larger lesions have higher risk. Prognosis for successful athletic performance following stifle arthroscopy is approximately 64%.[39] ■ **Subchondral cystic lesions (SCL)** – although some SCLs may be asymptomatic, all SCLs of the stifle (medial femoral condyle, proximal tibia) have a moderate to high risk for affecting future athletic performance. Communication with the articular surface increases the risk. In addition, surgical therapy (arthroscopic debridement) only carries a 56–74% success rate for successful athletic performance.[41] Shallow concavities of the distal medial femoral condyle without underlying subchondral changes on the articular surface are generally insignificant.[24] ■ **DJD**[26] – risk is high and treatment only palliative.

[a] All conditions should be assessed in light of the clinical examination. Only rarely do radiographic lesions by themselves allow a complete assessment of risk. Assessment of risk has been generalized for each condition. However, each horse should be evaluated as an individual.
[b] Cited references describe aspects of the radiographic, radiological or clinical features of each condition.

by the statute of limitations for the state or locality in which the veterinarian lives.

What are we looking for on prepurchase radiographs that may result in a reduced capacity to perform as an athlete? When viewing radiographs during the prepurchase examination a thorough examination of each film is performed.[26] Significant radiographic abnormalities associated with the appendicular skeleton of the horse have been reviewed.[26] Any abnormalities should be described in terms of size, shape, position, density and relationship to adjacent structures. With respect to the athlete, however, there are a number of recognized conditions or anomalies observed on radiographs that carry a degree of risk for reduced athletic performance (Table 62.2).[24–26] The examiner should look carefully for the presence of developmental orthopedic disease (age, breed and joint specific), osteoarthritis or evidence of 'wear and tear', fracture and bone modeling. In young untrained animals developmental orthopedic disease must be conscientiously ruled-out. In animals that have performed, especially older animals, osteoarthritis and 'wear and tear' injuries are important.

Limitations and problems associated with prepurchase radiographs Radiographic evaluation in the prepurchase environment has a number of limitations and these should be discussed with the purchaser. Routine radiographic views may not detect all lesions, apparently normal radiographs do

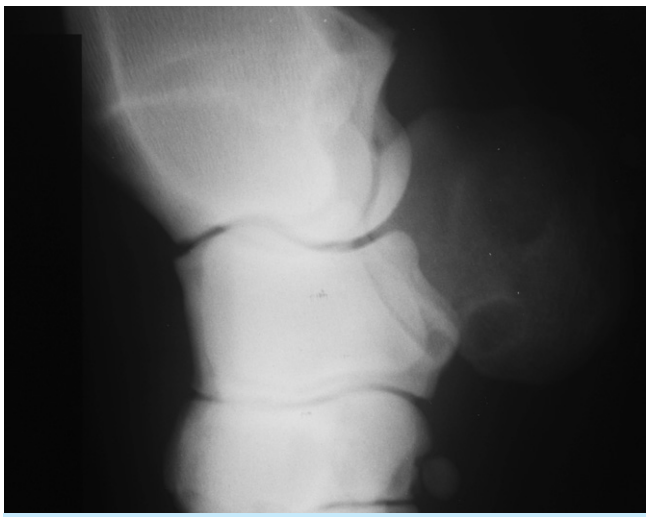

Fig. 62.2
Lateral to medial view of the left carpus of a 4-year-old dressage horse. Note the two, large, circular lucencies present in the accessory carpal bone. No clinical signs were associated with these findings.

not always exclude pathological processes (e.g. developing lesions may not be detected) and apparently abnormal findings may not have current or future clinical relevance. For example, Fig. 62.2 shows a radiograph of a lateral to medial view of the left carpus of a 4-year-old dressage horse. There are two, large, well-circumscribed lucencies in the accessory carpal bone. These are unlikely to be of clinical significance and the horse did not show any pain to palpation of the accessory carpal bone or lameness after carpal flexion. Another example of an obvious radiological lesion that is not necessarily clinically significant is shown in Fig. 62.3. An old apical fracture of the medial proximal sesamoid bone in the right hind leg of this 2-year-old Thoroughbred race horse is present. The horse was purchased at a public auction sale as a yearling and has shown no lameness or clinical signs associated with this joint. The best way of deciding on current clinical significance of a radiographic change is to match it carefully with the physical examination. This is why a rigorous five-stage examination is useful.

Fig. 62.3
Dorsoplantar view of the right hind fetlock of a 2-year-old Thoroughbred race horse. Note the old apical fracture of the medial proximal sesamoid bone. No clinical signs were associated with this finding.

More challenging is predicting the likelihood that radiographic changes will become a clinical problem when dealing with a young unproven animal that has not yet been subjected to training. This difficulty is compounded by the paucity of objective information relating radiographic changes with future athletic performance. The combination of physical examination, conformation analysis, intended use and published information is used to provide the prospective purchaser with an opinion on the level of risk a particular radiographic change might pose. For example, the radiograph in Fig. 62.4 shows an osteochondral fragment typical of osteochondritis dissecans (OCD) associated with the distal aspect of the medial malleolus in the tarsus of a 4-year-old Warmblood dressage horse that has had 6 months of basic training. Given the age of the horse, the fact there was no lameness on clinical examination, no effusion and no response to a hock flexion test, the client was advised that the OCD was not currently a clinical problem and the risk for future problems was considered low (less than 25%). Surgical removal carried a predicted success rate of approximately 80% if a problem developed. In contrast, Fig. 62.5 shows a dorsomedial-palmarolateral oblique radiographic view of the right front fetlock in a 2-year-old Thoroughbred race horse examined prior to purchase and export to Hong Kong. The medial proximal sesamoid bone shows evidence of moderate sesamoiditis with a focal lucency within the abaxial part of the bone. The palmar border of the sesamoid is irregular. This horse had a positive distal limb flexion test and was painful to focal pressure applied to the sesamoid bone. The risk for future lameness related to these findings was considered moderate to high.

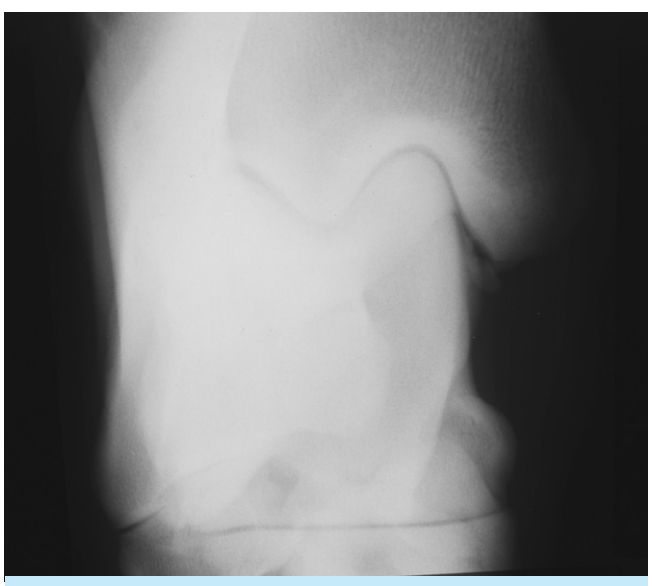

Fig. 62.4
Dorsoplantar view of the right hock of a 4-year-old dressage horse. Note the osteochondral fragment associated with the distal medial malleolus. This is typical of osteochondritis dissecans. There was no tarsocural joint effusion and a hock flexion test was negative.

Fig. 62.5
Dorsomedial–palmarolateral oblique view of the right front fetlock of a 2-year-old Thoroughbred race horse. Note the abnormal lucency in the abaxial part of the proximal medial sesamoid bone. The palmar border of the bone is also irregular. This change is typical of sesamoiditis and carries a moderate–high risk for future lameness problems. Pain could be elicited on deep palpation of this bone.

By giving purchasers an assessment of risk, rather than a 'pass or fail' opinion, the veterinarian can help facilitate a successful sale. However, the acceptance of risk by the purchaser can be variable and depending on the experience of the purchaser there is also a variable level of tolerance to faults or problems a horse may have. It may be advisable to seek more than one opinion on radiographic changes or send the films for review to a radiologist or surgeon.

Other imaging modalities

While not routine, ultrasonographic evaluation of the soft tissue structures distal to the carpus and hock has been performed with increasing frequency as part of the prepurchase examination in recent years. Common use of ultrasonography in equine practice, availability of good equipment and an expanded understanding of the importance of soft tissue musculoskeletal injury in athletic horses probably accounts for this. Indications for use include:[42]

- abnormalities identified during the clinical evaluation; careful palpation and comparison between limbs is required
- history of a previous injury
- at the purchaser's request.

In addition, some veterinarians recommend ultrasonographic examination in circumstances when they suspect an injury could be present but which is not reported (e.g. event horses or race horses that have been absent from competition for extended periods, were competing but have not competed recently, or where there is an unexplained reduction in work intensity).[8,42]

It is important that the veterinarian is familiar with the requirements for distal limb ultrasonography[42,43] including equipment, scanning technique and permanent image recording. Image interpretation requires considerable experience. Acute and chronic tendon or ligament injury may have major consequences for future athletic performance. The site, severity, age and state of healing of any injury, together with the intended use of the horse, will determine the risk assessment for future problems in an individual case.

Nuclear scintigraphy is another imaging modality that could be utilized in the prepurchase examination.[25] It is not generally used and the potential use as a 'screening tool' in the context of a prepurchase examination would be problematic and is not recommended. Expense and limited availability also preclude widespread use. However, in certain circumstances nuclear scintigraphy might be valuable and these include:

- assessing the current clinical significance of apparent radiological lesions or palpable osseous abnormalities
- assessing degree of healing of a previous injury, e.g. stress fracture of the pelvis or a dorsal metacarpal stress injury ('bucked shins')
- differentiating between chronic fractures and multipartite anomalies.[25]

Endoscopic examination of the upper respiratory tract and trachea

The use of endoscopy in the prepurchase examination is variable. Some veterinarians believe that endoscopy is only indicated if clinical examination findings determine that it would be useful (e.g. nasal discharge following exercise, abnormal respiratory noise heard at exercise). However, some abnormalities of the upper respiratory tract are not always associated with an abnormal respiratory noise, especially if the horse is not exercised fast enough. These might include ethmoid hematoma, mild arytenoid chondritis, some tumors, pharyngeal cysts and some epiglottic entrapments.[12] While dressage horses and showjumpers have competed successfully with significant laryngeal hemiplegia or other respiratory impediments, abnormal respiratory noise and reduced airflow may still affect performance and be of concern to rider and spectator. Endoscopy is recommended or indicated in the following situations:

- All race horses should ideally be endoscoped before and after strenuous exercise.
- Equine athletes unable or unsuitable to be exercised strenuously. This includes yearlings at auction sales.
- Elite sport horses.
- When abnormalities in the clinical evaluation are detected, e.g. abnormal respiratory noise at exercise, nasal discharge or cough, sinus swelling.
- Purchaser's request.
- When purchase price demands a more comprehensive examination.[44]

A complete endoscopic examination of the upper respiratory tract and trachea is seldom performed. A methodical

examination of both nasal passages, ethmoid turbinate areas, openings of the guttural pouches, pharynx, larynx and cervical trachea is usually sufficient. The examiner is looking for structural and functional abnormalities that would impair athletic performance, evidence of previous surgery or the origin of any observed nasal discharge or reason for cough.[44] It is important to document only that which was inspected and to record findings accurately. Use of a checklist is best.[44]

The limitations of the endoscopic examination should be made clear to the purchaser. A resting endoscopic examination is a *static* examination. There is therefore an inherent deficiency in the procedure to detect functional abnormalities that only become a problem when the horse is exercising at maximum intensity and when respiratory airflow is at a peak. Many of these abnormalities result in an abnormal respiratory noise at exercise. This is one reason why strenuous exercise is mandatory when examining the equine athlete for purchase. In the event an abnormal respiratory noise is heard at exercise but the resting examination is normal, videoendoscopy during a treadmill exercise test is recommended.[45] Conditions that may only be apparent during maximal exercise could include dynamic collapse of the arytenoid cartilage and vocal fold, intermittent dorsal displacement of the soft palate, dynamic collapse of the pharyngeal wall, intermittent epiglottal entrapment, dynamic medial collapse of the aryepiglottic folds, exercise-induced pulmonary hemorrhage and dynamic rostral displacement of the palatopharyngeal arch.

Difficulties arise when interpretation of laryngeal function is required and only a resting examination can be performed. Typically this occurs when scoping yearling Thoroughbred and Standardbred race horses at sales. Laryngeal movement can be variable and a number of grading systems have been used to evaluate arytenoid abductor function.[44,46–48] Regardless of the system used most veterinarians agree that horses that cannot achieve full arytenoid abduction after swallowing or nasal occlusion are at a greater risk for reduced athletic performance due to dynamic collapse of the arytenoid cartilage and vocal fold. Indeed, when indices of racing performance were evaluated in Thoroughbred race horses that had endoscopic evaluations at sale as yearlings were reviewed, horses that could not achieve full arytenoid abduction (grade 3 or 4) had significantly inferior racing performance compared with those that could.[46] Unfortunately, there are 'gray zones' and laryngeal abductor function does not always fit into precise categories. Probably the best system is that used at auction sales in the United Kingdom where yearlings are trained to canter at the lunge. Evidence of a characteristic inspiratory noise at exercise *and* endoscopic evidence of impaired arytenoid abductor function is required for the horse to fail the conditions of sale and be returned to the vendor. An arbitration panel settles disputes. This system has been shown to be robust and accurate.[47] Unfortunately, the limitations of a static examination mean that some animals with clinically significant respiratory impairment at exercise will be missed. In addition, some animals with subclinical laryngeal neuropathy will progress to become clinically affected animals. Recent evidence suggests that progression of laryngeal neuropathy in non-affected or minimally affected horses may be as high as 15%. Very importantly, the progression may be rapid and can occur within weeks of purchase.[48]

Examination of the Thoroughbred race horse

Prepurchase examination of the Thoroughbred race horse includes examination of yearlings at public auction sales, examination of young race horses (2 and 3 years of age) and examination of older proven race horses. The aim of the prepurchase examination of yearlings is to identify athletic individuals who have optimal conformation and no evidence of existing cardiac abnormalities, orthopedic disease (primarily osteochondrosis), or upper respiratory tract abnormalities. The aim of the prepurchase examination of young or proven race horses is similar but the emphasis is on identification of previous injuries or 'wear and tear' that will limit future successful performance. Apart from yearlings it is always best to perform a full five-stage evaluation as described earlier.

Prepurchase examination of yearlings at public auction sales

It is very important that the examining veterinarian be familiar with the conditions of sale for each sales company. Horses are auctioned with no warranty for use or soundness other than certain conditions listed in the conditions of sale.[49] The veterinarian must be familiar with certain diseases/disorders that if not declared prior to auction and identified after sale (within a specified time) may render the purchased horse returnable. These usually pertain to vices (windsucker), ataxia (wobbler), cryptorchidism, pregnancy and laryngeal hemiplegia. The process for arbitration of purchases in dispute is also in the conditions of sale. Drug testing is available at some sales. Conditions relating to endoscopic and radiographic examinations need to be carefully understood. These are printed in the sales catalog.

A description of the horse is not performed but the lot number (hip sticker) and presented animal should always be matched to the catalog description to ensure the correct horse is examined. It is preferable to work only for buyers with whom you have a relationship and whose requirements you understand. A limited examination is more commonly performed and accepted by buyers.[7] This is because the sales venue is a difficult environment to appraise animals carefully. Young excited horses with limited education can be difficult to examine. The combination of noisy surroundings, many other horses, poor lighting and crowds of people mean a complete examination is not possible. The examination generally includes:

- visual examination of the head, neck, body, external genitalia, fore- and hindlimbs
- palpation of the head, neck, body, fore- and hindlimbs and visible abnormality elsewhere on the body that is palpable; inspection of both eyes with a penlight

- auscultation of the heart (on both sides) and on some occasions the chest
- examination of conformation, limb movements during walking and coordination.

The veterinarian should make sure to:

- Carefully inspect the feet and hoof pastern axis. 'Long toe–low heel', weak or collapsed heels, poor-quality hoof, contracted feet, clubfeet, markedly mismatched feet and overly small feet are undesirable and predispose to lameness. Horses with varus deformities of any joint seldom stay sound. Moderate to markedly 'offset knees', 'back of the knee', 'sickle hocks' or overly straight hocks may predispose to lameness and are undesirable.
- Look for enlarged pasterns, sesamoid bones and flexor tendons.
- Examine all joints for effusion. Osteochondrosis is suspected until proven otherwise.[50] Some mild effusion within carpal joints appears normal in yearlings and a variable fat pad in the stifle may mimic stifle effusion.
- Horses that either cannot or have difficulty fully abducting both arytenoid cartilages are at high risk of performing poorly. Epiglottal entrapment, persistent dorsal displacement of the soft palate, arytenoid cartilage enlargement (chondritis), rostral displacement of the soft palate, subepiglottic cyst, cleft palate and marked hypoplasia of the epiglottis are all unacceptable conditions of the upper respiratory tract which will impair athletic performance. Conditions of sale at each sales venue will determine whether an animal is returnable or not.
- Radiological lesions, which indicate a risk for future performance limitations, are listed in Table 62.2.

Examination of the mature horse

The examination procedure for prepurchase examinations of Thoroughbred race horses is similar to other athletes. However, certain injuries in Thoroughbred race horses result in reduced performance or may even prohibit successful athletic performance and are not tolerated as they might be in other equine athletes. Chronic foot problems, chronic degenerative joint disease, subchondral bone injury, sesamoiditis, tendon/ligamentous injury and dynamic collapse of the arytenoid cartilages are conditions that have a high risk of reducing athletic performance. Chronic pulmonary hemorrhage and small airways disease are also responsible for poor performance. A recent review highlights foot, fetlock, carpal and suspensory ligament injuries as the most common orthopedic injury sites resulting in lameness in Throughbred race horses.[51,52] Therefore, the veterinarian should focus on these areas during the examination procedure.

A buyer's statement should be completed and the veterinarian should discuss in detail with the potential purchaser what extra examinations are to be performed, e.g. endoscopy, radiography, ultrasonography, blood/urine tests. It should also be clear what the expectations for future training and racing will be. The vendor's statement should be completed and a full history of recent training and racing attained.

A full five-stage examination is performed and endoscopy of the upper respiratory tract and trachea (preferably before and after exercise) and radiographs of the carpi, fetlocks and front feet are usually conducted. Other areas are radiographed if the clinical examination determines this would be beneficial. For stage 3 of the examination the horse should be sufficiently warmed up and then galloped hard with the last 600 m in 39–40 seconds. The veterinarian should position him/herself so that any abnormal respiratory noise can be heard. The jockey should be asked to pull the horse up as quickly as is safe and canter back to the examiner. This is often the time when noises typical of dorsal displacement of the soft palate can be heard and as the horse slows and stops such noises can disappear. The trachea is auscultated for fluid and the chest is auscultated while the veterinarian listens carefully for disturbances in heart rhythm and heart sounds. The nostrils are checked for discharge (blood/mucopus) and the mouth and lips checked for blood. The horse should have endoscopy performed as soon as possible and arytenoid function assessed and any pharyngeal or tracheal discharges identified and noted. After the horse has been hosed down an assessment is made of recovery with heart, respiratory rates and chest sounds noted at approximately 15 min intervals. The lower limbs are checked for interference injuries. The veterinarian should make sure of the following points:

- Evaluate conformation as for yearlings but pay close attention to the feet. Mild conformational flaws especially in the well-performed horse may have little significance. Conformational abnormalities play an important role in career longevity and they should be viewed with this in mind. It is interesting to note that a study of conformation of elite young Thoroughbred race horses and sires showed that in the forelimbs most horses had mildly offset and valgus 'knees', were slightly 'over the knee', had slightly broken back hoof– pastern axes but had little deviation from the fetlock to the ground ('toe in or toe out'). In the hindlimbs being slightly 'cow hocked' and being 'toe out' was considered normal.[18]
- Acquired hoof deformities/injuries such as collapsed heels, shear heels, wry hooves, bruising and corns, medial-lateral hoof imbalance, broken hoof–pastern axes, mismatched feet, poor shoeing and evidence of previous episodes of laminitis should be noted.
- Check for muscle asymmetry, especially differences in the gluteal musculature. Differences in height of the tuber sacrale if minor and unassociated with pain are often insignificant. Palpate the croup and back checking for pain and muscle spasm. 'Cycle the back' by inducing flexion and extension and assess lateral flexibility using a blunt probe that is run along the epaxial muscles on either side.[53]
- Look carefully for evidence of joint disease, pain/enlargement of the proximal sesamoid bones and ligamentous/tendinous thickening and sensitivity on palpation. Correlate findings with manipulative tests, radiographs and ultrasonographic examinations.
- Carefully record all findings and give opinions on current or future effects on performance in terms of an assessment of risk.

Examination of the Standardbred race horse

When performing prepurchase examination on Standardbred race horses, the use of the full five-stage examination is strongly advised. A number of purchasers request less extensive examinations and while this is appropriate, stages one and two should be considered a minimum examination as this allows for a detailed clinical examination and observation in motion. Beware of examination requests such as 'heart and wind only' or 'legs and heart' as use of these tailormade types of examination allow for omission of important observations.

Clinical examination

Conformation

Limb conformational defects of particular importance to Standardbreds tend to center on the 'knees'. Pacers with 'toe out' conformation (viewed cranially/caudally when walking) may be at risk for interference due to knee strike at speed. Bench or offset knees are often associated with 'toe out' conformation and can also exacerbate knee strike. Horses with long pasterns and long toes/low heels are at risk for tendon injuries.

Skin conditions

Scars or excoriations on the side of the neck can be evidence of steering difficulties from the use of steering correction devices such as a pricker or boring pole.

Common injuries

Careful examination of the forelimb suspensory ligaments is advised as subtle evidence of previous desmitis may only show as a thickening of the width of the ligament. Non-weight-bearing palpation of the palmar flexor tendons in the pastern area may indicate previous 'low bows' (tendinitis) in a similar fashion to suspensory desmitis, as an increase in the width of the palmar flexor tendons. Any visible medial effusion of the intercarpal joint space warrants a suggestion for carpal radiography. Curbs (thickening at the plantar aspect of the tarsus) are common but are rarely of clinical concern. Partial (uni-cortical) or small midsagittal fractures of the dorsal first phalanx are common and deep palpation of the proximal dorsal cortex of P1 should be performed in all four limbs, particularly the hindlimbs. Any subtle visible bony thickening of proximo-dorsal P1 should warrant pastern radiographs. In such cases often only the lateral to medial projection shows evidence of periosteal disruption and new bone deposition on the proximal dorsal first phalanx indicative of this fracture. Hoof imbalances become more important in older Standardbreds; imbalance in younger horses is correctable and should be advised. Any effusion of the tibiotarsal joint would warrant radiographs to look for OCD, most commonly seen on the distal aspect of the distal intermediate ridge of the tibia. The interpretation of intermediate ridge OCD lesions if found is difficult as there is controversy about their clinical significance especially with respect to performance. In young, unproven race horses with intermediate ridge OCD lesions any tibiotarsal effusion may be significant to future performance while in older proven race horses with intermediate ridge OCD lesions many can have adequate 'to date' racing performances even in the face of moderate joint effusion. In a number of horses where routine hock radiographs are taken, intermediate ridge OCD lesions can show up as incidental findings.

Stage 3 exercise

Horses should be observed working under race condition where possible (e.g. fast working over 2000 m, coming home the last 400 m in 28 seconds). Working near race conditions allows for observation of respiratory noise while working, listening for knee strike and observing recovery rate post exercise. At the end of the exercise phase is an ideal time for upper respiratory endoscopic examination if it is to be performed. Observation of laryngeal function shortly after work allows evaluation of the larynx while the horse still has an elevated respiratory effort during recovery and allows checking of the trachea for blood and mucopurulent discharge, often only seen post exercise.

Ancillary tests

Electrocardiographic examination

An ECG examination as part of the prepurchase is commonly requested by Australian buyers primarily for a 'heart score' determination. Apart from the numerical heart score and assessment of T wave changes (so-called 'heart strain') the ECG does not add greatly to the prepurchase examination and its use is based mainly on purchaser's request.

Upper airway endoscopic examination

In the absence of someone reliable (bloodstock agent or prominent driver) having driven the Standardbred race horse and consequently listened to the horse's respiratory noise under raceday conditions first hand, endoscopy is normally recommended as part of the prepurchase examination. Whilst laryngeal dysfunction is not as common in Standardbreds as Thoroughbreds, endoscopic examination is a reliable screening procedure for such problems. As mentioned previously, if a full five-stage examination is performed valuable information can be gained from examination of the tracheal lumen for blood and mucopus after exercise ('hot scoping'). Luminal fluid may not be evident when examined without exercise ('cold scoping'). If a 'cold' endoscopic examination is performed (e.g. associated with a partial stages 1 and 2 examination) this should be stated in the report.

Radiography

The majority of Australasian Standardbreds examined prior to purchase are young, 'up and coming' horses with little hard racing experience. As such it is unusual to find many radiographic abnormalities indicative of chronic 'wear and tear'. For this reason recommendations on radiography are generally based on purchaser request and the personal preference of the examining veterinarian. It is common to find the presence of fetlock bony fragments (ununited plantar eminence of the proximal phalanx, and type I OCD fragments of the palmar/plantar aspect of the first phalanx),[30] especially when routine hindlimb fetlock radiographs are taken. As with distal intermediate ridge OCD the interpretation of such fetlock fragments with respect to future performance is very difficult. The majority of the fetlock fragments are incidental findings and do not appear to be of clinical significance. Interestingly, routine multiple joint radiographs are normally associated with the prepurchase examination of more expensive and often well-proven Standardbred race horses. The interpretation of any such fetlock fragments must take into account that these horses have been performing well in the upper levels of competition and that it is most likely that these fragments have been present during their most recent performances and as such their clinical significance may be questionable. As with all radiographic findings their presence needs to be stated in the radiology report.

Examination of the proven race horse

The prepurchase examination of the older proven race horse follows the principles outlined above. In line with other breeds, the examination of proven animals compared with unproven ones requires special attention to signs and consequences of 'wear and tear'.

Hoof balance and shoeing abnormalities, e.g. long toes/low heels, should be looked for, as the chronicity of these is more important to the older race horse. Deep digital palpation of the proximal row of carpal bones should be carried out to check for any withdrawal, which can indicate carpal disease and warrants radiography, especially skyline views. Another area deserving of careful deep digital palpation is the origin of the forelimb suspensory ligaments. Withdrawal to deep palpation in this area can be indicative of chronic suspensory origin desmitis. Especially scrutinize this area if there are any differences to palpation between the two front legs. Most race horses are worked (stage 3) with knee boots on and it is worth examining these at the end of the exercise phase for evidence of brushing or knee strike.

In proven race horses it is more common to undertake extensive radiographic examinations looking for signs of disease; knees and front fetlocks are normally requested.

Examination at yearling sales

Compared with Thoroughbreds, Standardbred yearlings tend to be less well handled and this limits the types of examinations possible at yearling sales. An abridged examination mostly centered on a basic clinical examination and determination of conformational defects is carried out. Base narrow conformation and toe out forelimb conformation on walking may predispose to knee strike. Bench/offset knees and 'back at the knee' are also looked upon as important knee conformational defects. Joint effusion (especially tibiotarsal) may indicate OCD. As is standard at yearling sales, endoscopy is often conducted and advised.

Examination of the sport horse prior to purchase

This section focuses on specific aspects pertaining to the examination of event horses, showjumpers and dressage horses prior to purchase. The majority of showjumpers and dressage horses competing internationally are Warmbloods, whereas most event horses competing at that level are Thoroughbreds, frequently ex-race horses. Because these two types of horses are quite different and present with their own unique conformational and soundness issues they will be discussed separately.

Examination of the three-day event horse prior to purchase

Three-day eventing combines the disciplines of dressage, showjumping and cross-country, including a steeplechase and roads and tracks phase. Therefore, the event horse must primarily be a bold and clever jumper, with plenty of scope and speed. It is because of this that Thoroughbred horses tend to excel. However, in today's competitive environment speed and braveness alone are no longer enough to succeed at the top level, and the horse must also have good basic gaits and a temperament suitable for dressage training, combined with a careful showjumping technique. Because the horses compete on extremely variable terrain and footing, three-day eventing places huge strains on the musculoskeletal system and horses with poor conformation are especially at risk of injury. The majority of injuries sustained by top-level event horses are repetitive strain injuries to soft tissues and joints, particularly to the superficial digital flexor tendons, and injuries resulting from direct trauma during the cross-country phase. Exertional rhabdomyolysis ('tying up') is also a common cause of failure to complete the event.

When examining a potential event horse prior to purchase it is important to obtain a thorough history pertaining to the horse's athletic endeavors up to the point of sale. Most horses being purchased for eventing are Thoroughbred horses that have finished their racing careers, and many race horses are retired from racing due to injury. Therefore, if possible the exact reason for the horse's retirement from the track should be ascertained. Although some race horses are just too slow or are getting too old to continue racing competitively, many suffer from some kind of disability that has reduced their racing performance and may also affect their ability to become a top-class

event horse. Superficial digital flexor tendinitis, dorsal carpal bone chip fractures and dorsoproximal first phalanx chip fractures are all common causes of lameness in race horses that may result in their retirement from the racetrack. Similarly, a poor performer on the racetrack may suffer from respiratory problems such as left-sided laryngeal hemiplegia ('roaring') or exercise-induced pulmonary hemorrhage ('bleeding'). The owner's statement should include questions that specifically address these problems; i.e. whether the horse has ever been lame, whether it has ever bled from the nostrils and whether it has ever made an abnormal respiratory noise during exercise. If the horse has already competed as an event horse it is pertinent to determine how many events it has actually completed at what level, and the reasons for not completing events, such as being withdrawn from a competition due to unsoundness or exertional rhabdomyolysis.

After establishing a thorough history, a comprehensive clinical examination should be performed at rest with particular attention to conformation. Horses with poor foot conformation, very upright hoof–pastern axes, and horses that are back at the knees typically do not stand up well to top-level competition. In our experience Thoroughbred horses often have large front feet with flat soles, long toes and underrun heels. The long-toe, low-heel syndrome in particular appears to predispose these horses to chronic bruising and caudal heel pain when jumping large fences on hard ground, and foot-related lameness is one of the most common causes of event horses failing to complete the season. Synovial effusion, especially in the carpi and front fetlock joints, and a decreased range of joint motion with signs of resistance or pain on flexion should alert the veterinarian to the possibility of degenerative joint disease subsequent to injury. The digital flexor tendons and suspensory ligaments should be carefully palpated for size and evidence of inflammation or pain, and an ultrasonographic examination of the tendons should be performed if there is any suspicion of previous injury. Following completion of the examination at rest the horse should be assessed while walking and trotting in hand on a hard, level surface (preferably concrete or asphalt), both before and immediately after flexion tests of the distal limbs and carpi in the front limbs, and full limb (spavin) tests in the hindlimbs. The horse should be ridden at a trot and canter on both reins in order to assess its paces and temperament, and if facilities permit the horse should be galloped a sufficient distance for the veterinarian to observe any abnormal respiratory noise and to evaluate heart rate, sound and rhythm following exercise. An endoscopic examination of the upper respiratory tract is usually performed immediately post-exercise to assess laryngeal function and examine for evidence of exercise-induced pulmonary hemorrhage. Once cooled off from the gallop the horse should be lunged at the trot on a 10-meter circle in both directions, preferably on a hard, level surface, to examine for low-grade lameness induced by exercise.

Given that many Thoroughbred horses are broken in and raced at a young age, most purchasers request radiographs to be taken of the most commonly injured areas, including the front feet, pastern and fetlock joints, the carpi and the hocks. Other areas may be subject to radiography if a problem is determined to exist based on the clinical examination, such as a painful splint bone exostosis or effusion in a hind fetlock joint. Commonly observed radiographic changes in Thoroughbred ex-race horses being examined prior to purchase for eventing include evidence of pedal osteitis and chronic sesamoiditis, dorsoproximal first phalanx chip fractures, dorsal carpal osteophyte formation and/or chip fractures, and osteophyte formation on the dorsoproximal aspect of the third metatarsus at the level of the tarso-metatarsal joint space. Because radiographic evidence of pedal osteitis and sesamoiditis tends to persist throughout the horse's life we feel that they are generally not clinically significant provided that there is no evidence of ongoing pain or inflammation of these structures at the time of the examination. Traumatic chip fractures of the first phalanx and carpus usually result in the development of degenerative joint disease with ongoing exercise unless they are removed arthroscopically soon after forming, therefore they must always be regarded with caution in horses expected to go on to athletic careers. Osteophyte formation on the dorsoproximal aspect of the third metatarsal bone seems to occur frequently in young Thoroughbred horses and can be present at a relatively early age. They are often bilateral and radiographically appear smooth-edged and of uniform density. In our experience, provided that the tarso-metatarsal joint space is uncompromised and well defined, and the horse exhibits no signs of lameness or abnormal response to hindlimb flexion tests, this specific radiographic change has not become clinically significant when the horses go on to become event horses.

Examination of dressage horses and showjumpers prior to purchase

A good dressage horse must possess natural balance, elegance and athleticism, as well as power and a trainable mind. The majority of dressage horses competing internationally are Warmbloods with a high proportion of Thoroughbred blood, combining the athleticism of the Thoroughbred with the trainability of the Warmblood. Through training, the horse's center of gravity is shifted caudally by increasing the degree of flexion and loading of the hindlimbs, thereby freeing the forehand to create a more airborne, uphill type of movement. As well as the general increased loading of the hindlimbs, particularly the hock joints, the lateral movements required by the sport create a unique strain on the horse's back and additional twisting stress on the appendicular joints. Because the training of dressage horses predominantly involves repetitive exercises designed to maintain suppleness and increase muscle strength, these horses rarely suffer from acute traumatic injuries but more commonly from cumulative wear and tear lesions. This is exacerbated by the fact that it takes at least 5 years for a horse to be trained to Grand Prix level and most dressage horses continue to compete to an advanced age, often as old as 20 years.

As with top-level dressage horses, the majority of successful showjumpers are Warmbloods, usually large, well-balanced, athletic individuals. The showjumper must be strong enough to jump large fences with precision and care,

both from a virtual standstill and at speed, and supple enough to make sharp turns without losing impulsion. The stresses placed on the musculoskeletal system of elite showjumpers are huge, especially on the hocks and hindlimb suspensory apparatus during take-off and on the front feet and front limb suspensory apparatus at landing. Therefore, when examining dressage horses and showjumpers prior to purchase the veterinarian should pay specific attention to the front feet, pasterns, hocks, and the front and hind suspensory ligaments. The horse should be evaluated at rest, trotting freely in hand on a hard surface, and while ridden and lunged in both directions on a hard as well as a soft surface. It is important to remember when examining a dressage horse prior to purchase that a good rider is able to correct and hide a mild gait irregularity or lameness. Therefore the veterinarian should not just focus on the limbs but also look for changes such as increased resistance to bending in either direction or reluctance to accept the bit. It is useful to lunge the horse after it has been ridden to look for any differences in the gait that may be attributable to the rider.

Foot conformation is extremely important, as many Warmbloods have small feet relative to their bodyweight. Slight differences in the size and shape of the two front feet are common and not necessarily abnormal. However, marked asymmetry of the hooves is often an acquired condition as a consequence of a previous lameness (chronic under-loading of one foot relative to the other). The horse should be lunged or ridden in small circles on hard ground in both directions to exacerbate any low-grade, foot-related lameness. High suspensory (origin of suspensory) disease in the front limbs is very common both in dressage horses and in showjumpers. It results in a mild lameness that is typically observed most easily when the horse is circling in deep footing with the affected limb on the outside of the circle. Although most cases of front limb high suspensory disease resolve over time with the horse eventually returning to its previous level of competition, they can be very slow to heal. Hindlimb proximal suspensory ligament disease is a serious condition that frequently recurs with work. It tends to be associated with a straight hock conformation and is exacerbated by collection. Lesions of the suspensory body and branches are also common and are often the cause of retirement for showjumpers. Therefore it is important to carefully palpate the entire suspensory ligament for evidence of swelling, pain or inflammation. Digital flexor tendon sheath enlargement ('windgalls') that is bilaterally symmetrical is usually benign. However, extreme unilateral distension is the result of chronic inflammation and is often associated with synovial proliferation and development of adhesions that may cause lameness. The thoracolumbar region should be carefully palpated because the back is prone to low-grade muscular injury and bony abnormalities such as impingement of the dorsal spinous processes that can cause recurrent discomfort. However, asymmetry of the tuber sacrale ('hunter's bumps') is common in showjumpers and is usually considered insignificant provided there is no evidence of lameness, loss of performance or palpable pain in the lumbosacral area.

Because the respiratory requirements for dressage horses and showjumpers are modest compared with those of three-day event horses endoscopy may or may not be requested by the purchaser. Laryngeal hemiplegia is not usually performance limiting, but the noise produced may be disturbing to the purchaser especially when the horse's head and neck are flexed. Most purchasers do request radiographs to be taken of the areas most commonly associated with decreased performance, including the front feet, pastern and fetlock joints, and the hocks.

Radiographs of the front feet and navicular bones do not correlate well with the presence of clinical signs and should be interpreted with caution, but certain radiographic lesions are a cause for concern. For example, in the dorsoproximal-palmarodistal oblique (upright pedal) view, up to seven conical nutrient foramina along the distal border of the navicular bone are considered normal. However, multiple enlarged or misshapen foramina and large central radiolucent areas (cysts) are almost always abnormal. Although many horses with mild navicular pain that are managed appropriately are acceptable for pleasure riding and lower levels of competition, the tendency to adopt a shortened stride is detrimental in a dressage horse and the pain associated with landing makes this condition incompatible with jumping big jumps. Ossification of the collateral cartilages ('sidebones') is frequently seen, especially in larger, heavier horses, but is rarely a source of lameness or related to any clinically significant foot abnormalities. Both front and hind proximal interphalangeal (pastern) joints often show slight bony modeling of the dorsoproximal articular margin of the second phalanx. Although these early radiographic changes are usually of no clinical significance, they can occasionally progress to proximal interphalangeal degenerative joint disease ('ringbone'), especially in horses with short, upright pasterns. Small, smooth-edged radio-opaque bodies are often found at the dorsoproximal aspect of the first and third phalanges in Warmbloods. They are typically not considered clinically significant provided the joints are clinically normal and there is no radiographic evidence of degenerative joint disease. Similarly, small smooth-edged osteophytes on the dorsoproximal aspect of the third metatarsal bone are frequently present without any compromise in performance. However, because degenerative joint disease of the distal intertarsal and tarso-metatarsal joints is a common cause of lameness in dressage horses and showjumpers, any associated radiographic irregularity of the joint spaces and/or positive clinical response to hindlimb flexion tests should be viewed with extreme caution in a future performance horse.

Examination of the Western performance horse prior to purchase

Western performance horses perform in a wide variety of disciplines, each of which places unique demands on the horse.

Disciplines to be discussed include: reining and cutting, roping, barrel racing, and Western pleasure. Close attention to conformation should be made in all Western performance horse evaluations. Size of the hoof in relationship to body size, hoof balance, and hoof/pastern axis should all be closely evaluated. Abnormalities in these factors may predispose the horse to navicular syndrome and to degenerative joint disease of the distal limb joints.[54] Upright rear limb conformation may predispose the horse to degenerative joint disease of the distal limbs and to bone spavin. The distal forelimbs should be evaluated closely for neurectomy scars, especially in middle-aged horses, because of the high incidence of heel pain in these horses.[55]

The genetic background of horses of the Quarter Horse breed should be scrutinized for presence of the hyperkalemic periodic paralysis (HYPP) gene. The American Quarter Horse Association registration certificate will designate if the horse has HYPP parentage or other genetic defects such as parrot mouth or cryptorchidism.[56]

Reining and cutting horses begin rigorous training as 2-year-olds to prepare for futurity competitions that begin during their 3-year-old season. These horses make rapid starts and stops, and abrupt changes in direction that will stress many of their musculoskeletal structures. Reining and cutting horses usually have a short and slight body style that allows for maximum agility. Areas of concern include: distal limbs (navicular region, distal interphalangeal and proximal interphalangeal joints), tarsal region, and stifles. Developmental orthopedic diseases such as osteochondrosis and flexural deformity must also be ruled out in young horses. Radiographic evaluations of the distal forelimbs, tarsi and stifles are commonly a part of the prepurchase examination.[57]

Roping horses need to make repeated short bursts of rapid acceleration and rapid stops. They have a more muscled and substantial body style compared with reining and cutting horses. Areas of concern on the prepurchase examination include the distal forelimbs (particularly the navicular region and the distal joints), and the tarsi. Rear limb tendinitis and suspensory desmitis commonly occur in this group of horses and these structures bear close evaluation.[57]

Barrel racing horses, and horses that compete in Western performance games (gymkhana), place a premium on short bursts of speed and the ability to make short-radius, rapid turns. All the joints from the carpi and tarsi distal need close evaluation in these horses. Degenerative joint disease, tendinitis and desmitis occur with high frequency in these athletes.

Western pleasure horses begin competition as 3-year-olds so are in training at a young age. These horses work at very slow walk, trot and canter gaits in the ring. A premium is placed on a quiet disposition. Overt signs of displeasure by the horse such as tail wringing or excessive head and mouth movements are counted against the horse during competition. Areas of concern during prepurchase examination include the distal forelimbs, tarsi and back. Ring work at slow gaits predisposes some horses in this discipline to lower back pain. When possible, Western pleasure horses should be evaluated under saddle to determine their responses during work.

Appendix[7]

Buyer's statement

I, ... (Buyer/Buyer's Agent),

request that the horse..... undergo a pre-purchase examination for use as a

.....

This is to be undertaken by

Dr..... (Veterinarian)

..... (Practice)

The recipient of this report is deemed to be aware that if some stages of the standard procedure recommended by the Equine Branch of the New Zealand Veterinary Association are not carried out, any information or opinion contained in this report is based on partial examination only. Some clinical signs of disease, injury or abnormality that may have manifested themselves in the full five stage examination may not be apparent in the restricted examination.

Where this examination and report are requested for the purpose of a business they are deemed to have been carried out upon the basis that the examining veterinarian's liability, howsoever arising, shall be no greater than a sum equivalent to 100 times the fee charged for the provision of this report. In addition, liability for consequential losses of any nature is also excluded.

This contract is governed by New Zealand law.

The Buyer/Buyer's Agent irrevocably agrees that the Courts of New Zealand will have exclusive jurisdiction to hear and determine all disputes under or in connection with this contract. The Buyer/Buyer's Agent further acknowledges that New Zealand is the forum conveniens for the hearing and determination for all disputes in connection with this contract.

Ownership of X-rays: The Buyer/Buyer's Agent acknowledges that any radiographs taken in the course of this examination are the property of the veterinary practice listed herein, but it is further acknowledged by the practice that copies of the radiographs will be supplied at the Buyer/Buyer's Agent's request and expense.

Reliance upon this report will constitute an acceptance of the limitations of liability referred to above.

In addition, the nature and extent of this report has been determined by particular request. In the circumstances the examining veterinarian disclaims any liability whatsoever to any party other than the party directly responsible for requesting and paying for the services rendered.

Please indicate with a tick which aspects of the examination for purchase you do/do not wish to have carried out.

(a) Clinical Examination (which is carried out in five stages)

Indicate with a tick please		YES	NO
Stage 1	Preliminary	☐	☐
Stage 2	During walking, trotting, turning and backing	☐	☐
Stage 3	During and immediately after strenuous exercise	☐	☐
Stage 4	During period after exercise	☐	☐
Stage 5	During walking, trotting, turning and backing	☐	☐

The Clinical examination will be carried out substantially in accordance with the standard procedure recommended by the Equine Branch of the NZ Veterinary Association (1997).

(b) Ancillary Examinations

Indicate with a tick please	YES	NO
Endoscopy	☐	☐
Radiography (tick areas to be radiographed):-	☐	☐

front feet	( )	front fetlocks	( )	hind feet	( )
carpi (knees)	( )	tarsi (hocks)	( )	hind fetlocks	( )

Electrocardiography	☐	☐
Reproductive Examination	☐	☐

Other ancillary examinations (please specify)……
……..
……..
I understand the horse's usual veterinary attendant is……
(Veterinarian/Veterinarian's Practice)

Terms of payment. I understand that I will be responsible for payment for the examinations requested above.

Please note:- The certifying veterinarian takes no responsibility for, nor warrants the accuracy of, any information provided in the owner's statement including that given relating to the non-administration of drugs, freedom from vices, existing performance or suitability for intended use.

CHAPTER 63

International movement of athletic horses – quarantine and regulatory controls

Patricia M. Ellis and Keith L. Watkins

The elite athletic horse of today is a global commodity. During the 1990s, the volume of international movement of horses by air transport grew dramatically. Horses now travel for a diverse range of events including racing, dressage, eventing, show jumping, carriage driving, and endurance riding in an ever increasing number of countries. Traditionally most international events involving imported horses have been located in Europe and North America. New transport patterns are emerging with the advent of new competition venues in Eastern Europe, South America, the Arabian Peninsula, Asia, and Africa[1] and the development of complex itineraries by horses visiting multiple countries to compete in races held within a relatively short period.[2]

The modern equine athlete can move vast distances rapidly and complete journeys well within the incubation period of most infectious diseases. History has shown that without adequate safeguards this can lead to explosive outbreaks of disease.[3,4] The increased volume of horse movement in a changing world trading environment poses significant quarantine challenges to regulatory authorities, who must exclude foreign diseases from their countries without undue restriction to international trade.[1,5]

Governments and national authorities conducting international competitions have understandable concerns that:

- horses imported for a competition could bring in disease to the local population
- disease could occur in foreign horses due to exposure to a disease in the local horses
- a disease outbreak could result in cancellation of an important international event, especially if all horses (visiting and local) are held within the same competition venue
- prompt departure of foreign horses to their country of usual residency or next destination could be compromised by:
  - an outbreak of disease in the local population or in visiting horses
  - quarantine standards and management that do not meet the expectations of the horse's connections, the country of origin or country of next destination
  - inability to meet requirements for import to next destination
- horses returning from overseas could introduce disease into their country of normal residency.

Equine veterinarians in the private sector play an important role in the preparation of horses for export and in supervision of the health and welfare of horses during transport to and temporary residency in foreign countries. To avoid problems and unnecessary delays, they need to have a sound understanding of quarantine and regulatory requirements which allow horses to move safely between destinations.[6–8]

International spread of equine diseases

Economic, biological, political, and ecological factors

A variety of factors have the potential to affect the global distribution and occurrence of equine diseases including:[9]

- international trade in horses and horse semen, the single most important factor
- changes in international trading policy as a result of multinational trade agreements
- emergence of previously undescribed pathogens, such as contagious equine metritis and Hendra virus
- mutation of recognized pathogens and emergence of new biotypes
- climate-related phenomena such as global warming and the El Niño–Southern oscillation

- migration of reservoir and amplifying hosts such as birds and bats
- wind-blown carriage of insect vectors
- inadvertent introduction of exotic vectors such as ticks and mosquitos
- contamination or incomplete inactivation of vaccines
- deliberate, illegal introduction of a foreign disease, e.g. bioterrorism.

Changes in agricultural practices can indirectly influence the distribution of arboviruses by favoring the expansion of vector habitats.[10] For example, increases in irrigated rice production and expansion of the pig breeding industry are thought to have contributed to expansion of the geographic range of Japanese encephalitis in the Asian region.

Disease and horse-related factors

Potential for disease spread by international movement is influenced by the epidemiology of the disease, the intended use of horses, and whether horses are imported on a temporary or permanent basis.

The equine diseases most likely to be transferred by uncontrolled international movement are those characterized by an asymptomatic carrier state (e.g. equine infectious anemia, piroplasmosis, contagious equine metritis, equine viral arteritis, and dourine). The potential for their transfer is obviously greater if horses are imported on a permanent basis.[9] The last three diseases are transmitted by the venereal route.

Horses imported on a temporary basis for competition or performance pose little risk of introducing diseases spread by the venereal route if they are prohibited from breeding during temporary residency. Likewise, if the arthropod vectors of a disease are not present in a country, temporary import of horses that would be otherwise ineligible (e.g. horses testing positive for piroplasmosis) under controlled conditions presents a much lower risk than horses imported on a permanent basis and released into the national herd.[11] In the latter case potential for iatrogenic spread by contaminated needles would be possible.

Horses imported to a country on a permanent basis pose a far greater threat of introducing disease than horses imported for a short-term stay under appropriate conditions of management. Competition horses imported for major races and events are registered animals, travel on passports, and have a known residency, vaccination, and disease-testing history. They are kept under constant veterinary supervision before, during and after the event. During their brief residence, visiting horses have only limited exposure to the local horse population and are not used for breeding.[1,11]

Country factors

Evaluation of country factors, such as veterinary services, horse industry structure, disease control legislation, laboratory testing capacity, surveillance programs, zoning and border controls, are important inputs for assessing the likelihood of hazards being present in the horse population of an exporting country. Reliable and transparent information about the health status of a country's horses is critical for safe international movement.[12]

Impact of exotic disease outbreaks

An exotic disease outbreak can have a profound effect on the horse industry in an affected country and cause serious economic loss and disruption to normal activity.

Horses now travel from one hemisphere to another by air transport and complete their journeys within the incubation period of most major diseases. Spread of equine influenza, in particular, has increased since the introduction of air transport. In the past 20 years, the introduction of imported horses to susceptible indigenous populations has been responsible for explosive outbreaks of equine influenza in South Africa (1986), India (1987), Jamaica (1989), Hong Kong (1992), United Arab Emirates (1995/1996), Puerto Rico (1997), and Philippines (1997).[3,4,9,13]

Equine influenza was introduced to a naïve, unvaccinated South African horse population by imported horses from USA in December 1986. It spread throughout the country within a week. The explosive spread was aided by road transport from the north of the country to the south (with infected horses being offloaded at points in between), lack of an all-in, all-out postarrival quarantine policy and poor hygiene by transport operators, horse trainers, and veterinarians. Movement of horses by concerned owners from a show jumping competition that was cancelled because of horse illness also contributed. The impact of the outbreak included extensive losses of State revenue due to cancellation of race meetings and subsequent loss of wagering taxes. Normal racing schedules were only resumed in May 1987, yearling sales were delayed and many other major equestrian horse events were canceled or had to be rescheduled. The horse industry also incurred significant costs arising from veterinary treatment of sick horses and the costs of compulsory vaccination.[3]

Hong Kong suffered a similar fate in November and December 1992 when an outbreak of equine influenza, introduced by imported horses from UK or Ireland, led to a suspension of racing for 1 month. The outbreak resulted in the cancelation of seven race meetings, including an international event, with a potential loss of total betting turnover of nearly US$1 billion, over 15% of which would have been returned to the Hong Kong community by way of tax, duty, and donations.[4,14]

It is ironic that the disease which has had the most profound effect on horse movement in the new millennium is foot and mouth disease (FMD), a disease that does not infect horses. The outbreak of FMD in the UK in 2001 had a devastating effect on the horse and tourism industries, as well as on the farming community. Estimated horse industry losses reached £100 million per month in the first 3 months of the outbreak and the majority of horse-related sporting events were cancelled.[15]

International regulatory framework

The World Trade Organization

The World Trade Organization (WTO) is the body responsible for implementing international agreements resulting from the Uruguay Round of multilateral trade negotiations. In January 1995, the framework for international trade changed significantly when the WTO Agreement on the Application of Sanitary and Phytosanitary Measures (the SPS Agreement)[16] came into force. Sanitary measures relate to human and animal health and phytosanitary measures relate to plant health.

The intent of the SPS Agreement is to minimize the negative effects of unjustified and unscientific health barriers on international trade. It requires WTO Member Countries to develop harmonized measures to protect human, animal, and plant life and health based on international standards, guidelines, or recommendations, primarily those developed by the Office Internationale Epizooties (OIE). Countries can adopt animal health measures more stringent than OIE standards if they can demonstrate a scientific need, which in practice means that quarantine conditions in excess of OIE standards should be based on a risk analysis. The SPS Agreement also promotes recognition of the concept of disease-free zones and regions within countries.[16–18]

Some authors[17,18] have noted that the SPS Agreement does not apply to international movement of competition horses as these movements are not considered 'trade'. The situation has been clarified by Sluyter.[1] Movement of horses or equine products after sale falls under the SPS Agreement. Movement of competition or breeding horses, although not considered as 'trade', also falls within the SPS Agreement if a concurrent risk of disease is involved.

Office Internationale des Epizooties

The OIE is the world organization for animal health based in Paris and was created in 1924 to address international spread of animal diseases at a time when rinderpest was a major concern in Europe. In May 2001 the number of OIE Member Countries totaled 158, each with one vote and one delegate to the International Committee (the decision-making body).[19]

A major objective of the OIE is to facilitate international trade in animals and their products by setting guidelines and standards. Historically, its primary function has been to provide Member Countries with information about the prevalence, incidence, and distribution of serious animal diseases which endanger livestock or public health.[18]

Information is sent out immediately or periodically depending on whether the disease is categorized as List A or List B (see below). Each Member Country undertakes to report important infectious diseases detected within its jurisdiction. The OIE then alerts other countries so rapid action can be taken if needed. In addition, the OIE collects and analyses scientific and technical information on animal diseases. The OIE makes this available to assist Member Countries to improve disease prevention, diagnosis and control, and provides technical support and expertise when requested.[19]

Classification and reporting of diseases

Diseases recognized internationally as being of significant importance to trade in animals are defined by the OIE as List A diseases. These are diseases that can spread very rapidly, irrespective of national borders, and that have serious socioeconomic or public health consequences. African horse sickness (AHS) and vesicular stomatitis are the important List A diseases that affect horses. OIE Member Countries are obliged to report outbreaks of these diseases to the OIE within 24 h of occurrence or reoccurrence and to supply monthly situation reports on their presence or absence.

OIE also defines a second group of diseases (List B diseases), which are considered to be of socioeconomic or public health importance within infected countries and are significant in international trade. List B diseases of equines include contagious equine metritis, dourine, epizootic lymphangitis, equine encephalomyelitis, equine infectious anemia, equine influenza, equine piroplasmosis, equine rhinopneumonitis, equine viral arteritis, glanders, horse pox, Japanese encephalitis, mange, and Venezuelan equine encephalomyelitis (VEE). List B diseases must be notified to the OIE within 24 h if they occur in a country for the first time and thereafter on an annual basis.

The Food and Agriculture Organization defines a third group of List C diseases as being significant at local level and countries report these annually. List C diseases of horses include equine coital exanthema, melioidosis, *Salmonella abortus equi*, strangles, ulcerative lymphangitis, and warble fly myiasis.[20]

In addition, each country maintains a schedule of diseases notifiable under its animal health legislation, drawn from the above lists, which have to be reported within specified periods. Because some important diseases are not universally notifiable, the Thoroughbred industry has developed its own international reporting system through the International Thoroughbred Breeders Meeting. Quarterly disease reports are submitted to a collating center at the Animal Health Trust, Newmarket, UK, and distributed to 20 participating countries.[21]

OIE international health standards

Since the formation of the WTO, the OIE has assumed significant importance in international trade as the reference organization for the WTO on animal disease issues and trade disputes. International standards developed by the OIE are now recognized by the WTO as reference international sanitary rules and can thus be used legitimately as a basis for import restrictions without constituting unjustified barriers to trade.[17–19]

OIE international health standards relevant to the international movement of horses are the International Animal Health Code and the Manual of Standards for Vaccines and Diagnostic Tests.

OIE International Animal Health Code

The OIE International Animal Health Code[22] is an essential reference for any official veterinarian involved in international trade. It is periodically updated and available online.

Part 1 contains general provisions relating to:

- general definitions and notification of animal diseases
- obligations and ethics in international trade
- import risk analysis
- import/export procedures
- risk analysis for biologicals for veterinary use.

Part 2 contains chapters for each OIE List A and List B disease and recommended wording for international veterinary certification relating to that disease. Criteria are presented which countries or zones must satisfy to be recognized as free from African horse sickness, equine influenza, dourine, glanders, and VEE.

Part 3 contains appendices to the Code. Sections relevant to the international movement of horses include:

- prescribed and alternative diagnostic tests for international trade purposes
- health controls and hygiene in establishments
- disinfection and disinsection procedures
- transport of animals.

Part 4 contains:

- a model international veterinary certificate for equines to promote international harmonization of veterinary certification
- a model passport for international movement of competition horses.

OIE Manual of Standards for Diagnostic Tests and Vaccines

The OIE Manual of Standards for Diagnostic Tests and Vaccines[23] is a companion volume to the Code and is also available online. The purpose of the Manual is to foster harmonization of diagnostic methods for OIE listed diseases and other diseases of importance to international trade. Standards are described for laboratory diagnostic tests and for the production of veterinary vaccines. Specific chapters cover each of the diseases listed in the OIE International Animal Health Code. Each disease chapter includes a well-referenced summary intended to provide information for veterinary officials and other readers who need a general overview of the tests and vaccines available for each disease. This is followed by a text giving greater detail for laboratory workers. The Manual also includes a list of OIE Reference Laboratories which have been designated by the OIE as centers of excellence in their particular field.

Import risk analysis

Risk analysis is a valuable tool for decision making that can assist global movement of horses and open up new markets without compromising the health status of importing countries.[24]

As mentioned earlier in this review, WTO Member Countries are encouraged to base quarantine conditions (SPS measures) on international standards, guidelines, and recommendations or on a scientific assessment of risk. The OIE International Health Code[22] is the international standard referenced in the SPS Agreement and contains guidelines and principles for the conduct of import risk analyses in Chapter 1.3.

The components of risk analysis are hazard identification, risk assessment, risk management, and risk communication. Briefly, the procedure should be science based and involves consideration and documentation of:

- potential exotic agents and pests of concern (hazards) that could be introduced by imported horses
- how exotic agents might be introduced into a country or zone by imported horses
- how horses in the importing country might be exposed to exotic agents thus introduced
- adverse health or environmental consequences resulting from exposure of domestic horses to such exotic agents
- how identified risks can be best managed to protect the domestic horse population without having an unjustified effect on trade.

Risk communication involves exchange of information and opinions with potentially affected and interested parties at all stages of the process.

Risk analysis has already proved its value in overcoming potential barriers to the international movement of competition horses testing positive for piroplasmosis. Government authorities in USA used risk analysis as a decision-making tool when considering import of horses for the 1996 Olympic Games.[24,25] Australia also amended its quarantine conditions to permit temporary importation of horses serologically positive for equine piroplasmosis following a detailed import risk analysis. Previous conditions banned the import of seropositive horses. The amendments were prompted by and of particular relevance to the Sydney 2000 Olympic Games. Under certain scientifically based restrictions, seropositive horses were allowed to enter Australia on a temporary basis.[26] This allowed horses that otherwise would have been ineligible to travel to Australia to compete in all three equestrian disciplines at the Sydney 2000 Olympic Games.[1] The important legacy of this risk analysis for Australia is that it also applies to future importations for other equine sports including racing.

A comprehensive risk analysis of disease risks associated with import of live horses has been completed by the Ministry

of Agriculture and Forestry, New Zealand in 2000 and was used as a basis for review of import standards.[11] The analysis includes a section relating to the temporary import of horses for racing and sporting events and recommended measures for their management.

Structured risk analysis, in compliance with OIE principles, provides countries importing horses with an objective and defensible method to assess risks associated with importation and to determine how those risks may be managed. Transparency is important. Exporting countries must be provided with clear and documented scientific reasons if import restrictions are imposed or if importation is refused.[22] Transparent decisions also assure local horse industry organizations and other interested parties that all potential risks have been evaluated and are being managed appropriately.

Regionalization

Regionalization and risk analysis are closely related.[24] Traditionally, the distribution of animal diseases has been viewed on a country-by-country basis, with the presence or absence of a particular disease anywhere within a country's borders serving to establish the status of the entire country. This conservative approach fostered an all-or-nothing standard of risk avoidance in quarantine policy development that precluded consideration of factors such as disease-free zones or regions within a country.

The contemporary approach endorsed by the OIE recognizes that there are gradations in disease risk, more often tied to climatological, geographical and biological factors and to husbandry systems than to national political boundaries. If a disease is contained within a defined zone, then export of horses from disease-free areas elsewhere in the country should not be affected. OIE guidelines relating to zoning and regionalization can be found in Chapter 1.3.4 of the OIE International Animal Health Code.[22]

Application of the concept to horse diseases was first prompted by outbreaks of AHS in previously free areas of Spain and Portugal in the years leading up to the 1992 Olympic Games in Barcelona. International movement controls relating to AHS were reviewed by the European Commission and the OIE. The OIE International Animal Health Code was amended to provide for regionalization in respect of AHS.[27] Countries allowed horses to enter Spain on a temporary basis to compete in equestrian events at the Games despite the existence of an AHS-infected area in the south of Spain.[24]

Regionalization is a valuable tool of trade for countries with significant endemic diseases of trade concern. South Africa's regionalization of AHS enabled resumption of export of horses to member states of the European Union and a number of other countries thus overcoming trade bans that had been in place for nearly 40 years. Recognition of the Cape Peninsula of the Western Cape Province as an AHS-free area was accepted by the EU (Commission Decision 97/10/EC) based on, *inter alia*:[28]

- the absence of clinical disease in the south-western part of the Western Cape Province of South Africa
- serological studies showing that AHS was not present in the area
- separation of this area by substantial geographic barriers from those parts of South Africa where AHS occurs annually
- strict movement controls to ensure that AHS is not introduced into the free area
- appropriate risk reduction measures for exported horses including minimum residency periods in the AHS-free area, quarantine in vector-protected premises, vaccination and pre-export testing
- ongoing surveillance in the free area and adjacent surveillance zone, including monthly blood testing of sentinel horses and autopsy of horses to exclude AHS as the cause of death.

Role and responsibilities of government officials, shipping agents, and veterinarians

Government officials, private practitioners, and shipping agents all share responsibility for moving horses between countries and must communicate openly and frequently during the shipping process to avoid difficulties and delays.[8]

Government officials

The chief concerns for the veterinary authorities of any country hosting an international event are potential for spread of disease, animal welfare considerations, and trade facilitation.[14]

Governments in importing countries have a primary responsibility to control the entry of foreign horses to protect the national horse population from exotic diseases. At the same time, they have to satisfy international obligations and facilitate trade. The importing country establishes import health requirements for horses by negotiation with their foreign counterparts, taking into account the disease status of the exporting and importing country and relevant international standards.[5,8,9]

An import permit may have to be obtained in advance of shipment for each consignment of horses. Often import conditions are attached to this permit. Import permits are used to ensure that only agreed and current conditions are used in trade, advance notice is given of consignments and that quarantine space is available for incoming horses (when appropriate).

The government of an exporting country is expected to act as the official independent agent of the importing country and is responsible for supplying or endorsing accurate official veterinary certification which satisfies all the health requirements of the importing country. If a problem arises with a shipment, officials in the exporting country cannot unilaterally alter agreed health conditions but must seek a dispensation from the country of destination.

Often shipments of horses transit other countries *en route* to their final destination. Governments in countries of transit may require that a transit permit be obtained in advance and/or that horses passing through meet the import requirements of the transit country in case a prolonged delay occurs due to mechanical failure of an aircraft.

Shipping agents

International transport of horses requires adequate lead time and considerable forward planning. Veterinarians approached for advice should recommend that clients engage a reputable and experienced shipping agent as the first step in commencing preparations for any international journey[6,7] as the key to success is often the competency of the shipping agent involved.[8]

A shipping agent acts as a representative of the owner and coordinates all facets of the shipping process from origin to destination. Shipping agents identify the most suitable and quickest route, prepare a travel plan, obtain all necessary permits and documentation, book road transport and air cargo space, liaise with airlines, provide shipping containers that conform to airline and welfare standards, and supervise loading. They also interact with the quarantine and customs authorities of the countries of origin and destination and coordinate arrangements for and timing of any pre-export quarantine, premises certification, veterinary examinations, testing and vaccination necessary for the completion of the official export health certification. Agents may also supply experienced attendants to escort horses during the journey.[29]

Enquiries should also be made in advance about quarantine policy in the country of destination relating to the import of tack, horse feed, supplements and veterinary medications.[30]

An additional consideration, which is sometimes overlooked, is that quarantine protocols for return of horses to their country of normal residency should be investigated before horses depart to establish whether that country imposes any special conditions on the management of horses during temporary residency in a foreign country. For instance, to return directly within a specified time period without additional testing, traveling horses may have to be isolated from other horses during a temporary absence.[30]

Equine veterinarians

In many countries, veterinarians in the private sector play a major role in preparing horses for export. Their duties may include:

- collecting blood samples for laboratory testing
- conducting or supervising pre-export treatments and vaccinations
- providing certification about the health status of horses and the premises from which they originate.

Veterinarians engaged by clients or accredited by governments to perform export duties need to work closely with quarantine authorities and shipping agents. Contact must be made with government animal health officials at an early stage to obtain or confirm the current import requirements for the country of destination. The veterinarian must understand and fulfill these requirements exactly.[8] Responsibilities include:

- being accredited for export duties (if appropriate)
- accurate completion of entries in horse passports and on other identification documents
- recording horse markings accurately by actual inspection of horses (rather than by copying other documents)
- confirming and recording the identity of each horse at the time of conducting any procedure so that any certification can be definitively linked to the animal
- collecting and submitting blood samples, performing inspections and administering vaccinations or treatments within the specified timeframes
- labeling samples clearly and accurately
- transporting samples to the laboratory using correct techniques and appropriate storage conditions
- submitting samples to approved laboratories
- requesting the tests specified in the import conditions
- providing conscientious certification about the health status of horses and premises.

Honest, accurate and reliable veterinary certification is the cornerstone of international movement.[31] Any certification provided must be completed carefully and conscientiously and match the requirements of the importing country precisely. Even if some of the requirements appear unreasonable and raise difficulties for the client, the certifying veterinarian must ensure these requirements are met or contact a government official for guidance on interpretation of the wording. Conflict of interest should be avoided and integrity of certification must not be compromised because of commercial pressures.

Misleading, inaccurate or false certification reflects adversely on the signing veterinarian and affects the reputation of the veterinary profession and government animal health services, nationally and internationally. Such certificates may result in loss of trade, spread of disease, financial loss to clients and exporters and litigation.[32]

A document entitled *The 12 Principles of Certification* was produced by the British Veterinary Association, UK Ministry of Agriculture, Fisheries and Food and the Royal College of Veterinary Surgeons in 1994.[31] A chapter on certification procedures is also included in the OIE International Health Code.[22] Both documents are recommended to veterinarians involved in the preparation or certification of animals for export as useful guides to their ethical obligations and responsibilities.

Before departure, private veterinarians traveling internationally with horses should also check whether the country of destination places any restrictions on import of veterinary medications and equipment or has any special registration requirements relating to veterinary practice by foreign veterinarians.

Equine practitioners attending recently imported horses in quarantine stations should pay close attention to personal

hygiene and comply with any operating procedures specified by quarantine management. They should be aware that a veterinarian was, in part, responsible for the quarantine breakdown that led to the disastrous South African equine influenza epidemic in 1986.[3]

Welfare legislation and standards

Welfare legislation governing international movement of horses by road and air varies from country to country. The International Air Transport Association (IATA) publishes *Live Animal Regulations* (LAR)[33] annually, which set standards for the safe and humane transport of animals by commercial airlines. The LAR contain useful information about the responsibilities of carriers and shippers, stocking density guidelines for horses, optimum temperature ranges, container standards, and specific handling procedures for horses transported by air. The LAR recommend that one competent groom be provided for each pallet of horses being shipped or, if more than four pallets are carried on the same flight, that the appropriate number of grooms (beyond four) be determined by the carrier in agreement with the shipper.

Generic recommendations for the transport of animals are presented in Chapter 1.4.1. of the OIE International Animal Health Code.[22] The Code notes that the IATA LAR are approved by the OIE and recommends their adoption. An increasing number of countries, including member states of the European Union, have formally adopted the guidelines and incorporated their provisions into legislation.

Role of horse industry organizations

For maximum efficiency, measures to prevent international spread of equine diseases require industry participation and support[5] in addition to the efforts of government veterinary authorities. At international level, the umbrella bodies of the various sporting disciplines play an important role in setting international standards for the protection of the health and welfare of horses relevant to particular disciplines. The host nation of an international event has a responsibility to provide facilities and supervision that meet these standards.

When preparing for an international event, close and continued liaison between horse industry and quarantine officials is required from an early stage to negotiate and resolve the many quarantine issues that may arise.[14,30]

In some instances, the host organization may provide and manage quarantine facilities.[14] Convenient access to good training facilities is critical for the successful participation of foreign horses. If a country that quarantines or isolates imported horses after arrival wishes to host an international event, the responsibility for establishing an approved quarantine facility for foreign horses often rests with the organization conducting that event. Most government-operated quarantine premises do not have easy access to adequate training facilities where imported horses can maintain competitive fitness in isolation.[30]

Horse industry organizations also play an important role in the regulation and control of international movement of athletic horses by issuing horse passports and by setting mandatory vaccination standards to protect the health of visiting and local horses against diseases such as equine influenza and Japanese encephalitis.

Passports

The use of passports to assist the movement of competition horses across national boundaries is well established. Internationally accepted passports must meet certain criteria set by the OIE, international horse authorities and, in Europe, by the EU.[1]

Passports are intended to serve as a unique identification document containing harmonized information about vaccinations and results of laboratory tests. They are issued by the relevant national horse industry organization of the country in which the horse is registered and should accompany a horse at all times. In some countries this is a legislative requirement. For instance, in the European Union all registered horses must have an accompanying passport during transportation.[1]

Vaccinations

In many jurisdictions, vaccination against equine influenza is compulsory for horses entering competitions or races and the vaccination status of all horses is regularly checked by horse industry officials.

It is important to establish before a horse departs on an international journey if local or foreign quarantine authorities impose any special requirements additional to or different from those known to apply to a specific discipline. For instance, because Australia is free from equine influenza, vaccination requirements for importation of horses to Australia are more stringent than those routinely required by racing authorities in Europe.[30] Likewise, in some instances, sporting authorities conducting events in certain Asian countries require vaccination against Japanese encephalitis to protect visiting horses. The recent advent of nasal vaccines for equine influenza may lead to changes in current international requirements (Roland Devolz, personal communication).

Vaccination requirements can vary from country to country and between disciplines and hence will not be detailed in this review. The main point for veterinarians is that the vaccination requirements of quarantine authorities and sporting organizations for each consignment should be established well in advance of the proposed date of horse departure. The time frames specified by quarantine authorities for courses of vaccination are not arbitrary and must be respected.

Racing authorities

The International Federation of Horseracing Authorities (IFHA) is an umbrella body for the world's Thoroughbred

racing authorities. The organization has developed an International Agreement on Breeding and Racing (IABR).[34] The general aim of the IABR is to protect the integrity of racing, thus leading to improvement of the Thoroughbred breed, enhanced welfare of trainers, riders and horses and, confidence of owners and the public in the sport. The IABR consists of a series of recommended international guidelines which are agreed and endorsed (in whole or in part) by national racing authorities and carried forward into their own rules for racing and breeding. Of particular interest to veterinarians are Article 6 of the IABR, which contains the template definition of a prohibited substance, and Articles 22 to 25, which relate to the control of infectious diseases and management of foreign race horses. Articles 22 to 25 contain general recommendations relating to passports, hygiene of transport vehicles and establishments, treatment procedures, veterinary inspections, vaccinations, health certificates, and exchange of information about equine disease outbreaks.

The IFHA has established a Permanent Liaison Committee on the International Movement of Horses (PLCIMH) to improve communication between countries conducting international races and to make recommendations about health issues that restrict trade. Significant expansion of international racing in recent years has resulted in logistical problems when horses compete in multiple countries within a short period of time before returning to their country of usual residency. Quarantine protocols vary from country to country and are usually developed to cater for direct movement to and from a specified country for competition. Complex itineraries cause logistical complications for racing authorities, government animal health services, connections of horses and shipping agents. Problems arise from variations between countries in quarantine requirements relating to health certification, minimum residency periods, testing, vaccination, housing and training during temporary residency and periods of quarantine or isolation.[2]

To address these problems and foster cooperation and international harmonization of health requirements, the PLCIMH has recently developed detailed guidelines to facilitate the safe movement of registered race horses competing on an international circuit with specific reference to testing, vaccination, certification, quarantine/isolation facilities and training of horses. The guidelines were presented to IFHA for consideration, comment and approval at its 36th Conference in Paris on 7 October 2002 and were adopted for use as a basis for discussion by IFHA member countries with their government veterinary authorities. The *Guidelines to Facilitate the Temporary Movement of Registered Racehorses for International Races* will be available online at www.horseracingintfed.com. It is anticipated that the guidelines will be reviewed and updated regularly and that IFHA will work closely with the OIE to ensure that guidelines are based on sound scientific principles.[2]

Passports have been used for the identification of Thoroughbred horses for many years. Passports have to be inspected and endorsed for foreign travel by racing authorities before each exportation and subsequently before the horse runs in a foreign country. Internationally, stud books are now moving toward an electronic identification system that incorporates DNA parentage verification and horse markings, and which also uses the number of an implanted microchip to create a unique passport number and international life number for the horse. Passport details of incoming horses can be down-loaded by registration authorities from the internet, thus speeding clearance procedures between countries.[35]

Federation Equestre Internationale

The Federation Equestre Internationale (FEI) is the international governing body of equestrian sport recognized by the International Olympic Committee and is responsible for international administration of equestrian events in the disciplines of show jumping, dressage, eventing, driving, vaulting, reining, and endurance riding. National Federations administer these disciplines at national level.[36,37]

The FEI has developed comprehensive rules and regulations to govern the above sports. Of particular relevance to equine veterinarians are the FEI Veterinary Regulations,[38] which protect the health and welfare of horses competing in international events under FEI control. The Veterinary Regulations cover, *inter alia*, the duties of veterinarians, health and hygiene requirements and responsibilities, passport control, examinations and inspections of horses during events, control of prohibited substances and treatment of horses while under FEI control.

Horses are identified by a written description and a diagram in FEI passports. Only veterinarians approved by a National Federation are authorized to complete this page and the description must be completed in accordance with the FEI Manual on Identification of Horses.[39] The vaccination section of the passport must be endorsed by a veterinarian and demonstrate that the horse has received a full course of equine influenza vaccinations in accordance with the requirements of FEI Veterinary Regulations.[38]

The FEI collaborates closely with the OIE and has played an important role in negotiating expanded international movement of horses for competition in the Olympic disciplines,[36,37] a legacy which is of benefit to athletic horses of all breeds.

Overview of quarantine controls of major equine sporting nations

There are various internationally accepted risk management strategies that quarantine authorities use to reduce disease risks associated with importation of horses.[14] Individually, each may not be perfect but, when used in combination, these measures can reduce the probability of importing an infected horse to a very low level, regardless of the starting probability. The combinations adopted vary from country

to country depending on the country's health status and quarantine policy.

Certification of origin from a disease-free source

The risk of introducing a disease agent can be reduced by sourcing horses from a disease-free country, region, zone, or premises. Alternatively, horses from an infected area may be required to be resident in an area free of the disease of concern for a specified period prior to export, a period long enough for that disease to be obvious if the horse is infected. Reliable and transparent information about the government veterinary services and disease surveillance programs in the country of export is obviously critical to the value of this strategy.

Separation

Separation of horses from other potentially infected horses (before export) and from susceptible horses (for a period after import) reduces the risk of disease transmission and the likelihood that infected horses will remain undetected. It also provides an opportunity for observation, diagnosis, and treatment (if appropriate) before imported horses are permitted to contact the domestic population. The risk of importing infected horses or releasing infected horses after arrival is thus reduced even further.

If suitable training and stabling facilities are available, separation need not disadvantage horses visiting for competition. At international race meetings in Asia[14] and Australia,[30] temporary equine imports are isolated from resident horses and horses from countries not of equivalent health status except at the time of racing.

Separation from the host population and, if there are significant variations in health status, separation of temporary residents by region, ensures the success of international competitions. It is recommended as best health practice to prevent the spread of infectious diseases and also protects the health status of visiting horses, thus assisting their prompt and uneventful departure to their next destination.

Satisfactory arrangements to separate visiting horses from the domestic population can also give foreign animal health authorities confidence that their horses can visit safely even in the face of a local disease incident. For example, prompt action by racing and animal health officials in USA salvaged European participation in an international race meeting at Arlington International Racecourse when an outbreak of equine viral arteritis occurred there in 1993.[40]

Diagnostic testing

Testing may be used to identify infected horses before or after export. The value of diagnostic tests in risk reduction depends on the availability and use of standardized tests of high sensitivity, the ability of a test to identify infected horses correctly. For example, a serological test may have a sensitivity of 99% in individual infected horses. Thus the probability of missing the disease when testing a single infected horse is 1%.

For import purposes, the negative predictive value of a test, the probability that a horse is not infected when a test result gives a negative result, is of paramount importance. Predictive values vary markedly according to the disease prevalence in the population from which the tested horse was drawn. As disease prevalence decreases, negative predictive value increases.[41] Reliable and transparent information about the prevalence of disease in the country of origin is critical for interpretation of test results.

When test results vary between different laboratories in different countries, trade problems can ensue.[9,42] Official approval of laboratories, adoption of OIE prescribed tests for international trade and use of the testing standards detailed in the OIE Manual of Standards for Vaccines and Diagnostic Tests[23] minimizes such problems.[9]

Rapid diagnostic tests are becoming more widely available and the Directigen FLU-A enzyme immunoassay[43] has been extensively and effectively utilized for both screening and diagnostic purposes of horses for the equine influenza virus both pre- and postimport in many countries since 1993.

Vaccination

Vaccination against specific disease agents such as Japanese encephalitis can reduce the risk of disease in horses sourced from or imported into an infected region. For other diseases, for example equine influenza, vaccination is of limited value as a risk management option. Equine influenza vaccination can prevent overt disease but a horse can still be infected and shedding virus at the time of import.[4,13,14]

Treatment

Treatment can be used to reduce the risk of importation of exotic parasites such as ticks. Insecticides may be applied to horses to minimize exposure to insect vectors during training sessions[30] and transport. Countries may also require horses to be treated for internal and external parasites before export.

Restrictions on destination, activity, and season of import

An example of this strategy is avoidance of exposure to insect vectors by import into a vector-free zone[26] or, by only permitting importation during a season when insect vectors are not active. Another example is requiring competition horses not to breed or be resident on breeding premises during a period of temporary residency.

Protection of health status during international travel

Government authorities may require horses to travel on approved routes through approved countries and have no contact

with other horses not of the same health status during transport. Special conditions may apply during transit of countries en route or if horses are transhipped from one aircraft to another during a transit. Conditions may be prescribed regarding cleaning and disinfection of horse transport vehicles and shipping containers, and protection of horses from insect vectors during transport.

Restrictions on duration of temporary residency

Visiting horses may only be permitted to remain in countries for a maximum specified period. The period may be set by the importing country or the country of usual residency, or both.

Contact information for major regulatory agencies

Each country has very specific quarantine conditions for temporary and permanent import of horses which are subject to change. Consequently, specific details cannot be given in this review and veterinarians should always seek advice from government officials or a reputable shipping agent before commencing preparation of horses for export. Many agencies now publish their quarantine conditions electronically. Readers are referred to contact information below. Some animal health sites on the internet such as Animal Health Australia (www.aahc.com.au) have good links to a wide range of other international animal health agencies.

CHAPTER 64

Transport of horses

David J. Marlin

General recommendations for horse transport

- Prior to embarking on long distance transport (greater than approximately 12 h duration for road or flights over 3–4 h), it is advisable to ensure good respiratory health by undertaking endoscopy of the respiratory tract at least 2 weeks in advance of transport. This allows a reasonable period of time for treatment of any pre-existing conditions prior to transport.
- Owners should be advised to always take the rectal temperature of horses prior to embarking on any transport and not to risk transporting pyrexic horses unless in case of other emergency.
- Water and feed should be provided almost on an *ad libitum* basis. Water should be available at all times and not offered only when at rest stops. Damping of feeds with water and soaking of hay or feeding of haylage is important to minimize the inhaled allergen load.
- It is preferable to travel horses with the minimal amount of clothing possible. In conditions where it is unclear whether horses require rugs, then it is better to travel without than with. Under temperate conditions, the risks associated with horses becoming cold are significantly less than them becoming hyperthermic. Increased body temperature will compound the sweat and respiratory fluid losses and dehydration (due to decreased fluid intake) that usually occur in any case with transport, possibly placing the horse at an increased risk of developing colic or respiratory disease.
- If possible, monitor weight loss and recovery following transport. Horses losing more than 5% bodyweight should be considered as candidates for immediate involuntary rehydration either by administration of nasogastric or intravenous fluids.
- An appropriate period of recovery should be built into any transport plans. For road transport in excess of a days transport (~8 h) at least an overnight rest is advisable. For flying, a rule of thumb is 1 day for every 2 h of flying.
- Horses with pre-existing medical conditions, such as rhabdomyolysis or recurrent airway obstruction (RAO, formerly known as equine COPD or 'heaves'), are likely to require special care during and following transport.
- The administration of mineral oil prior to transport as a laxative is commonly undertaken. This is likely to have an effect on the gut flora. The extent to which this will aid or hamper the adjustment to a different fiber source is unknown.
- Where possible, to minimize disturbance to the gastrointestinal tract, abrupt changes in fiber source should be avoided. This is particularly relevant following air transport. If exporting of hay or preserved hay is permitted, then it is advisable to export this to the destination in advance (e.g. by road or sea). Alternatively, if export is not permitted, import a small amount of the fiber to be fed at the destination and wean horses onto it gradually prior to departure.

Almost every domesticated horse will experience some form of transportation at some time in its life. The most common reasons for transport include transport to competitions, for breeding purposes, when bought or sold, for veterinary treatment and for slaughter. The predominate means of transporting horses today is by road, with trailers or floats and

custom-made or modified lorries, trucks, vans, or articulated vehicles. However, the number of horses moved by air in the case of race horses and sport horses competing at international level is not insignificant. In some parts of the world horses are still transported by train and boat in specially adapted carriages or containers. For example, it is still possible to transport polo ponies by boat from Argentina to Europe, or between islands in Greece, and boats and trains are still used to move horses in India. In the UK it used to be common for horses to be taken to race courses by rail, and horses were also transported across the American continent by rail. However, in developed countries, sea and rail transport are now infrequently used, with the exception of horses transported in lorries on relatively short journeys (e.g. across the English Channel).

The successful transport of valuable horses by air and road requires highly skilled staff, good practice and the right fleet of vehicles. While many small transport companies exist, there are also a number of major international transporters. In road transport, the names of companies such as Sallee in the USA and Fritz Johansmann in Europe are prominent. The major airlines that move horses on a regular basis include Lufthansa, Air Canada, KLM, Air France, DHL, FEDEX, Singapore Airlines, Korean Airlines and El Al.

The last 20 years have seen major improvements in many aspects of transport as a result of research undertaken in many different countries. In the early days of transport of horses by air, the only way for the horse to be loaded was by walking across the tarmac and up a ramp. Once in the plane the air-stall was constructed around the horse. Although this type of containment is still used on smaller aircraft for short flights, for larger aircraft and longer journeys the horse is usually loaded into a modern air crate, well away from the plane and runways, which is then towed to the plane and loaded by lifting platforms (Fig. 64.1). With today's freight-movement technology and approaches to moving horses, it is possible to load a full load of horses (~80 horses) onto a Boeing 747 in approximately one and a half hours. In some cases freight is loaded off the back of the plane while horses are loaded on the front, dramatically reducing turnaround times.

There is no doubt that the majority of horses that are moved distances from as little as a few miles to thousands of miles experience little if any discomfort, stress, or ill effects. However, the effects of transport can have a noticeable negative effect on performance without obvious clinical signs of illness or disease or the effect being directly linked to pre-

Fig. 64.1
(A) Horse being loaded into an air-crate. (B) Two horses in a three-horse air-crate. (C) Three air crates containing horses being towed out to be loaded. (D) Two air crates containing horses being loaded onto a 747 cargo plane.

ceding transport. More serious consequences for health can result from transport-related effects on various body systems, most notably effects on the gastrointestinal and musculoskeletal systems, and respiratory tract.

Effects of transport on the respiratory tract

Air quality

Transport of horses by either road or air can present a significant challenge to the respiratory tract. Air quality may be compromised by inappropriate bedding, feed, and poor ventilation resulting in accumulation of irritant (e.g. ammonia from urine, dust), allergic (e.g. molds from hay and straw bedding), and infectious (e.g. bacteria) material in the traveling compartment. For example, during a horse flight from the UK to Australia, airborne bacterial and fungal colony-forming units increased by up to 20- and 7-fold, respectively, with peaks occurring during stationary periods on the ground.[1] However, even during flight when the plane's air-conditioning/circulation system was in operation, bacterial and fungal numbers of colony-forming units were up to five times higher than at the start of the flight. Warm and humid conditions that develop due to heat dissipation of the horse (i.e. sweating) and exhaled moisture can provide an ideal environment for horse to horse transmission of infectious agents.

Ammonia is a potent irritant to the respiratory tract. During 24 h of road transport by trailer, mean ammonia concentration was reported to be less than 1 ppm.[2] In another study, for horses transported 36 h by truck, ammonia concentration was reported to increase from ~0.2 to 2 ppm.[3] The bedding used in these studies was not stated and this may have a profound impact on conversion of urea into ammonia by bacteria present in the bedding. At present it is unclear whether the concentrations of ammonia reported in these studies would induce airway inflammation. However, exposure to 2–17 ppm of ammonia for 40 h has been reported to induce cough and nasal discharge and changes to cilia in the trachea.[4] The ammonia concentrations for air transport have not been reported, but with increasing journey duration significant increases in ammonia are more likely. Zeolite-containing compounds absorb and reduce airborne ammonia concentrations. The compounds are available commercially and are particularly recommended for use during moderate to long periods of transport (in excess of 8–10 h). The zeolite-containing compound is spread on the floor under the bedding (Fig. 64.2).

Fig. 64.2
Ammonia is a potent respiratory tract irritant. Zeolite-containing compounds can be laid under bedding material and help to absorb any ammonia produced from urine by bacteria, thereby reducing ammonia concentrations in air.

Table 64.1 Approximate respirable dust loads (particles per m^3) for different fiber sources, hard feeds, and bedding materials. Adapted from[51]

	Respirable dust (particles/m^3)
Fiber sources	
Haylage (silage)	~4 000
Good hay	~60 000
Alfalfa pellets	~9 000
Grains/concentrates	
Whole grains (e.g. oats)	~4 000
Rolled grains	~120 000
Molassed concentrates	~2 000
Beddings	
Wood shavings	~30 000
Good straw	~11 000
Flax straw	~9 000

Increases in airborne dust can lead to airway inflammation, increased mucus viscosity, increased mucus secretion, and mucostasis. Concentrations of airborne dust were small in horses transported by road for 36 h (0.2–0.4 mg/m^3).[3] In a subsequent study, the concentration of respirable dust (<5 μm) averaged 9 μg/L of air over 24 h of road transport.[2] In both studies it was stated that hay was fed, but not whether this was dry or soaked, nor was the bedding used stated; both can have a marked impact on the respirable dust load. The measured respirable dust loads for a number of different feeds and beddings are shown in Table 64.1. It should be noted that use of unsoaked hay, even if of good quality, and wood shavings for bedding, which are both commonly used in both road and air transport, present a considerable respirable dust load.

Mucocilary clearance

Transport is also frequently associated with dehydration, which can decrease mucociliary clearance. Following 24 h of trailer transport in which horses lost a mean of only ~3% bodyweight, lung clearance of inhaled ^{99m}Tc-DPTA from peripheral airways showed a trend to decrease by around 20%.[2] Unfortunately, clearance from the larger, ciliated

airways was not assessed and the degree of dehydration induced was much lower than can commonly occur during transport. There are currently no reports of pulmonary clearance following air transport. However, a study of mucocilary clearance of ^{99m}technetium–sulfur colloid in non-transported horses demonstrated a marked effect of head and neck position on clearance, with reduced clearance during enforced maintenance of a high head position.[5]

The drying of the airways and increases in mucus viscosity can be further exacerbated by increases in mucus production stimulated by inhalation of dust or allergic material. Warm and humid conditions inside the transport compartment can also cause the horse to increase its ventilation[6] (as a thermoregulatory response to increase heat dissipation), with the result that more particles are deposited in the airways and airway drying is further increased. In addition, maintenance of an elevated head position, as is almost universal during transport of horses, has been shown to result in marked increases in mucus and numbers of bacteria and neutrophils in the trachea within as little as 6–12 h of elevation.[5,7,8]

It is not uncommon for some horses to exhibit signs of mild airway inflammation following prolonged transport, particularly in 'heaves'-affected animals. Similarly, animals that begin a journey with pre-existing airway inflammation will almost certainly not improve and are more likely to suffer exacerbation of their condition. Generalized 'stress' responses in animals that are poor travelers could possibly contribute to pulmonary or systemic immunosuppression. At present, although there is widespread agreement that current common transport practices result in respiratory tract inflammation, there is little if any evidence to suggest that this is due to functional impairment of pulmonary defenses as a result of immunosuppression.[9–11]

Shipping fever

Transport in general has been identified by a number of authors as an important risk factor for the development of respiratory disease.[12–14] The risk clearly increases with journey duration, especially in excess of 10 h. A severe manifestation of the effects of transport on the respiratory tract may be the development of 'shipping fever'. Affected horses most usually exhibit pyrexia, depression, and reduced appetite, with or without specific respiratory signs including cough, nasal discharge, and increased respiratory rate. Shipping fever can progress to pneumonia or pleuropneumonia if not treated appropriately, and can be fatal. The reported causative agents implicated in shipping fever include *Streptococcus equi*, *Streptococcus suis*, *Streptococcus zooepidemicus*, and *Pasteurella caballi*.[15,16] However, it is generally believed that the most common agent involved is *S. zooepidemicus*.

The risk of shipping fever increases with duration of travel whether by road or air. Road transport in excess of 10 h appears to markedly increase the risk of shipping fever,[12,14] although this author has experienced horses developing shipping fever after journeys of as little as 6 h by road. In a study carried out in Japan over a 5-year period from 1989 to 1994, the incidence of shipping fever following road transport of 25–28 h was 11.9%.[17] Another study in Japan over a more recent 4-year period indicated that for all horse movements by road the incidence of shipping fever was 1.4%.[11]

The incidence of horses completing transport and showing clinical signs of respiratory disease that does not progress to shipping fever is even higher. When respiratory disease was defined on the basis of rectal temperature in excess of 38.6°C, cough, nasal discharge and lethargy, the percentage of horses showing such signs following 36 h of road transport was 45%.[3] Similarly, the prevalence of pyrexic horses was found to increase markedly beyond 20–24 h of road transport.[3]

Other risk factors for the development of shipping fever include air quality, number and density of animals in the transport compartment, and the presence of respiratory disease in individual horses prior to the onset of transport.

Effects of transport on the gastrointestinal tract

Effects of transport on the gastrointestinal tract may relate to generalized stress responses resulting in an increase in fecal water content and hence increased dehydration. Alterations in gut flora may also occur and can contribute to decreased gut transit times, increased water loss, and decreased digestibility. Decreased feed and water intake during transport may lead to decreases in intestinal motility and predispose to colic. Conversely, dehydration may decrease gastrointestinal tract water content and slow the passage of ingesta with an increased risk of impaction colic. Changes in hard feed (i.e. grains, pellets, etc.) and/or forage, imposed either due to costs of transporting feed or to import restrictions, will almost certainly cause marked disturbances to gut flora and have been identified as risk factors for the subsequent development of colic.[18] There is evidence to suggest that such disturbances may persist for 2–3 weeks following an abrupt change in feed,[19] again with implications for digestibility and gastrointestinal tract water content. This may result in horses losing weight or recovering weight slowly following transport and may have important implications for sporting disciplines in which the gastrointestinal tract serves as an important source of water to offset fluid losses through sweating, such as endurance and eventing.

Digestibility and feed intake may be further compromised when there has been a significant change in time zone to that from where the horses originated their journey. This is effectively similar to jet-lag in people. Decreased feed and water intake are not uncommon in the first few days following air transport across three or four time zones.[20] Under normal conditions, around two-thirds of a horse's water intake is associated with feed intake, and *vice versa*. The effect of disturbance to normal feed intake is likely to be worse when small numbers of large feeds are given. If the horse is nor-

mally fed at 7 a.m. and 7 p.m., and following a flight is fed at these times at the destination, then for a destination where the local time is 8 h behind, the horse will be fed at the equivalent of 3 p.m. and 3 a.m. It may therefore take horses 2–3 days to adjust to these new feeding times.

Weight loss during transport

Almost all horses, whether experienced and relaxed travelers or nervous or inexperienced travelers, lose weight during transport. Weight loss during transport may result from decreased feed and water intake, increased postural energy expenditure, and decreased digestibility of feed, although most weight loss is likely to be due to loss of fluid. This may occur because of increased fecal water content and increased thermoregulatory-associated losses (increased sweating and increased respiratory water loss). In the case of air transport, the low humidity will increase insensible water loss (water loss due to the permeability of skin to moisture) without obvious sweating.

Weight loss and recovery following road transport

A summary of studies reporting weight loss during road transport is shown in Table 64.2. Factors that increase weight loss are duration of journey, warm or hot environmental conditions, and failure to provide feed and/or water. Differences in type of vehicle used, breed, previous transport experience, fitness, distance traveled, environmental conditions, and provision of food and/or water make direct comparison between studies difficult. However, the rates of weight loss for journeys of 4.5 to 14 h[11,20–22] show a similar range of rates of weight loss of 0.33–0.42% bodyweight/h. Whereas journey times in excess of 24 h are associated with increased absolute weight loss, the rate of weight loss is reduced compared with shorter journeys[11,23–25] (Marlin, unpublished data).

It should be remembered that most studies are likely to have been conducted using professional drivers and vans, or at least by researchers driving sympathetically. In circumstances where the vehicle design is suboptimal or the vehicle is badly driven,[2,11] or there is significant turbulence in the case of flying, animals have limited space to move,[23] ventilation is poor and environmental temperature is high, rates of weight loss may be doubled.

Table 64.2 Summary of weight loss in different transport studies

Breed/Type	Vehicle	Training status	Distance (km)	Duration (h)	Weight loss (%)	Weight loss (%/h)	Weather	Fed/ Watered	Reference

NS, not stated; TB, Thoroughbred.

There are less data relating to weight loss and recovery following flying. For fit Thoroughbred racehorses transported by road and air for total durations of 6–36 h, weight loss during flying was around 3.6% bodyweight.[26] In a group of fit, three-day event horses of mixed breed with no previous flying experience and flown 9 h, the mean weight loss was 4.5% bodyweight or 0.5% bodyweight/h.[20]

The time for recovery in bodyweight following transport to that before transport depends on the duration of transport, the amount of weight lost, the environment to which the horse has traveled, the individual temperament of the horse, and possibly on previous transport experience. Changes in hay or hard feed (i.e. grains, cubes, pellets) may further delay recovery in bodyweight. Fit three-day event horses took 3 days to recover bodyweight following a road-transport-induced loss of 5% bodyweight.[20] Fit Thoroughbreds transported for 7 h by road and losing 2–3% bodyweight took less than 24 h to regain their pretransport weight (Marlin, unpublished data), whereas fit, elite three-day event horses took 24–48 h to recover following three consecutive days of road transport (Marlin, unpublished data). Foss and Lindner[21] reported that of losses in bodyweight of 1.5–3.0% induced by road transport, within 24 h in all cases the average deficit had been reduced to approximately 1.5% bodyweight, irrespective of the degree of transport-induced loss.

Weight loss and recovery following flying

Following flying and an average loss of 3.6% bodyweight, Thoroughbred race horses continued to show a deficit of 2.4% bodyweight compared to before transport at three days after arrival.[26] In a study where horses were followed for a longer period, recovery in bodyweight following a loss of 5% bodyweight was not attained until 7 days after arrival in a hot and humid climate.[20]

Diurnal changes in bodyweight

Bodyweight may vary by as much as 10–15 kg or 2% body weight in horses that are fed, watered, stabled, and rested or exercised (Marlin, unpublished data). Horses are normally found to be lightest prior to their morning feed and heaviest around 6 p.m. to 12 a.m. after consumption of feed throughout the day. Morning exercise may mean that the lowest bodyweight is recorded mid to late morning. This has some implication in assessing transport weight losses. A horse traveling morning to evening that arrives at the same bodyweight as it left has effectively lost weight, because it should arrive heavier on a normal diurnal cycle. However, in two studies where horses were kept in pens or paddocks in warm to hot conditions, weight loss was similar to those for an equivalent duration of transport. For horses kept in paddocks for 7 h at 21–27°C without food or water, weight loss was 3% bodyweight or 0.42% bodyweight/h.[21] Horses kept in paddocks for 30 h in hot conditions without water lost 12.8% bodyweight (0.43% bodyweight/h) but only 3.5% bodyweight (0.12% bodyweight/h) when allowed access to water.[25]

Fluid intake during transport

Most studies have reported a decrease in water intake during transport compared to an equivalent stabled period when horses were not transported. In one study, despite water being provided continuously, none of the horses consumed any water during an 8 h road journey, although all continued to eat.[22] This response may have been due to limited previous transport experience of this group of horses. During 7 h of road transport, mean water consumption was 23 L compared with 30 L for the same period of time in the stable (Marlin, unpublished data). In a group of elite three-day event horses transported for 9 h a day for three consecutive days, mean daily water intake was 26 L and was not different to the 3-day mean before transport (28 L) or following arrival (28 L). However, in two horses, individual water intake dropped to 7 and 11 L on the first day of transport, but in

Fig. 64.3
A horse in an air crate with continual access to water in a bucket suspended within the crate from a lead rope.

both horses increased to 32 and 27 L, respectively on the second day of transport (Marlin, unpublished data). Smith et al.[2] reported that during 24 h of road transport in a two-horse trailer, water consumption was reduced to a mean of 27 L/24 h compared with 53 L/24 h before transport. In this study the horses were given access to water during 15 min stops every 3.75 h.

In spite of transport inducing dehydration, transported horses that were not permitted access to water during transport but then given water after transport, only consumed a mean of 21 L.[27] This was in contrast to horses that were kept in pens for a similar duration, which consumed a mean of 38 L. This may be related to other effects of transport, such as fatigue, not directly related to dehydration.

There is limited published information relating to water consumption during air transport. During a 9-h flight, when water and feed were provided continuously (Fig. 64.3), water intake averaged 33 L compared to 25 L for the three days prior to the flight.[20]

Effects of transport on the musculoskeletal system

Confinement and collision with internal structures of the transport vehicle might reasonably be expected to increase indicators of muscle damage such as creatine kinase (CK) and aspartate aminotransferase (AST). The extent of such increases might therefore be reasonably expected to depend on factors such as transport vehicle design; orientation within the vehicle; the nature of the flooring material; the quality of driving; road surface conditions; the amount of cornering, stopping, accelerating, braking; degree of turbulence during flying; and the age and health of the animals being transported. However, as dehydration is common during transport of horses, small increases in CK and AST following transport might be due to dehydration rather than muscle damage *per se*.

Serum CK and AST activities were not increased significantly by 14 h of road transport or 9 h of flying in a group of competing three-day event horses.[20] Mean CK and AST activities in a group of elite three-day event horses were also unchanged following three consecutive days of road travel with overnight rest stops (pretransport 34 U/L versus post-transport 26 U/L) (Marlin & Killingbeck, unpublished data). In contrast, CK activity was increased significantly in horses transported for 24 h, but only by a mean of 74 U/L and returned to pretransport activities by 24 h post-transport.[24] Similarly, CK activities increased by means of 3, 113, and 217 U/L in horses trailered by road for 2.4, 4.8, and 7.2 h.[21] However, in the same study, horses kept in pens also showed a mean increase in CK of 66 U/L over a 7.2 h period. There is also a report in the literature that indicates that both serum CK and AST activities show diurnal variation, with elevations in the afternoon compared with the morning.[28]

In race horses transported by road and air for between 6 and 39 h, CK and AST were not elevated immediately on arrival, but some horses showed an increase over the first 24 h at the destination.[26] In 12 healthy, adult horses transported by road for 130–200 km, the mean plasma CK activity increased 93 U/L.[29] Following a 300-km road journey, in a group of 40 Thoroughbred race horses the mean increase in plasma CK activity was only 60 U/L and had returned to pretransport activities by 24 h.[30] In contrast, a short 70-min road journey was reported to increase CK in a group of 30 healthy stallions.[28] Although most studies show minimal increases in CK following transport, there is one report of four horses developing rhabdomyolysis during transport.[31]

Generalized responses to transport

Heart rate and energy expenditure

Increases in oxygen consumption indicate an increase in tissue metabolic activity and energy expenditure, which can usually be ascribed to increased muscular effort, in the absence of fever. In transported horses, increases in oxygen consumption may be attributable to increased energy expenditure in order to maintain posture in response to changes in speed and/or direction. Increases in heart rate may also indicate an increase in energy expenditure, but can also be a result of reactions to external stimuli or a generalized stress response. However, it should also be noted that increases in oxygen consumption and/or heart rate may result from increased thermoregulatory demands as a result of increased temperature and humidity within the traveling compartment.

In most studies, heart rate of horses during road transport has been reported to be higher than that for the same horses either at rest in the transport vehicle or in their own stables.[2,32–37] Clark et al.[32] reported a mean heart rate during 18 min of transport in a two-horse trailer of 85 bpm in horses with little or no previous transport experience. Smith et al. reported a mean heart rate of 66 bpm for eight Thoroughbred geldings with unknown previous transport experience during 100 min of road transport in a four-horse trailer, compared to a mean heart rate of 48 bpm when the trailer was parked.[34]

However, in contrast, in a transport study of 30 mature mares and geldings, during 6 h of road transport in a large trailer, mean heart rate was only around 5 bpm higher compared to horses kept in pens for the same period of the day.[25] Similarly, in trained Thoroughbred horses with previous but no recent transport experience, mean heart rate during 7 h of road transport in a two-horse lorry was only around 5–7 bpm higher than when the horses were in their stable during the same period of the day (Marlin et al., unpublished data). Doherty et al.[33] also reported that mean heart rate in Shetland ponies during 30 min of road transport was only

approximately 5 bpm higher than when standing. However, in this study the 'resting' (standing) mean heart rate of 54 bpm would be considered high.

In many studies, the previous transport experience of horses used is not stated or possibly not known. It does appear that there are marked differences in transport responses in horses that are effectively transport naive compared with horses that are transported on a regular basis.

There is also evidence that heart rate responses to transport also depend on the stage of the journey and on the transport vehicle configuration and orientation of the animals within the vehicle. For example, heart rate has been reported to show the greatest elevation during the initial movement of the vehicle, with a gradual decline over the first 10–30 min of transport.[32,34,35]

A number of studies have investigated the orientation preference of horses during road transport and whether there are differences in behavior or physiologic or other responses assumed to be indicative of stress when horses are transported in different orientations relative to the direction of forward travel. A review of the literature indicates that multiple factors, including size and design of vehicle, space allocation, duration of transport, road conditions, journey route, and number of horses transported, as well as individual horse preferences that determine the response to or selection of different orientations during transport.[32–35,38–40]

During enforced orientation during road transport, rearward-facing transport has been reported to be associated with reductions in side and total number of impacts with the vehicle interior, losses of balance, vocalization, and movement.[32,37,38] Only one study has reported a significant reduction in heart rate during a rearward compared to forward-facing transport in a lorry for 60 min,[37] whereas others have reported trends[33] or no difference.[32,34] Two studies have, however, reported lower heart rates for rearward-facing loading and during the initial movement of the vehicle.[32,37] In relation to other indicators of stress or comfort, Clark et al.[32] reported no difference in plasma cortisol for horses transported forward- or backward-facing for 18 min by road.

In studies where horses have been allowed to select their own orientation (i.e. when transported loose), results have been highly variable. For example, Smith et al.[35] reported that out of eight horses transported loose in a four-horse stock trailer, one was in constant motion whereas five spent more than half the time during transport facing backward. In contrast, in a group of 12 horses transported in a commercial straight-deck, topless trailer, loose horses spent the greatest percentage of time (57%) facing forwards at angles of between 22° and 67° to the direction of travel.[38] In the same study, however, when horses were tied to the trailer, the side to which they were secured determined the direction they chose to face, with the greatest percentage of travel time facing backwards when tied to the left side of the trailer. Overall, these authors reported that the horses studied showed a slight preference for travel at 45° to the direction of forward movement, but no significant preference for facing toward or away from the direction of transport. Thus, whether forward- or rearward-facing transport is preferable is still unresolved and appears to depend on individual horse preference and possibly other factors such as previous transport experience, degree of acclimation transport prior to study, presence of other horses, vehicle configuration, and possibly duration of journey, as most studies cited have been relatively short.

Although it was noted previously that elevations in heart rate may be due to excitement, stress, or stimulation rather than to increased energy expenditure *per se*, a recent study utilizing EMG, heart rate, and video recording during road transport did show that muscle activity and heart rate were very closely correlated.[41] The implication from this is that most elevations in heart rate are related to the muscular efforts to adjust posture. As concluded by Giovagnoli et al., simultaneous increases in heart rate and EMG almost certainly reflect both emotional and physical stress, and are most likely primarily determined by road conditions and driving style. Whereas an increase in oxygen uptake would have been inferred by the increased EMG activity in the study by Giovagnoli et al.[41] in an earlier study, Doherty et al.[33] showed nearly a two-fold increase in energy expenditure (estimated from direct measurement of oxygen consumption) in Shetland ponies during 30 min of road transport compared to when standing.

There appears to be only one report of heart rates during air transport.[42] Heart rates were recorded during transport of horses for 12 and 24 h in enclosed containers (Airstable®) designed to prevent the ingress of insects that could act as potential vectors for equine infectious diseases. Mean heart rate for the whole period of each flight ranged from 39–57 bpm and was similar to the mean heart rate of horses on the same flights that were traveled in conventional open stalls (range 34–46 bpm). Peaks in heart rate associated with take-off and landing were around 80–100 bpm and are not considerably different from those seen in horses transported by road. This should not be surprising, as it is likely that the horse is unable to differentiate between flying and road transport but reacts simply to visual, audible, and/or mechanical cues, irrespective of their origin. Thus, in the absence of turbulence, and accepting the likelihood of poorer air quality, on a per hour basis it would be expected that horses would be less affected by flying than by road transport.

Hematology and biochemistry

Road transport

Leukogram In contrast to studies of flying, most studies of road transport have reported increases in peripheral white blood cell (WBC) count. For example, WBC count was increased in horses transported for between 5 and 32 h by road, or for 24 h by road, respectively,[24,43] although Smith et al. [2] reported no increase in WBC count following 24 h of road transport. A mean increase from 6.6 to 9.9 × 10^9 WBC/L blood following ~14 h of road transport has been reported,[20] but no change in total WBC count following 7 h of transport, although there was a significant increase in neutrophil count (Marlin, unpublished observations). Stull and Rodiek [24] reported an increase in WBC from around 8 to

13×10^9 WBC/L blood following 24 h of road transport, although it is worth drawing attention to the fact that the majority of the increase occurred in the first few hours of transport.

Hematocrit and total protein Packed cell volume (PCV) and total protein have been measured in a number of transport studies and will generally reflect the extent of dehydration. However, as it is easy to provoke an acute increase in PVC through excitement, protein measurements are likely to be more reliable as an index of hydration status. Perhaps not surprisingly, shorter duration (<7 h) journeys by road have reported no changes in PCV or total protein[30,44] (Marlin, unpublished data). Following longer-duration journeys (in excess of 24 h) PCV and total protein have not always been shown to increase in parallel. For example, both Smith et al.[2] and Stull et al.[24] found an increase in PCV but no change in total protein following 24 h of road transport. This suggests that PCV was most likely elevated either due to excitement during transport or sampling or the entrance of people into the horse compartment rather than by dehydration *per se*. In the study by Friend,[25] as would reasonably be expected, total protein was considerably higher at the end of transport in the non-watered group compared with the watered group.

Electrolytes Fewer studies have measured plasma electrolyte concentrations and results are contradictory for shorter-duration road transport.[30,44] However, for 30 h of road transport,[25] in horses receiving water, serum sodium and chloride concentrations were both increased by 8 h of transport, but were no different to pretransport after 30 h. This was in contrast to marked increases in sodium and chloride concentration at 30 h in the non-watered group. Following a 9 h flight, plasma sodium (pre 136 versus post 141 mmol/L), chloride (98 versus 104 mmol/L), potassium (3.6 versus 4.1 mmol/L), and total protein (66 versus 73 g/dL) concentrations were all significantly increased.[20] These changes were much more marked than when the same horses were transported ~14 h by road. Van den Berg and colleagues investigated water and electrolyte balance in Thoroughbred horses during 8 h of road transport in comparison to a non-transport control.[22] Dehydration was modest (~3% bodyweight loss) and intake of sodium and chloride were unaffected by transport, although potassium intake was decreased. Interestingly, sodium and potassium losses in urine and feces were similar, whether horses were maintained in stables (control) or transported, but potassium output was reduced in the transported group during the post-transport period. There do not appear to be any other reports in the literature of plasma electrolyte changes following air transport.

Air transport

There is limited published information concerning changes in hematology and biochemistry following air transport. Thornton[42] reported no changes in hematology and/or biochemistry following flights of 12 or 24 h. Leadon et al.[26] reported no changes in WBC, plasma sodium or potassium, but small increases in chloride, PCV, and fibrinogen. In a separate study the same authors also found no increase in WBC count following flying, although the WBC was decreased at 2 days postflight, suggesting that the values before flight may have been elevated. In the same study the authors reported a doubling of blood neutrophil counts and no change in globulin concentration. In contrast, following a 9-h flight, the author and colleagues have reported increases in WBC, sodium, chloride, albumin, and total protein concentrations.[20]

Hormonal responses to transport

Cortisol

Cortisol is the hormone that has been most frequently measured in transport studies. During road transport, plasma cortisol concentration has been reported to either increase or remain unchanged. In a number of shorter studies there has been a marked increase in plasma cortisol concentration in the early stages of transport,[32,44] whereas studies of longer duration have reported little or no increase in cortisol concentration[2,25] (Marlin, unpublished data). In fact, in the study by Friend[25] the greatest increase in cortisol concentration was in non-transport controls kept in pens without access to water. In one of the longer duration road transport studies which did report a large (4-fold) increase in cortisol concentration, almost half the increase occurred in the first few hours of transport.[24] When the results of the various studies are considered together, the implication is that increases in cortisol concentration are probably due to handling, loading and the initial movement of the vehicle, rather than prolonged movement or confinement.

Other hormones

With respect to other hormone measurements during transport, a decrease in serum aldosterone concentration has been reported following short-term road transport.[44] No changes were found in plasma adrenocorticotrophic hormone (ACTH), dopamine, epinephrine (adrenaline), or norepinephrine (noradrenaline) concentrations following 7 h of road transport (Marlin, unpublished data). ACTH and 11-hydroxycorticosteroid peaked within 5 h of the start of a 41-h road journey.[11] Although only 18 min of road transport doubled plasma cortisol concentration, it had no effect on plasma thyroxine concentration.[32] A combination of road and air transport of Thoroughbred race horses lasting a total of 6–39 h produced a small increase in plasma cortisol,[26] whereas there was no overall change in plasma β-endorphin in horses flown for 30 h.[42] Li and Chen reported an increase in plasma β-endorphin of around 40% only 30 min after the onset of road transport, but a decrease by 60 min of transport.[45] However, in all these examples of changes in circulating concentrations of hormones, the changes induced by transport are considerably lower than those commonly reported for exercise.

Rest stops

Perhaps surprisingly, there are no studies in the scientific literature looking at the use of rest stops during transport,

Fig. 64.4
Exercising horses by walking in hand while waiting for loading onto a cross-channel ferry from France to the UK.

although these are used to varying degrees by almost all people who transport horses. The current consensus appears to be that horses should at least be checked approximately every 4 h of transport, and preferably the vehicle stopped and the horses unloaded; this is sometimes not feasible. Ideally, horses should not be transported for more than 8–10 h at a time, particularly by road, without an overnight rest. Sometimes there are opportunities to exercise animals when waiting for a change in transport, e.g. from road to air or road to boat (Fig. 64.4), however, extreme care should be taken to evaluate the surroundings before unloading horses, especially in airports.

Immune function

The observation that horses develop respiratory disease during or following transport has led to the suggestion that the stress associated with transport may in turn lead to immunosuppression. This speculation is usually linked to the belief that increases in cortisol as part of a stress response to transport will lead directly to immunosuppression. Wheras cortisol is an immunomodulator, increased concentrations of circulating cortisol do not conclusively result in immunosuppression. Furthermore, as reviewed above, transport is not universally associated with increases in circulating cortisol.

The effects of transport on the immune system of the horse have recently been reviewed[46] and will therefore only be dealt with briefly. In relation to pulmonary immune function and in considering whether local immunosuppression contributes to the development of respiratory disease during transport (i.e. shipping fever), the role of immunosuppression is difficult to dissociate from impaired mucociliary clearance and associated bacterial proliferation.[5,8,47] Indeed, a number of studies have failed to demonstrate any impairment of alveolar macrophage function following transport.[10,48] Following 7 h of road transport, there was no change in lymphocyte proliferation in response to concanavalin A and phytohemagglutinin or in lymphocyte expression of CD4 or CD8 (Marlin, Kydd, Hannant, unpublished data). Other reports of immune function and transport in the literature are in other species, including cattle and pigs. Thus, it is conceivable that in some individuals the development of conditions such as shipping fever may be facilitated by a component of immunosuppression, but this does not appear to be a universal occurrence in transported horses.

Jet-lag, transport and possible effects of transport on performance

Transport may have a direct impact on subsequent performance due to injury, impaired respiratory health, fatigue, 'stress', and disorientation. The influence of jet-lag on the function of, for example, airline pilots[49] and performance in athletes[50] continues to be an area of interest. Although it is accepted that jet-lag occurs to some extent in all humans as a result of rapid air travel across a number of time zones, it is less clear to what extent horses are affected. It has been reported that following 9 h air transport across six time zones (i.e. –6 h at destination compared to origin) there was a reversal of the normal diurnal rectal temperature relationship, an increased frequency of uneaten meals, and changes in pattern of water consumption.[20] Although these changes may be consistent with development of jet-lag, they are impossible to differentiate from the effects of transport *per se* (i.e. fatigue, dehydration, disorientation).

Summary

The majority of horses are transported without incident. However, there may still be subclinical effects of transport, which may or may not noticeably impair performance. At the other end of the scale, a small proportion of horses become ill and may die as a result of conditions occurring that are directly associated with transport, particularly 'shipping fever'. The reasons why some transport events result in illness in some but not all individuals are presently unclear. However, the marked variation in response to transport that occurs around the world is also reflected in the marked variation between the controlled experimental studies of horse transport presented in this review. The variation in response to transport, in many cases in what appear to be similar studies, is most likely due to a combination of different factors, which could include age, breed, sex, temperament, fitness, presence of pre-existing disease, previous transport experience, external and internal environmental conditions, transport vehicle design, and the feeding and watering regimen.

CHAPTER 65

Detection of drug use in performance horses

Cynthia Kollias-Baker and Scott Stanley

There is an increasing sense of concern on the part of horsemen, veterinarians, and the horse-loving public regarding the abuse of drugs and medications in horses participating in athletic competitions. Whereas it is recognized that therapeutic medications can benefit the horse, the overuse of these agents, as well as the administration of illegal drugs, have the potential to alter a horse's performance and mask serious injuries. In the show- and race-horse industries, private and government regulatory officials are responsible for developing drug and medication rules to protect the health and welfare of the horses and horsemen, assure a fair and level playing field for all competitors, and safeguard the public interest whenever pari-mutuel wagering is involved. Drug and medication rules are enforced through the testing of blood and urine samples collected from horses competing in athletic competitions for the presence of unauthorized drugs and medications and for drug concentrations greater than that permitted (overages) of authorized medications.

Enforcement is a two-step process, with all of the samples first subjected to a series of screening tests. If the results of any of these tests suggest that there is a violation of the medication rule, the sample will undergo a second confirmatory testing process. In the past few years, there have been significant technological advances in the screening and confirmation processes that have resulted in improved control over the use and abuse of medications and drugs in performance horses. These advances, however, have also led to the detection of residues of therapeutic medications and environmental contaminants. The performance horse industries and their regulatory bodies are currently trying to balance the need to control the abuse of unauthorized medications, avoid penalizing individuals for inadvertent environmental contamination, and desire to provide optimal veterinary care to equine athletes.

The drug-testing process

Sample type and collection

Sample collecting procedures must take into consideration both scientific and legal aspects. An important legal side to the process is chain-of-custody documentation, which is a tamper-resistant trail of documentation indicating where the sample has been and who has had custody of it at all times.

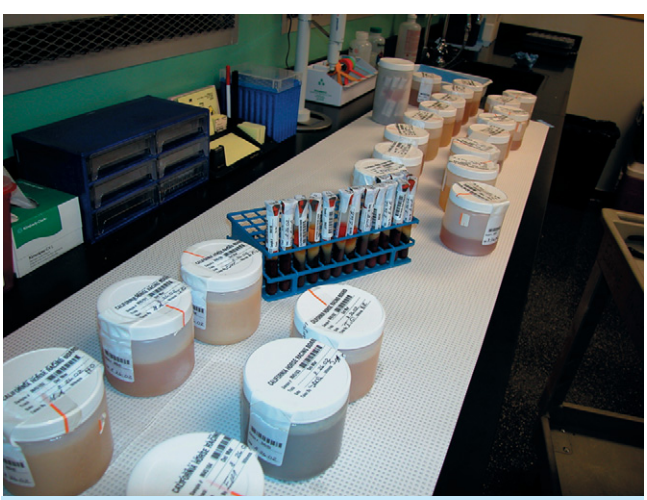

Fig. 65.1
Sample handling and chain of custody – sealed and labeled containers.

For this reason, the actual drug-testing process begins when a sample is collected. The collection container must be new, clean, and sealed and the sample must be obtained in a manner that avoids possible contamination from the environment (Fig. 65.1). It is important that drug-testing personnel maintain accurate records of sample collections, as this represents the beginning of the chain-of-custody process. Once collected, the samples are sealed with tamperproof evidence tape and secured for transport to the testing laboratory. Commercial courier services provide a complete external chain-of-custody with tracking information available through the bill of freight. The testing laboratories must also keep accurate records as to when the samples were received and document their internal chain-of-custody. In addition, security procedures must be in place to prevent the samples from being tampered with or compromised in some other manner during the collection, shipping, and testing processes.

Urine is the primary body fluid used for drug testing in most programs because it is relatively easy to obtain, and because most drugs and their metabolites are present in higher concentrations in urine than in blood. Generally, urine samples are collected from horses following competitive events. In the horse-racing industry, sample collection is usually a straightforward procedure. Following the race, the winner and one or two additional horses, which are generally chosen at random by the racing stewards, are taken to a secure and isolated detention barn where they are bathed, cooled out, and allowed access to water. Sometime during this cool-down period, most horses will void naturally. In contrast, collecting urine from show horses is often problematic. Horses to be tested are usually selected at random, although winners are always tested in some programs. Once a horse is chosen, the testers must remain with the horse until a sample is obtained or the process is halted due to the horse's failure to urinate in a timely manner. Show horses frequently compete in several classes, and often will not urinate until they are cooled out and untacked at the end of the day. Altogether, collecting urine samples from show horses can be a prolonged and time-consuming process.

Blood samples are also commonly collected if a veterinarian or veterinary technician is available to draw the sample. Because the concentration of many potent drugs in blood is too low to detect using current analytical methods, plasma or serum samples are rarely tested for unauthorized medications. For example, small doses of medications, such as detomidine, mepivacaine, and albuterol, while pharmacologically active, may not be present at detectable concentrations in the plasma or serum. Instead, blood samples are primarily used to regulate the use of authorized medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs), because therapeutic plasma or serum concentrations of these agents are usually readily detectable using current analytical methods. Maximum permitted concentrations of authorized medications are established in serum or plasma, and the laboratories analyze the blood samples to ensure that these limits are not exceeded.

In the past decade, interest in the analysis of hair for detection of administered drugs has increased in forensic sciences. For example, in the USA, analysis of hair collected from cattle has been used to screen for the administration of agents, such as clenbuterol, which are banned for use in food-producing animals. In addition, in horses that were administered morphine detectable concentrations of the drug were found in mane hair samples.[1] In addition, the amount of morphine found in the mane sample correlated with the dose of morphine that was administered to the horse. The results of another study demonstrated that the ability to detect drugs in hair samples depended on the location on the body where the sample was collected (i.e. neck, back, tail and mane) as well as the season of the year.[2] For example, the tail hair was determined to be the best choice for long-term drug detection, because of its length and continuous growth. In contrast, body hair, because it is short and continually shed, was the least likely to contain detectable concentrations of any of the administered drugs. It must be remembered, however, that not all drugs administered to the horse will be incorporated into growing hair.

One major drawback to the use of hair analysis in equine drug testing is that it is difficult to determine when the drug was administered to the horse. A mane sample positive for morphine, for example, could be the result of an administration 6 months earlier, and some horses may have been bought and sold several times over that period. For this reason, the usefulness of hair analysis and the legal and ethical ramifications of proceeding with regulatory action against an owner or trainer based on a positive hair test, remain to be determined.

Occasionally, saliva samples have also been tested for the presence of unauthorized medications. The principal value of testing saliva samples is the ability to detect agents recently administered by the oral route due to residual contamination of the mouth and pharyngeal area. Saliva is collected by swabbing the horse's mouth with cotton gauze held in forceps. The main disadvantage of saliva testing is that it is difficult to obtain a useful volume, as yields rarely exceed more than 5 g of fluid.

Testing scheme overview

Over the years, the drug-testing process has evolved into a two-step procedure. When the samples arrive at the laboratory, small aliquots of each are subjected to one or more screening tests. Ideal screening test methods are rapid and sensitive, but they do not have to be highly specific, because the results are only presumptive. Regulatory actions should never be taken based on a positive result in a screening test. In North America, the three screening methods that are most commonly used to detect the presence of unauthorized substances in equine urine samples are thin-layer chromatography (TLC), enzyme-linked immunosorbent assays (ELISAs), and instrumental techniques employing mass spectrometry. If the results of all of the screening tests are negative then the sample is declared negative and no further action is taken. However, if the results of one or more of the screening tests are suspicious, the sample will undergo a second round of

testing to confirm the presence and identity of the substance. Because the confirmation test result must typically withstand legal challenge and intense scrutiny, mass spectral identification of the substance is essential. Although gas chromatography–mass spectrometry (GC-MS) has been the most commonly used method of confirmation, liquid chromatography–mass spectrometry (LC-MS) is rapidly becoming the method of choice in most laboratories testing equine samples.

Split-sample analysis

As described above, before a reputable laboratory reports that a sample contains an unauthorized drug or an overage of an authorized medication, the sample has undergone a screening and confirmation testing process using validated analytical procedures. Nevertheless, a split- or referee-sample analysis is permitted in all racing jurisdictions. The referee or split sample is a small portion of the original sample, which was poured into a separate container, or 'split off', immediately after collection (Fig. 65.2). In an ideal situation, the referee sample is stored frozen at a secure site, physically separate from the primary testing laboratory. In horse racing, if the primary laboratory reports a finding for an unauthorized substance or an overdosage of an authorized medication, the owner or trainer of the horse implicated has the option to have the referee sample sent to a second independent laboratory. The second laboratory repeats the analysis to confirm the violation. Most racing jurisdictions maintain a list of reputable and reliable laboratories, from which the owner or trainer may select. The purpose of the split-sample analysis is to verify the results of the original laboratory, and in so doing guard against laboratory mistakes or contamination of the original sample during the collection or testing process. If the second laboratory does not confirm the presence of the unauthorized substance or the overage of the authorized medication found by the primary laboratory, no regulatory action is taken.

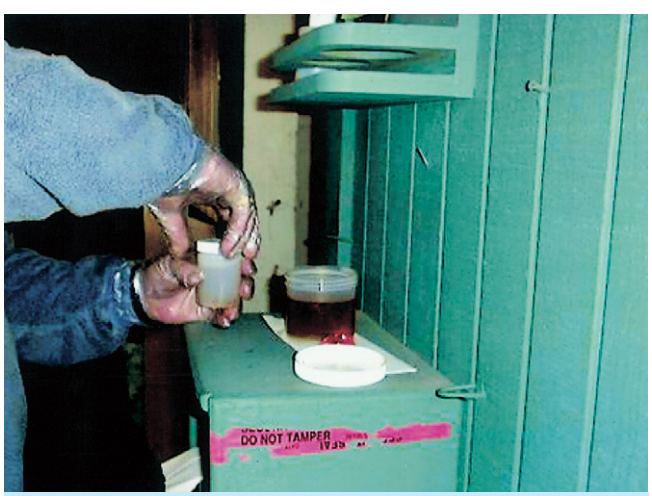

Fig. 65.2
A primary urine sample is split to create the primary and the referee or split sample.

There are several variations in split-sample analysis programs outside of the racing world. For example, under Fédération Equestre Internationale (FEI) regulations, a split-sample analysis is automatically conducted by a second FEI-associated laboratory following any finding of a violation of their drug and medication rule.[3] Should the second analysis fail to confirm the original finding, however, the rule does not stipulate whether regulatory actions will or will not be taken. For years, the American Horse Shows Association, which was the predecessor of USA Equestrian and which regulated the vast majority of horse shows in the USA, did not have a split-sample analysis program. Instead, the organization offered a reanalysis of the original sample in their primary testing laboratory. USA Equestrian, however, recently implemented a program that allows for collection of a split sample and testing of that sample at a second referee laboratory.[4] Unlike most racing jurisdictions, however, USA Equestrian does not maintain a list of approved laboratories. Instead, the rule states that the choice of second laboratory will be made by mutual agreement between USA Equestrian and the individual deemed responsible and accountable for the implicated horse. In addition, if the organization deems that only the laboratory that performed the original testing has demonstrated proficiency in performing the necessary confirmatory analysis for the drug or medication in question, then that laboratory will perform the split-sample analysis. In these aspects, the USA Equestrian rule still differs significantly from the split-sample programs utilized by most racing jurisdictions.

Analytical chemistry methods used to detect drugs and medications

Sample preparation

Sample preparation prior to testing for unauthorized medications uses variable sample volumes and can be employed for either urine or blood. The goal of the extraction process is to select and concentrate compounds of interest, often called analytes, from the sample while removing endogenous matrix materials that could interfere with the analytical process.

Liquid–liquid extraction

Probably the simplest and most traditional method of sample preparation is liquid–liquid extraction (LLE). In LLE, the aqueous sample is mixed in a glass vial with an organic solvent that is not miscible with the sample. Most drugs are more soluble in the organic solvent than in the aqueous media of the sample, and they therefore partition into and concentrate in the organic phase during the mixing process. Continuously agitating the mixture ensures that all parts of

the sample come into contact with the extracting solvent. Because the two liquids are not miscible in one another, the sample/solvent mixture will separate into two liquid layers when agitation ceases. The selection of optimal conditions, such as pH and solvent polarity, will result in the majority of any analyte present being extracted into the chosen solvent. To complete LLE, the two liquid layers are separated and the solvent layer is kept for further manipulation, such as concentration through evaporation.

Solid-phase extraction

Solid-phase extraction (SPE) is another technique used to separate and concentrate analytes from urine and blood samples. Whereas LLE uses a liquid solvent to separate the analytes from the sample matrix, SPE uses adsorption to a solid surface to achieve this same separation. The most common form of SPE is a prepackaged column containing bonded silica sorbents to which functional groups, such as hydrocarbons or ion exchange groups, have been bound. After the column of material has been conditioned, or washed and buffered to the desired pH to facilitate analyte binding, the liquid sample is passed through the bed of adsorbent particles. Analytes will be retained and contaminating matrix material will be removed by washing the column with water or some other buffer or solvent. In the final step the column is buffered to a particular pH to facilitate release of the analytes, which are then eluted into a small amount of solvent. In equine drug testing, three buffers with different pHs are used to produce an acidic, a neutral, and a basic drug fraction from each sample. Different drugs or drug classes will elute into the different fractions based on their physicochemical properties. For example, barbiturates and amphetamines will be present in the basic fraction, whereas corticosteroids will elute into the acid fraction. Each fraction then undergoes an evaporation process to further concentrate any analytes present prior to the analytical process.

Fig. 65.3
As depicted in this cartoon the final spots produced using thin-layer chromatography methods provide only average resolution, but permit the simultaneous detection of a wide range of substances in a single test.

Screening methods

Thin-layer chromatography

In TLC analysis, aliquots or small portions of the original test samples undergo a series of extractions, as described above, designed to separate any drugs present from endogenous sample matrix and concentrate them into small volumes of volatile solvent. These extracts are then applied or 'spotted' onto thin glass plates, which are coated with adsorbent material, such as silica gel, which serves as the stationary phase. The plates are then placed into a chamber with a small volume of organic solvent, which serves as the mobile phase. Drugs and other compounds are carried up the plate in the mobile phase by capillary action at a rate and distance that depends on their physicochemical properties (Fig. 65.3). Although a few agents produce visible spots, most drugs are visible only after applying certain dyes or regents. These reagents are sprayed onto the plate, where they interact with functional groups on the drug molecules to produce color changes, which make the spots visible. Different drugs may have similar migration patterns, and therefore the identification of a drug based on TLC analysis is only presumptive.

Racing laboratories have used TLC for over five decades and it remains one of the most common screening methods used in North America, despite numerous disadvantages to the methodology. For example, TLC methods require large volumes of both sample and solvent. In addition, they are time-consuming and labor-intensive, and the spots produced by the method require interpretation by the chromatographer, which can be subjective. Finally, the sensitivity of TLC is often not adequate to detect many of the more potent drugs in use today. For example, the smallest concentrations of drugs that can be detected, which are commonly referred to as limits of detection (LOD), by TLC are greater than 100 nanograms per milliliter (ng/mL) or parts per billion (ppb) for most analytes. In contrast, the LOD for ELISA and instrumental screening methods are commonly in the range of 1 to 10 ng/mL. Nevertheless, TLC remains in favor as an

analytical method because of its simplicity (extraction and spotting technicians can be trained in a few weeks), dependability (no moving parts or automation is required), relatively low cost (80% of the cost is labor), and its capacity to simultaneously detect a wide range of substances in a single analysis.

Enzyme-linked immunosorbent assay

Although ELISA testing has only been available since the 1980s, it has rapidly become an integral part of routine equine drug testing, primarily because of its simplicity and sensitivity. The majority of laboratories in North America use ELISA to complement their TLC screening methods, although several laboratories have developed screening schemes based solely on ELISA tests. The principal components in enzyme immunoassays are: (1) a drug molecule labeled with a specific enzyme conjugate; (2) a polyclonal antibody specific for the drug; and (3) a substrate, such as tetramethylbenzidine, capable of producing a measurable optical signal or color change when bound by the enzyme conjugate. The antibodies used in ELISA are specific for one drug or a drug class in which members have a similar chemical structure. In the test, the enzyme-labeled drug binds to the antibody, which results in a color change when the substrate is added. If there is drug in the test sample, it will compete with the enzyme-labeled drug for binding sites on the antibody. As a result, there will be less of the enzyme-labeled drug bound to the antibodies, and so there will be little or no color change when the substrate is added (Fig. 65.4). The testing process is simplified by the use of automated microtiter plate readers that rapidly screen the plates at their optimal wavelengths and calculate the test results with vendor-supplied software. When authentic reference standards are used to create a multipoint calibration curve, the results of ELISA testing can provide semiquantitative results or an estimation of the amount of the drug in the sample.

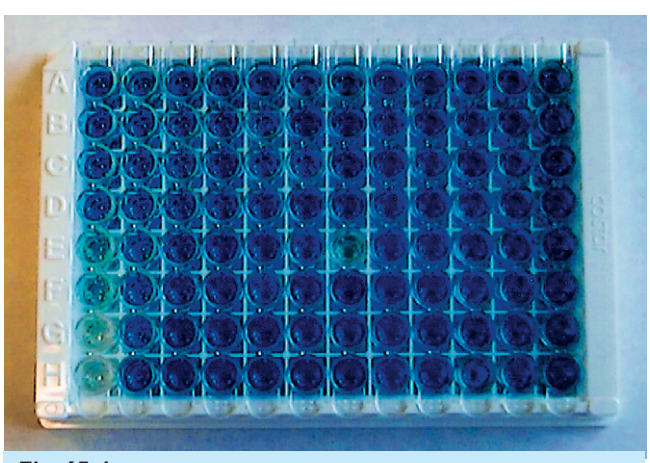

Fig. 65.4
A developed ELISA plate with a suspect sample depicted on row E, column 7. The 96-well plate configuration allows the analysis of 88 test samples and 8 reference standards, which are shown on this plate in the column on the far left.

As mentioned previously, one of the advantages of the use of ELISA testing is its superior sensitivity. The LOD for most drugs using ELISA tests are in the range of 1–10 ng/mL. When employing ELISA for specific drug or drug classes LOD of 1 ng/mL are achievable for many substances. As with any immunologically based assay, non-specific cross-reactions can occur and therefore, as with TLC, ELISA results represent only provisional drug identifications. A more specific test, generally based on mass spectrometry, must be used to confirm the presence and the identity of the drug.

Instrumental analysis

With the availability of lower-cost analytical instruments and automated sample preparation, instrumentally based drug testing programs using GC-MS and LC-MS have been employed for a number of years in Europe, Australasia, and Africa and are rapidly becoming the gold standard for equine drug testing in North America. These instrumental approaches provide a wide range of coverage (i.e. >750 drugs), excellent sensitivity, and superior specificity. Limits of detection of less than 1 ng/mL can be achieved when extraction and chromatographic separation are optimized.

Chromatographic separation

The first step in mass spectrometric analysis involves the separation of any analytes in the sample from one another and from biological matrix contaminants. The two most common instruments used for separation in equine drug testing are the gas chromatograph (GC) and the high performance liquid chromatograph (HPLC). Separation on a GC is achieved utilizing a long flexible capillary column that contains a low polarity stationary phase (i.e. 95% dimethyl 5% diphenyl-polysiloxanes). A programmed oven maintains the column at the desired temperatures (i.e. 60–280°C) according to the specific method. Following the extraction process, any analytes contained in the original sample will be present in a small volume of extraction solvent. An aliquot of each extracted sample is injected into one end of the capillary column and volatilized by heating. The volatilized sample is carried through the column by the gas mobile phase, usually helium or hydrogen, which is maintained at a constant flow.[5,6] As with any other chromatographic method, compounds travel through the column at different rates based on their physicochemical properties. The capillary columns produce excellent resolution, which is useful when trying to separate the complex matrix typical of equine urine. In a well designed GC-MS method, the chromatographic step provides sufficient separation to isolate individual compounds, and the choice of chromatographic column is the key to this separation. GC-MS systems, configured for large volume injection (~50 μL), have been demonstrated to be sensitive, precise, and rugged, making high throughputs possible. Thus, these systems are ideal for screening for drugs that are extracted into the basic fraction, because most of these agents are stable and volatile at the high temperatures used in GC-MS analysis.

The use of HPLC to produce analyte separation prior to mass spectral identification is rapidly becoming one of the most widely used analytical methods in equine drug testing, because it is applicable to a wide range of organic compounds. By some estimates, 80% or more of organic compounds can be separated by HPLC compared to only 20% by GC. The HPLC techniques can separate many drugs that are not amenable to GC separation, because they are too polar, not volatile, or have very high molecular weights (> 700 atomic mass units). In HPLC analysis, a liquid mobile phase is pumped under pressure through a column of microparticulate packings (typically 3–5 μm diameter), which serves as the stationary phase. Compounds in the extracted sample are carried in the mobile phase to the column, where they are retained on the stationary phase. Numerous types of microparticulate packing material can be used in the columns, depending on the physicochemical properties of the compounds that are to be separated. In general, different compounds will have different affinities for the microparticulate column material, and so they will be retained on it for different periods of time. The length of time that a compound is retained on the column, which is referred to as its retention time, can also be controlled by varying the composition of the mobile phase. For example, by making the mobile phase more polar, the polar compounds can be eluted off the stationary phase more quickly. There are two modes of HPLC separation, normal-phase and reverse-phase. Nearly 90% of all applications use reverse-phase, in which the mobile phase is more polar than the column packing material.

Mass spectral analysis

Following chromatographic separation, compounds isolated from the sample are serially injected into the mass spectrometer. The compounds first enter the ionization chamber where they are bombarded with an electron beam that ionizes them, causing the compounds to fragment into smaller molecules. The fragments, as well as the original ionized parent molecules, are then accelerated through a magnetic field and focused into an analyzer that measures the mass to charge ratio and abundance of each ion. A plot of the abundances of the ions versus their mass/charge ratios is referred to as the compound's mass spectrum (Fig. 65.5). The most intense peak in the spectrum is referred to as the base peak and all other peaks are reported relative to its intensity. The highest molecular weight peak in a spectrum will usually represent the parent molecule, minus a single electron (ionized), and is referred to as the molecular ion. The process of fragmentation follows predictable chemical pathways and the most chemically stable ions will always be formed. Therefore, every drug or medication has a unique mass spectrum in a manner similar to every person having a unique set of fingerprints. This is the reason that mass spectral identification is considered the gold standard for absolute drug identification during the confirmation process.

If desired, the HPLC method can be designed to produce complete separation of compounds before introduction to the mass spectrometer. This allows for the analysis of very complex mixtures, or samples with high matrix interference

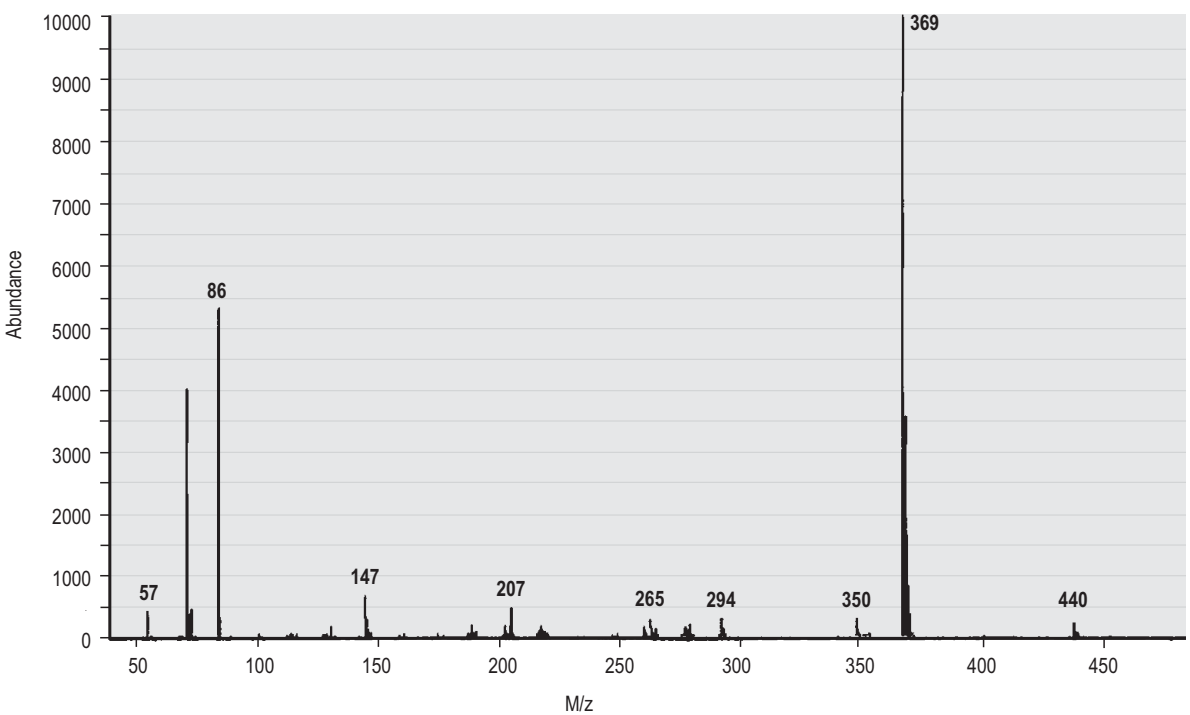

Fig. 65.5
Electron impact full scan mass spectrum of albuterol-TMS derivative as determined by gas chromatography–mass spectrometry.

or very small drug concentrations. However, because of the discriminating power of the mass spectrometer, a reduced amount of resolution may be acceptable and will have the added advantage of decreasing the time required for the compounds of interest to elute off the column. This is particularly true in MS-MS operation, because the two-stage mass analyzer provides an additional separation device.

The LC-MS ion trap mass spectrometers with an inline photodiode array detector have been employed for the combined acid/neutral fraction because this fraction by and large contains compounds that are not volatile or are otherwise unsuitable for GC-MS analysis. These ion trap methods are rapid, sensitive, and very reliable, allowing for the detection of corticosteroids, anabolic steroids, and other related drugs.

Miscellaneous testing methods

In addition to its use as a separation method prior to mass spectral analysis, HPLC is also occasionally used as a screening and confirmation method in conjunction with several different types of detectors. Ultraviolet (UV) absorption is probably the most common type of detection method used in equine drug-testing programs, because it is both sensitive and reliable with broad applicability. UV detectors are available at fixed, selectable, and continuously variable wavelengths or as diode-array detectors. Most commonly, HPLC with UV detection is used to determine the concentration of authorized medications, such as NSAIDs, in serum or plasma samples. Some laboratories, however, are still using these detectors to screen acid extracts of equine urine samples for unauthorized medications. The fluorescence detector measures the fluorescence of a drug or its derivative, if it does not naturally fluorescence. It is generally very sensitive, but it is of limited usefulness in drug-testing programs because only a few drugs naturally fluoresce and because it is difficult and time consuming to make fluorescent derivatives. Electrochemical detectors, which can only detect the limited number of substances that are electroactive at a particular electrode in response to an applied potential, are not commonly used in equine drug-testing programs.

Testing approaches

Pre-race testing

Since the 1960s, pre-race testing has been heralded as a solution to many of the drug and medication problems facing the horse-racing industry. The rationale behind this approach is to test all horses prior to racing in order to disqualify any horse with an unauthorized drug or medication in its system. Throughout the 1960s, 1970s and early 1980s, various racing jurisdictions, including Maryland, Illinois, and New York, conducted pre-race testing using a number of different methodologies, including GC, HPLC, TLC, and ELISA. By the 1990s, however, except for bicarbonate analysis, pre-race testing was largely abandoned in favor of post-race analysis for a number of reasons. First, only blood samples can be obtained in the short time period immediately prior to racing, and the concentrations of many drugs in plasma are often not detectable using current analytical methodology. Second, the process is extremely expensive, because equipment and personnel have to be near the racetrack, and testing has to be conducted during weekends and evenings to accommodate the racing schedule. Finally, there are legal ramifications to disqualifying a horse from a race based on only the results of a screening test. These results are only presumptive and are not considered definitive evidence of the presence of a drug or medication. If further definitive testing, such as mass spectral analysis, failed to confirm the presence of the drug, then an argument could be made that the owner and trainer were unjustly forced to withdraw the horse from the race. Despite the limitations and difficulties of conducting pre-race testing, it remains an attractive approach with regulators and owners, because if successful it has the potential to prevent horses from competing under the influence of unauthorized substances, instead of penalizing the owner and trainer after the fact.

In Europe and Asia, pre-race testing is carried out for a limited number of substances, such as anabolic steroids, prior to large international events. Horses are sequestered upon arrival and tested prior to selected sales and/or racing events. The timeframe for the testing is such that both screening and confirmation analysis can be completed on collected urine samples. This practice allows racing authorities to strictly control the use of these agents in horses in these jurisdictions by disqualifying any animal from the sale or race that does not meet their local criteria for medication control.

Alkalinizing substances

The oral administration of sodium bicarbonate or other alkalinizing agents to horses just prior to racing is referred to as 'milk shaking'. To control this practice, many racing jurisdictions have established venous blood gas criteria for detecting pre-race administration of alkalinizing agents. Blood samples are collected from horses pre-race, as close to race time as practical, and screened using a blood gas analyzer for bicarbonate or total carbon dioxide. Thresholds have been adopted which represent the maximum serum concentrations of these analytes that could occur naturally without the exogenous administration of bicarbonate. In the event that a horse exceeds the threshold on race day, the horse is disqualified from the event and the trainer may be fined and have his or her license suspended. The process, however, is not without controversy because the upper limits for normal serum values for bicarbonate and total carbon dioxide are not universally accepted.

Out-of-competition testing

To enforce the ban on the use of performance-enhancing drugs, such as anabolic steroids and human recombinant erythropoietin (rHuEPO), in human athletics,

out-of-competition drug testing has become standard practice. This approach was adopted because the effects of some drugs can persist beyond the length of time that current testing methods can detect them in urine or blood samples. If the goal of the drug and medication control program is to strictly prohibit the use of a particular drug by athletes, then out-of-competition testing is the only mechanism by which this can be accomplished. Despite its acceptance in human athletics, out-of-competition testing has not been generally practiced in the horse racing industry for several reasons. First, the drug and medication rules in most racing jurisdictions are worded to prohibit the presence of any unauthorized drug or medication in the horse at the time of the race. Most do not forbid or in any way limit what drugs are administered to the horse during the training period, as long as the drug is not detectable in the post-race urine sample. In addition, out-of-competition testing would increase the cost of administering a drug-testing program because more samples would need to be collected and tested. Recently, however, rumors of the use of rHuEPO have led to an exploration of out-of-competition testing for race horses. Current testing methods for rHuEPO limit the detection period to 48–72 h after administration, although the effects of repeated administrations can last for weeks. Therefore, if the racing industry and regulatory authorities determine that rHuEPO should be banned from use in race horses, out-of-competition testing will be the only feasible mechanism of controlling its use until a more sensitive test can be developed.

Authorized medications

In recent years, many USA drug- and medication-control programs have permitted a limited number of therapeutic agents to be used in horses during competitions. The NSAID phenylbutazone is the most widely used authorized medication. Other NSAIDs, such as flunixin, meglumine, and ketoprofen, are also authorized by some race- and show-horse medication rules and the diuretic furosemide (frusemide) is allowed to be administered to horses suffering from exercise-induced pulmonary hemorrhage (EIPH) in most racing jurisdictions in North America. It is the desire of these programs to control the use of these authorized medications by limiting the amounts of the drugs that can be administered. This limitation is achieved by adopting maximum serum concentration for authorized medications, such as NSAIDs, as shown in Table 65.1. Most programs collect blood samples ostensibly to regulate the use of authorized medications.

Although NSAIDs are permitted in many jurisdictions in the USA, in Europe and Australasia they are unauthorized medications and their presence at any concentration is prohibited in post-race samples. Recently published studies indicate that environmental sources of NSAIDs may result in detectable concentrations of those agents in equine urine samples. For example, in one study ibuprofen was present in urine samples collected from a horse that consumed feed that had been prepared by someone with ibuprofen gel on their hands.[7] In another study, untreated horses housed in stalls previously occupied by horses treated with therapeutic doses of flunixin had detectable concentrations of that NSAID in their urine for up to 14 days.[8] The results of these studies emphasize the importance of good barn hygiene. After administering any medication, barn workers should thoroughly was their hands. If at all possible, horses being administered medications should by segregated from untreated horses, and their stalls should be stripped and re-bedded once treatment is terminated.

Table 65.1 Plasma regulatory limits for non-steroidal anti-inflammatory agents in US racing and show horses

State	Phenylbutazone	Flunixin	Ketoprofen	Meclofenamic acid	Naproxen
AZ, AL, CO, FL, ID, IL, IN, LA, MA, MI, MN, NJ, OH, OK, OR, TX, WA, WV	5.0 μg/mL	Not authorized	Not authorized	Not authorized	Not authorized
CA	5.0 μg/mL	0.5 μg/mL	0.05 μg/mL	Not authorized	Not authorized
KY	Not regulated	Not regulated	Not regulated	Not regulated	Not regulated
MD	2.2 μg/mL	Not authorized	Not authorized	Not authorized	Not authorized
NY	< 2.0 μg/mL	Not authorized	Not authorized	Not authorized	Not authorized
PA	5.0 μg/mL	0.1 μg/mL	Not authorized	Not authorized	Not authorized
USA Equestrian	15.0 μg/mL	1.0 μg/mL	0.25 μg/mL	2.5 μg/mL	40.0 μg/mL

Furosemide

Furosemide (frusemide) is a loop diuretic that induces natriuresis, chloruresis, increased hydrogen ion excretion, and a profound diuresis.[9] These effects are mediated by the inhibition of Na^+–K^+–$2Cl^-$ transporters in the thick ascending limb of the loop of Henle. Furosemide also has important extrarenal effects. For example, it produces a significant venodilation that appears to be mediated by stimulation of prostaglandin and nitric oxide production.[9,10] This effect was dependent on the presence of a functional kidney but not on the development of diuresis. Furosemide also has been shown to prevent bronchoconstriction in humans and ponies, an effect that may be mediated by decreased production of inflammatory mediators.[11–13] In addition, furosemide was shown to improve gas exchange in anuric humans suffering from severe pulmonary disease.[14] The improvement in gas exchange was due to furosemide-induced decreases in ventilation–perfusion mismatches, and not to changes in blood volume.

In all US and Canadian racing jurisdictions, furosemide is considered an authorized pre-race medication, which can be administered to horses that suffer from EIPH. Whether or not furosemide is an effective therapy for EIPH, however, has yet to be definitively proved. For example, in 1985 Pascoe et al.[15] concluded that furosemide decreased the severity of EIPH in race horses. That study, however, used an admittedly subjective grading scale to judge the severity of the disease, and the results are therefore not conclusive. Nevertheless, if the pathogenesis of EIPH is associated with the unusually high pulmonary arterial pressures (>70 mmHg) that develop in the horse during intense exercise, as has been proposed, then there is evidence to support the use of furosemide as a therapeutic agent.[16,17] For example, multiple studies have demonstrated that furosemide decreases the peak pulmonary vascular pressures that develop in horses during intense exercise.[18,19] The mechanism by which furosemide produces this effect, however, is still unclear. The results of one study indicated that the reduction in pressure could be partially reversed by the administration of cyclooxygenase inhibitors, whereas another study concluded that prostaglandin production was not involved in the process.[20,21] Another simple explanation for the reduction in pulmonary arterial pressures is the decrease in blood volume secondary to the profound diuresis induced by furosemide.

Apart from any effects on the severity of EIPH, furosemide has also been proposed to enhance the athletic performance of horses. It is hypothesized that the diuretic-induced fluid losses result in a moderate, but significant, weight loss in the horse, which can enhance its athletic performance. In support of this theory, in treadmill exercise tests carried out in horses that did not suffer from severe EIPH, some parameters of exercise performance improved following furosemide administration.[22,23] These improvements, however, were reversed when fluid losses were replaced by intravenous administration of equivalent amounts of balanced electrolyte solutions. A field study carried out by the same laboratory also concluded that superior performances in races horses in the USA were associated with the administration of furosemide.[24] The North American racing industries, as well as some in the scientific community, however, have not generally accepted the results of this study, but given its provocative conclusions this lack of acceptance is hardly surprising.

In addition to the controversy regarding the effects of furosemide on equine athletic performance, it has been proposed that the dilute urine that follows furosemide administration may interfere with the detection of other drugs.[25,26] Therefore, the dose and timing of furosemide administration are regulated to minimize the chance that urine samples collected post-race will be dilute (i.e. urine specific gravity (SG) < 1.010). Most commonly, furosemide administration is restricted to no more than 250 mg, administered intravenously no closer than 4 h to post time. Due to the wide variability of furosemide pharmacokinetics following i.v. administration in horses, the use of serum furosemide concentrations alone is not an appropriate method to monitor compliance with furosemide dosing regulations.[25,27] The use of urine SG measurements to monitor compliance is also insufficient because of the wide range of SG measurements, obtained in both untreated control and furosemide-treated horses.[27] Despite the limitations of each test individually, screening for furosemide violations becomes much more specific by combining measurements of both urine SG and serum furosemide concentration.[28] When a urine SG less than 1.012 and a serum furosemide concentration greater than 100 ng/mL are present simultaneously, the proportion of horses expected to be erroneously classified as being in violation of furosemide dosing regulations approaches 0%.

Drug and medication rules

The Association of Racing Commissioners' International

Association of Racing Commissioners' International (ARCI) is an organization consisting of racing regulators primarily from the USA, Canada, and the Caribbean. The organization has no enforcement power but rather encourages standardization by adoption of model rules and racing polices for a broad range of topics. The organization has adopted a Uniform Classification Guideline for Foreign Substances consisting of five classes, and which currently lists over 800 agents.[29] The classification scheme is based on the potential for the agent to affect a horse's athletic performance, and whether or not it has a recognized therapeutic use. For example, drugs listed in the Class 1 category are considered to have the most potential to affect racing performance and have no accepted medical use in the horse. In contrast, drugs listed in the Class 5 category are therapeutic medications, which are considered to have very little potential to affect athletic performance. One limitation of the classification system is that it is based on the effects of the drugs on healthy horses. For example, the corticosteroid agents commonly used as

intra-articular medications, such as methylprednisolone and triamcinolone, are listed as Class 4 agents, which are described as therapeutic agents with limited ability to influence performance. Although intra-articular corticosteroids may have limited potential to alter the performance of a sound horse, they have enormous potential to alter the performance of a horse with an inflamed, arthritic joint.[30,31]

The ARCI has also adopted recommended penalties for violations based on the classification system. It does not, however, have the power to force states to adopt the guidelines or the model rules. Although few states have adopted the program in its entirety, states have used portions of it when drafting their own drug and medication rules.

Fédération Equestre Internationale

The FEI is the governing body recognized by the International Olympic Committee. It establishes the rules and regulations, including those for medication use, under which the international equestrian disciplines of Jumping, Dressage, Eventing, Vaulting, Driving and Endurance Riding compete. The organization was founded in 1921, and as of 2002 some 130 countries were members.

The stated objective of the FEI drug and medication rule is to protect the integrity of equestrian sports through controlling the use of substances capable of giving a horse an advantage or disadvantage in an event, contrary to its natural abilities.[3] The FEI considers a prohibitive substance to be any agent capable at any time of acting on one or more of the following mammalian body systems: the nervous system, the cardiovascular system, the urinary system, the reproductive system, the musculoskeletal system, the blood system, the endocrine system, the immune system (other than licensed vaccines), the digestive system (other than the orally administrated antiulcer medications omeprazole and ranitidine) and the skin. An extensive list of specific prohibited agents is approved each year. The medication rule states that the finding of a prohibited substance means the detecting of the substance itself, a metabolite of the substance, an isomer of the substance, or an isomer of a metabolite.[3] In addition, the finding of any biological or scientific indicator of administration or other exposure to a substance is equivalent to the detection of the substance itself. This latter aspect of the rule allows for methods of detection that do not specifically identify the substance itself, but rather detect some secondary physiological change that occurs following its administration.

The list of medications not considered prohibited substances is quite short and includes rehydration fluids, oxygen, antibiotics, and antiparasitics. There are limitations, however, as to how and when even these agents can be administered, so veterinarians must consult with the FEI Veterinary Delegate prior to treating any horse in an FEI event.

As discussed below, the FEI, as well as many other regulatory bodies, have adopted thresholds on a number of different substances. Unlike many other drug and medication rules, however, the FEI strictly limits the type of substances for which thresholds may be adopted. Their rule states that thresholds can only be adopted for substances endogenous to the horse, substances arising from plants traditionally grazed or harvested as equine feeds, and substances in equine feed arising from contamination during cultivation, processing, treatment, storage, or transportation.[3]

USA Equestrian

Formerly known as the American Horse Show Association, USA Equestrian is the largest regulatory organization for show horses in the USA. It is a member of the FEI and serves as the national governing body for the US Olympic Team, and also oversees much lower-caliber horse shows and events. Numerous riding and breed disciplines compete under the USA Equestrian umbrella, including Arabian, Eventing, Connemaras, Reining, and Vaulting. USA Equestrian has two drug and medication rules and each discipline chooses under which rule they wish to compete. The No Foreign Substance Rule is the same as the FEI medication rule and currently only FEI and the Endurance Riding events are conducted according to its provisions. The remaining disciplines compete under the Therapeutic Substance Rule. This rule is considered more permissive than the No Foreign Substance rule. Under this rule, forbidden substances are any stimulant, depressant, tranquilizer, local anesthetic, or psychotropic agent and/or drug that might affect the performance of a horse and/or pony or any metabolite and/or analogue of any such substance except where expressly permitted.[4] Unlike the No Foreign Substance Rule, the Therapeutic Substance rule allows for a number of permitted medications to be present in the horse's system during an event or show. For example, up to two NSAID agents are allowed to be administered to a horse, as long as the plasma concentrations do not exceed the specified maximum permitted limits.[4] The NSAIDs that are currently permitted and their respective maximum allowed serum concentrations are shown in Table 65.1. The Therapeutic Substance rule also allows the use of the muscle relaxant methocarbamol in show horses, as long as the plasma concentration does not exceed 4.0 μg/mL. USA Equestrian does not, to the authors' knowledge, provide a definitive list of forbidden substances, but will generally address practitioners' questions regarding non-permitted medications and provide withdrawal guidelines whenever possible.

Factors affecting detection times and withdrawal times

Commonly, veterinary practitioners want to know withdrawal times (how long before an event or race they should discontinue treatment) for medications to avoid having a horse test positive for that agent. Unfortunately, it is very difficult for laboratories to generate accurate withdrawal times for therapeutic medications because many different

factors can affect their detection times (how long a drug is detectable in a sample after administration). Probably the most important factor in the detection time of a medication is the sensitivity of the testing method that is being used by the laboratory. As discussed previously, there are large variations in the LOD for different analytical methods. For example, in general, TLC is much less sensitive than instrumental or ELISA analysis. Therefore, a detection time for a medication tested for by TLC in one laboratory would be significantly shorter than the detection time determined by another laboratory that used instrumental analysis as their testing method. Even if the same technique is used, differences in sample preparation can result in higher or lower analyte recoveries that can ultimately affect the detection time.

In addition, many other factors outside of the laboratory also affect detection times. For example, the higher the administered dose, generally the longer the detection time. In addition, some drugs, such as clenbuterol and isoxsuprine, accumulate in the body and after several days of administration, drug residues can persist in urine samples for 30 days or longer. There can also be large variations in the clearance rates of many drugs between different horses. The actual withdrawal time for a specific medication in a particular horse may be substantially different than the laboratory's estimated time, because laboratories often base their withdrawal times on data from only one or two horses. In summary, although many laboratories will provide withdrawal times to veterinarians, these should be used only as guidelines.

Thresholds, reporting levels, and cutoffs

As analytical chemistry methodology has improved, the smallest amount of a drug or medication that can be detected in bodily fluids has progressively decreased. Currently, the LOD in urine for most substances of concern are in the low ng/mL range. As a result of this sensitive testing, the use of drugs and medications in equine sports is considered by many to be well controlled. The side-effect of this sensitive testing, however, is also the detection of substances that were not purposely administered to the horse. In some situations these agents are contaminants in the horse's environment. For example, theobromine can be found in cocoa husks, and scopolamine and atropine occur naturally in many plants in the *Datura* genus. In addition, it is now recognized that some substances thought to be exogenous synthetic agents are actually endogenous, albeit usually only produced in very small amounts. For example, both hydrocortisone and nandrolone are now recognized as naturally occurring hormones.

As a result of the sensitive testing and the recognition that some substances may be endogenous to the horse or contaminants in its environment, almost every organizational body that regulates equestrian activities has adopted thresholds or cutoffs for a number of substances. The philosophy is to prevent horses from competing under the influence of unauthorized medications, while still allowing veterinarians to provide the best-quality medical care possible to equine athletes. Horses may compete in sanctioned events with the presence of these substances in their tissues, body fluids, or excreta provided the concentration of the substance does not exceed the predetermined threshold value. Table 65.2 lists a number of thresholds accepted by many regulatory bodies.

Table 65.2 Internationally accepted serum or urine threshold concentrations

Contaminating substance	Concentration
Dimethyl sulfoxide	15 μg/mL in urine or 1 μg/mL in plasma
Arsenic	3 μg/mL in urine
Hydrocortisone	1 μg/mL in urine
Salicylic acid	750 μg/mL in urine or 6.5 μg/mL in plasma
Testosterone	0.02 μg free and conjugated/mL in urine from geldings, and 0.055 μg free and conjugated/mL in fillies and mares (unless in foal)
Theobromine	2 μg/mL in urine

A few regulatory agencies have taken the idea of thresholds a step further and adopted reporting limits on therapeutic medications. The California Horse Racing Board, for example, has adopted urinary decision levels or thresholds on the eight medications and environmental contaminants shown in Table 65.3. The rationale behind the adoption of these levels is to allow veterinarians to administer therapeutic medications to the horse up to 48 h before a race without concern that residues of those administrations will result in positive analytical findings in post-race urine samples. Although it is likely that the urine concentrations of these agents are not associated with significant pharmacological activity, definitive evidence of this is lacking for some of these agents. Although some racing jurisdictions, especially those in Europe, have been critical of this approach, a number of others in the USA, including Washington and Ohio, have followed suit and adopted similar decision levels for therapeutic medications.

Table 65.3 Urine threshold concentrations adopted by the California Horse Racing Board for therapeutic medications and environmental contaminants

Substance	Concentration
Acepromazine	25 ng/mL
Mepivacaine	10 ng/mL
Promazine	25 ng/mL
Albuterol	1 ng/mL
Benzocaine	50 ng/mL
Procaine	10 ng/mL
Salicylates	750 μg/mL

Drugs in dispute

Recombinant proteins

The tremendous advances in molecular biology that have occurred in recent years have led to the commercial production of numerous recombinant proteins and hormones for use in treating many different types of diseases. Although most of these products are of human origin, such as rHuEPO, at least one equine product, recombinant growth hormone (rEqGH), is already available. Recombinant hormones are particularly difficult medications to control using traditional drug-testing methods for a number of reasons. First, although ELISAs can be developed for these recombinant proteins, routine mass spectrometry methods used in the confirmation process are not suitable for protein analysis. Second, the recombinant hormones are difficult, if not impossible, to distinguish from their endogenous counterparts. Obviously, equine recombinant proteins may be identical to the endogenous hormone, but because many proteins have a high degree of homology across species, it may also be difficult to distinguish a human recombinant hormone from its equine endogenous counterpart. Finally, because many of the effects of these hormones persist for weeks after administration, most of these agents would be used primarily during the training process, as opposed to during the competition. Therefore, the concentration of the hormone in urine or serum samples collected during a competition is likely to be small, making detection and confirmation difficult.

To control the use of these medications, significant changes in the traditional approaches and analytical methods of drug testing will be necessary. For example, rEqGH is indistinguishable from endogenous equine GH and has a very short serum half-life. Therefore, it would be very difficult to effectively control the use of rEqGH by adopting a maximum permissible serum growth hormone concentration consistent with a normal physiological level of the hormone. Exogenous administration of rEqGH, however, is also associated with an increase in the serum concentration of insulin-like growth factor-1 (IGF-1). It has been proposed that IGF-1 can serve as an indirect marker of rEqGH administration, with serum threshold concentrations of IGF-1 greater than 800 ng/mL being indicative of the administration of rEqGH.[32]

In addition to using non-traditional approaches, the use of alternative confirmatory methods, such as isoelectric focusing or new mass spectrometry methods, for protein sequencing may be needed to detect administration of recombinant proteins. For example, in June of 2000 Lasne and de Ceaurriz published a method that could differentiate endogenous human EPO from the rHuEPO protein.[33] This isoelectric focusing method capitalized on the subtle differences in the sialylation (sialic acids in the glycolylated side chains) between the recombinant and the endogenous human hormone that resulted in unique isoelectric points (pI). In addition, if regulators want to control the use of these substances during training they must develop a protocol for out-of-competition testing, similar to what is used for human Olympic competitors, due to the difficulty of detecting these agents on the day of a competition.

Anabolic steroids

Many drugs and hormones, such as β_2-agonists, insulin, growth hormone, and androgenic and estrogenic steroids, can induce a positive nitrogen balance in the body and are therefore said to have anabolic effects. In practice, however, the androgenic steroidal agents, which are similar in structure to testosterone, are the drugs most commonly used when anabolic effects are desired. Although testosterone is the most potent of these agents, it also produces the most androgenic effects. Synthetic agents are therefore often preferred, because modifications in their chemical structure have decreased their androgenic effects in favor of anabolic activity. Anabolic/androgenic steroids were first used in the 1940s to improve recovery from starvation, and major injuries and surgery.[34] Although their use today in human medicine is severely limited, they are still widely used in horses in North America. For example, while they are approved for use in debilitated, starved, or severely stressed animals, they are commonly administered to horses undergoing race or event training, at least in part to maintain their appetite and vigor.

In many human amateur sports, the use of anabolic steroids is strictly forbidden and rigorous out-of-competition testing is used to enforce the ban. Most of the general public assumes that equine athletic events are carried out under similar auspices. Although this is true in Europe and Australasia, this is not the case in North America. The explanation for this dichotomy is both philosophical and analytical. For example, in 1988 the European Community issued a directive banning the use of anabolic steroids in all meat-producing animals, which included the horse. This directive essentially eliminated all legal formulations of anabolic steroids for use in large animals throughout Europe.[35] The racing industries in Europe and Australasia supported the ban on the use of anabolic steroids in horses, primarily out of concern for the potential performance-enhancing effects of these agents. In response to these events, racing laboratories in these jurisdictions developed sensitive ELISA screening tests and GC-MS confirmatory methods to control the use of anabolic steroids. In contrast, in North America anabolic steroids are still used as growth-promoting agents in food-producing animals and multiple formulations are available and approved for use in the horse. In addition, the racing industry in North America has traditionally not supported tighter regulations on the use of anabolic steroids and the regulators have not viewed them as agents with significant potential to alter a horse's racing performance. For example, anabolic steroids are listed as Class 4 agents by the ARCI Drug Classification Guideline, which indicates that they are considered therapeutic medications with less potential to affect performance than drugs in Classes 1 through 3. Partly because of their classification, drug-testing laboratories in North

America have not developed or implemented sensitive testing methods for anabolic steroids. Recently, many of the breeders of performance horses in North America have begun to express concern over the rampant use of anabolic steroids and their possible detrimental effects on the integrity of the breed. Whether or not this concern eventually spreads throughout the racing industry remains to be determined.

Morphine

Opiates, such as morphine, are commonly used as analgesics and preanesthetic drugs in many species, including man. In horses, however, opiates can cause central nervous system stimulation and are therefore used only occasionally, and then generally in combination with sedatives or tranquilizers.[36] Morphine, however, has occasionally been detected in urine samples collected from horses after racing. Typically, the concentrations of morphine found in these post-race urine samples are less than 50 ng/mL, and in most cases morphine is not present in detectable concentrations in the corresponding plasma samples. The presence of any opiate at any concentration in post-race urine samples, however, is of concern to racing authorities, because in the past these drugs have been administered to horses in illicit attempts to enhance their racing performances.

The opiate morphine is derived from the opium poppy, *Papaver somniferum*, a plant native to the Far and Middle East but widely cultivated throughout the world. In addition, seeds of the plant are commonly imported into many countries for use in baking. The poppy plant and seeds contain variable amounts of naturally occurring opiates, such as morphine, codeine, and thebaine. It has been well documented that the consumption of poppy seeds by human subjects, generally in the form of baked goods, can result in the excretion of detectable concentrations of morphine in urine.[37–39] There are several ways in which horses could inadvertently consume poppy seeds. For example, bakery byproducts, which could contain poppy seeds, are occasionally used in the preparation of animal feeds. In addition, bakery products, such as bagels and muffins, are sometimes fed to horses as treats.

In one study that used GC-MS methodology, morphine was present in detectable concentrations for up to 24 h in urine samples collected from horses following administration of 1, 5, and 10 g of poppy seeds that contained approximately 73 μg of morphine per gram of seeds.[40] As shown in Fig. 65.6, 1 g is not a large volume of poppy seeds. In this same study, plasma samples collected up to 4 h after administration of 10 g of poppy seeds also contained detectable concentrations of conjugated morphine metabolites. In a different study, morphine was also detected in urine samples collected from horses administered 2 g of poppy seeds.[41]

Besides poppy seeds, it is also possible that analytical findings of morphine in post-race urine samples could result from contamination of the horse with either illegal opiates, such as heroin, or prescription medications, such as morphine or codeine, which is metabolized to morphine.[42] In humans, a unique minor metabolite of heroin, 6-monoacetylmorphine has been identified, but it has not been determined whether horses also produce this metabolite.[42] In addition, in most regulatory situations the concentrations of morphine and its major metabolites found in urine samples are quite small, and it would be unlikely that minor metabolites would be present in detectable concentrations. Of course, it is also possible that analytical findings of morphine in post-race urine samples are the result of the purposeful administration of morphine or other opiates to the horse. Thus, although there is growing evidence that there are multiple possible sources of morphine in a horse's environment, at this time it is not possible to distinguish the source of low-level morphine positives in post-race urine samples.

Cocaine

Current drug-testing methods for detection and confirmation of the primary metabolites of cocaine, benzoylecgonine (BZE) and ecgonine methyl ester (EME) are extremely sensitive. For

Fig. 65.7
Two and a half milligrams of analytical grade cocaine powder shown in comparison to a US dime.

example, when four horses were administered 2.5 mg of cocaine sublingually, urine samples contained detectable concentrations of BZE for up to 24 h postadministration (unpublished data). As shown in Fig. 65.7, this amount of cocaine is quite small and could conceivably be consistent with the residue left on a cocaine abusers hands. At the present time, only the Ohio and Louisiana Racing Commissions have officially adopted a urinary threshold of 150 ng/mL for BZE, the primary cocaine metabolite. In other racing juridictions, regulatory authorities are understandably reluctant to overlook contamination with illegal drugs. In addition, it is not possible to determine whether the source of a cocaine metabolite finding is contamination or the purposeful administration of cocaine to the horse.

Nutraceuticals

The world of human sport provides numerous examples of the hazards of nutraceuticals. For example, multiple athletes in the 2002 Winter Olympics claimed that positive tests for nandrolone resulted from consumption of nutraceuticals contaminated with the steroid. These same hazards exist for competitive equine athletes subjected to drug testing. For example, in California in 2000, a herbal supplement that contained small amounts of ephedrine and pseudoephedrine was identified as the source of exposure for numerous positive post-race analytical findings for norpseudoephedrine and phenylpropanolamine (unpublished data). The label for the product did not indicate that it contained any unauthorized medications. Unfortunately, quality control for many of these products is lacking and the presence or absence of contaminating unauthorized substances may vary from batch to batch.

Methylxanthines

Caffeine, theobromine, and theophylline are all examples of methylxanthine agents. Best known for their mild stimulatory effects on the CNS, these agents also have a number of other systemic effects including bronchodilation, diuresis, and in humans increases in the skeletal muscle workload capacity.[43] The results of several studies indicate that caffeine, in particular, may enhance certain types of athletic performance in humans. For this reason, regulators have often viewed the finding of even small amounts of methylxanthines in post-race urine samples as serious infractions of drug and medication rules. These agents, however, are pervasive in the horse's environment and opportunities for inadvertent contamination abound. Sodas, chocolate, coffee, and tea all contain varying amounts of caffeine and theobromine. In one study, horse's administered 10 peanut M&Ms, which are peanuts covered in chocolate and a thin candy shell, had detectable concentrations of theobromine and caffeine in their urine samples for up to 48 h.[44]

In some situations, trainers may not be aware that they are administering caffeine-containing substances. For example, in California in the 1990s a number of horses had detectable concentrations of caffeine in their post-race urine samples and the source of the drug was traced to an electrolyte supplement (unpublished data). The supplement contained guarana extract, which is a plant that naturally contains caffeine, although the label gave no indication that the product contained caffeine. Trainers and veterinarians need to be especially wary of any supplement that claims to have energizing effects as these often contain unauthorized substances, such as caffeine, even though the label may not indicate its presence.

Summary

Drug-testing programs are implemented in order to enforce drug and medication rules. Most programs consist of a two-part testing process, which utilizes urine as the primary sample type. All samples are tested in a preliminary screening process and any samples with suspicious results undergo an additional round of confirmatory testing.

The most common drug violations in equine drug-testing programs are overdosages of authorized medications. Veterinarians need to be aware of the drug and medication rules under which their clients compete and need to follow recommended withdrawal guidelines to avoid unintended positives.

CHAPTER 66

Drug effects on performance

Kenneth W. Hinchcliff

Pharmacological agents can be administered to performance horses for a number of reasons. Drugs may be administered to treat an existing condition, which may or may not impair the horse's performance. Additionally, drugs may be administered so that the apparently normal horse can attain standards of athletic performance greater than would be attained without the agent or, conversely, with the intention of decreasing performance. The Association of Racing Commissioners International has compiled a catalog in which drugs are categorized based on their ability to affect performance of race horses.[1]

Detection of drug effects on performance is difficult for a number of reasons. First, winning margins in many athletic events are small compared to the duration of the event. Consequently, small drug effects have the potential to influence performance. Second, small drug effects are difficult to detect experimentally because of the large variability in performance. Detection of a 1% improvement in performance, which would equate to almost five lengths in a Thoroughbred race, is experimentally very difficult. Studies to detect such a small effect must be designed so that the statistical power to detect a small effect on performance is optimized. Detection of such effects requires use of large numbers of horses performing under standardized conditions. A shortcoming of many studies of drug effects on the performance of horses has been inadequate statistical power as a result of use of small numbers (e.g. six) of horses. Failure to detect an effect of the drug in such instances does not mean that the drug does not have an effect – it simply means that in almost all cases the statistical power to detect a meaningful difference was inadequate. Demonstration of an effect is useful, but failure to detect an effect in such studies does not mean that the drug under study has no effect on performance that is meaningful in competition. For an effect of performance to be apparent when numbers of experimental subjects are small, the effect of the drug must be large and repeatable. The most meaningful test of drug effects on performance is undertaken using large numbers of horses (100s to 1000s) competing under conditions that mimic the conditions of interest. There are obvious financial and logistical shortcomings to this approach, although it is feasible under certain conditions.

Another approach has been to predict the effect of a drug on performance based on its effects in resting horses. This approach may be reasonable for drugs that have profound effects, for instance tranquilizers or sedatives used at therapeutic doses, but is of no use for most compounds. There has been no demonstration that drug effects, such as measured by spontaneous locomotory activity or physiological variables including heart or respiratory rates, detected in resting horses are of any use in predicting effects on performance.

Diuretics

Furosemide

Furosemide (frusemide) administration on the day of racing as prophylaxis for exercise-induced pulmonary hemorrhage (EIPH) is permitted in a number of racing jurisdictions worldwide (Fig. 66.1).[2] Within the USA and Canada, almost all Thoroughbred, Standardbred and Quarter Horse racing jurisdictions permit administration of furosemide before racing. During the late 1990s, approximately 85% of all Thoroughbred race horses in the USA and Canada received furosemide at some stage of their career and, on average, 75% of horses in a race received furosemide.[3] These proportions do not appear to have declined, making furosemide

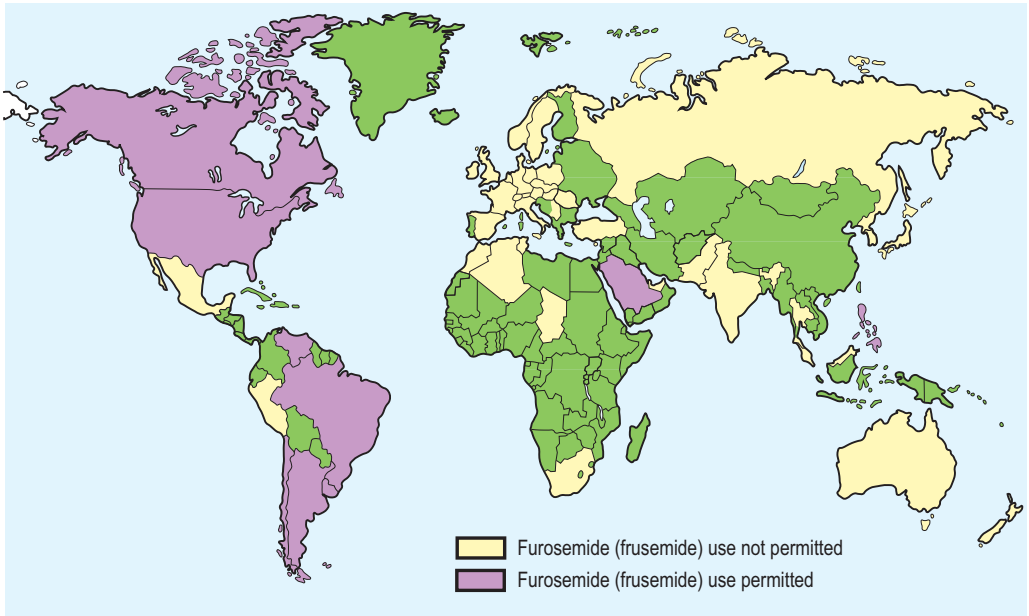

Fig. 66.1
Map showing those countries in which administration of furosemide (frusemide) to horses before racing is permitted by the rules of racing.[2]

among the most widely used drug in race horses in these regions. Although accurate numbers are not available, it appears that a smaller proportion of Standardbred and Quarter Horse race horses receive furosemide before racing. Furosemide was administered to 22–32% of Standardbred race horses and 19% of racing Quarter Horses in two racing jurisdictions in the USA.[4–6]

Pharmacokinetics and mechanism of action

Furosemide is rapidly eliminated by horses, having α, β, and γ half-lives of 5.6, 22.3, and 159 min, respectively.[7] The elimination half-life of furosemide is longer after intramuscular administration.[8] The majority of intravenously administered furosemide is eliminated unchanged in the urine within 4 h.[9] Furosemide inhibits chloride transport in a number of tissues, including the thick ascending limb of the loop of Henle, vascular smooth muscle, and tracheal epithelium by binding to the chloride binding site of the Na^+–K^+–$2Cl^-$ cotransporter. Furosemide may also exert some of its pharmacologic effects by increasing prostaglandin production, as evidenced by the antagonistic effect of drugs, such as phenylbutazone, that inhibit prostaglandin production.[10,11]

Furosemide produces a diuresis, natriuresis and chloruresis in horses,[12–16] through inhibition of the reabsorption of sodium and chloride in the thick ascending limb of the loop of Henle.[17] Urine production during the 4 h after furosemide administration (1 mg/kg, i.v.)to horses averages 25 mL per kg bodyweight.[15,18] The furosemide-induced diuresis decreases plasma volume of resting horses denied access to water.[18,19] Furosemide administration is associated with increased consumption of both salt and water in horses.[20]

Natriuresis, kaliuresis, and chloruresis is profound after furosemide administration to horses. Urinary sodium excretion increases from 8 mmol to 1629 mmol per 3 h and urinary potassium excretion increases from 222 mmol to 556 mmol per 3 h after intravenous administration of 1 mg/kg bodyweight of furosemide.[15] Similarly, intramuscular administration of furosemide (1 mg/kg) increases sodium excretion by six-fold, potassium excretion by two-fold and chloride excretion by 15-fold over the subsequent 8 h.[14] Associated with increased urinary excretion of these electrolytes are reductions in plasma concentrations of potassium, chloride, calcium, and hydrogen. Sodium concentrations are unchanged following furosemide administration to horses.[14] Furosemide administration results in increases in venous pH, Pco_2, Tco_2 and bicarbonate concentration.[5,14,21] Furosemide administration results in a transient decline in urine pH.[14]

Cardiovascular effects

In addition to its effect on the kidney, furosemide also affects the cardiovascular and respiratory systems. Intravenous administration of furosemide causes an immediate and significant dose-dependent decrease in right atrial pressure, pulmonary arterial pressure, pulmonary arterial wedge pressure, cardiac output, and stroke volume in standing horses.[16,22,23] Furosemide also modifies the hemodynamic response to exertion in both horses and ponies. Running is associated with marked changes in cardiovascular function in horses. Cardiac filling pressures increase during exercise; mean left atrial pressures exceed 70 mmHg, and mean right atrial pressures exceed 40 mmHg during intense exertion (Chapter 32). Similarly, mean pulmonary artery pressure may

exceed 80 mmHg, systolic pulmonary artery pressures may exceed 100 mmHg, and pulmonary artery wedge pressure increases from resting values of approximately 18 mmHg to 56 mmHg or higher during intense exertion. Administration of furosemide results in a significant attenuation of the exercise-induced increase in pulmonary vascular pressures, including pulmonary capillary pressure, and right atrial pressure of horses.[22,24–28] Administration of furosemide (2 mg/kg) reduces pulmonary artery and right atrial pressures during strenuous exercise by 16 and 31%, respectively, of values observed when the horses are not treated.[22] Similarly, furosemide administration reduces pulmonary capillary and pulmonary wedge pressures during exercise to 36 and 28 mmHg, respectively, from 41 and 35 mmHg in untreated horses.[25] A similar effect of furosemide is reported in other studies using different measurement techniques, although the absolute values for estimated pulmonary capillary pressure were higher.[28] The hemodynamic effects of furosemide are dose dependent,[8,22] although this effect is not consistently reported for exercising horses.[29]

The effect of furosemide on systemic hemodynamics in rats, dogs and humans is attributed to an increase in venous compliance.[30–32] However, higher concentrations of furosemide than those achieved in plasma of horses after administration of routine doses are required to exert a direct relaxant effect on preconstricted canine pulmonary vessels.[33] This finding is consistent with the conclusion that in horses the hemodynamic response to furosemide is almost entirely attributable to the diuretic effect and subsequent reduction in plasma volume.[24,34,35]

Administration of furosemide to horses results in a rapid and profound decrease in plasma and blood volume.[18,19] In horses not provided with access to water after the administration of furosemide, the reduction in blood and plasma volume persists for at least 4 h.[18,19] Based on measurement of plasma total protein concentration or hematocrit, the reduction in plasma volume persists during brief, intense exercise performed 4 h after furosemide administration.[22,24,36,37] The reduction in plasma volume is temporally associated with attenuation of exercise-induced increases in pulmonary artery and right atrial pressure and with a reduction in pulmonary artery and right atrial pressure in standing horses.[22,23,34] Furthermore, restoration of plasma volume by intravenous infusion of isotonic, polyionic fluids prevents the furosemide-induced decreases in right atrial pressure in sedentary horses and attenuation of exercise-induced increases in pulmonary artery and right atrial pressures in strenuously exercising horses.[24,34] It is likely that furosemide exerts its hemodynamic effect in horses primarily through a reduction in blood and plasma volume.

Furosemide has bronchodilatory activity in ponies with recurrent obstructive airway disease ('heaves') when administered intravenously and by nebulization. Furosemide increases dynamic compliance and decreases pulmonary resistance, but does not affect Pao_2 or $Paco_2$.[38] Dynamic compliance and pulmonary resistance of normal ponies are not affected by furosemide.[38] The bronchodilatory effect of furosemide in horses with heaves is blocked by prior administration of flunixin meglumine.[39] Furosemide administration (1 mg/kg) by inhalation to healthy horses 2 h before intense exercise on a treadmill does not affect respiratory mechanics or arterial blood gas tensions, indicating that in normal horses furosemide does not exert a bronchodilatory effect during exercise.[40]

Interaction with non-steroidal anti-inflammatory drugs

Indometacin and other non-steroidal anti-inflammatory drugs (NSAIDs) inhibit the diuretic, natriuretic and chloruretic responses to furosemide in laboratory animals and humans.[41,42] The mechanism of this interaction is inhibition of loop prostaglandin synthesis; indometacin does not inhibit the tubular secretion of furosemide.[42] Phenylbutazone, administered in high doses (8.8 mg/kg, q12 h for two doses, one oral and the second intravenous), inhibits the cardiovascular and renal effects of furosemide in standing horses.[11,16] Furosemide-induced reductions in right atrial pressure and increases in diuresis, natriuresis, and chloruresis are attenuated by phenylbutazone administration. Phenylbutazone reduces by 25% the amount of furosemide excreted in the urine, but does not affect the efficacy of excreted furosemide, indicating that in horses phenylbutazone does not influence the activity of furosemide in the renal tubule.[11] The mechanism of phenylbutazone's antagonism of furosemide's renal and hemodynamic effects in horses is likely a result of the reduction in diuresis.[35]

The effect of prior administration of phenylbutazone or flunixin meglumine on the hemodynamic effect of furosemide in exercising horses is unclear, with conflicting results reported. Administration of phenylbutazone (4 mg/kg i.v.) or flunixin meglumine (1.1 mg/kg, i.v.) before exercise and before administration of furosemide abolishes the effect of furosemide on right atrial and pulmonary artery pressures during exercise.[43] However, others have not detected an effect of flunixin meglumine administration (1.1 mg/kg q8 h for 3 days, i.v.) on the furosemide-induced attenuation of increases in pulmonary vascular pressures during exercise.[44] The differing results likely reflect different experimental protocols and measurement techniques. The weight of evidence from both horses and other species supports an effect of non-steroidal anti-inflammatory drugs in attenuating the renal and cardiovascular effects of furosemide.

Furosemide and exercise-induced pulmonary hemorrhage

Furosemide is the most commonly used drug to prevent or treat EIPH.[45] The pathogenesis of EIPH and treatment of EIPH are reviewed in Chapter 29. The efficacy of furosemide in treatment of EIPH is uncertain. While field studies of large numbers of horses do not demonstrate an effect of furosemide on the prevalence of EIPH,[46,47] studies of Thoroughbred horses running on a treadmill provide evidence that furosemide reduces the severity of EIPH.[48,49] Under field conditions, based on tracheobronchoscopic evaluation of the severity of bleeding, furosemide has

been reported to reduce or have no influence on the severity of bleeding.[47,50] The apparent inconsistency between field studies and those conducted on horses running on a treadmill may be attributable to measurement of red blood cell counts in bronchoalveolar lavage fluid of horses that have run on a treadmill not being representative of effects of furosemide under field conditions. The weight of evidence from field studies does not support a role for furosemide in preventing or reducing the severity of EIPH.

The mechanism by which furosemide may reduce the severity of EIPH is unknown although it is speculated that furosemide, by attenuating the exercise-induced increase in pulmonary artery and pulmonary capillary pressure of horses, reduces the frequency or severity of pulmonary capillary rupture.[25,51]

Effect on performance

The widespread use of furosemide in race horses raises the question of the effect of furosemide on performance. A number of studies have attempted to address this issue, although most were hindered by low statistical power because of the small number of horses examined. Small differences in speed, that may have an important effect on the outcome of a race, are difficult to detect unless large numbers of horses are examined. The studies in which no effect of furosemide was detected examined either small numbers of horses or analyzed race times collected retrospectively and not corrected for variables that may have affected speed.[8,52] In contrast, studies with adequate statistical power demonstrate clearly that furosemide administration before racing is associated with superior performance in both Thoroughbred and Standardbred race horses.[3,4,46,53]

The effect of furosemide on performance is not consistent within and among studies with the effect of furosemide varying depending upon breed, sex, quality of horse, age, and length of the race, among other factors. Furosemide administered to Thoroughbred horses with EIPH resulted in a decrease in race times corrected for track variant and length of the race in horses in the higher of two value categories.[53] Speed was compared in five races before diagnosis of EIPH with that of five races immediately after diagnosis of EIPH. Horses were administered furosemide before each of the races after the race in which EIPH was diagnosed. Diagnosis of EIPH and administration of furosemide were associated with a significant reduction in adjusted race times. It is likely that furosemide caused the reduction in race times after diagnosis of EIPH but the effect of other treatments is unknown. Importantly, diagnosis of EIPH and furosemide administration did not affect race times in the horses of lower value with EIPH nor in any of four groups of horses with epistaxis.[53] Thus, the effect of furosemide in this study was not consistent and an effect of other factors associated with the diagnosis of EIPH cannot be excluded.

Similarly, Sweeney et al examined the effect of furosemide on corrected racing times of 79 Thoroughbred horses that did not have EIPH.[46] Horses raced on three occasions and received furosemide before the second race only. Geldings had

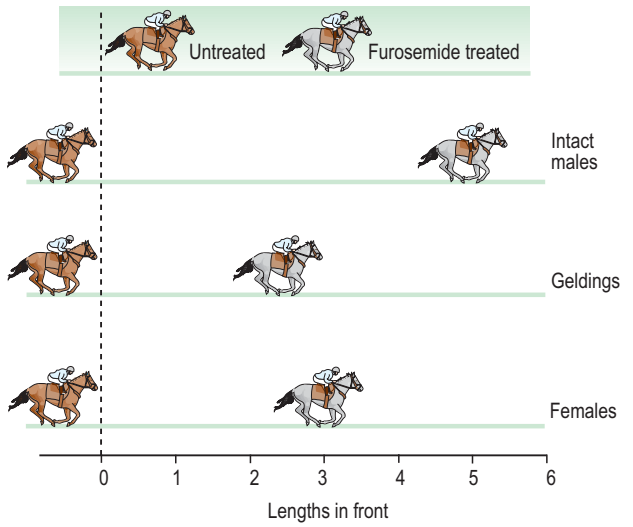

Fig. 66.2
The relative association between furosemide (frusemide) administration and 1200 m (6 furlong) race time for Thoroughbred intact males, geldings, and females. Data from Gross et al.[3]

shorter race times during the second race, after furosemide administration, compared to race times during the first race. However, the reduction in race time was also present in the third race when furosemide was not administered. There was no difference between race times in the second and third races. Thus, an effect of furosemide is likely but debatable, given that the absence of furosemide administration in the third race did not result in a return of race times to values similar to those of the first race. Alternatively, an effect of furosemide may have persisted during the third race, although this possibility appears unlikely.

An examination of the race times of 22 589 Thoroughbred horses racing on dirt tracks in North America between 28 June and 13 July 1997 revealed a significant effect of furosemide on speed, probability of winning or placing, and amount of money won.[3] The magnitude of the effect of furosemide varied by sex of the horses (fillies or mares, geldings, and stallions) with horses administered furosemide racing 0.0006 to 0.00116 furlongs per second faster than horses that did not receive furosemide. When standardized to a race distance of 6 furlongs (1200 m), horses receiving furosemide finished the race in 0.56 to 1.09 s less than horses not receiving furosemide, a difference equivalent to 3 to 5.5 lengths (Fig. 66.2).[3] No attempt was made to determine whether horses in this study were affected with EIPH at the time the study was conducted.

A similar effect of furosemide on race times is evident for Standardbred pacers with treated horses pacing 0.67 s faster for the 1 mile race.[4] The effect of furosemide varied by sex and age, but race times were consistently shorter in treated horses. Furthermore, treated horses finished on average 3.4 lengths behind the winner, compared with 5.0 lengths for non-treated horses.

There is strong and persuasive evidence that furosemide improves the performance of Thoroughbred and Standard-

bred race horses. An effect of furosemide to reduce race times is apparent in horses with and in horses without EIPH at the time of study.[46,53] Therefore, the effect of furosemide on race times appears to be independent of whether the horse has EIPH, raising the question of the mechanism of furosemide's effect on race time.

Mechanism of furosemide's effect on race times

Furosemide is a potent diuretic that alters cardiovascular and respiratory function and acid–base status of horses, as described above. A number of these effects could account for the ergogenic activity of furosemide.

Urine production and reduction in bodyweight The reduction in bodyweight associated with furosemide administration is attributable to increased production of urine.[14,54] The diuretic effect of furosemide is short lived with most urine being produced within the first 30 min of intravenous administration, the rate of urine production returning to baseline values or less within 2 h.[8,14–16] If horses are not permitted to drink after furosemide administration, the diuresis is associated with a marked reduction in bodyweight.[20,22,54] The reduction in bodyweight of horses after administration of furosemide varies between 1 and 5.5%, with the larger reductions occurring after administration of larger doses (2 mg/kg) or intramuscular administration.[14,21,22,36,54] Standardbred horses administered furosemide 4 h before racing have a reduction in bodyweight of 1.3% compared to 0.2% in untreated horses.[55]

Effect of bodyweight changes on energy metabolism The amount of energy needed to run is directly related to the weight being moved (horse, rider, and handicap) and the speed at which it is moved. Increasing weight, for a given speed, results in a proportionate increase in the amount of energy required. Thus, horses that are lighter require less energy to cover a given distance at a specified speed, leading to speculation that furosemide administration may be associated with a reduction in the amount of energy needed for a horse to run a given distance at a given speed.[54,56]

Energy for running is provided by a combination of aerobic and anaerobic metabolism. At speeds achieved during racing, it is estimated that 70–80% of energy is supplied by aerobic metabolism with the balance being supplied by anaerobic metabolism. The rate of aerobic metabolism during racing is believed to be at its maximum as racing occurs at an exercise intensity above that which induces the maximal rate of oxygen consumption ($\dot{V}O_{2max}$). The maximal rate of oxygen consumption is considered an important indicator of athletic capacity.

The maximal rate of oxygen consumption is expressed as either an absolute number (liters of oxygen consumed per minute per horse) or relative to bodyweight (milliliters of oxygen consumed per kilogram bodyweight per minute). Expression of the rate of oxygen consumption as a function of bodyweight provides an index of the maximum rate of energy generation from aerobic metabolism, per kilogram of bodyweight. Increases in the maximal rate of oxygen consumed per kilogram of bodyweight may therefore be consistent with an increase in athletic capacity. During an incremental exercise test, furosemide administration (0.5 mg/kg, intravenously) results in an increase in the maximal rate of oxygen consumption expressed as a function of bodyweight.[56] Furosemide also increases the maximal relative rate of oxygen consumption, but not the maximal absolute rate of oxygen consumption, of horses during a high-speed exercise test on a treadmill.[36] These data demonstrate a physiologically important effect of furosemide in increasing aerobic capacity of horses.

Furosemide administration also reduces the accumulated oxygen deficit and rate of appearance of lactate in blood of horses during a 2-min, high-speed exercise test on a treadmill.[36] A reduction in the accumulate oxygen deficit indicates a reduction in the amount of energy supplied by anaerobic metabolism during the exercise test. The effect of furosemide on accumulated oxygen deficit was directly attributable to furosemide increasing the maximal relative rate of oxygen consumption by the horses during the exercise test. Further evidence that furosemide decreases the use of anaerobically supplied energy during exercise is the observation that furosemide decreases the rate of carbon dioxide production and blood lactate concentration of horses performing an incremental exercise test.[54]

The furosemide-induced reduction in bodyweight may be the cause of the increase in relative aerobic power of horses.[36,56] This is supported by the observations that carriage of weight equal to that lost as a result of furosemide administration normalizes the relative rates of oxygen consumption during a high-speed exercise test and the relative rate of carbon dioxide production and blood lactate concentration during an incremental exercise test.[36,54] While normalization of the rate of oxygen consumption by weight carriage does not conclusively demonstrate that it is weight loss that causes the increase in aerobic power, it does suggest a means of correcting for the effects of furosemide on aerobic power.

Table 66.1 Pharmacologic effects of furosemide (frusemide) in horses

Body system	Effect
Renal	Diuresis
	Natriuresis
	Chloruresis
	Kaliuresis
	Decreased specific gravity
	Increased urine acidity
Electrolyte and acid–base	Hypokalemia
	Hypochloremia
	Increased serum bicarbonate
	Alkalosis
Cardiovascular	Decreased blood volume
	Decreased plasma volume
	Decreased right atrial pressure
	Decreased left and right end-diastolic pressure
	Decreased pulmonary artery pressure

Furosemide-induced alkalosis Alkalosis induced by furosemide administration persists during both strenuous, incremental exercise and brief, high-speed exercise on a treadmill.[37,57] Bicarbonate and base excess concentration and pH are both higher during exercise in horses administered furosemide than in horses not administered furosemide.[37,57] The effect of furosemide to attenuate exercise-induced decreases in blood pH and bicarbonate and base excess concentrations is inhibited when the horses carry weight equal to that lost after furosemide administration.[57] The effect of induced alkalosis on athletic capacity of horses is unknown.

Reduction in severity of EIPH The effect of furosemide on prevalence and severity of EIPH is dealt with elsewhere (Chapter 29). For furosemide to affect athletic performance by decreasing the severity of EIPH, it is necessary that EIPH impair performance and that furosemide reduce the severity of EIPH. Neither of these presumptions have been conclusively demonstrated.

Bumetanide and ethacrynic acid

Bumetanide and ethacrynic acid are structurally different to furosemide, but both are potent diuretics that inhibit chloride transport in the loop of Henle, as does furosemide. Ethacrynic acid given orally to adult horses induces a dose-dependent diuresis; 400 mg (p.o.) induces a diuresis that, assessed subjectively, is maximal 1 h after dosing and persists for 3 h.[58] Ethacrynic acid also increases urinary sodium excretion of ponies.[13] Bumetanide is a benzoic acid derivative with potent diuretic activity.[59] Bumetanide is a potent diuretic when administered intravenously or intramuscularly to horses at dose rates of 10 to 20 μg/kg.[60] Bumetanide is a potent saluretic and kaliuretic in humans and likely exhibits similar activity in the horse, although this activity has not been conclusively demonstrated in horses.[13] The elimination half-life of bumetanide in horses is 6.3 min after intravenous administration and 11 to 27 min after intramuscular administration.[60] The effect of these compounds has not been reported in exercising horses.

Non-steroidal anti-inflammatory drugs

Phenylbutazone and other NSAIDs are among the most commonly used drugs in athletic horses. Phenylbutazone was administered to 50% of 14 600 Thoroughbred horses racing at tracks in the USA and Canada that permitted use of this drug, or presence of the drug in the horse's blood, on race day.[3] The high proportion of athletic horses receiving phenylbutazone is likely a reflection of the frequency of musculoskeletal disorders in these animals and the efficacy of phenylbutazone and similar drugs in alleviating signs of inflammation including heat, pain, and swelling. Phenylbutazone and other non-steroidal drugs are potent analgesics, in addition to inhibiting inflammation, and are especially effective for treatment of disorders involving the musculoskeletal system. Administration of phenylbutazone is associated with a marked reduction in signs of pain and permits more normal gait in horses with induced carpal disease.[61] Treatment with these drugs minimizes tissue damage and may hasten recovery, permitting continued training and racing of the treated horse.

The efficacy of phenylbutazone, and related compounds, is attributable to their ability to penetrate damaged and inflamed tissues and inhibit prostaglandin production. Inhibition of prostaglandin production in inflamed or damaged tissue, and the consequent therapeutic effect, persists after concentrations of drug have reached undetectable levels in plasma. The prolonged effect of phenylbutazone is due to ion 'trapping' of the drug in inflamed tissue – the pH of the inflamed tissue is such that more of the ionized form of phenylbutazone is present in that tissue. Ionized forms of phenylbutazone or its active metabolites cross lipid membranes more poorly than does the unionized form, with the result that the concentration of phenylbutazone is higher in inflamed tissue. Administration of phenylbutazone, which has an elimination half-life of approximately 6 h in horses, inhibits prostaglandin E production in inflamed tissue for up to 24 h.[62,63] Thus, administration of phenylbutazone provides long-lasting inhibition of inflammation and pain.

NSAIDs act by inhibiting the activity of cyclooxygenase enzymes (COX-1, COX-2), thereby reducing the rate at which various prostaglandin compounds, such as prostacyclin, prostaglandin $F_{2\alpha}$, prostaglandin E, and thromboxane are formed from arachidonic acid. Inhibition of prostaglandin synthesis is thought to be the principal mechanism by which the NSAIDs exert their potent anti-inflammatory, antipyretic, and analgesic activities. COX-1 is a constitutive enzyme involved in production of prostaglandins necessary for normal physiologic activity, whereas COX-2 is an enzyme whose production is induced by tissue damage. Consequently, COX-1 is always present in certain tissues, such as the kidney and gastrointestinal tract, in which it mediates or modulates various normal physiologic functions, whereas COX-2 is only present after injury or damage to tissue. The enzymes are genetically and functionally distinct. Recognition of these two forms of this enzyme has resulted in production of compounds that selectively inhibit COX-2 with the intention of maximizing therapeutic efficacy and minimizing adverse side effects.[64] Use of these compounds in horses has, to date, been limited. NSAIDs used in horses and with some selectivity for COX-2 include etodolac, meloxicam, and carprofen.[64]

While there is an extensive body of literature about NSAIDs and their use in horses,[64] there is limited information of the effect of these drugs in exercising horses.

Exercise and prostaglandin production

Prostaglandin production is altered by exercise, although the effects on plasma or urine concentrations are variable among species and exercise type and intensity. The plasma

concentrations of PGE_2, 6-keto $PGF_{1\alpha}$, and $PGF_{2\alpha}$ of humans increase during running and exercise increases the urinary excretion rate of a metabolite of prostacyclin, 2,3-dinor-6-keto-prostaglandin $F_{1\alpha}$, but not of the metabolite of thromboxane, 2,3-dinor-thromboxane B_2.[65–67] Exercise on a stationary cycle induces a two-fold increase in femoral venous PGE_2 concentrations over those measured at rest, indicating a net production of PGE_2 in working muscle.[68] In horses, plasma concentration of 6-keto-prostaglandin $F_{1\alpha}$ increases during incremental treadmill exertion,[69,70] although others have not detected a similar effect of exercise on this metabolite of prostacyclin (PGI).[71,72] However, both intense exercise and endurance exercise increase the plasma concentrations of thromboxane A2.[69,71,72]

Cardiovascular system

The increases in prostaglandin production and/or plasma concentration during exertion likely indicate a physiologically important role for the prostaglandins in exercising horses. Inhibition of prostaglandin synthesis alters the physiological responses to exertion in horses and other species.[73–76] In general, prostaglandin E_2 and prostacyclin (also known as PGI_2) are vasodilatory compounds, whereas prostaglandin $F_{2\alpha}$ and thromboxane are vasoconstrictor compounds. Prostanoids are produced by endothelium of blood vessels (thromboxane is produced by platelets) and contribute to maintenance of vascular tone in a number of vascular beds including pulmonary, skeletal muscle and renal.[77] The importance of these actions is illustrated by the observation that inhibition of production of vasodilatory prostanoids by indometacin results in flow-induced vasoconstriction in skeletal muscle blood vessels.[78] Indometacin and aspirin similarly inhibit exercise-induced increases in calf muscle and forearm blood flow in humans and indometacin accentuates the exercise-induced increase in systolic and diastolic arterial pressures and decreases the heart rate response to exercise.[79]

The issue of alteration by NSAIDs of the hemodynamic responses to exercise is important given the number of horses that exercise or race after administration of phenylbutazone. However, to date, studies of the impact of non-steroidal anti-inflammatory drugs on the hemodynamic responses of horses to exercise have revealed only minor effects on heart rate and right atrial pressure. Phenylbutazone and flunixin meglumine accentuate the exercise-induced increase in heart rate of horses,[76,80,81] and decrease the treadmill velocity at a heart rate of 200 beats per min (V200).[82] However, this effect is not consistent among studies, perhaps reflecting the different exercise and drug administration protocols used.[83,84] Meclofenamic acid does not affect heart rate of horses during an incremental exercise test on a treadmill.[85] Phenylbutazone administration accentuates the exercise-induced increase in right atrial pressure, but does not affect systemic vascular or pulmonary arterial pressures of exercising horses.[76,83,84] The effect of phenylbutazone on right atrial pressure has not been consistently detected.[83] The lack of an effect of the NSAIDs on pulmonary vascular pressures suggests that these compounds should not be expected to exacerbate the severity or increase the frequency of exercise-induced pulmonary hemorrhage. However, this aspect of the pharmacology of these drugs has not been examined in detail.

Oxygen consumption

Phenylbutazone and meclofenamic acid do not alter the rates of oxygen consumption or carbon dioxide production during moderate to intense submaximal exercise.[76,85] Flunixin administration does not affect peak oxygen consumption or carbon dioxide production of horses during an incremental exercise test.[69]

Blood lactate, electrolytes, and acid–base balance

The administration of NSAIDs may alter the blood or plasma lactate response to exercise. However, this effect is variable among studies and may depend on the exercise intensity and duration and the drug and dosage administered. Administration of flunixin meglumine (1 mg/kg, i.m.) or meclofenamic acid (2.2 mg/kg, p.o.) before running results in lower venous lactate concentrations after exercise than occur during drug-free trials.[80] Meclofenamic acid also increases the running speed at which a blood lactate concentration of 4 mmol/L is achieved and decreases the extrapolated venous lactate concentration at V200.[80,85]

Lactate concentration is not altered by phenylbutazone administration before 1 h of submaximal exercise.[84] Nor was blood lactate concentration after a simulated race on a track altered in Standardbred trotters nor in horses performing an incremental exercise test on a treadmill.[76,86]

Gait

A further factor to consider when discussing the effect of the NSAIDs on athletic performance is the ability of these drugs to decrease the pain associated with musculoskeletal disease. Flunixin meglumine restores the stride length of horses with induced carpal inflammation and similar results have been reported for phenylbutazone.[61,87] Flunixin meglumine administration is associated with decreased stance time and increased swing time and range of limb angles in apparently normal Standardbred horses trotting over ground.[81] These results demonstrate that administration of NSAIDs to horses with musculoskeletal pain may restore gait to more normal parameters.

Traditional wisdom is that lame horses do not perform as well in athletic competition as sound horses. The administration of phenylbutazone, or other NSAIDs, to lame horses may therefore allow them to compete more effectively. However, the risks of further injury to the horse if it is allowed to race after administration of NSAIDs have not been determined. It is possible that allowing a horse with clinically significant lameness, such as would need to be treated by administration of a NSAID, to race could exacerbate the injury.

Performance

There was no detectable effect of phenylbutazone on performance of 14 600 Thoroughbred horses racing in North America at tracks that permitted presence of the drug in the horse at the time of racing.[3] Similarly, flunixin meglumine does not affect run time to fatigue of Thoroughbred horses during an incremental exercise test on a treadmill.[69]

Hormones and analogs

Anabolic steroids

Anabolism, the production or generation of tissue, can be stimulated by a variety of anabolic steroids. While estrogens and related steroids have an anabolic effect, the androgenic steroidal hormones are more potent anabolic agents and are therefore more commonly used for this purpose. The anabolic/androgenic steroids are a group of compounds similar in structure to testosterone. Modification of the testosterone molecule has resulted in the production of compounds with reduced androgenic activity but maintained anabolic activity.[88] Various modifications have been made to the basic steroid structure to enhance its lipid solubility, thereby rendering it more soluble in the lipid vehicles used for parenteral injection, or reducing its rate of metabolism by the liver, thereby decreasing the 'first-pass effect' and permitting oral administration.[88] While oral administration of anabolic steroids to horses is unusual, with the exception of use of ethyestrenol in Australia, and steroid-induced hepatopathy has not been reported, the relatively constant rate of absorption from a site of intramuscular injection is an important aspect of the pharmacology of these drugs.

After parenteral administration the duration of effect of the anabolic steroid depends to a large extent on the rate with which it is released from the injection site. The rate of release is determined by the chemical nature of esters of the compound: acetic and propionic acid esters permit rapid absorption and a short duration of action (several days); phenylpropionic, cyclopentylpropionic, and undecylenic acid have a duration of approximately 2–4 weeks; and laureate, decanoate, and heptanoate esters slow absorption and extend the duration of action to 1 month or longer.[88] The ester used has important consequences for both the duration of action of the steroid and the period for which it can be detected. Undeclared substitution of nandrolone decanoate for nandrolone undecylenate, as may occur with some veterinary products produced by unreliable manufacturers, may result in nandrolone being detectable in the urine of treated horses for longer than expected. It is important to recognize that even using the same product the period during which steroid can be detected after intramuscular administration of anabolic steroids to horses is highly variable and unpredictable.

Testosterone is the archetypical androgenic/anabolic steroid. It exerts potent anabolic and androgenic (masculinizing) effects. The androgenic activity of testosterone or other androgenic steroids results in development of masculine characteristics in females or geldings, or prepubertal males. These changes include development of male behavioral traits including aggressiveness, frequent flehman exhibitions, mounting and erections (in geldings) and clitoral enlargement.[89,90] Because of testosterone's potent androgenic effects, use of anabolic steroids with lesser androgenic activity is often preferred.

The steroid hormones exert their effect by binding to intracellular (cytoplasmic) protein receptors. The hormone–receptor complex then interacts with nuclear material in a hit-and-run fashion to induce the synthesis of specific RNA and, consequently, proteins.[91] Testosterone acts in most body tissues, although the active intracellular hormone depends on the tissue. Testosterone is metabolized to the more active 5α-dihydrotestosterone by 5α-reductase in reproductive tissues, whereas in muscles, which have little 5α-reductase activity, testosterone is the predominant anabolic hormone.[88] This difference in tissue sensitivity to testosterone is important in mediating the effect of the synthetic anabolic/androgenic agents. Synthetic anabolic steroids that are resistant to reduction by 5α-reductase therefore exert minimal androgenic activity in reproductive and central nervous system and may exert considerable anabolic activity in muscle cells.

Effect on performance

Administration of anabolic steroids to men and women results in an increase in lean body mass and decease in body fat percentage.[92] While most studies of horses have found that administration of anabolic steroids to healthy horses does not enhance muscle development or increase bodyweight,[90,93–95] nandrolone laurate (0.3 mg/kg q7 days) increases the cross-sectional area of type 1 fibers and the percentage of type IIA fibers in trotting horses.[96] It also increases red cell volume of Finnish trotters in race training over that of similarly trained, untreated horses.[97] Furthermore, the rate of repletion of muscle glycogen after exercise is enhanced by administration of nandrolone laurate (1 mg/kg q7 days).[98] This effect is associated with higher plasma insulin concentrations after exercise and, the authors speculate, greater liver glucose production, although this was not measured.[98] Nandrolone administration also increases citrate synthetase and 3-hydroxyacyl-CoA dehydrogenase activity in muscle.[98] These are critical enzymes in energy transduction in muscle and increases in their activity may indicate increased capacity for energy metabolism by muscle of anabolic steroid-treated horses.

Administration of anabolic steroids to human athletes improves performance in sports that depend on optimal skeletal muscle function.[92,99–101] Administration of anabolic steroids increases muscle mass and improves strength and power output of both male and female human athletes.[99–101] However, an effect of anabolic steroid administration on athletic performance of horses has not been detected in any of the three published studies that have examined this variable.[94,95,97] This apparent lack of effect of anabolic steroids

on performance of horses may be a result of study design and the inability of studies of small numbers of horses to detect what would be, under racing conditions, important effects of the treatment.

The contrasting effects of anabolic steroids in horses and humans may well be due to species differences in response to the drugs, but more likely is a result of dosage. Human athletes often take doses of anabolic steroids (e.g. 3–6 mg/kg testosterone weekly) that may be 10–40 times the therapeutic dose (the amount needed to support physiologic function in agonadal males). Additionally, human athletes often 'stack' steroids, a practice in which the athletes take more than one anabolic steroid at a time.[92] It may be that administration of larger doses of anabolic steroids, simultaneous administration of more than one anabolic steroid, or prolonged administration may have detectable effects on body composition and athletic performance of horses.

Adverse effects

The use of anabolic/androgenic steroids is associated with a number of adverse side-effects. Virilization (masculinization) is often pronounced in females, castrated males, and prepubescent males.[89,97,102] Impaired reproductive function is noticeable in both fillies and stallions and is attributable to the direct effect of anabolic/androgenic hormones on the pituitary–gonadal axis.[89,103] These adverse effects dissipate and both stallions and mares appear to have normal fertility after cessation of treatment, although this return to normal fertility may take many months.[104]

Long-term administration of anabolic steroids has been associated with adrenal insufficiency in a horse.[105] Confirmation of the tentative diagnosis is based on lack of an increase in serum cortisol concentration in response to administration (1 IU/kg) of adrenocorticotropic hormone (ACTH). However, this case is unusual and short-term administration of stanozolol or boldenone undecylenate is not associated with changes in serum cortisol or ACTH concentrations.[106]

Liver disease, including cholestasis, hepatitis and neoplasia, occurs, albeit uncommonly, in humans ingesting C-17 α-alkylated anabolic steroids.[107] There are no reports of liver disease associated with anabolic steroid administration to horses.

Recombinant human erythropoietin (rhEPO)

Erythropoietin is a glycoprotein growth factor synthesized by cells adjacent to the proximal tubular cells in the kidney.[108] Production of erythropoietin increases in response to stimuli associated with reduced oxygen-carrying capacity of blood. Erythropoietin binds to specific receptors on erythroid precursors in bone marrow and other erythropoietic tissues stimulating the progenitor cells to continue their development to erythrocytes.[108] In the absence of stimulation by erythropoietin, the erythroid precursor cells die. Plasma erythropoietin concentrations in humans increase in an exponential manner with decreases in hematocrit such that hematocrits of less than 20% are associated with 100-fold increases in plasma erythropoietin concentration.[108]

Recombinant human erythropoietin (epoietin) was marketed for use in humans in 1985 and other products (darbopoietin) have been developed since that time. These products have been administered to horses in an apparent attempt to increase performance by increasing hematocrit and oxygen-carrying capacity. Administration of recombinant human erythropoietin to horses results in increases in red cell count, red cell mass and hematocrit.[109,110] This effect is achieved with administration of one dose of 120 IU/kg or dosages of 30 IU/kg three times weekly for 4 weeks.[109,110]

Plasma concentrations in clinically normal horses are 3.6 ± 2.3 (mean ± standard deviation) mIU/mL with 102 of 104 horses having values of 9 mIU/mL or less.[110] However, the range of values from normal horses likely depends on the methodology used to measure equine erythropoietin. Peak concentrations of recombinant human erythropoietin in horse plasma after administration of 30 IU/kg range from 25 to 120 mIU/mL, and decline with a half-life of approximately 13 h.[111]

Administration of recombinant human erythropoietin (15 IU/kg, three times weekly for 3 weeks) to splenectomized horses increases hematocrit from 37% to 46% and $\dot{V}O_{2max}$ by 19%,[109] suggesting the potential of this compound to improve athletic capacity. Similarly, administration of recombinant human erythropoietin (50 IU/kg, three times per week for 3 weeks) to horses with a spleen increases red cell mass, $\dot{V}O_{2max}$, and speed at $\dot{V}O_{2max}$.[112]

Adverse effects of administration of recombinant human erythropoietin to horses are potentially fatal. While there is substantial similarity and cross reactivity of erythropoietin among species,[113] administration of recombinant human erythropoietin to horses may induce production of products, likely anti-erythropoietin antibodies, that inhibit the activity of endogenous erythropoietin.[114] Administration of human recombinant erythropoietin is therefore associated with severe anemia secondary to red cell aplasia in an unknown proportion of horses to which it is administered (see Chapter 44).[114] The anemia may be refractory to treatment and result in death of the horse.[115]

An additional concern is that polycythemia induced by erythropoietin administration may increase blood viscosity with subsequent exacerbation of exercise-induced increases in pulmonary artery pressure and a worsening of exercise-induced pulmonary hemorrhage.[116] However, such concerns have not been substantiated at this time.

Growth hormone (somatotropin)

Growth hormone is a protein produced by the anterior pituitary gland. It is essential for normal growth and development in young individuals through both direct effects on tissue and effects mediated by somatomedins including insulin-like growth factor-1 (IGF-1).[117] Growth hormone

increases the rate of protein synthesis in cells, mobilizes fatty acids from adipose tissue, decreases glucose utilization, and influences fluid and electrolyte balance.[117] Recognition of the potential for growth hormone to exert anabolic effects lead to its use by human athletes.[92] However, studies of highly conditioned athletes have demonstrated that growth hormone administration does not increase fat-free mass, skeletal muscle protein synthesis, or strength in highly trained humans.[118,119] Growth hormone is effective in the treatment of individuals with a documented deficiency of the hormone but currently is considered ineffective as an anabolic agent in clinically normal human athletes.[92]

Recombinant equine growth hormone (eST) is available commercially. Although growth hormone deficiency has not been documented in horses, this compound has been administered to both old and young horses in studies of mineral balance, growth, immune function, bone mineralization, wound healing, and exercise capacity.[120–125] There is no detectable effect of growth hormone administration on athletic capacity of immature Standardbred or geriatric Standardbred and Thoroughbred mares.[124,125] However, studies of the effect of eST on exercise capacity of mature, athletic horses have not been reported.

Administration of growth hormone may be detected by measurement of serum concentrations of insulin-like growth factor.[126,127] Plasma concentrations of IGF-1 are increased for hours to days after administration of eST, whereas eST has a very short half-life and detection of increased concentrations is therefore difficult.[126] Concentrations of IGF-1 vary with age in horses, and normal values have been established.[126,128]

Sympathomimetics

The sympathetic nervous system mediates many of the homeostatic functions vital for existence. Exercise is a potent stimulus of increased sympathetic activity with large increases in concentrations of epinephrine (adrenaline) and norepinephrine (noradrenaline) occurring soon after the start of exercise.[129] Most of the actions of the sympathomimetic amines – the naturally occurring catecholamines and drugs that mimic their actions – can be explained through their effect to mimic the activity of the sympathetic nervous system. Catecholamines and the sympathetic amines produce, among other effects, bronchodilation, positive inotropy and chronotropy, altered vasomotor tone (either vasodilation or vasoconstriction, depending on the vascular bed and agent), and altered carbohydrate and fat metabolism.[130] Both epinephrine and norepinephrine, and the sympathetic amines isoprenaline (isoproterenol), clenbuterol, salbutamol, and terbutaline exert one or more of these effects in horses.[130–132] The predominant use of catecholamines or sympathetic amines in horses is in the relief of airway constriction attributable to bronchoconstriction. Sympathomimetic agents used to effect bronchodilation in horses include clenbuterol, albuterol (salbutamol), salmeterol, terbutaline, and isoproterenol.[132]

Clenbuterol hydrochloride

Clenbuterol hydrochloride is a β_2-adrenergic agonist used for the treatment of respiratory disease associated with bronchoconstriction in horses.[133] It has an elimination half-life of approximately 10.4 h, although the drug may be detected for up to 11 days in urine of horses administered multiple doses.[134,135]

Clenbuterol has pronounced cardiopulmonary effects in horses.[136] Intravenous administration of clenbuterol to healthy horses (0.8 μg per kg) minimally reduces non-elastic pulmonary resistance although this effect persists for longer than 3 h.[136] In horses with airway obstruction (heaves) clenbuterol decreases the maximal change in pleural pressure during respiration, airway resistance and the work of breathing. These effects are mediated by relaxation of constricted bronchial smooth muscle, with effects in vitro being maximal at 100 nM and not detectable at concentrations less than 0.1 nM.[137,138] Plasma concentrations achieved with twice daily administration of 0.8 μg/kg, orally, are 1.0 to 1.5 nM.[135] Notably, the bronchodilatory effect of clenbuterol in horses with no evidence of respiratory disease is minimal, although detectable, while the effect in horses with airway obstruction associated with bronchospasm is much greater.

Clenbuterol has minimal effect on respiratory variables during exercise by fit horses free of detectable respiratory disease. Blood gas tensions ($Paco_2$ and Pao_2) are not affected by clenbuterol administration, with the exception of one report of slightly lower $Paco_2$ during submaximal exercise.[135,139–141] Similarly, with the exception of one report of clenbuterol increasing tidal volume of normal horses during exercise, there is no effect of clenbuterol on respiratory mechanics during strenuous exercise on a treadmill.[135,139,141] The lack of effect of clenbuterol on respiratory variables of normal horses during intense exercise is not surprising given the minimal effect of clenbuterol in standing normal horses and the intense adrenergic stimulation associated with large increases in sympathetic tone and plasma epinephrine and norepinephrine concentrations during exercise.[129] The intense sympathetic stimulation during strenuous exercise may result in maximal bronchodilation, leaving no margin for a pharmacologic effect of clenbuterol. However, the effect of clenbuterol on responses to exertion of horses with chronic obstructive airway disease (heaves) is not reported.

Clenbuterol does not affect the rate of oxygen consumption during incremental exercise tests performed on a treadmill.[135,139–141] However, the effect of clenbuterol on the maximal rate of oxygen consumption, an indicator of maximal aerobic capacity, has not been reported.

Clenbuterol causes a transitory increase in heart rate and decrease in mean arterial pressure in standing healthy horses, but does not affect right atrial or pulmonary arterial pressures, after intravenous administration.[136,139,142] Clenbuterol has minimal cardiovascular effects on healthy horses during exercise. It causes a slight increase in heart rate, over that of untreated horses, at low work intensities but this effect is not apparent at higher work intensities.[139] Clen-

buterol does not attenuate the exercise-induced increases in pulmonary artery, pulmonary capillary or pulmonary wedge pressure in horses running on a treadmill,[142] nor does it alter furosemide's hemodynamic effect in exercising horses.[143]

Administration of clenbuterol (2.4 μg/kg, orally twice daily, 5 days per week) for 8 weeks to Standardbred horses is associated with left ventricular dilation, and increases in left ventricular free wall thickness at the end of systole and aortic root diameter.[144] These changes are interpreted as potentially detrimental to the horse's wellbeing.[144] A deleterious effect of chronic or repeated, high-dose, β-adrenergic stimulation on myocardium of dogs, sheep, rats, and mice is reported.[145,146] Changes observed include necrosis and hypertrophy of myocardial cells. However, the doses used were, on a body-weight basis, much larger than those associated with cardiac disease in horses. The importance of the changes in heart and aortic size reported with clenbuterol administration to horses remains to be determined.

Clenbuterol is a potent repartitioning agent in a number of species including mice, cattle, and horses.[147,148] Clenbuterol increases muscle mass, muscle protein synthesis and body-weight and decreases fat mass in these species. At a dose of 2.4 μg/kg orally twice daily, 5 days per week for 8 weeks, clenbuterol increases fat-free mass and decreases fat mass and the proportion of fat in the body in unexercised horses. Similar effects are noted in horses that trained while being administered clenbuterol.[147] The importance of this change in body composition on athletic capacity is not reported.

Chronic administration of clenbuterol decreases both endurance and sprint running capacity of rats.[145] The effect of clenbuterol on exercise capacity of horses or humans has not been reported.[149] While extrapolation of results obtained during submaximal exercise should be done with caution, results of none of the studies to date clearly indicate a likely effect of clenbuterol to increase athletic capacity of horses.

Albuterol (salbutamol)

Albuterol (salbutamol) is a β_2-adrenergic agonist administered to horses orally, intravenously, intratracheally, or by inhalation for treatment of bronchoconstriction.[150] The plasma elimination half-life is not reported but the drug is not detectable in urine 24–48 h after the last dose, although this will vary depending on the dose, animal characteristics, and method of detection used.[151]

After inhalation by horses with recurrent airway obstruction, bronchodilation occurs within 5 min and persists for 30 min to 3 h.[150] However, no effect of albuterol (360, 720, or 900 μg total dose by inhalation) on respiratory mechanics, $\dot{V}O_{2max}$, maximum heart rate, or blood lactate concentration has been reported in healthy horses running on a treadmill.[152,153] By contrast, others have reported a significant effect of albuterol (900 μg total dose by inhalation) on $\dot{V}O_{2max}$ and run time to fatigue of healthy horses.[154] $\dot{V}O_{2max}$ increased from 122 to 130 mL/kg/min and run time to fatigue increased from 406 to 431 s. The reason for these disparate results is not apparent, although it is speculated that the horses in the later study may have had some degree of bronchoconstriction that was relieved by albuterol administration.[153]

Amphetamines

Amphetamine is an indirectly acting sympathomimetic amine; its mechanism of action involves release of norepinephrine from storage sites in nerve terminals.[155] Consequently, the effects of amphetamine administration are predominantly those of α- and β_1-adrenergic stimulation, including increases in both systolic and diastolic blood pressure and a reflex reduction in heart rate.[155] However, the primary effect of the amphetamines is in the central nervous system.[156] Central effects of amphetamine include medullary and cortical stimulation and possibly reticular activating system stimulation. Stimulation of these areas results in mood elevation, euphoria, and decreased sense of fatigue in humans. Amphetamines also increase metabolic rate, oxygen consumption, and plasma free-fatty acid concentration.[157]

In resting horses amphetamine increases respiratory rate slightly (9 breaths per minute) without altering the heart rate.[158,159] Amphetamine sulfate administered intravenously 30–60 min before a gallop produces an immediate post-race heart rate that is significantly less than that of controls.[158,159] Smetzer and Senta reported a similar observation with doses of amphetamine of 150 and 300 mg per horse.[159] However, in another trial in which amphetamine was administered intravenously (0.55 mg/kg) 20 min before a submaximal exertion test, the heart rates of the treated horses were higher than those of control horses after completion of the run.[160] Cardiac arrhythmias occur during the immediate postexertion period in amphetamine-treated horses.[158,159] The arrhythmias included second-degree atrioventricular (AV) block, sinus arrhythmia, and ventricular or AV junctional beats.[159] The arrhythmias resolved in 3 to 5 min.[158] Amphetamine also increases respiratory rate, rectal temperature, and blood lactate concentration immediately after high-speed trotting or pacing.[161]

Amphetamine has been used by human athletes because of its ability to reduce fatigue and enhance athletic performance.[156,162] Amphetamines may be ergogenic in human beings, improving acceleration and increasing lactate accumulation and time to exhaustion, but not muscular power, speed, or maximal aerobic capacity.[156] Amphetamine administration is also associated with significant increases in knee extension strength, acceleration, anaerobic capacity, time to exhaustion, and pre-exercise and maximum heart rates.[157] Lactate accumulation during an incremental exercise test is increased, but $\dot{V}O_{2max}$ is not.[157]

Administration of amphetamine to Thoroughbred horses before each of five trials increased the speed over the corresponding control gallop, however, the overall difference was not statistically significant and the statistical power was

low.[158] The effect of amphetamine administration on equine athletic performance is unknown.

Methylamphetamine

Methylamphetamine, a derivative of amphetamine, produces variable effects on recovery heart rates when it is administered before exercise. The effect of methylamphetamine on heart rate appears to depend on the intensity and possibly the duration of the exertion involved.[163] Methylamphetamine improves performance in a variety of submaximal speed tests at doses of 0.1 to 0.4 mg/kg, intramuscularly,[164] but the importance of this action to competitive endeavors is unknown.

Methylphenidate

Methylphenidate is structurally related to amphetamine and its pharmacologic effects are essentially those of the amphetamines. There has been minimal evaluation of the effect of methylphenidate in horses. The time for cardiac deceleration after lungeing is longer in horses administered methylphenidate than in untreated horses.[163] Methylphenidate increases recovery heart rate, respiratory rate, venous lactate concentration, rectal temperature, and cardiac output over those values in untreated horses after a submaximal exercise test by trained Standardbred horses.[160] These results suggest that methylphenidate may have a detrimental effect on these variables during exercise and therefore has the potential to impair performance. However, methylphenidate consistently increased the speed of running in four types of submaximal exercise tests.[163]

Ephedrine

Ephedrine is both an α- and β-adrenergic agonist that stimulates heart rate and increases cardiac output of non-exercising human beings. The administration of ephedrine to horses does not affect heart and respiratory rates after lungeing, nor speed performance of horses.[164]

Cocaine

Cocaine is a naturally occurring alkaloid with potent peripheral sympathomimetic activity and central nervous system stimulating effects. Cocaine is also an effective local anesthetic, an effect enhanced by cocaine's induction of localized vasoconstriction and consequent delayed absorption and dissipation from the site of application.[165] The mechanism of the peripheral systemic effects of cocaine is unclear but may be due to inhibition of reuptake of norepinephrine at presynaptic terminals of sympathetic nerves, direct stimulation of release of catecholamines from peripheral nerves, or centrally mediated release of adrenal catecholamines.[156] Whatever the mechanism, cocaine administered intravenously to humans and horses elevates blood pressure and heart rate, and may induce arrhythmias.[166,167] The central nervous system effects of cocaine administration to humans includes euphoria, a positive alteration in mood, and a decreased sense of fatigue. These effects are likely the result of cocaine inhibiting reuptake of dopamine in the CNS, with a resultant increase in dopamine concentration at dopamine (D2) receptors.[156]

Cocaine enhances athletic capacity for short-term, intense exertion but not for prolonged, submaximal activities by humans.[156] However, this effect does not appear to be related to increased aerobic capacity.[168] Cocaine increases heart rate and mean arterial pressure of horses during an incremental exercise test and decreases the anaerobic threshold in a dose-dependent fashion.[167] Cocaine-treated horses have higher blood lactate concentrations at maximal, fatiguing, work intensities.[167] Notably, endurance time, as measured by time to fatigue during an incremental exercise test, is significantly prolonged by cocaine administration.[167] This study provided persuasive evidence of an ergogenic effect of cocaine that is dose related. Interestingly, cocaine also demonstrates dose-related effects on spontaneous locomotor activity of horses, with the highest no effect dose being 0.02 mg/kg.[169]

Sympatholytics

The adrenergic receptors, via increased sympathetic nervous system activity and increased concentrations of circulating epinephrine and norepinephrine, play a significant role in mediating the physiologic and metabolic responses to exertion. Therefore, it is not surprising that β-blockade modifies these responses and impairs exercise performance.[170–173] Furthermore, given that the β-adrenergic system comprises two receptor subtypes, β_1 and β_2, which subserve different physiologic functions, it is apparent that non-selective and selective β-blockade have the potential to modify different physiologic responses to exertion. The modification of the physiologic responses by both selective and non-selective β-blockade during exertion has been extensively investigated in humans, in part because of the importance of β-blockade and exercise in cardiac rehabilitation programs. The effects of a number of different β-blockers on the physiologic responses to exertion have been examined in humans and animals.

β-Blockade attenuates the exertion-induced increase in heart rate and cardiac output of horses,[174] and reduces heart rate during the recovery period from exercise.[173] Propranolol (0.22 mg/kg, i.v.) attenuates the elevation in pulmonary artery flow velocity (an indicator of cardiac output) and right ventricular dP/dt, while augmenting the increase in mean pulmonary artery and right ventricular pressures of ponies during an incremental exercise test.[175] Propranolol did not alter the response of the mean systemic arterial pressure to exertion.[175]

The effect of β-blockade on $\dot{V}O_{2max}$ has not been reported for horses. However, $\dot{V}O_2$ is maintained at submaximal work intensities through an increase in oxygen extraction by tissue, manifest as a reduction in venous oxygen content.[174] At maximal work rates, however, the increased arterial–venous oxygen difference can no longer compensate for the decreased cardiac output and maximal oxygen consumption in humans is diminished.

β-Adrenergic blockade has significant effects on exercise-induced changes in metabolism.[173,174,176] Propranolol increases plasma glucose concentrations, decreases plasma insulin concentrations, attenuates the increase in plasma glucagon and free fatty acid concentration in horses during submaximal exercise.[176] The rate of appearance of glucose in blood was increased from 30.5 +/– 3.6 to 42.8 +/– 4.1 μmol/kg/min during exercise at 50% $\dot{V}O_{2max}$, and from 54.4 +/– 4.4 and 73.8 +/– 4.7 μmol/kg/min during exercise at 65% by prior propranolol administration.[176] Similarly, the rate of disappearance of glucose from blood, an indicator of skeletal muscle uptake of glucose, during exercise was approximately 40% higher after propranolol administration. Propranolol also augmented carbohydrate oxidation, with a concomitant reduction in fat oxidation, during exercise. Muscle glycogen utilization was similar between trials and therefore the increase in carbohydrate oxidation with propranolol administration was due to increased use of plasma glucose. Evidently, beta-adrenergic mechanisms restrain glucose uptake by tissue during exercise.[176]

Propranolol administration also decreases blood and muscle lactate accumulation during brief, intense exercise, and attenuates the decrease in arterial and venous pH.[174] However, these effects are likely attributable, at least in part, to the shorter duration of exercise in propranolol-treated horses.[174] Similarly, the rise in blood glucose, glycerol and lactate concentrations immediately after exercise over values before exercise is reduced by both propranolol and metoprolol administration, but these changes could be attributable to the slower speed at which horses ran after treatment.[173]

In horses sweating is under β_2-adrenergic control.[177] Propranolol reduces the sweating response of isolated equine skin after stimulation with either epinephrine or terbutaline,[177] and of horses to exertion.[173] Metoprolol does not decrease sweat production, consistent with the β_1 selectivity of this drug.[173] Reduction in the rate of sweat production is likely the reason for elevated body temperature of horses during exercise after administration of propranolol.[174,176,178]

Beta-adrenergic blockade reduces exercise performance in both humans and horses.[173–176,178,179] Non-selective β-blockade (propranolol) causes a greater reduction in exercise performance than selective (metoprolol) β-blockade.[172,173,180] The reduction in exercise capacity of horses occurs during both moderate- and high-intensity exercise. Run time of Thoroughbred horses running on a treadmill at a speed equivalent of 105% $\dot{V}O_{2max}$ was reduced from 119 to 82 s by propranolol administration.[174] Similarly, exercise duration for horses running on a treadmill for 30 min at 50% $\dot{V}O_{2max}$ and then 30 min at 65% $\dot{V}O_{2max}$ was reduced to 49 min by propranolol administration.[176] Ponies that could easily complete an incremental exercise test to 3.4 m/s on a treadmill were only able to achieve 2.8 m/s after propranolol administration.[175] The speed of galloping by Thoroughbred horses was reduced by 7% after propranolol administration and 5% after metoprolol administration.[173] The effect of β-blockade on exercise performance is likely the result of impaired cardiovascular, metabolic and thermoregulatory responses to exercise.

Sedatives and tranquilizers

The sedatives and tranquilizers used frequently in equine practice are phenothiazine derivatives (promazine, chlorpromazine, acepromazine, fluphenazine) and the α_2-adrenergic agonists (xylazine, detomidine, and romifidine).[181]

Promazine, acetylpromazine, chlorpromazine, and fluphenazine

The predominant mechanism of action of the phenothiazine derivatives is as dopamine antagonists in the mesolimbic–mesocortical, and nigrostriatal regions of the brain.[181] The mesolimbic–mesocortical pathway is involved in behavior, whereas the nigrostriatal pathway is integral to the coordination of voluntary movement. The phenothiazines therefore reduce spontaneous motor activity in horses.[182] Phenothiazines also block the peripheral actions of catecholamines, an action that may account for acepromazine's hypotensive effect.[183,184] The phenothiazine derivatives have little or no analgesic activity.[185]

Fluphenazine is a potent dopamine antagonist used in human medicine as an antipsychotic. Long-acting preparations (ethanate or deconoate) suitable for intramuscular use are available and are administered to horses to induce prolonged, mild sedation. Extrapyramidal signs occur in humans administered fluphenazine and include grimacing and muscle spasms of the head, neck, jaw and proximal extremities, and motor restlessness evident as pacing or rocking.[186] Fluphenazine-induced extrapyramidal signs have been reported in Thoroughbred racehorses.[187,188]

The terminal half-life of acepromazine in serum is approximately 150 min,[189] although the drug or its metabolites may be detectable for much longer (120 h) in urine.[190] Repeated administration of acepromazine may further prolong the period for which it can be detected in plasma or urine.

There are few studies of the effect of the promazine tranquilizers on physiologic responses to exercise. Acepromazine (0.0066 mg/kg i.v. 20 min before exercise) decreases plasma lactate concentration of Thoroughbred horses 2 and 30 min after galloping 1000 m.[191] However, there was no effect of acepromazine on plasma potassium, cortisol, norepinephrine or epinephrine concentrations.[191] Similarly, promazine does not influence a number of physiologic variables of horses during a submaximal exertion test,[161] but does increase the heart rate immediately after completion of a high-speed run.[158] Chlorpromazine increases the heart rate and causes penile ptosis of male horses during submaximal running on a track.[192]

Sedatives may reduce athletic performance of horses, depending on the nature and intensity of the exercise and the personality of the horse. Acepromazine increased the time taken for Thoroughbred horses to run 1000 m by 0.6 s, although this was not statistically significant.[191] Interestingly, two nervous horses had improved run time after acepromazine administration, whereas more relaxed horses had markedly worsened run times when affected by acepromazine.[191] Both acetylpromazine and promazine reduce performance in horses subjected to a short gallop or cavalleti.[163] Promazine significantly decreases speed of Thoroughbred horses when administered 30–60 min before a simulated race.[158] Chlorpromazine has a pronounced effect in decreasing running speed of Thoroughbred horses.[192]

α_2-Adrenergic agonists

The α_2-adrenergic agonists exert their sedative and analgesic effects by binding to α_2 receptors in the central nervous system and suppressing axonal release of norepinephrine and dopamine.[181] α_2-Adrenergic receptors are found in many other tissues of the body and this likely accounts for the endocrine and cardiovascular effects of the α_2-agonists.[193] The cardiovascular effects of the α_2-agonists are due to the combined effects of inhibition of central nervous system sympathetic tone and norepinephrine release from peripheral sympathetic nerves, and an apparent reflex increase in vagal tone secondary to α_2-agonist-induced increase in systemic blood pressure.[193]

Xylazine, detomidine, and romifidine are α_2-agonists available for use in horses.[181] Although their relative potency varies, all three drugs are potent analgesics and sedatives in horses. Both xylazine and detomidine exert dose-dependent effects on systemic hemodynamics of conscious horses. Xylazine and detomidine cause an initial brief increase in systemic arterial pressures, which is followed by a more prolonged hypotension.[194] Heart and respiratory rate and cardiac output are reduced, while cardiac filling pressures are increased by xylazine or detomidine administration to horses.[194] These drugs also decrease intracranial pressure in conscious horses,[195] cause hyperglycemia and reduced insulin secretion, and transiently increase urine output.[196,197]

While the α_2-agonists are drugs frequently used in performance horses the effect of α_2-agonists on athletic capacity of horses has not, to our knowledge, been reported. However, the profound sedative, hemodynamic and endocrine effects of these drugs in resting horses would suggest that they have the capacity to reduce maximal athletic capacity.

Reserpine

Reserpine is a compound used to produce long-lasting sedation in horses, for which it is sometimes used as an aid in training young or fractious horses. Reserpine depletes norepinephrine, dopamine, and serotonin stores in synapses resulting in long-lasting (10 days) sedation.[181] There is a lag time between administration of reserpine and onset of sedation. Administration of reserpine (5 mg, i.v., single dose) decreases spontaneous motor activity of horses with maximal sedation occurring 3–5 days after injection.[198] Sedation occurs even after reserpine is no longer detectable in blood or urine, although the period during which reserpine can be detected depends on the method of analysis of samples.[199,200] There are no reports of the effect of reserpine on athletic capacity, however it could be expected to reduce maximal athletic capacity. Reserpine toxicosis is characterized by bradycardia, depression, miosis, ptosis, and paraphimosis.[201]

Methylxanthines

Theophylline (and its salt, aminophylline), theobromine, and caffeine are methylxanthine alkaloids that share similar structures, pharmacologic effects, and mechanisms of action. All act as stimulants of the central nervous system and heart, relax smooth muscle, induce diuresis, and increase basal metabolic rate and plasma concentrations of free fatty acids, probably mediated via antagonism of adenosine.[202,203]

Caffeine

Ingestion of caffeine by humans causes increased alertness (i.e. less drowsiness and clearer thought), but impairs coordination and task performance.[156] Increasing doses of caffeine increase central nervous system stimulation resulting in, progressively, nervousness and anxiety, restlessness, insomnia, tremors, hyperesthesia, and convulsions.[203] Caffeine also affects skeletal muscle function. In vitro caffeine potentiates twitch tension, and in vivo it increases muscle force output at low electrical frequencies (10–59 Hz) but does not alter the strength of maximum voluntary contractions.[156] Caffeine does not improve short-term or maximal power output of humans, and it may or may not improve endurance performance.[156,204]

Caffeine is often detected in urine samples collected as a result of drug-control procedures. In many instances, these positive findings are a result of dietary caffeine, such as feeding horses chocolate treats, rather than deliberate administration of caffeine.[205] The elimination half-life of caffeine in horses is approximately 10 h.[206]

Caffeine spontaneously increases locomotor activity of horses, but the effect is short lived and apparent only after intravenous injection of the drug.[206] The highest no-effect dose for spontaneous locomotor activity of horses is 2.0 mg/kg i.v.,[207] although the relationship between this variable and racing performance is unknown. Caffeine (2.5 and 5.0 g/horse, s.c.) enhances running performance, as assessed by timed runs of Thoroughbred horses running at submaximal speeds,[208] likely reflecting an increased alertness or willingness to run rather than a change in exercise capacity. Heart rates during submaximal exercise and recovery are higher after caffeine administration than during drug-free trials.[208] Variable effects on performance and heart and respiratory rates were observed in two horses

administered caffeine (4.0 and 16.0 mg/kg, p.o.), although there are insufficient data to draw any conclusions.[164]

Theophylline

Theophylline is a potent dilator of constricted airways, and is often used in the treatment of recurrent obstructive pulmonary disease (heaves, COPD) of horses. Theophylline, like caffeine, has pronounced effects on other body systems, including the central nervous system, heart, and kidneys. Theophylline induces dose-dependent increases in heart rate, sweating, sensitivity to auditory and visual stimuli, urine flow, and muscle tremors in horses.[209] The suggested upper therapeutic plasma concentration of theophylline in horses is 15 μg/mL.[210]

Theophylline affects some of the physiological responses of horses to exertion. Theophylline accentuates both the heart rate and blood lactate concentration responses of horses to incremental exertion on a treadmill.[80,211] The effect of theophylline on athletic performance of horses is unknown, although in humans intravenous aminophylline does not increase maximal oxygen uptake, maximum work rate, or maximum minute ventilation.[212]

Alkalinizing agents

Sodium bicarbonate

Bicarbonate is an endogenous substance present at predictable concentrations in blood and body fluids. Endogenous bicarbonate is produced as a result of the hydration of carbon dioxide:

$$CO_2 + H_2O \Leftrightarrow HCO_3^- + H^+$$

This reaction is catalyzed by the enzyme carbonic anhydrase. This enzyme is highly active in red blood cells and renal tubular cells, among other tissues, where it has important action in carbon dioxide transportation and maintenance of acid–base balance. Bicarbonate is eliminated by the reverse reaction occurring in the lungs, with subsequent exhalation of carbon dioxide. Bicarbonate is also eliminated by renal excretion. Variable proportions of bicarbonate filtered at the glomerulus are then reabsorbed in the proximal tubule. Excess bicarbonate is not reabsorbed and is excreted as predominantly sodium or calcium bicarbonate in urine.

The concentration of bicarbonate in blood depends on the rates of production from carbon dioxide in red blood cells and plasma, elimination of carbon dioxide from the lungs, and excretion in urine. Formation of bicarbonate from carbon dioxide produced in metabolically active tissues is quantitatively important in the transport of carbon dioxide and its elimination in the breath.

Exercise, which is associated with increases in carbon dioxide production, increases bicarbonate concentration in venous blood. This increase in plasma bicarbonate concentration is short lived, resolving within seconds to minutes of the cessation of exercise (see Chapter 39) as the excess carbon dioxide is exhaled. The increase in venous blood bicarbonate concentration is proportional to the intensity of exercise and partially attenuates the exercise-induced acidemia associated with intense exercise.

A number of factors, including exercise, diet, ambient temperature, administration of supplements and medications, and disease have been demonstrated or claimed to effect blood bicarbonate concentrations. The potential for these factors to affect blood bicarbonate concentration has important consequences for regulation of administration of alkalinizing agents to horses and have therefore attracted considerable attention. The influence of a number of these factors has been described elsewhere.[213–216]

Pharmacokinetics

Alkalosis and increased blood bicarbonate concentrations persist for periods varying with dose and route of administra-

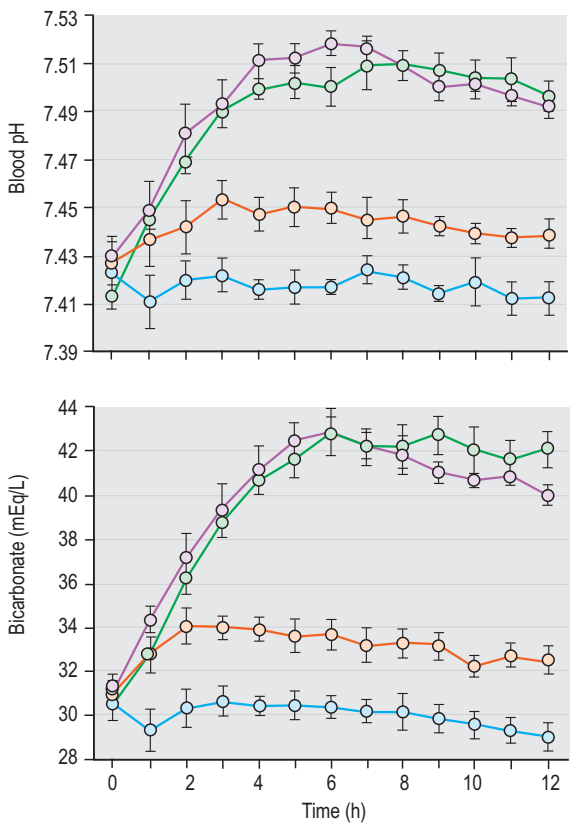

Fig. 66.3
Effects of dosages of sodium bicarbonate of 250, 1000, and 1500 mg/kg bodyweight administered orally to horses. Notice the prolonged time to peak concentration with larger doses and the lack of a higher peak with dosages above 1000 mg/kg. ●, sodium bicarbonate, 1500 mg/kg, orally; ●, sodium bicarbonate, 1000 mg/kg, orally; ●, sodium bicarbonate, 250 mg/kg, orally; ●, water, 3L, orally.
Data are from Rivas et al.[219]

tion and whether the horse is permitted to drink water after receiving sodium bicarbonate. Increases in blood bicarbonate concentration are detectable within 1 h of administration of bicarbonate orally.[217–220] Peak blood bicarbonate concentrations occur at times proportional to the dose of bicarbonate. Smaller doses of sodium bicarbonate result in lower peak concentrations achieved sooner after administration. Dosages of 400 mg/kg, orally, result in peak concentrations of bicarbonate in blood 2–4 h after administration, whereas after dosages of 1000 to 1500 mg/kg, orally, peak blood bicarbonate concentrations are not achieved for 6–8 h (Fig. 66.3).[217,219–221] Alkalosis persists for more than 12 h after administration of ≥ 250 mg/kg sodium bicarbonate orally to horses that are then not provided access to water.[217,219,220,222] The alkalinizing effect of orally administered sodium bicarbonate is not affected by feeding.[217]

The alkalinizing effect of sodium bicarbonate is proportional to the dose administered, up to a dosage of 1000 mg/kg.[219] Dosages of sodium bicarbonate of 250–300 mg/kg, orally, induce an increase in blood bicarbonate concentration of approximately 4 mEq/L, a dose of 0.5 mg/kg increases blood bicarbonate concentration by 8 mEq/L, whereas increases of 10–12 mEq/L are detected after oral administration of 1000–1500 mg/kg.[217–219,223] Dosages of 1500 mg/kg, orally, do not induce greater increases in blood bicarbonate concentration than do dosages of 1000 mg/kg, perhaps because of limits to the rate of absorption of sodium bicarbonate from the small intestine.[219]

Effect on blood and urine constituents

Administration of sodium bicarbonate has profound effects on blood pH and serum electrolyte and protein concentrations, osmolality and hematocrit, as well as urine composition and volume. Serum concentrations of sodium and plasma protein increase whereas serum potassium concentration declines after administration of sodium bicarbonate. Serum osmolality increases, with greater increases observed in horses that are not permitted to drink after administration of sodium bicarbonate.[217,219] Urine flow increases, regardless of whether the horses are permitted to drink, whereas urine osmolality may drop, remain unchanged, or increase slightly, depending on the dose of sodium bicarbonate and whether the horses have access to water.[217,219]

Blood pH, both arterial and venous, increases in a dose-dependent fashion up to dosages of sodium bicarbonate of approximately 1000 mg/kg, orally. Venous pH increases by approximately 0.04 units after dosages of 250–300 mg/kg, orally, and by 0.1 units after dosages of 1000–1500 mg/kg, orally.[214,217–221,223,224] However, the effect of dose is not entirely predictable, although being a major component of any increase in pH, and other factors may influence the increase in blood pH after administration of sodium bicarbonate.

Venous Pco_2 increases after administration of sodium bicarbonate. Venous Pco_2 increases by 4 to 8 mmHg after administration of 250–1500 mg/kg of sodium bicarbonate orally.[214,217,219,220,224–226] Increases in arterial Pco_2 have been reported, but are variable and inconsistent among studies.[227]

Increases in serum sodium concentration after administration of sodium bicarbonate vary to some extent with the dose administered. However, it is not possible to determine the dose of sodium bicarbonate from serum concentrations of sodium in the horse. Dosages of 1000 mg/kg increase serum sodium concentrations by approximately 10 mEq/L in horses not provided with access to water.[219,225] Similarly, dosages of 500 mg/kg increase serum sodium concentration by approximately 6 mEq/L.[217] However, the increase in serum sodium concentration is attenuated when sodium bicarbonate is administered with water.[225]

Serum potassium concentration declines after administration of sodium bicarbonate with greater declines occurring after larger doses.[219,225] Serum potassium concentration may decrease to less than 2.5 mEq/L in resting horses administered sodium bicarbonate. Serum chloride concentrations usually decline after administration of sodium bicarbonate, especially when horses are allowed to drink or water is provided with the sodium bicarbonate.[217,225] The decline in serum chloride concentrations is approximately 5–9 mEq/L. Others have not detected a decline in serum chloride concentration.[219]

Consistent with the increase in serum sodium concentration is an increase in serum osmolality, the magnitude of which depends on dose and access to water. Administration of dosages of 250 mg/kg increase serum osmolality by less than 10 mOsmol/kg whereas administration of 1000 to 1500 mg/kg increases serum osmolality by approximately 25 mOsmol/kg.[219] Access of the horses to water attenuates the increase in serum osmolality.[217]

Plasma protein concentrations are unchanged in horses that are not provided access to water after administration of sodium bicarbonate.[219] However, plasma protein concentration declines by approximately 1.0 g/dL (10 g/L) after administration of 500 mg/kg of sodium bicarbonate in horses that are permitted to drink.[217] The decline in plasma protein concentration is likely secondary to an increase in plasma volume, although such changes have not been detected by direct measurement of plasma volume.[225]

Urine flow increases after sodium bicarbonate administration, regardless of whether the horses have access to water.[217,219] Urine volume in the 12 h after administration of 3 L of water, 250, 1000, or 1500 mg/kg of sodium bicarbonate in 3 L of water was 3.3, 3.5, 7.7, and 9.3 L, respectively.[228] Horses provided access to water after administration of sodium bicarbonate increase their water consumption from control levels of 0.5 L/h to 2.3 L/h.[217] The rate of water consumption returns to control levels by 18 h.[217] Horses administered sodium bicarbonate and denied access drink readily when subsequently provided with water likely indicating enhanced thirst.

Increases in urine volume are associated with increases in sodium excretion. During the 24 h after administration of 500 mg/kg of sodium bicarbonate, horses excreted 3400 mmol of sodium, compared with 600 mmol during an equivalent control period.[217] The excretion of sodium is dose dependent, with 12-h sodium excretion of 198, 457, 1700,

and 2400 mmol after oral administration of 3 L of water, or 250, 1000, or 1500 mg/kg orally, respectively, of sodium bicarbonate.[228] The increase in sodium excretion is associated with increased urine osmolality in horses not provided access to water,[228] and decreased osmolality in horses permitted to drink.[217]

Urine pH increases by 0.5 to 0.8 units after administration of 250 to 1500 mg/kg, although there does not appear to be a dose-dependent effect.[217,228] The increase in urine pH is associated with an increase in urine bicarbonate concentration, with the effect increasing with increasing dosage up to a dosage of 1000 mg/kg, orally.[228] Bicarbonate excretion in urine is 604, 1034, 2734, and 3370 mEq in the 12 h after administration of 3 L of water or 250, 1000, or 1500 mg/kg of sodium bicarbonate, respectively.[228]

Effect during exercise

Sodium bicarbonate administered a sufficient time before exercise to induce alkalosis at the start of exercise attenuates the acidosis induced by intense exercise, and increases blood lactate and sodium concentrations during exercise.

The venous and arterial pH of horses is higher during intense exercise after sodium bicarbonate administration than in untreated animals. This attenuation of acidemia is associated with higher venous and arterial concentrations of bicarbonate and higher Pco_2 tensions during and immediately after both intense, but submaximal exercise, and during work at speeds greater than that which induces $\dot{V}o_{2max}$.[214,218,227,229,230] Sodium bicarbonate attenuates the exercise-induced decrease in venous pH (6.97 and 7.06, respectively, for water or bicarbonate) at the end of a sprint in horses running on a treadmill.[227] Similarly, the decrease in both arterial and venous blood bicarbonate concentration is attenuated by sodium bicarbonate administration with values of 24.5 and 29.7 mEq/L (venous) at end of sprinting after administration of water or $NaHCO_3$, respectively.[227]

Blood lactate concentrations during exercise are higher in horses administered sodium bicarbonate.[223,224,227,229,231,232] Blood, plasma or serum lactate concentrations are typically 3–6 mmol/L higher in horses administered sodium bicarbonate, with the increase depending in part on the dose of sodium bicarbonate, the intensity of exercise and therefore lactate concentration, and on whether lactate was measured in whole blood, plasma, or serum. Generally, the increase in blood lactate concentration is larger when lactate concentrations are higher, as occurs during intense exercise. Not all investigations have detected an effect of sodium bicarbonate administration on blood lactate concentrations, possibly because these studies used low dosages of bicarbonate (300–600 mg/kg).[226,230,233] Increases in blood lactate concentration have been attributed to increased movement of lactate from sites of production in muscle to the blood after sodium bicarbonate administration. However, muscle lactate concentrations are not affected by sodium bicarbonate administration.[226,231,233] The lack of apparent effect of alkalinization on muscle lactate concentrations may be attributable to the insensitivity of measurement techniques to detect a reduction secondary to enhanced efflux of lactate from the muscle. Enhanced rates of lactate efflux and lower lactate concentrations in muscle have been detected using isolated dog or rat muscle.[234]

Sodium bicarbonate administration attenuates the ionized calcium concentration of serum of horses during intense exercise (iCa of 1.58 and 1.44 mmol/L before exercise, and 1.69 and 1.49 end sprint, for water and $NaHCO_3$ treatments, respectively), but does not affect total calcium concentrations in serum.[227] Bicarbonate administration decreases plasma ammonia concentrations during and after intense exercise, although this effect is not consistently reported.[224,231] Sodium bicarbonate administration does not affect blood hypoxanthine or xanthine concentrations at rest or during and after exercise.[233]

Muscle concentrations of adenosine-5-monophosphate and inosine-5-monophosphate are lower after exercise in horses administered sodium bicarbonate.[231] However, muscle concentrations of glucose-6-phosphate, creatine phosphate, and ATP before and immediately after intense exercise are not detectably affected by sodium bicarbonate administration.[226,233]

Mechanism of action

Muscular work is associated with increases in the concentration of lactate and hydrogen ions in muscle cells. These changes occur as energy for muscle contraction is provided by anaerobic glycolysis, the metabolism of glucose to lactate and pyruvate. Under aerobic conditions lactate is metabolized, and hydrogen ions are consumed, via pyruvate and the citric acid cycle to carbon dioxide. However, if the oxygen supply is limiting, as may occur in muscles during intense exercise, then lactate and hydrogen ions accumulate in the muscle cells. When the buffering capacity of the cell is exceeded then the intracellular pH falls, the activity of pH sensitive processes in the cell declines, and the cell's ability to generate power diminishes.[235] Sodium bicarbonate may delay the onset of fatigue by providing additional buffering and thereby slowing the decline in intracellular pH. However, whereas metabolic alkalosis favors the release of lactate from muscle cells, it does not affect cellular creatine phosphate and ATP concentrations, nor does it increase muscle performance.[236] The mechanism by which sodium bicarbonate exerts any ergogenic effect is unclear.

Effect on exercise performance

There have been numerous studies of the effect of sodium bicarbonate on athletic capacity of human beings (see Heigenhauser[234]). The findings of these studies are inconsistent and often contradictory. Comparison of the studies is confounded by the range of doses of sodium bicarbonate used, including doses that are now regarded as ineffective (0.2 g/kg and less), the variable time between ingestion and the exercise test, and the variety of exercise tests employed. A meta-analysis of studies of the effects of sodium bicarbonate ingestion by humans on anaerobic performance found that overall performance was enhanced although the effect size

Table 66.2 Effect of sodium bicarbonate on exercise capacity of horses

Dosage (mg/kg body-weight)	Number of horses	Breed	Type of exercise	Exercise intensity	Effect	Effect relative to control treatment	Comments	Reference
1000	6	TB	Treadmill	Incremental to 110% $\dot{V}O_{2max}$	P	+42 s (+32%) time to exhaustion	$P < 0.02$. Control was sodium chloride	229

ranged from –0.12 to 2.86, with a mean increase in time to exhaustion of 27 ± 20%.[237] Although the effect on time to exhaustion was only weakly related to the degree of induced alkalosis, studies that demonstrated an effect on performance employed larger dosages and were associated with a greater decline in pH during exercise (indicating more strenuous exercise).[237]

Similar to the use of sodium bicarbonate in human beings, studies of the effect of sodium bicarbonate on athletic capacity in horses have produced conflicting results (Table 66.2). The conflicting results are attributable to differing study designs using varying breeds of horses, a wide range of dosages of sodium bicarbonate and differing means of assessing athletic capacity. Studies that use the time to fatigue of horse performing exercise above 100% $\dot{V}O_{2max}$ have an effect range of –22 to +32% (time to fatigue compared to control), with four studies demonstrating a negative effect of sodium bicarbonate on time to fatigue and one demonstrating a prolongation of time to fatigue. Not all these results were statistically significant. In five studies examining the effect of sodium bicarbonate on times in simulated or match races, the effect size varied from –2.4 to +0.1%, with two studies finding longer race times and three detecting shorter times to cover a defined distance. Again, not all of these results were statistically significant.

Adverse effects

Gastrointestinal discomfort is frequently reported in human beings who ingest large quantities of sodium bicarbonate (>0.4 g/kg) or insufficient water. Theoretically, cardiac arrhythmias will develop secondary to the serum electrolyte abnormalities encountered after sodium bicarbonate ingestion, but sodium bicarbonate-induced arrhythmias are not reported in the horse. The concurrent administration of furosemide and sodium bicarbonate to horses induces a profound metabolic alkalosis and severe serum electrolyte abnormalities, and is associated with dehydration, synchronous diaphragmatic flutter, and mild diarrhea.[238] Concurrent administration of sodium bicarbonate and furosemide should be avoided. Mild diarrhea is reported after administration of oral sodium bicarbonate to horses.[219,230] Fatal aspiration pneumonia has been observed in horses after the inadvertent intratracheal administration of sodium bicarbonate solution.

Other alkalinizing agents

Administration of sodium citrate, potassium bicarbonate, ammonium chloride, and tromethamine (TRIS buffer, THAM) may induce alkalosis in horses.[239] However, administration of sufficient quantity of these compounds increases blood pH and bicarbonate concentrations, which are detectable with appropriate testing. There are no reports of the effects of these compounds on athletic capacity. Administration of calcium carbonate does not affect blood pH or bicarbonate concentration of horses.[240]

INDEX

Notes
Page numbers in *italics* refer to figures: those in **bold** refer to tables or boxed materials.
To save space in the index the following abbreviations have been used:
EIPH - exercise-induced pulmonary hemorrhage
EPM - equine protozoal myeloencephalitis
HYPP - hyperkalemic periodic paralysis
IAD - inflammatory airway disease
NSAIDs - non-steroidal anti-inflammatory drugs
RAO - recurrent airway obstruction
As the subject of this book refers to horses, this has not been used as a main entry. Readers are advised to seek more precise terms. Please note *vs.* indicates a comparison.
